Clostridium difficile is a toxin-secreting gram-positive rod that damages colonic epithelial cells, resulting in sloughing of the mucosa and the development of pseudomembranes (pseudomembranous colitis). In most cases, *C. difficile*-associated pseudomembranous colitis occurs following antibiotic therapy, presumably as a result of alterations of the colonic bacterial flora.

Patients with pseudomembranous colitis develop watery diarrhea, abdominal pain, distension, and leukocytosis. In severe cases, some individuals may show systemic manifestations such as hypotension, fever, and a change in mental status. Serologic measurement of *C. difficile* toxin is a highly sensitive method of detecting infection with this organism. In most cases, the diagnosis of pseudomembranous colitis is evident on endoscopic examination. Punctate or confluent plaques of yellow–tan fibrinous pseudomembranes adherent to an edematous, erythematous, and ulcerated mucosa are often seen (Fig. 4). The right colon is typically more severely affected than the left, but fulminant disease may involve the entire colon.

The pathologic changes are characteristic. The pseudomembranes consist of an admixture of denuded epithelial cells and inflammatory cells enmeshed within fibrinous and mucinous debris, which appear to "erupt" from the colonic crypts (Fig. 5). Initially, the pseudomembranes form discrete plaques; however, in severe disease, the mucosa may become extensively ulcerated and associated with confluent pseudomembranes, signaling a possible evolution toward toxic megacolon. Importantly, a number of infectious agents, including some strains of *Escherichia coli* and *Shigella*, may also cause a pseudomembranous colitis indistinguishable from that due to *C. difficile*.

The management of affected patients is determined by the severity of their illness. The mainstay of medical therapy is antibiotics, such as Flagyl or, less commonly, oral vancomycin. Surgical resection of the colon is reserved for patients who do not respond to antibiotic therapy or develop systemic toxicity despite medical therapy, or develop toxic megacolon. In addition to toxic megacolon, other complications may occur, including colonic perforation, which is associated with a high mortality rate.

Viral Colitis

Although a variety of different viruses may cause disease in the gastrointestinal tract, most are not pathogenic in the colon, and, with rare exception, the development of colonic ulcers occurs as a result of infection by only a few different viruses.

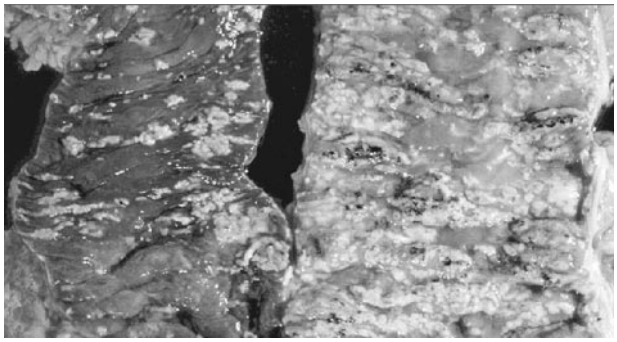

FIGURE 4 Pseudomembranous colitis. The mucosa is covered by numerous pseudomembranes. The background mucosa is edematous and erythematous.

FIGURE 5 Pseudomembranous colitis. Aggregates of cellular debris appear to "erupt" from the damaged mucosa. These aggregates are composed of necrotic epithelial cells enmeshed in mucin and fibrinopurulent material.

Cytomegalovirus Colitis

Cytomegalovirus (CMV) may cause a severe, life-threatening form of colitis associated with ulcers. Although CMV colitis has been reported to occur rarely in immunocompetent individuals, it is much more commonly encountered among immunocompromised patients. In this setting, the infection usually represents reactivation of latent disease that becomes apparent following immunosuppression. CMV demonstrates a predilection to infect rapidly proliferating fibroblasts and endothelial cells present in granulation tissue of ulcers, so it may complicate pre-existing colonic diseases such as inflammatory bowel disease and ischemic colitis.

Most patients with CMV colitis complain of fever, bloody diarrhea, and abdominal pain. In some cases, CMV colitis develops as a complication of immunosuppressive therapy for ulcerative colitis or Crohn's disease, such that the clinical picture is one of progressively severe colitis that persists despite increasing levels of immunosuppression. Serologic assays for CMV, including reverse transcription polymerase chain reaction (RT-PCR), may be extremely useful in establishing the correct diagnosis in these cases.

The endoscopic appearance of CMV colitis is nonspecific. Generally, there is a predilection for the right colon, but this is not always the case. The distribution of disease is usually segmental, characterized by the presence of severe colitis with edema and erythema of the mucosa, as well as deep ulcers. CMV induces a nonspecific histologic pattern of injury to the colonic mucosa. Frequently, the mucosa is ulcerated and the affected biopsy fragments consist entirely of granulation tissue and fibrinopurulent debris. Biopsy fragments obtained from the non-ulcerated mucosa often show active colitis with cryptitis and crypt abscesses. The diagnosis of CMV colitis rests on identification of pathognomonic viral inclusions in the cytoplasm and nuclei of infected cells by routine stains or by immunohistochemistry. The virus typically infects endothelial cells and fibroblasts, producing granular, brightly eosinophilic cytoplasmic inclusions as well as large eosinophilic "owl's eye" intranuclear inclusions (Fig. 6). Occasionally, viral inclusions may be encountered in the glandular epithelium as well, but these are much less common.

Treatment of CMV colitis includes the use of antiviral therapy with ganciclovir. Complications include systemic manifestations of infection, superinfection with other organisms, and colonic perforation in the acute setting.

Herpes Simplex Virus Colitis

Herpes simplex viruses (HSV I and HSV II) may cause colonic ulcers and are an important cause of proctitis in some patient populations. Importantly, HSV may cause disease in both immunocompetent and immunocompromised individuals. In immunocompetent patients, the disease usually occurs as a result of direct contact between the colonic mucosa and infected secretions or mucosal lesions. As a result, HSV-associated ulcers are almost exclusively encountered in the distal rectum and anus. In immunocompromised individuals, however, the disease may occur as a result of either direct contact or as a manifestation of systemic disease in otherwise severely ill patients.

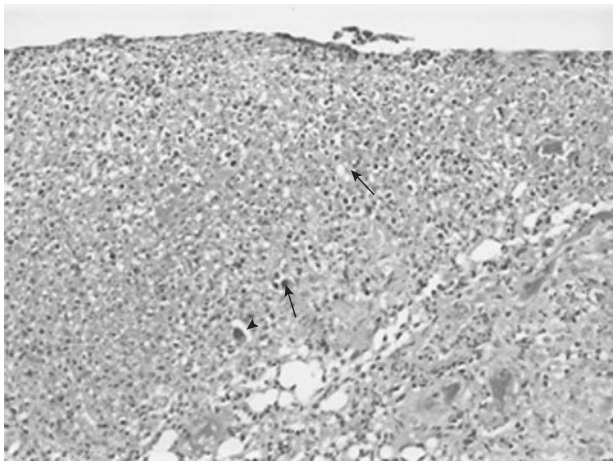

FIGURE 6 Cytomegalovirus colitis. This biopsy fragment consists entirely of inflamed granulation tissue. Many of the stromal and endothelial cells contain both cytoplasmic (arrow) and intranuclear (arrowhead) inclusions.

Patients present with anorectal pain, constipation, tenesmus, pain on defecation, and gastrointestinal bleeding or bloody diarrhea. Characteristic vesicular lesions may be present on the anorectal mucosa or perianal skin. Endoscopically, the viral-infected lesions are often located circumferentially within the affected colon and usually appear as small vesicles on a background of erythematous mucosa. As the vesicles enlarge, they frequently rupture, resulting in the formation of shallow, well-demarcated ulcers.

The histologic features of the ulcers are not specific. They are often associated with a marked inflammatory infiltrate rich in neutrophils, as well as a fibrinopurulent exudate. Diagnostic multinucleated giant cells with "ground glass" or amphophilic intranuclear inclusions and nuclear molding are most commonly encountered in the stromal cells of the submucosa and can be identified on routine stains or by immunohistochemistry.

Treatment of herpetic colitis/proctitis includes the management of symptoms in the acute setting as well as the use of antiviral medications. In most instances, the lesions resolve completely with therapy and are not associated with complications.

Fungal Colitis

Fungal colitis is extremely rare and is encountered almost exclusively as a terminal event in seriously ill individuals who are also immunocompromised. Some of the more common organisms associated with fungal colitis include *Aspergillus* and *Candida* species. Both cause a severe, ulcerative form of colitis characterized by the presence of neutrophilic abscesses as well as invasive yeast forms within the lamina propria.

Protozoan-Induced Colitis

Amebiasis

Amebiasis, particularly that due to *Entamoeba histolytica*, is a major cause of ulcerative colonic disease and dysentery worldwide. The trophozoites cause disease by adhering to epithelial cells and invading the underlying mucosa, destroying the tissue via elaboration of a variety of proteolytic enzymes and cytolytic agents.

Patients typically complain of acute-onset abdominal pain, bloody diarrhea with mucus, tenesmus, and fever. The correct diagnosis is often suspected on endoscopic examination because the organisms demonstrate a predilection for the cecum and right colon. However, the entire colon may be involved in severe cases. The ulcers are usually deep, flask shaped, and exudative, but may be confluent in severe cases. The adjacent mucosa may be erythematous, but is usually relatively unaffected.

The pathologic features of amebic colitis include deep, excavating ulcers that are typically associated with a marked inflammatory infiltrate (Fig. 7). Abundant fibrinopurulent material is often present overlying the ulcers and, although the organisms may be found within the mucosa, they are more frequently identified in the overlying necroinflammatory debris. *Entamoeba histolytica* trophozoites also ingest red blood cells, thus the presence of red cell fragments within the organisms confirms the diagnosis.The treatment of amebic colitis consists of antiprotozoal therapy and supportive care. Although complete resolution and restoration of the colonic mucosa may occur following treatment,

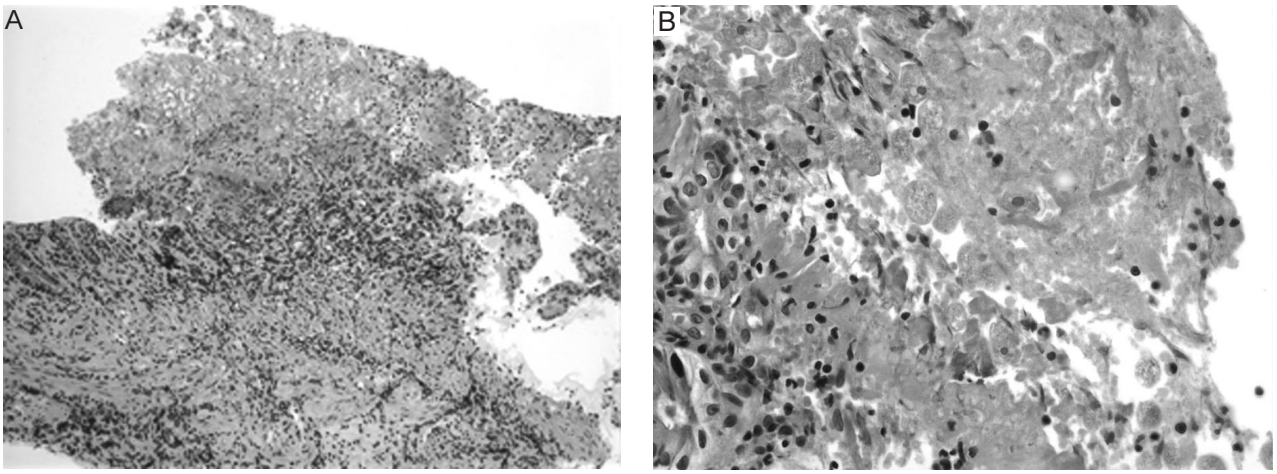

FIGURE 7 Amebiasis of the colon results in the development of deeply ulcerating lesions associated with a fibrinous exudate and mucosal necrosis (A). The organisms are usually apparent within necrotic debris on the mucosal surface (B).

complications, including the development of colonic strictures secondary to healing of deep ulcers, are not uncommon.

DRUG-INDUCED COLONIC ULCERS

Nonsteroidal Antiinflammatory Drugs

It is well-known that nonsteroidal antiinflammatory drugs (NSAIDs) cause ulcers in the gastrointestinal tract by inhibiting prostaglandin synthesis in the mucosa and altering local blood flow. In fact, NSAID use is one of the most common causes of gastrointestinal bleeding. Although NSAID use is more commonly associated with upper gastrointestinal disease, it has recently become clear that inflammation and ulceration may involve the colon as well. The clinical manifestations of NSAID-induced colonic injury are variable. In some cases, patients are asymptomatic and lesions are identified during endoscopic colon evaluation performed for other reasons. Symptomatic patients may complain of rectal bleeding, abdominal pain, and/or bloody diarrhea.

Typically, NSAIDs cause an acute self-limited type of colitis that is endoscopically indistinguishable from that due to infections. Ulceration occurs more often in the cecum and ascending colon. The mucosa may show erythema and edema with or without superficial ulcers. However, deeper ulcers associated with perforation may rarely occur. The use of NSAID-containing suppositories has also been associated with severe ulcerating proctitis. The pathologic features of NSAID-induced colitis are essentially non-specific. The mucosa is infiltrated with a mixed inflammatory cell population rich in neutrophils. Cryptitis and crypt abscesses, as well as mucosal ulcers, are variably present. The use of NSAIDs has also been linked to the development of collagenous and lymphocytic colitis, which are characterized by the presence of increased stromal and intraepithelial lymphocytes, eosinophils, and a thickened subepithelial collagen layer in the former.

The clinical and pathologic features of NSAID-induced colonic injury usually resolve with cessation of drug intake and are not normally associated with chronic mucosal injury, except in rare and unusual circumstances, such as the development of "diaphragm disease." This condition is characterized by the development of colonic obstruction due to the presence of web-like strictures composed of mucosa and submucosa, which cause luminal stenosis.

Oral Contraceptives

Estrogen and progesterone compounds may induce ischemic lesions in the colon due to decreased splanchnic blood flow and the development of small thrombi in the mesenteric veins and small venules. Patients may be asymptomatic or may present with lower abdominal pain, rectal bleeding, or bloody stools. In most instances, lesions involve the colon in a segmental fashion, resulting in mucosal erythema. Erosions and superficial ulcers as a result of epithelial cell necrosis may also be identified.

The pathologic features are indistinguishable from those of ischemic colitis due to other causes and consist of mucosal ulceration, fibrin deposition in the lamina propria, and regeneration of the colonic crypts. In most instances, the mucosal changes are completely reversible on cessation of contraceptives. However, severe, transmural disease may result in perforation or scarring.

Vasoconstrictive Drugs

Other medications that decrease splanchnic blood flow, such as cocaine and vasopressive agents, may result in ischemic colitis and ulceration. These medications may produce ischemic-type ulcers in the colon, resulting in gastrointestinal bleeding. The endoscopic appearance is that of a segmental area of colitis with mucosal erythema, edema, and ulcers. The histologic features include mucosal hemorrhage, fibrin deposition, and regeneration of injured colonic crypts associated with ulceration. Treatment is supportive and most of the changes are reversible on cessation of the drug.

Enemas

A number of different bowel preparations and enema solutions may cause colonic injury and mucosal ulceration. Mildly irritating enema solutions produce mucosal edema, but hypertonic solutions [Fleet PhosphoSoda (CB Fleet Co, Lynchburg, VA), bisacodyl, or hydrogen peroxide] may cause more severe colonic injury, such as mucosal erosions. The histologic changes are generally mild and consist of a variable amount of epithelial cell mucin depletion and acute inflammation.

In contrast, oral preparations and enemas that contain Kayexelate have been associated with the development of severe intestinal ulceration, which may be life threatening. Histologically, the lesions are characterized by necrosis, ulceration, and granulation tissue, which may contain refractile basophilic (Kayexelate) particles (Fig. 8). Interestingly, this complication occurs in association with Kayexelate preparations that contain a sorbitol carrier (Sanofi Winthrop Pharmaceuticals, NY), but does not develop with preparations that contain a lactulose carrier. Thus, most believe that the injury is the result of sorbitol, because similar lesions

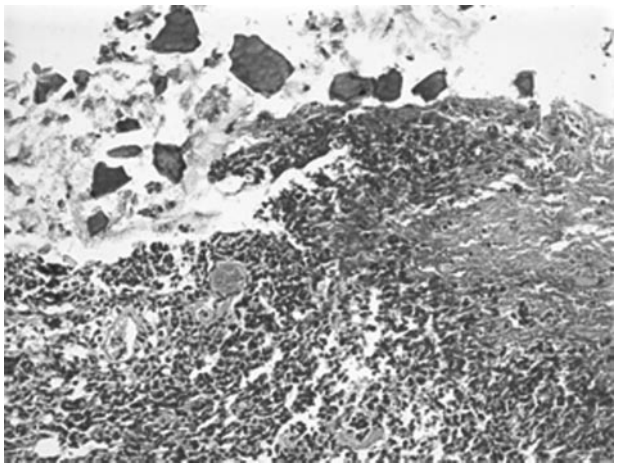

FIGURE 8 Kayexelate-induced colonic injury. Kayexelate preparations that contain a sorbitol carrier may induce ulceration. Kayexelate crystals may be identified in the mucosa or in ulcer debris and appear as rhomboid-shaped structures.

have been induced in animals using sorbitol enemas without Kayexelate.

MECHANICAL DISORDERS

Diverticulitis

Colonic ulceration may occur uncommonly in the setting of acute diverticulitis when the inflammation involves the mucosal surface. However, in some cases, an unusual form of chronic colitis, "diverticular disease associated colitis," may develop in patients with diverticulosis. This disease shows segmental mucosal erythema, friability, and ulceration, which is more pronounced at the orifices of the diverticula but involves the interdiverticular mucosa as well. The pathologic features include mucosal ulcerations, increased mononuclear cell inflammation of the lamina propria and deeper layers of the bowel wall, transmural lymphoid aggregates, and crypt architectural changes, such as crypt atrophy and/or branching. Treatment includes medical treatment of the diverticulitis as well as immunosuppressive therapy. Surgical intervention may be necessary in some cases that are refractory to medical management.

Trauma

Traumatic causes of colonic ulceration are uncommon and are generally limited to the distal rectum. Most cases result from foreign bodies, which may produce mucosal ulceration or pressure-induced ischemic injury. The changes may vary from mild to severe proctitis. Chronic injury may result in the development of inflammatory polyps and lumenal stenosis.

Obstruction and Pseudo-obstruction

Mechanical obstruction and pseudo-obstruction may produce colonic ulceration as a result of stasis of fecal contents ("obstructive colitis"). Initially, mucosal changes such as patchy erythema and ulceration may be identified. However, as the condition persists, histologic evidence of ischemic colitis may develop.

Solitary Rectal Ulcer Syndrome (Mucosal Prolapse)

Solitary rectal ulcer syndrome is an inflammatory disorder of the distal colon; it results from ischemia, torsion, and twisting of the mucosa due to chronic constipation and straining on defecation. It is associated with a primary malfunction of the internal anal sphincter and/or rectal musculature, and is more commonly encountered in older females. Affected patients may present with a variety of clinical manifestations, including rectal bleeding, pain on defecation, and incomplete rectal emptying. Some cases are entirely asymptomatic and are discovered only incidentally on routine examination.

The endoscopic features of solitary rectal ulcer syndrome are variable because they are temporally related to the stage of disease. Features include ulceration, erythema, and inflammatory polyps. Most lesions occur on the anterior wall of the distal two-thirds of the rectum. However, other areas of the rectum and sigmoid colon may be affected as well. At the time of endoscopic evaluation, mucosal prolapse may be demonstrated if the patient is asked to "bear down" during the procedure.

Histologically, the disease is characterized by the presence of ulceration, hemorrhage in the lamina propria, increased active inflammation, and regeneration and hyperplasia of the crypts. Inflammatory polyps typically have a smooth surface, but may be irregularly shaped and/or ulcerated. The polyps may contain regenerative crypts that are cystically dilated, resulting in a localized form of colitis cystica profunda. The mucosa of both ulcerating lesions and inflammatory polyps demonstrates fibromuscular hyperplasia of the lamina propria, which represents a proliferation of smooth muscle fibers arising from the muscularis mucosae. Fibromuscularization of the lamina propria results from chronic prolapse of the mucosa into the lumen, where the increased pressure and trauma induce a localized form of ischemic injury (Fig. 9).

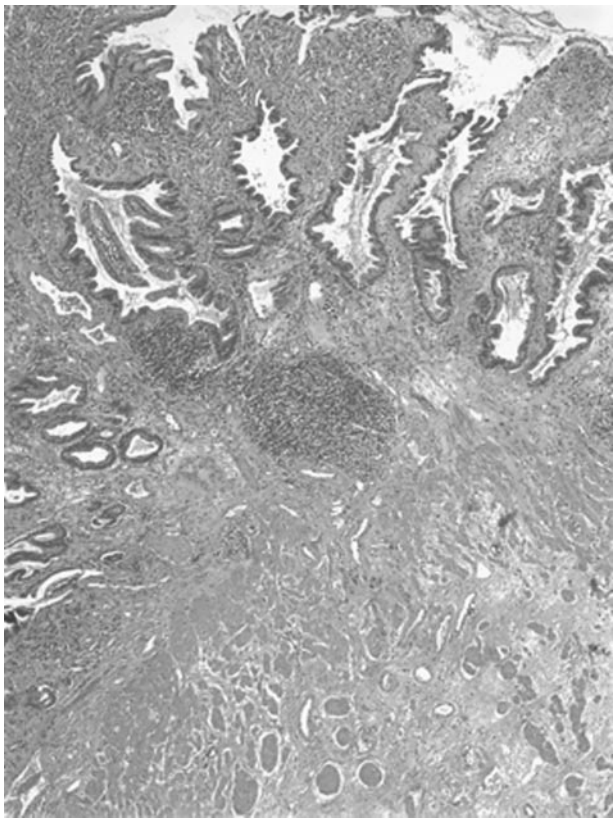

FIGURE 9 Solitary rectal ulcer syndrome (mucosal prolapse syndrome) may produce localized ischemic changes and ulceration in the mucosa. This polypoid lesion contains numerous cystically dilated hyperplastic colonic crypts. Acute and chronic inflammation and fibromuscular hyperplasia are present in the lamina propria.

Because solitary rectal ulcer syndrome/mucosal prolapse results from a mechanical disorder of sphincter and pelvic floor function, the treatment of these patients depends on dietary modification, stool softeners, and behavior modification, as well as medical management of symptoms. Although the polypoid lesions of solitary rectal ulcer syndrome may be resected or biopsied endoscopically, these lesions are generally not responsive to surgical management.

Stercoral Ulcers

Stercoral ulcers are defined as lesions that occur due to fecal impaction; they are therefore more commonly encountered in the distal colon. Ulcers typically develop following periods of severe constipation. Patients complain of severe constipation, abdominal pain, rectal pain, pain on defecation, and bleeding. The endoscopic appearance of stercoral ulcers is characteristic. Most lesions are small, range in size from a few millimeters to a few centimeters in diameter, are normally well demarcated, and are superficial in nature. The adjacent mucosa is frequently edematous and congested. Within the ulcerated area, there is tissue necrosis with loss of the epithelium and fibrin deposition in the lamina propria. Hemorrhage and entrapped fecal material may be present as well. With time, granulomatous inflammation and foreign-body-type giant cells develop in areas of entrapped fecal material.

The treatment of stercoral ulcers is mainly supportive. This includes the use of stool softeners and dietary modification. Most cases heal without sequelae. However, rare cases may be associated with colonic perforation, strictures, and obstruction.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE

Crohn's Disease

Colonic involvement in Crohn's disease is common. It occurs in approximately 50% of patients with Crohn's disease, affecting other sites in the gastrointestinal tract, and the colon is the only site of disease in approximately 30% of patients. Affected patients complain of lower abdominal pain that may be crampy in nature, abdominal bloating, and bloody diarrhea. Many patients are anemic at the time of presentation and may also have a history of weight loss, particularly if they suffer from small intestinal disease as well.

The endoscopic manifestations of the disease include several different patterns of injury. Generally, colonic involvement in Crohn's disease is segmental in distribution. However, diffuse colonic involvement may occur as well. In milder cases, the affected mucosa is erythematous and edematous, with multiple punctate or aphthous ulcers. However, deep fissuring ulcers arranged in a longitudinal fashion are often present in patients with more severe disease. Luminal stenosis as a result of transmural injury and scarring may occur in chronic disease as well.

Microscopically, Crohn's disease is characterized by acute and chronic changes. Nonnecrotic granulomas are present in approximately 30% of cases. However, their presence is merely a marker of the disease and does not necessarily imply the presence of disease activity. Acute changes include segmental inflammation of the colonic mucosa with crypt abscesses and associated ulcers. The ulcers that occur in the setting of Crohn's disease are morphologically variable and include aphthous, flask-shaped, linear, and fissuring-type lesions. Most commonly encountered are aphthous ulcers, which are shallow, well-delineated

lesions that are confined to mucosa or superficial submucosa and tend to occur over lymphoid aggregates. Deeper ulcers may be flask shaped with a broad base centered in the submucosa, or fissuring, knifelike cracks lined by granulation tissue extending into the submucosa or muscularis propria (Fig. 10). Linear ulcers that course through the submucosa parallel to the mucosal surface are also a common feature and are typically lined by granulation tissue and marked acute and chronic inflammation. Chronic changes that develop in Crohn's disease include mucosal abnormalities, such as crypt architectural changes, Paneth cell metaplasia, increased mononuclear cell inflammation, and basal plasmacytosis. Crohn's disease may also cause chronic changes in the colonic wall, including transmural lymphoid aggregates, hypertrophy of nerves in the muscularis propria and submucosa, mural fibrosis, strictures, and fistulous tracts.

Immunosuppression of disease activity is the mainstay of therapy for Crohn's disease. Unfortunately, patients with Crohn's disease frequently develop complications of the disease, such as fistulas, sinus tracts, fissures, and luminal obstruction due to strictures. These complications usually require surgical intervention. Additionally, patients with colonic Crohn's disease should undergo regular surveillance for the possibility of epithelial dysplasia and carcinoma.

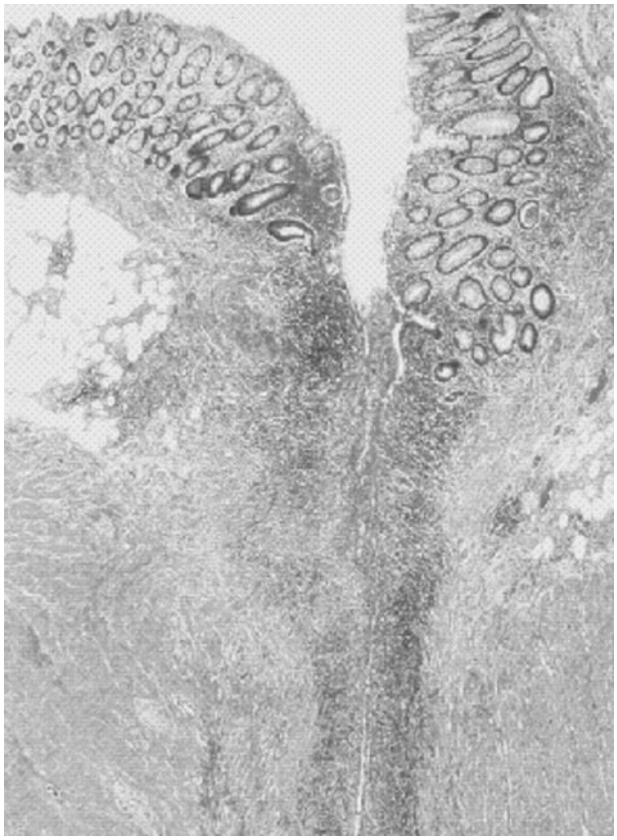

FIGURE 10 Crohn's disease. Sharply delineated fissuring ulcer lined by granulation tissue may involve all layers of the bowel wall.

Ulcerative Colitis

Ulcerative colitis is a chronic ulcerating disease of the colon that demonstrates a bimodal age distribution, with most cases occurring in young adults and a second peak in late adulthood. Although the mechanisms underlying its development are not entirely clear, it appears to be a multifactorial immune-mediated process that results from the complex interplay of a variety of genetic and environmental factors.

Patients typically present with crampy abdominal pain, bloody diarrhea, mucus discharge, and fever. Extraintestinal manifestations of the disease are not uncommon and include large-joint arthritis, primary sclerosing cholangitis, skin manifestations (erythema nodosum and pyoderma gangrenosum), sacroileitis, and ocular disease. Endoscopically, the mucosa is friable, erythematous, and frequently eroded or frankly ulcerated. Although ulcerative colitis classically involves the colonic mucosa in a contiguous retrograde fashion, this is not always the case. The distribution of disease may be discontinuous, involving the left side of the colon, sparing the middle and ascending colon, and involving the cecum and appendix. Such a pattern of disease has been termed a "cecal patch" of ulcerative colitis and does not imply the presence of Crohn's disease. Additionally, endoscopically and pathologically evident "skip areas" may be present early in the course of the disease. However, the process usually becomes confluent over time. Finally, skip areas of uninflamed colonic mucosa are frequently encountered in patients who have received oral or topical therapy for ulcerative colitis.

The pathologic features of ulcerative colitis include the presence of active inflammation on a background of chronic colitis. Depending on the severity of the disease, there may be a variable amount of cryptitis, crypt abscesses, or mucosal ulceration associated with an acute and chronic inflammatory exudate. Chronic changes include the presence of a lymphoplasmacytic inflammatory cell infiltrate, crypt architectural distortion, crypt atrophy, Paneth cell metaplasia, and basal plasmacytosis (Fig. 11). As the disease progresses, the ulcers become confluent, resulting in the formation of mucosal pseudopolyps

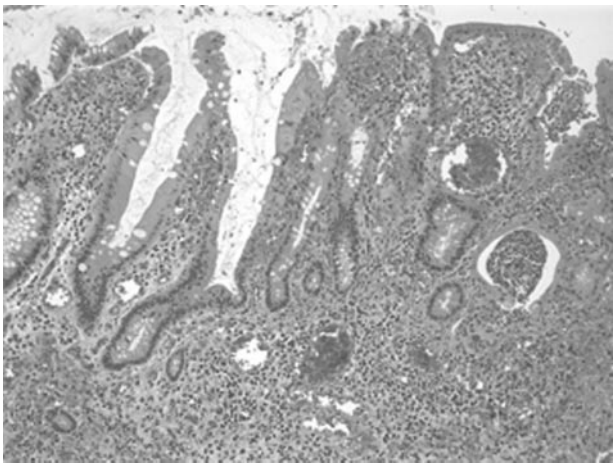

FIGURE 11 Ulcerative colitis. Active changes include the presence of crypt abscesses and superficial mucosal ulcerations. Chronic changes, including crypt atrophy and architectural distortion, increased mononuclear cell inflammation of the lamina propria, and basal plasmacytosis, are also present.

that represent islands of residual intact mucosa surrounded by ulcerated tissue.

Most cases of ulcerative colitis are managed with medical immunosuppression. Surgical intervention may be required in cases refractory to medical therapy or in the setting of toxic megacolon. Patients with ulcerative colitis are at risk for the development toxic megacolon and colonic perforation in the acute setting, as well as several complications of long-standing disease. Chronic immunosuppression predisposes patients to colonic superinfection with cytomegalovirus and other opportunistic organisms. Chronic complications of ulcerative colitis also include glandular dysplasia and the development of carcinoma.

OTHER COLITIDIES

Allergic Colitis

Allergic colitis may result in colonic ulceration as a result of hypersensitivity to foodstuffs. This disease most commonly affects infants and demonstrates a predilection for males. Patients generally present with bloody diarrhea that promptly resolves on withdrawal of the offending agent, which, in most cases, is cow's milk or soy protein. Rarely, breast milk may be the inciting agent. Peripheral eosinophilia may also be present, but this abnormality is not necessary in order to establish a diagnosis. Endoscopically, areas of mucosal erythema, occasionally associated with small ulcerations, may be observed.

The histologic changes of allergic colitis consist of an increase in eosinophils in the lamina propria and epithelium associated with eosinophilic cryptitis and rarely, mucosal erosions or ulceration. Mild lesions demonstrate focal infiltration of the crypts, and multiple sections may be necessary to demonstrate the lesions. More severe disease results in necrosis and ulceration of the surface epithelium. Treatment of the disorder requires discontinuation of the offending agent. In most instances, the mucosal injury heals completely and, thus, the disease is not associated with any significant sequelae.

Endometriosis

Colonic endometriosis typically results in mural fibrosis, inflammation, and stricture formation. However, it rarely involves the colonic mucosa, but, in these cases, may induce ulceration and lower gastrointestinal bleeding. The endoscopic appearance varies from mucosal erythema and ulceration to the presence of polypoid luminal masses (inflammatory polyps) or even ulcerative lesions that may resemble malignancy.

The pathologic features of endometriosis are characteristic. Aggregates of endometrial glands enmeshed in a myxoid or cellular stroma are typically present in the wall of the colon. Frequently, these aggregates are associated with marked hypertrophy of the muscularis propria as well as increased fibrosis of the muscularis propria and submucosa. Endometriosis involving the colonic mucosa may induce changes reminiscent of active colitis with cryptitis, increased neutrophilic inflammation of the lamina propria, and ulceration. However, endometrioid glands composed of mucin-depleted cells, some of which are ciliated, as well as endometrioid stroma, are features distinct from those of the native lamina propria.

The management of colonic endometriosis is variable and dependent on the colonic manifestations of the disease. Endometriosis associated with mucosal ulceration and colitis may be medically managed with hormonal therapy, whereas mass lesions may necessitate surgical resection due to luminal obstruction.

Idiopathic Ulcers and Isolated Cecal Ulcers

In some instances, the etiologic agent responsible for colonic ulceration may not be readily identifiable. These "idiopathic ulcers" demonstrate a predilection for the antimesenteric border of the cecum and proximal ascending colon and, less commonly, the sigmoid colon. As a result, they have occasionally been termed "isolated cecal ulcers." The anatomic distribution of disease

suggests that these lesions may occur as a result of a preexisting lesion, such as congenital diverticula or angiodysplasias in older individuals. However, many are due to an unidentified toxic metabolic agent or drug, such as NSAIDs.

Idiopathic or isolated cecal ulcers may occur in all age and gender groups. Right-sided lesions often present with occult blood loss, frank bleeding, or bloody diarrhea, whereas left-sided ulcers usually present with hematochezia, colonic obstruction, tenesmus, rectal pain, or pain on defecation.

The endoscopic appearance of these lesions is nonspecific. In many cases, they are solitary and range from one to several centimeters in greatest diameter. In most cases, they are superficial. However, they may penetrate deep into the colonic wall. The pathologic features of ulcers are also entirely nonspecific. Increased acute and chronic inflammation, hemorrhage, granulation tissue, and fibrosis are seen in the base of the ulcer. The adjacent, unaffected mucosa may be normal or may demonstrate mild changes with increased mixed cellular inflammation, edema, and hemorrhage.

The treatment of these lesions is variable and is determined by the severity and extent of the ulcers. Small, superficial ulcers may be managed expectantly. Large or deep ulcers may require surgical resection. Complications of these lesions include massive lower gastrointestinal bleeding and colonic perforation.

TUMORS

A variety of malignant tumors of the colon may present as endoscopically apparent ulcerated masses. Most commonly, these lesions are conventional adenocarcinomas. However, other lesions, such as lymphomas, gastrointestinal stromal tumors, unusual sarcomas, and metastases to the colon, may also infiltrate the colonic mucosa, resulting in mucosal ulceration.

Colonoscopy

TROY D. SCHMIDT
Duke University Medical Center

argon plasma photocoagulation Use of ionized argon gas to produce a high-frequency current for the purpose of thermally coagulating tissues.
conscious sedation Level of sedation in which the patient is relaxed, comfortable, and perhaps in a state of light sleep. The patient is easily arousable and able to protect his or her airway.
digital rectal examination Use of the finger to manually inspect the anus, anal canal, and lower rectum for palpable or visual lesions.
heparin window Use of intravenous or subcutaneous heparin in between the time a patient, requiring anticoagulation, stops taking a long-acting oral anticoagulant (e.g., warfarin) and the time the procedure is performed. This practice is aimed to reduce thromboembolic risk while off warfarin for an invasive procedure such as colonoscopy.
informed consent Agreement and acknowledgment of understanding by the patient for a procedure or intervention following an explanation of the risks, benefits, and alternatives.
insufflation Installation of air into the colon for the purpose of distending the walls for examination.
looping A suboptimal curvature of the colonoscope within the colon, making it difficult to advance the colonoscope.
pneumatosis Gas within the submucosa or subserosa of the bowel wall, indicative of a loss of mucosal integrity. This may represent partial or impending perforation.

The first report of a completed colonoscopy was in 1969. Since that time, colonoscopes have evolved and colonoscopy has proven to be a very important tool for gastroenterologists. Colonoscopy allows for a variety of diagnostic and therapeutic options. For example, physicians use colonoscopy to diagnose or exclude inflammatory bowel disease and other forms of colitis. Physicians can diagnose and treat bleeding sources such as ulcers, angioectasiae, and polypectomy sites. Furthermore, the procedure allows for other therapeutic options such as stricture dilation/stenting, foreign body removal, and colon decompression. Because it gives such detailed views of the colonic mucosa, colonoscopy is the most sensitive examination for diagnosing colon polyps and cancer. As a result, it is now a commonly used screening tool for colorectal cancer. This article reviews the colonoscopy procedure, proper indications, complications, and patient preparation.

COLONOSCOPES

The modern colonoscope (Fig. 1) is a flexible instrument with a light and lens at its tip for visualization. It has four-way tip deflection and is typically 160–170 cm long. Control cables run the length of the shaft and are manipulated using two dials at the head of the instrument (Fig. 2). The light seen at the tip of the shaft is connected to the head with fiber-optic cables and these cables are further connected to an imaging console through what is frequently called "the umbilical cord." Fiber-optic connections allow the display of images onto a color monitor and this monitor is placed in front of the endoscopist for visualization. Having images displayed in such a manner allows both the endoscopist and the assistant to see lesions and coordinate the use of therapeutic instruments. It also allows for teaching during the examination because multiple people can watch the procedure in real time.

Colonoscopes have two buttons near the control dials (Fig. 2). When depressed, one button results in suction of colonic contents through the colonoscope and into a waste canister. The endoscopist insufflates

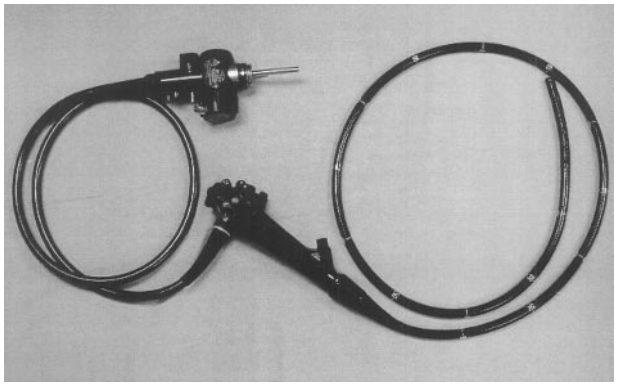

FIGURE 1 The modern colonoscope.

 Copyright 2004, Elsevier (USA). All rights reserved.

the colon by covering a small hole in the center of the second button. When fully depressed, this button cleans the lens with a spray of water.

Colonoscopes have either one or two channels located just below the instrument head (Fig. 2). These are often referred to as either suction or instrument channels because they are used for both. The channels allow endoscopists to flush the colon with water and then suction out residual stool or blood. The endoscopists can also suction out air or small, resected polyps. Polyps are collected in a trapping device before being suctioned into the main waste canister. All available therapeutic instruments are passed through the same channels.

Finally, some manufacturers have recently produced colonoscopes with adjustable stiffness capabilities. This allows the endoscopist to make the colonoscope more rigid as it is passed through the colon. Some studies have reported faster cecal intubation rates and improved patient satisfaction with these newer colonoscopes. An example of this type of colonoscope is found in Fig. 2.

THE PROCEDURE

Colonoscopy requires informed consent from the patient. The physician discusses the reasons for the examination, explains the procedure, and then lists the options, potential benefits, and potential risks. After the patient and physician sign the appropriate documentation, the patient typically receives conscious sedation while having careful cardiopulmonary monitoring. Although sedation is not medically required, most patients in the United States are sedated for colonoscopy. Surveys have indicated that patients prefer sedation.

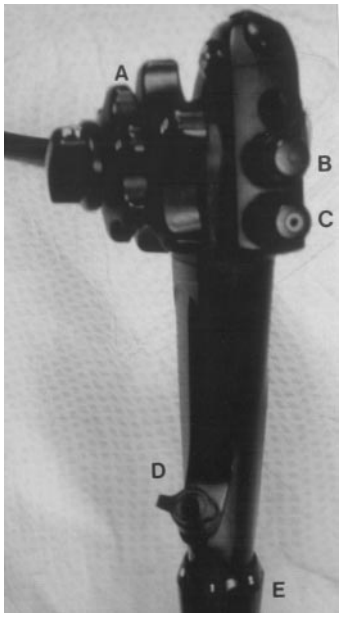

FIGURE 2 The instrument head: (A) control dials; (B) suction button; (C) air/water button; (D) instrument/suction channel; (E) colonoscope stiffening control knob.

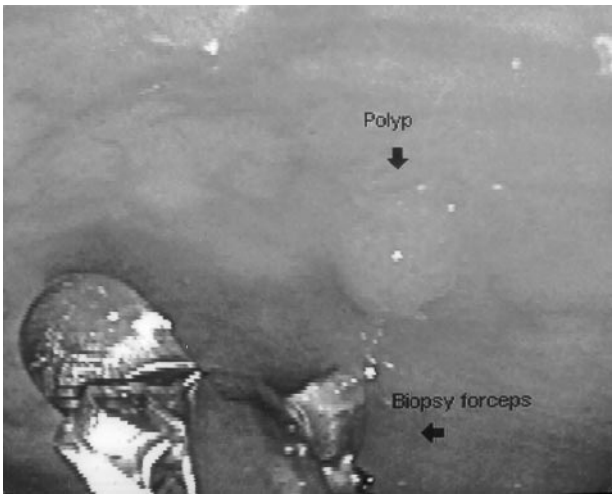

FIGURE 3 Biopsy forceps moving toward a polyp.

Prior to colonoscopy, the physician performs a digital rectal examination to exclude obvious lesions at the anus and lower rectum. Thereafter, the shaft of the colonoscope is lubricated with surgical jelly and inserted into the rectum. The operator carefully maneuvers the instrument to the cecum and/or terminal ileum. This is accomplished by using the control dials and torque to manipulate the shaft. The cecum is readily identified by the presence of the appendiceal orifice and the ileocecal valve. In certain cases, it may be necessary to examine the ileum before withdrawing the colonoscope (e.g., to assess inflammation as with inflammatory bowel disease).

Once the cecum and (or) terminal ileum have been properly examined, the colonoscope is withdrawn slowly. The mucosa is surveyed in a circumferential manner. During polyp screening or surveillance, small polyps (<5 mm) are removed with forceps (Fig. 3). Larger polyps are removed with a snare or with a combination of snare and forceps. Polyps too large to be removed endoscopically are biopsied and then tattooed with India ink for surgical removal.

If the procedure is performed for bleeding treatment and a source is discovered, several options exist. Bleeding angioectasiae may be treated with an electrocautery probe or with argon plasma coagulation. Bleeding vessels, ulcers, diverticula, or polypectomy sites can be treated with injection of epinephrine (1 : 10,000 dilution) and/or electrocautery. Appropriate therapy is

based on the nature of the lesion and the skill of the endoscopist. Other therapeutic issues are discussed below.

After the colon has been fully examined and appropriate therapies have been performed, the colonoscope is removed from the patient. The patient is then taken to a recovery area where vital signs are monitored until the patient awakens.

INDICATIONS

Common indications for diagnostic colonoscopy are summarized in Table I. These indications correspond to recommendations of the American Society for Gastrointestinal Endoscopy (ASGE) with the addition of screening colonoscopy for persons over the age of 50. Screening colonoscopy for the detection of colon cancer is rapidly becoming more widely accepted in the medical community. It is likely that medical societies and insurance carriers will endorse screening examinations for persons within that age group. The effectiveness of flexible sigmoidoscopy for screening purposes is limited because it does not involve examination of the entire colon.

Common indications for therapeutic colonoscopy are listed in Table II. As noted previously, a variety of instruments are available for therapeutic purposes. In addition to polypectomy and bleeding techniques, endoscopists are able to remove foreign bodies with snares, baskets, or forceps. Mesh stents are available for palliative placement in patients who have obstructing colon lesions and are not surgical candidates. Balloon dilation can be performed to open stenotic surgical anastamoses. Colonic decompression can be performed with placement of a decompression tube when the use of neostigmine is contraindicated or ineffective. Sigmoid volvulus can also be reduced when radiologic decompression with gastrografin enema fails. It is likely that therapeutic capabilities will continue to expand as technology improves and as needs arise.

CONTRAINDICATIONS

There are times when colonoscopy is contraindicated (Table III). It is unwise to perform colonoscopy in situations of suspected perforation, toxic megacolon, severe diverticulitis, and fulminant colitis because there is considerable risk for perforation during insufflation. Perforation can be the result of direct distension of mucosa already weakened by underlying disease or it can result from ensuing ischemia that occurs as the colonic wall becomes more distended.

LOW-YIELD EXAMINATIONS

Just as there are indications and contraindications for colonoscopy, there are certain situations in which colonoscopy has a low diagnostic yield or is not indicated. An example of this is when colonoscopy is considered to exclude colon malignancy as the source for metastatic adenocarcinoma of unknown primary type. Previous studies demonstrate that colonoscopy is not

TABLE I Routine Indications for Diagnostic Colonoscopy

1. Abnormal adequate barium enema (e.g., filling defect)
2. Exclusion of right-sided colon polyps when polyps are found during flexible sigmoidoscopy
3. Hematochezia not thought to originate from the rectum or perineum
4. Melena of unknown origin (negative upper gastrointestinal evaluation)
5. Positive fecal occult blood test
6. Unexplained iron deficiency
7. Evaluation of the entire colon to exclude synchronous cancer or neoplastic polyps in a patient with a treatable colon cancer or neoplastic polyp
8. Follow-up at 1 year and at 3- to 5-year intervals after colonic resection of cancer or neoplastic polyp
9. Surveillance exams every 3–5 years for persons with established adenomatous polyps
10. Screening every 2 years beginning at age 25, or 5 years younger than earliest age of a relative with colorectal cancer, in patients at risk for hereditary nonpolyposis colorectal cancer; yearly colonoscopy at age 40
11. Screening every 5 years, beginning 10 years earlier than the age of an affected relative when that relative developed colorectal cancer before age 60; surveillance every 3 years if adenomas found
12. Screening for colon polyps in average-risk patients over age 50
13. Exclusion of cancer or dysplasia at 1- to 2-year intervals in patients with chronic ulcerative colitis if they have pancolitis for greater than 7 years or left-sided colitis for greater than 15 years
14. Chronic inflammatory disease of the colon when precise *diagnosis* will influence immediate management
15. Chronic inflammatory disease of the colon when determination of *disease activity* will influence immediate management
16. Clinically significant diarrhea of unexplained etiology
17. Intraoperative identification of the site of a lesion that cannot be found by gross inspection or palpation

TABLE II Routine Indications for Therapeutic Colonoscopy

1. Active lower intestinal bleeding secondary to lesions such as ulcers, polypectomy sites, vascular malformations, and diverticula
2. Foreign body removal
3. Decompression of acute nontoxic megacolon or sigmoid volvulus
4. Palliative stent placement across a stenosing neoplasm
5. India-ink tattooing a cancer or neoplastic polyp for surgical resection
6. Dilation of stenotic lesions such as anastamotic strictures
7. Snare polypectomy of polyps too large for safe resection during flexible sigmoidoscopy

cost-effective or of high utility in such cases, particularly when patients do not have lower intestinal symptoms. Other examples are included in Table IV.

BOWEL PREPARATION

General Instructions

When preparing for colonoscopy, the patient should take only clear liquids by mouth beginning the day before elective examination and should have nothing but medications and/or preparation solution on the day of the exam. Physicians should instruct patients to avoid red food coloring or red liquids so as not to mistake passage of these for blood. Further instructions include discontinuation of iron supplements 1 week before examination to reduce surface epithelial discoloration.

Polyethylene Glycol–Electrolyte Solutions

A variety of bowel preparations have been used over the years to cleanse the colon for examination. Many of these have proved less than ideal. Currently, the two most widely accepted and useful preparations include electrolyte solutions of polyethylene glycol (PEG–ELS) or oral sodium phosphate (Table V). The available PEG–ELS agents are iso-osmotic electrolyte (mainly sodium) solutions, which are not readily absorbed by the intestinal mucosa. Assuming that the patient does not take dietary sugar with the preparation (which facilitates the absorption of sodium), all electrolytes and water remain within the bowel lumen. When taken over 2–3 h, there is rapid washout of the entire bowel. The volume required for adequate preparation ranges from 2 to 4 liters or more. Typically, the bowel preparation begins early in the afternoon on the day before elective colonoscopy. This schedule minimizes patient bowel movements late into the night.

TABLE III Contraindications for Colonoscopy

1. Established or suspected perforated viscus
2. Toxic megacolon (e.g., *C. difficile* colitis)
3. Severe acute diverticulitis
4. Fulminant colitis

Oral Phosphasoda Solutions

Recently, oral sodium phosphate solutions have been used for colon preparation. Results from comparative studies demonstrate that they are as effective as the PEG–ELS solutions. Phosphasoda solutions are highly osmotic and require much less volume than PEG–ELS solutions. The patient takes 1.5 oz (45 ml) with approximately 32 oz of water on the afternoon before colonoscopy. The same preparation is repeated the next morning. Although complications of preparations are discussed below, it is worth noting that this preparation can cause mild mucosal inflammatory reactions and may not be the best preparation for patients who are having examinations to exclude inflammatory bowel disease or other forms of colitis.

SEDATION

Just as bowel preparation regimens have changed through the years, so have sedation techniques. Whereas meperidine was widely used for many years, it was recently discontinued in many units because of its duration of action and the potential for seizures related to drug metabolites. Fentanyl has replaced meperidine for both its shorter half-life and reduced side effect profile. Patients tend to recover from colonoscopy more quickly after fentanyl sedation.

Another change has been the increased use of midazolam rather than diazepam. As with fentanyl, midazolam has the benefit of a shorter duration of action. The combination of fentanyl and midazolam has become a useful combination for adequate conscious

TABLE IV Situations in which Colonoscopy Is Not Indicated or Has a Low Diagnostic Yield

1. Chronic, stable irritable bowel syndrome or abdominal pain
2. Acute, self-limited diarrhea
3. Metastatic adenocarcinoma of unknown primary when the patient has no lower intestinal symptoms and when diagnosis will not alter management
4. Routine follow-up of inflammatory bowel disease
5. Preoperative assessment for patients undergoing elective abdominal surgery for noncolonic disease
6. Melena or other gastrointestinal bleeding when an upper source is identified

TABLE V PEG–ELS and Oral Phosphasoda Bowel Preparation Solutions

PEG–ELS	Oral phosphasoda solution
2–4 liters over a 2 to 3 h period the day before colonoscopy; repeat preparation if not clear; may be delivered via nasogastric tube for emergent, rapid preparation	1.5 oz of solution in 8 oz of water, followed by another 32 oz of water; taken the afternoon before the exam and on the morning of examination
May be given to most any patient	Avoid in patients with congestive heart failure, cirrhosis, or creatinine >1.5
Not known to cause mucosal inflammation	May cause mild inflammatory mucosal reactions that endoscopically resemble forms of colitis

sedation during most colonoscopies. Most patients report good outcomes with this regimen.

When fentanyl and midazolam do not provide adequate sedation, it may be necessary to pursue other options. One option is propofol, which has a very short half-life. Sedation lasts only as long as the drug is being administered. Patients are generally well sedated for the examination and tolerate the procedure without difficulty. However, there are issues regarding propofol that make it less than ideal for routine colonoscopy. First, it often provides a level of sedation beyond that of conscious sedation. In many units, an anesthesiologist and/or respiratory therapist must be available during administration should the patient become oversedated and require intubation. Second, the medication is more expensive than fentanyl and midazolam, making the approach less cost effective.

In the very rare case that conscious sedation or propofol is inadequate, the endoscopist can consider general anesthesia. This requires coordination with an anesthesiologist and is typically scheduled in advance. Patients often go for a preprocedure anesthesiology clinic evaluation. This form of sedation adds considerable cost to the procedure but should be used when necessary.

RISKS AND POTENTIAL COMPLICATIONS

Bleeding

The potential complications of colonoscopy are listed in Table VI. One of the more common complications is bleeding. Although the risk of bleeding from a diagnostic exam is only 0.02–0.03%, the rate can be as high as 1.6–5.4% among patients who have undergone polypectomy. Higher rates are reflected by resection of lesions greater than 2 cm. Postpolypectomy bleeding is most common within the first 12 days of the exam, but there have been reports of bleeding as late as 29 days. Management of a postpolypectomy bleed involves hemodynamic stabilization, transfusion as required, and reversal of anticoagulation in certain cases. If bleeding does not stop spontaneously, then repeat examination may be indicated. Bleeding polypectomy sites can often be treated with injection of epinephrine (1 : 10,000 dilution) and/or electrocautery, depending on the nature of the lesion. Occasionally, interventional radiologic or surgical intervention is required when endoscopic therapies fail.

Perforation

Although perforation is likely the most feared complication of colonoscopy, the rate of occurrence secondary to a diagnostic exam is approximately 0.045%. The risk can be higher following polypectomy, with some older studies reporting an incidence as high

TABLE VI Potential Complications of Colonoscopy and Bowel Preparations

1. Bleeding
   - Diagnostic exam 0.02–0.03%
   - Therapeutic exam 1.6–5.4%
2. Perforation
   - Diagnostic exam 0.045%
   - Therapeutic exam $<1\%$
3. Infection $<1\%$
4. Pain
5. Allergic reaction to sedatives
6. Hypotension or hypoxemia secondary to oversedation
7. Thrombophlebitis at intravenous entry site
8. Cardiac ischemia or arrhythmia
9. Postpolypectomy distension syndrome
10. Postpolypectomy coagulation syndrome
11. Hyperphosphatemia and/or hypocalcemia secondary to phosphasoda bowel preparations
12. Volume overload secondary to phosphasoda bowel preparations
13. Intravascular volume depletion secondary to phosphasoda bowel preparations

as 1%. Perforation can result from mechanical force, colonic distension, and effects of polypectomy. A looped colonoscope may create excessive mechanical stress and perforation as the colon wall is stretched outward. The bowel can also rupture if the colonoscope is pushed blindly through a lumenal segment or if an instrument tip (e.g., biopsy forceps) pierces the wall. Pneumatic dilation causes perforation when the lumen is overdistended during insufflation. Finally, polypectomy may cause perforation because of full-thickness cuts or burns and there may be delayed rupture of necrotic tissue in some instances.

Factors that increase the risk of perforation include poor visualization secondary to inadequate bowel preparation, acute bleeding, and an uncooperative patient. There is also considerable perforation risk in cases of fulminant colitis, severe diverticulitis, toxic megacolon, or in cases where pneumatosis has been visualized on diagnostic imaging. Care should be taken to recognize and/or reduce perforation risks before a colonoscopy is begun.

Perforation can manifest in several ways. Direct visualization of the peritoneum is the most obvious sign. However, perforation may not be immediately apparent during colonoscopy. Patients may not develop abdominal pain (beyond that expected for gaseous distension), rebound tenderness, hypotension, fever, or tachycardia until after transfer to the recovery area. Others may not have symptoms for several days after the procedure.

Diagnosis of suspected perforation requires careful physical examination followed by radiographic imaging. An abdominal X ray will show pneumoperitoneum when a considerable amount of air has escaped the bowel lumen. In some cases, diagnosis requires an enema with water-soluble contrast (gastrograffin). Leakage of contrast is diagnostic of perforation.

Whenever there is pneumoperitoneum or contrast extravasation on imaging, surgical intervention is immediately required. When there is no obvious evidence for gross perforation, treatment might involve intravenous antibiotics and supportive care. In either case, a surgical consultation should be made as soon as the problem is recognized or suspected.

Infection

Systemic Infection

The risk of developing systemic infection from colonoscopy is very low. In several studies looking at bacteremia following colonoscopy, the combined incidence was 0.01%. In these studies, blood cultures were drawn within 5 min of colonoscopy completion and none of the study patients developed an acute illness afterward. Follow-up cultures were persistently negative in these cases.

Endocarditis

Although endocarditis can be a concern for patients with increased generalized risk, there are no well-documented reports of endocarditis following colonoscopy. Still, some authors have implicated colonoscopy as the cause in a few cases. Antibiotic prophylaxis to prevent endocarditis is not recommended for most patients and will be discussed below.

Arrhythmia and Cardiac Ischemia

Generally, it is recommended that patients have continuous cardiac monitoring during colonoscopy because a number of studies have demonstrated transient and variable electrocardiogram abnormalities during colonoscopy. Although rare, there have been reports of myocardial infarction occurring during colonoscopy. Care should be taken to reduce cardiac ischemic risk in patients undergoing colonoscopy whenever possible.

Postpolypectomy Distension Syndrome

Postpolypectomy distension syndrome (PDS) refers to pain caused by excessive insufflation of the colon. The pain of this syndrome can be quite impressive. In fact, it can be difficult to distinguish from perforation in some cases. The key differentiating factors are that patients with PDS do not develop peritoneal signs, fever, tachycardia, hypotension, or other common signs of perforation. The treatment for this problem is to turn the patient onto his or her right side so that air moves up to the splenic flexure and then through the left colon for release. It is expected that this problem will resolve spontaneously with patient movement and expulsion of gas.

Postpolypectomy Coagulation Syndrome

Polypectomy coagulation syndrome (PCS) results from deep tissue injury caused by electrical currents in a polypectomy snare, "hot" biopsy forceps, or cautery probe. Whereas the operator intends to apply thermal energy only to a polyp or other lesion at the mucosa or submucosa, PCS results when tissue damage extends into the muscularis propria and/or serosa. PCS is most often caused by prolonged application of electrical current. Although the colon is not perforated, there can be transmural necrosis, which sometimes leads to perforation.

Clinical evidence of PCS typically manifests within hours to 5 days after colonoscopy and symptoms can mimic perforation. Patients may present with peritoneal signs, fever, leukocytosis, tachycardia, or hypotension. Abdominal imaging should be used to exclude perforation in such cases. Thereafter, treatment consists of bowel rest, intravenous fluid hydration, antibiotics, and supportive care. If the patient's condition worsens, repeated radiography should be used to exclude new perforation.

Complications of Bowel Preparations

As previously discussed, the most common solutions used for bowel preparation are PEG−ELS and oral sodium phosphate. The advantage of PEG−ELS solutions is that they have no real toxicity. Volume overload is avoided because sodium and fluids are not readily absorbed during preparation. This is especially important for patients with renal disease, congestive heart failure, or cirrhosis. The disadvantages of PEG−ELS preparations are that patients are required to drink large volumes (4 liters or more) and the taste is often poorly tolerated. Because of the large ingested volumes, patients may experience abdominal distension, nausea, vomiting, and even aspiration. This can lead to poor compliance with the preparation, a poorly cleansed colon, or more serious health problems.

Oral sodium phosphate solutions have become popular because of their smaller preparation volumes, improved taste, and lower cost. However, these solutions can cause significant electrolyte and fluid shift abnormalities as phosphate and salts move in and out of the vascular space. One risk is hyperphosphatemia. Although most documented cases have been asymptomatic, there have been several deaths related to phosphate overload. There can be also arrhythmic complications resulting from hypocalcemia and hypokalemia. Furthermore, there is a risk for transient volume overload related to phosphate absorption and fluid shifts into the intravascular space. These factors have led to the recommendation that phosphasoda preparations be avoided in patients with renal insufficiency (creatinine >1.5), congestive heart failure, and cirrhosis.

Although there can be transient volume overload with oral phosphasoda preparations, there is also the risk of volume depletion. This occurs secondary to fluid and electrolyte losses in the stool. These preparations should be prescribed only for the appropriate patient and the patient should be counseled to drink large volumes of water after the preparative solution has been consumed.

Combustion of Colonic Gases

A good bowel preparation is important for reducing the chance of a colonic explosion. Colonic bacteria release hydrogen and methane gas during normal metabolism. If bacteria and stool are not adequately removed, there is a chance of explosion when using electrocautery. This is more than a theoretical risk as there have been published reports of explosions occurring in poorly prepared colons.

ANTIBIOTIC PROPHYLAXIS

Infectious complications from colonoscopy are uncommon. Although there is a risk of transient bacteremia during colonoscopy, only a few published reports have directly attributed infective endocarditis to colonoscopy. Furthermore, there are no prospective, controlled trials proving that antibiotic prophylaxis prevents the development of endocarditis in this setting. Because of these facts, and because bacteremia rates are very low during colonoscopy, the ASGE has not made formal recommendations for antibiotic prophylaxis in any individual undergoing colonoscopy. The ASGE has left it to the practitioner's discretion whether to administer prophylactic antibiotics to patients considered "high risk" for the development of infective endocarditis. These patients include those with a history of endocarditis and those with prosthetic heart valves or surgically constructed systemic−pulmonary shunts or conduits. There are insufficient data to recommend antibiotic prophylaxis for all other patients, including those with cirrhosis, prosthetic joints, or synthetic vascular grafts and other immunocompromised patients. As with the high-risk patients described above, the decision of whether to give prophylaxis to a patient with a synthetic graft less than 1 year old is left up to the practitioner.

When antibiotic prophylaxis is administered, current recommendations are for the use of preprocedure intravenous ampicillin and gentamicin. Thirty minutes before colonoscopy, the patient is given 2 g of ampicillin and 1.5 mg/kg (up to 80 mg) of gentamicin. Six hours after the colonoscopy, the patient is given a 1.5 g oral dose of ampicillin. In the case of penicillin allergy, 1 g of vancomycin is given in place of the ampicillin.

ANTICOAGULATION ISSUES

Many patients take anticoagulants for reasons such as mechanical heart valves, previous stroke, myocardial infarction, and deep venous thrombosis. When making decisions about withholding anticoagulants for

TABLE VII ASGE Recommendations for Anticoagulation Management among Patients Undergoing Colonoscopy, Based on Their Thromboembolic Risk when Off Medication

Procedure risk+ thromboembolic risk	Recommendation
Low+Low	Do not change anticoagulation; delay elective procedures if INR supratherapeutic
Low+High	Do not change anticoagulation; delay elective procedures if INR supratherapeutic
High+Low	Discontinue warfarin 3–5 days prior to the procedure and restart after the procedure
High+High	Discontinue warfarin 3–5 days prior to the procedure and consider using a "heparin window"

colonoscopy, physicians must weigh procedural bleeding risks against the thromboembolic risks of stopping anticoagulation. It is useful to divide bleeding and thromboembolic risks into low- and high-risk categories when making these decisions. For example, diagnostic colonoscopy (with or without biopsy) is of low risk for causing bleeding (<1%). However, colonoscopy with snare polypectomy, coagulation therapy, or pneumatic dilation carries a much higher risk (1–5%). Likewise, persons with a low risk for thromboembolic complications are those with previous deep venous thrombosis, chronic/paroxysmal atrial fibrillation (without valvular disease), bioprosthetic heart valves, and mechanical aortic valves. High-risk patients include those who have mechanical mitral valves, atrial fibrillation plus valvular heart disease or mechanical valves, and mechanical valves in the setting of prior thromboembolic disease. ASGE recommendations for anticoagulant management are found in Table VII.

With regard to aspirin and other nonsteroidal anti-inflammatory agents, the ASGE has recommended continued usage through most endoscopic procedures. However, many physicians will ask patients to discontinue aspirin for therapeutic colonoscopy because of the inherent bleeding risks. Although there have been insufficient data for formal recommendations regarding use of dipyridimol and ticlodipine, many physicians follow the same recommendations as for aspirin.

Colorectal Adenocarcinoma

PAUL J. LIMBURG AND DAVID A. AHLQUIST
Mayo Clinic and Foundation

aberrant crypt foci Clusters of colonic crypts that typically appear larger and thicker than normal; lumenal shape may also be altered; thought to represent an early precursor of adenocarcinoma, especially when dysplasia is present.

adenocarcinoma A malignant neoplasm derived from glandular epithelium.

adenomatous polyp (or adenoma) A premalignant neoplasm arising from glandular epithelium.

case-control study An epidemiological study design wherein exposures are compared between a group of individuals with the disease of interest (cases) and a group of individuals without the disease of interest (controls); also called a retrospective study, since the exposure information is collected after a diagnosis has been established.

chemoprevention The use of chemical compounds to prevent, inhibit, or reverse carcinogenesis before dysplastic epithelial cells invade across the basement membrane; may refer to either nutritional or pharmaceutical agents.

cohort study An epidemiological study design wherein a group of exposed individuals and a group of non-exposed individuals are followed forward in time to compare incidence rates for the disease of interest; also called a prospective study, since the exposure information is collected before a diagnosis has been established.

distal colon Anatomic subsite of the colorectum that includes the descending colon, sigmoid colon, and rectosigmoid colon; may sometimes include the rectum as well.

meta-analysis The analysis of combined data from multiple epidemiological studies, for the purpose of integrating the findings; often used to increase statistical power and/or provide a broader perspective when individual study results are inconsistent.

metachronous neoplasia Tumors (adenomas, adenocarcinomas, or a combination of both) that are diagnosed at different points in time; in clinical practice, metachronous neoplasms may refer to newly formed and newly discovered tumors.

proximal colon Anatomic subsite of the colorectum that includes the cecum, ascending colon, and transverse colon.

Surveillance, Epidemiology, and End Results (SEER) program An authoritative source of information on cancer incidence and survival in the United States; coordinated by the National Cancer Institute; currently collects and publishes cancer incidence and survival data from 11 population-based cancer registries and 3 supplemental registries, which cover approximately 14% of the U. S. population in total.

synchronous neoplasia Tumors (adenomas, adenocarcinomas, or a combination of both) that are diagnosed at the same point in time.

TNM staging system A universal cancer classification system that is based on tumor extent (T), lymph node status (N), and the presence or absence of distant metastases (M); provides a standardized measure for planning treatment and predicting prognosis.

Among all cancers, colorectal cancer (CRC) has the third highest incidence rate in the world, trailing only lung and breast cancers. According to recent estimates, 944,700 new CRC cases are diagnosed annually and 492,400 deaths are attributed to this disease each year. In the United States, approximately 1 in every 18 persons will be afflicted with CRC over the course of a lifetime. Despite these sobering statistics, emerging data suggest that the large majority of CRC cases may be prevented through the design of (and compliance with) effective early detection programs. Advances in CRC treatment and control strategies should further reduce the societal burden imposed by this relatively common disease.

CLINICAL ASPECTS

Ninety-eight percent of all malignancies that develop within the large intestine arise from glandular mucosa and are thus classified as adenocarcinomas by histology. Less frequently encountered histologic subtypes include lymphomas, carcinoid tumors, and leiomyosarcomas. Metastatic lesions rarely present within the colorectum, but can include adenocarcinomas arising from the breast, ovary, prostate, lung, or stomach. Malignant melanomas may occasionally spread to the colorectum as well. Because nearly all lower gastrointestinal tract neoplasms are primary adenocarcinomas, the term colorectal cancer (CRC) generally refers to this tumor subtype. This convention is used throughout the remainder of the text.

Carcinogenic Process

Colorectal carcinogenesis is a multistep process that begins with the clonal expansion of genetically altered epithelial cells (Fig. 1). Clustering of these abnormal cells results in the formation of aberrant crypt foci. Aberrant crypt foci (ACF) represent the earliest stage of dysplasia that can be recognized using current technology. In response to poorly understood molecular signals, a subset of ACF advance to become adenomatous polyps, which are often referred to simply as adenomas. Adenomas can further progress in terms of size (diminutive to small to large), glandular distortion (tubular to tubulovillous to villous), and/or dysplasia grade (low to high). When dysplastic cells invade across the basement membrane, the requisite criterion for transformation from a benign adenoma to a malignant adenocarcinoma is achieved. This process is thought to occur in a small fraction (8–12%) of all adenomas.

Although less fully characterized, a minority of CRCs are thought to arise *de novo* or from "flat" colorectal adenomas. These lesions tend to be found in the proximal colon and likely progress through an alternate pathway of carcinogenesis. Data regarding the prevalence and natural history of less-understood precursor lesions are currently being gathered. Ongoing research in this area may reveal new insights regarding the clinical characteristics of nonpolypoid CRCs during the next several years.

Presentation and Staging

The clinical manifestations of CRC relate in part to tumor location. Typical signs and symptoms of proximal (cecum, ascending, transverse) colon malignancies include ill-defined abdominal pain, weight loss, and occult bleeding. Distal (descending, sigmoid) colon and rectal cancers commonly present with altered bowel habits, decreased stool caliber, and hematochezia. Regardless of anatomic subsite, CRCs often remain asymptomatic until relatively late in the disease course. Accordingly, patients who delay seeking medical attention until after symptoms develop are more likely to be diagnosed with advanced-stage disease.

Colonoscopy is the test of choice for establishing the diagnosis of CRC. Once cancer has been histologically confirmed, a staging work-up is performed among potential surgical candidates. Computerized tomography (CT) of the abdomen and pelvis is used as the primary tool for detecting both regional and distant metastases. In the setting of a lumenally obstructing CRC, CT colonography can be used to rule out synchronous neoplasia in the proximal colon, while simultaneously providing an abdominopelvic survey. For rectal cancers, endoscopic ultrasound helps to determine the locoregional extent of disease, which might influence the timing of adjuvant chemotherapy and/or radiation therapy. Positron emission tomography (PET) affords a whole body screen for malignant disease. However, because of its high cost and limited accessibility, PET scanning is often not included in the initial CRC staging evaluation.

The most definitive assessment of CRC stage is made from surgical pathology specimens. Tumor size, depth of invasion, lymph node involvement, and distant metastases represent core elements of the TNM staging system (Table I). TNM stages I–IV have been shown to correlate with 5-year survival rates. In general, stage I disease is associated with a very favorable prognosis, whereas stage IV disease portends a rapidly fatal outcome. Within TNM stages, 5-year survival rates are lower for rectal cancers than for colon cancers. This observation may be related, at least in part, to differences in anatomic structure (i.e., lack of a serosal lining in the rectum) and physiologic function between these organ subsites.

HOST FACTORS

Similar to many other malignancies, CRC risk increases with advancing age. Based on data from the Surveillance, Epidemiology, and End Results (SEER) program, CRC incidence rates begin to rise rapidly after the age of 50 years and increase steadily until the age of approximately 80 years. Fewer than 5% of all CRC cases occur among persons younger than 45 years of age. With respect to premalignant colorectal neoplasia, adenoma prevalence rates also increase

TABLE I Colorectal Cancer Survival by TNM Stage

TNM Stage	Description	Approximate 5-year survival rate (%)
0	Confined to the epithelium or invading into the lamina propria (Tis); no lymph node involvement (N0); no distant metastases (M0)	100
I	Invasion of the submucosa (T1); no lymph node involvement (N0); no distant metastases (M0)	95
	Invasion of the muscularis propria (T2) no lymph node involvement (N0); no distant metastases (M0)	90
II	Invasion through the muscularis propria into the subserosa or nonperitonealized pericolic/perirectal tissues (T3); no lymph node involvement (N0); no distant metastases (M0)	80
	Perforation of visceral peritoneum or direct invasion into adjacent organs or tissues (T4); no lymph node involvement (N0); no distant metastases (M0)	75
III	Any depth of invasion (Tis−T4); metastases in 1−3 pericolic or perirectal lymph nodes (N1); no distant metastases (M0)	72
	Any depth of invasion (Tis−T4); metastases in 4 or more pericolic or perirectal lymph nodes (N2); no distant metastases (M0)	60
	Any depth of invasion (Tis−T4); metastases in lymph nodes along a named vascular trunk or tumor invasion of adjacent organs (N3); no distant metastases (M0)	40
IV	Any depth of invasion (Tis−T4); any nodal status (N0−N3); distant metastases present (M1)	5

with age, with estimates of 30% at 50 years, 40−50% at 60 years, and 50−65% at 70 years of age. Gender is not strongly associated with overall CRC risk, but CRC distributions by anatomic subsite are different between men and women. Most notably, the rate ratio of proximal : distal CRCs is much higher among women (1.23) than among men (0.86) after the age of 65 years.

For reasons that remain incompletely defined, racial and ethnic subgroups of the U. S. population experience fairly striking dissimilarities in CRC incidence, mortality, and 5-year survival rates. For example, among the six race/ethnicity subgroups recognized by the SEER program, African Americans have the highest CRC incidence rate, highest CRC mortality rate, and the second lowest 5-year survival rate. Further exploration of CRC risk associations within and across racial, ethnic, and culturally diverse subject groups is needed to determine the predominant mechanisms of, and appropriate interventions to disrupt, carcinogenesis in these population subsets.

In addition to age, gender, and race/ethnicity, several host and environmental factors have been convincingly associated with CRC risk. Key points regarding these risk associations are highlighted below.

Personal History of Colorectal Neoplasia

Patients with a history of colorectal adenomas are three to six times more likely to develop metachronous neoplasms (adenomas or CRC diagnosed at a later point in time) than are persons of the same age, gender, and race/ethnicity in the general population. Adenomas that are large in diameter ($\geq$1 cm), multiple in number ($\geq$3 total), or "aggressive" by histology (villous glandular formation or high-grade dysplasia) portend the highest risks. In a retrospective study of patients with adenomas $\geq$1 cm in diameter that were managed by observation only (prior to the widespread availability of colonoscopy), CRC risks were found to increase progressively over time. After 5, 10, and 20 years of follow-

up, 2.5, 8, and 24% of these patients developed CRC. Data from the National Polyp Study additionally showed that recurrent adenomas were significantly more common at the first surveillance exam among patients with large adenomas (<1 cm in diameter; odds ratio 1.6; 95% confidence interval 1.1−2.5) or multiple adenomas (≥ 3 total; odds ratio 2.4; 95% confidence interval 1.7−3.5) at baseline, compared to patients with smaller and fewer adenomas, respectively. Importantly, neither diminutive hyperplastic polyps nor diminutive or small tubular adenomas ≤ 2 in total number appear to be associated with increased CRC risk.

Patients with a history of CRC are prone to developing recurrent primary cancers, second primary cancers, and metachronous adenomas. The majority of recurrent CRCs are diagnosed within 3 years (85%) of the initial operation. Median time to detection of metachronous adenomas ranges from 19 to 32 months in this patient group.

Family History of Colorectal Neoplasia

Familial clustering can be observed in up to 20% of all CRC cases. Large epidemiologic studies have shown that CRC risk is increased by 1.5- to 2-fold among first-degree relatives of patients with colorectal neoplasia. Although less thoroughly investigated, having second- or third-degree relatives with CRC also appears to confer a modestly increased risk. In a minority of families, multiple individuals are found to have documented histories of CRC or other cancers. Heritable cancer syndromes should be strongly considered in this context, particularly when a kindred includes one or more family members diagnosed with malignant disease at an early age (see Heritable Syndromes).

Inflammatory Bowel Disease

Idiopathic inflammatory bowel disease (IBD) is an established risk factor for CRC. Among patients with ulcerative colitis, cumulative CRC incidence rates range from 1.8% after 20 years to 43% after 35 years of disease. The extent of colonic inflammation is also thought to modify CRC risk (i.e., CRC risk is higher among patients with pancolitis than among patients with distal colitis or proctitis). In contrast, colitis severity and colitis activity appear to have little influence on CRC risk. Relatively few studies have specifically addressed an association between CRC and Crohn's disease. However, existing data suggest that CRC risks are similarly elevated among patients with either Crohn's disease or ulcerative colitis after adjusting for the duration of IBD. Other chronic inflammatory conditions such as microscopic colitis and lymphocytic colitis have not been convincingly associated with CRC risk.

Other Medical Conditions

Type II diabetes mellitus (DM) has been positively associated with CRC risk in some, but not all, epidemiologic investigations. In the largest prospective study reported to date, men with DM were 30% more likely to die from CRC than men without DM. CRC mortality rates were also higher among diabetic women, but this risk estimate was slightly lower (16%) and was not statistically significant. Acromegalics may be metabolically and/or anatomically predisposed to higher CRC risks. However, due to the relative rarity of this condition, most observational studies have lacked adequate statistical power to confirm or exclude a true risk association. Cholecystectomy results in altered fecal bile acid composition. Two recent meta-analyses found that CRC risk was increased by up to 34% after gallbladder removal. Yet, because of limitations in the design of some previous studies, this association remains controversial.

ENVIRONMENTAL FACTORS

Diet and Nutrition

An estimated 30% of all cancers may be avoidable through dietary modification. Unfortunately, identifying the food components that are most important to colorectal carcinogenesis remains an ongoing challenge. Select macro- and micronutrients with a putative influence on CRC risk are discussed below.

Macronutrients

Dietary fats induce the excretion of primary bile acids, which can then be converted into procarcinogenic secondary bile acids by the colonic bacteria. Although ecological studies have repeatedly shown a strong association between per capita fat consumption and CRC incidence rates (with correlation coefficients ranging from 0.8 to 0.9), data from case-control and cohort studies have been less consistent. In a comprehensive report published jointly by the World Cancer Research Fund and the American Institute for Cancer Research in 1997, total fat intake and saturated fat intake were both concluded to be possible, but not definite, CRC risk factors. Further exploration of hypothesized positive and negative associations with specific fatty acid subtypes (such as ω-6 and ω-3 polyunsaturated fatty acids, respectively) is needed to clarify the potential role of dietary fats in CRC risk modulation.

Fiber enhances stool bulk, stimulates intestinal transit, decreases secondary bile acid concentrations (possibly pro-carcinogenic), and increases short-chain fatty acid concentrations (possibly anti-carcinogenic). Numerous epidemiological studies have observed inverse associations between high fiber intake and CRC risk. However, several large clinical trials using various fiber-based interventions have been completed with little, if any, beneficial effects observed against the surrogate end-point of adenoma recurrence.

Micronutrients

Calcium binds to intralumenal toxins and may also decrease cellular proliferation within the colorectum. In one recent clinical trial, calcium supplementation was associated with a statistically significant 19% reduction in the adenoma recurrence rate among postpolypectomy patients after 4 years. Antioxidants (including retinoids, carotenoids, ascorbic acid, α-tocopherol, and selenium) neutralize free radical compounds, which might stimulate tumorigenesis within the colorectum. Observational data referent to antioxidant intake and CRC risk have been generally unimpressive. Similarly, mixed results have been obtained from five clinical trials, with the largest and most rigorously designed study finding no statistically significant benefits from either a combination of vitamin C and vitamin E or a combination of vitamin C and β-carotene. Methyl donors, including folate and methionine, are critical for maintaining normal cellular functions such as nucleotide synthesis and gene regulation. Data from most prospective observational studies support an inverse association and several folate intervention trials are under way.

Lifestyle Factors

Alcohol induces cellular proliferation, blocks methyl group donation, and inhibits DNA repair. In a meta-analysis of 27 case-control and cohort studies, consumption of two alcoholic beverages per day was associated with a modest, but statistically significant, 10% elevation in CRC risk. Cigarette smoking appears to increase CRC risk after a prolonged latency period of perhaps 3–4 decades. CRC incidence rates among tobacco users who began smoking in the distant past have usually been two to three times higher than those observed among never smokers. Physical activity appears to have a protective influence on CRC risk, which may be related to lower serum insulin concentrations among nonsedentary individuals. Overall, regular physical activity seems to reduce CRC risk by approximately 40–50%.

HERITABLE SYNDROMES

Although familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) contribute to only 5–10% of all CRC cases, these syndromes are of substantial clinical and research importance. The germ-line mutations responsible for FAP (*APC* gene) and HNPCC (*MLH1*, *MSH2*, *MSH6*, *PMS1*, and *PMS2*, and perhaps other as yet unrecognized genes) are inherited in an autosomal dominant fashion, have a high degree of penetrance, and lead to malignant disease at a relatively early age. The major features of these syndromes are discussed below. Further details regarding FAP, HNPCC, and other heritable cancer syndromes are available in the American Gastroenterological Association's technical review on hereditary CRC and genetic testing.

Familial Adenomatous Polyposis

Germ-line mutations in the *APC* gene occur in approximately 1 in 5000 persons in the United States. Up to 20% of FAP probands represent new onset *APC* mutations with an unremarkable family history. The hallmark lesion of FAP is diffuse colorectal polyposis, with hundreds to thousands of adenomas typically developing at puberty or during adolescence. Extracolonic manifestations of FAP include the following: duodenal adenomas, gastric fundic gland hyperplasia, mandibular osteomas, supernumerary teeth, congenital hypertrophy of the retinal pigmented epithelium, desmoid tumors, epidermoid cysts, fibromas, lipomas, and thyroid, adrenal, or hepatobiliary cancers. Rarely, patients with germ-line *APC* mutations also develop medulloblastomas. Without prophylactic colectomy, FAP patients are almost universally diagnosed with CRC at a relatively young age (mean = 45 years). A subset of patients with attenuated FAP have relatively fewer adenomas (<100) and develop CRC at a slightly older age (mean = 56 years). Interestingly, colonic neoplasms are frequently found in the proximal colon in patients with attenuated FAP, for reasons that remain unclear.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC is characterized by early onset CRC (mean = 44 years), which tends to occur in the proximal colon and exhibits the microsatellite instability phenotype. Up to 25% of HNPCC patients are found to have more than one CRC at the time of their initial diagnosis. Endometrial, ovarian, gastric, small bowel, hepatobiliary, and genitourinary cancer risks are also increased

within HNPCC kindreds. Clinical data can be used to identify families with HNPCC. According to the revised Amsterdam Criteria II, at least three relatives must have an HNPCC-associated cancer and (1) one person is a first-degree relative of the other two; (2) two or more successive generations are affected; and (3) one or more cancers were diagnosed before the patient was 50 years of age. Muir-Torre syndrome represents a subset of HNPCC patients with sebaceous neoplasms in addition to the above-mentioned clinical manifestations (ratio of men : women = 2 : 1).

EARLY DETECTION

The several-year dwell time of benign and presymptomatic malignant colorectal neoplasms seemingly offers an ample window of opportunity for effective early detection. To succeed, CRC screening and surveillance interventions must be accurate, efficient, safe, and affordable when periodically applied to appropriate at-risk populations. A general early detection algorithm for colorectal neoplasia is provided in Fig. 2. Salient features of the current screening and surveillance guidelines are presented below, followed by discussions of the available tools and emerging technologies.

Current Screening and Surveillance Guidelines

Average-Risk Screening and Surveillance

Screening should begin at age 50 years for asymptomatic adults who have no identifiable CRC risk factors. The American Cancer Society and other organizations endorse several options and testing intervals including the following: (1) fecal occult blood test every year; (2) flexible sigmoidoscopy every 5 years; (3) fecal occult blood test every year and flexible sigmoidoscopy every 5 years; (4) barium enema every 5 years; and (5) colonoscopy every 10 years. Selection of a particular option is ideally based on an informed discussion with patients that considers estimated effectiveness, risks, and costs of each approach.

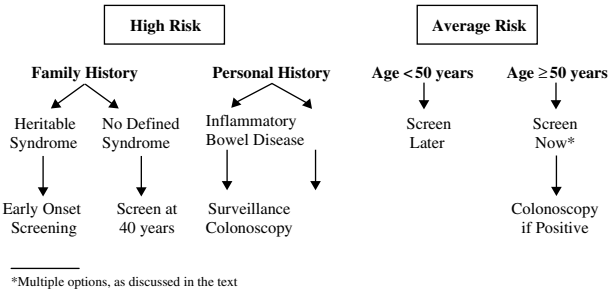

FIGURE 2 Basic algorithm for the early detection of colorectal neoplasia. Copyright Mayo Foundation.

After a complete clearing colonoscopy has been performed, surveillance colonoscopy is indicated at 3 years for patients with advanced or multiple adenomas at baseline or with a family history of CRC. Surveillance procedures can be delayed for 5 years among low-risk patients (i.e., those with only one or two diminutive or small adenomas and no family history of CRC). Once a negative surveillance colonoscopy has been documented, subsequent surveillance examinations may be deferred for 5 years. Patients with previously resected sessile adenomas >2 cm in diameter should be reendoscoped in 3–6 months. If residual adenomatous tissue is still present after two or three attempts at therapeutic colonoscopy, surgical consultation should be considered.

High-Risk Screening and Surveillance

For high-risk patients, the following early detection recommendations have been adopted:

- FAP-flexible sigmoidoscopy every year, beginning at puberty;
- HNPCC-colonoscopy every other year, beginning at age 20 and increasing to every year after age 40;
- Family history of colorectal neoplasia (not FAP) or HNPCC-colonoscopy every 5 years, beginning at age 40 or 5 years, before the youngest case diagnosis, whichever is earlier;
- Inflammatory bowel disease-colonoscopy every year after 8 years of pancolitis or after 15 years of distal colitis only.

Malignant Polyps and Post-CRC Resection

Malignant polyps are defined as neoplasms with dysplastic cells invading through the muscularis mucosae and can be treated endoscopically in some cases. The following criteria have been proposed as determinants of acceptable risk for endoscopic management: (1) the lesion has been completely excised and submitted to the pathologist in its entirety; (2) the depth of invasion, grade of differentiation, and completeness of excision can be accurately determined from the endoscopic resection specimen; (3) no signs of poor differentiation, vascular invasion, or lymphatic involvement are identified; and (4) the margin of excision is free of cancer cells.

For patients with a history of curatively resected CRC, clearing colonoscopy should be performed within 1 year of the initial operation. The first surveillance colonoscopy should be performed at 3 years and if

this examination is negative, the second surveillance examination can be delayed for 5 years.

Fecal Occult Blood Tests

Fecal occult blood testing has been widely practiced for more than 3 decades as an approach to colorectal cancer screening. Though a variety of fecal occult blood tests (FOBTs) are available, the guaiac-impregnated Hemoccult card has been most commonly used. Three large controlled trials have demonstrated that Hemoccult screening over more than 10 years significantly reduces colorectal cancer mortality, although reductions were modest at 15–33%. Furthermore, the impact of FOBT screening on colorectal cancer incidence was either negligible or slight. Such outcomes are consistent with a tool that misses most premalignant lesions and many early stage cancers. Indeed, direct comparisons of Hemoccult testing against colonoscopy in a screening population have revealed Hemoccult point sensitivities for cancer of 11–50% and for advanced adenomas of 5–25% with Hemoccult specificity ranging from 88 to 98%. The likelihood of finding a colorectal cancer or advanced adenoma with a positive Hemoccult test result (positive predictive value) has ranged from 8 to 20% depending on the test technique and population studied. Immunochemical FOBTs may offer some advantages in specificity, as they do not react with dietary or other fecal constituents that confound guaiac testing.

FOBT screening is noninvasive, relatively inexpensive, requires no cathartic preparation, and can be performed without a formal healthcare visit. These advantages must be balanced against its low sensitivity, relatively modest impact on colorectal incidence and mortality, and high false-positive rate.

Flexible Sigmoidoscopy

Case control studies have estimated that sigmoidoscopy screening reduces both incidence and mortality rates from colorectal cancer and that the benefit is preserved with screening frequencies as low as every 10 years. However, failure to inspect the proximal colon is an inherent shortcoming of sigmoidoscopy and case control studies suggest that sigmoidoscopy has no effect on mortality from proximal colon cancer. Although no rigorous sensitivity studies have been carried out, current length flexible sigmoidoscopes may detect only 30–50% of colorectal cancers due to incomplete insertion and other technical limitations in common practice. Moreover, the incidence trend toward more proximal cancers will continue to compromise sigmoidoscopic detection rates over time. Most practitioners advocate that the proximal colon should be evaluated if polyps are found on sigmoidoscopy and this approach has the potential to increase overall cancer detection rates slightly.

The advantages of sigmoidoscopy include its general availability, lack of sedation requirement, and lower cost compared to colonoscopy. Disadvantages include its incomplete inspection of the colon, modest effectiveness in overall cancer mortality reduction, and associated discomfort. Some surveys have indicated that fewer than half of those patients undergoing sigmoidoscopy are willing to return for repeat screening by this modality.

Barium Enema

Few data are available on the effectiveness of colorectal screening by barium enema radiography. The sensitivity of colon X rays for colorectal neoplasms >1 cm may be only approximately 50%, based on comparisons against colonoscopy in asymptomatic screening populations. Although barium X rays image the entire colorectum, viewing is limited to a two-dimensional plane with confounding due to superimposed radiodensities and other technical factors. Specificity may be no higher than 80–85%, meaning that 15–20% of normal patients will have false-positive test results.

The advantages of barium enema radiography include avoidance of sedation and imaging of the full length of the colorectum. This approach may have special attractiveness in individuals who are on anticoagulants or who have structural impediments to safe colonoscopy (e.g., fixed and narrowed sigmoid colons due to dense diverticulosis). Offsetting disadvantages include the uncertain benefit of this approach, the requirement for full cathartic preparation (and repreparation if a lesion is found), and a high false-positive rate.

Colonoscopy

Most clinicians consider colonoscopy to be the diagnostic gold standard for colorectal evaluation. However, owing to its expense, invasiveness, and small risk of fatal complications, colonoscopy had not been considered for average-risk screening until recently. Lacking controlled trials on the effectiveness of colonoscopy, various models suggest that colonoscopy is the most effective tool available to reduce colorectal cancer incidence and mortality. At a frequency of every 10 years beginning at age 50, screening colonoscopy is estimated to reduce colorectal cancer by 75–90%. Medicare now covers colonoscopy for average-risk screening.

The advantages of screening colonoscopy are its unparalleled point sensitivity and specificity, high

level of effectiveness in reducing colorectal cancer risk, and capacity to remove premalignant lesions without additional procedures. Disadvantages include the inconvenient and unpleasant bowel preparation, time away from daily activities, sedation, limited or delayed access in many areas, and small risk of serious complications. Furthermore, at a frequency of every 10 years, the most aggressive neoplasms (i.e., those with the shortest premalignant dwell time) may be missed.

Emerging Technologies

New approaches to colorectal cancer screening may offer patient-friendly improvements and encompass more accurate stool tests, especially those that target DNA markers, and minimally invasive structural evaluation by CT colonography (virtual colonoscopy).

DNA-Based Stool Testing

DNA-based stool testing represents a novel early detection method with considerable promise. Because DNA is released into the fecal stream continuously via exfoliation, rather than intermittently via bleeding, targeting this class of markers should lead to enhanced sensitivity over fecal occult blood testing. Moreover, since DNA originates directly from the neoplasm, rather than from the circulation, a higher level of specificity is possible. Known genetic alterations associated with colorectal carcinogenesis can be targeted as markers. Sensitive laboratory techniques allow for the detection of minute amounts of fecal DNA and these analytes also appear to be stable during transit and storage. Finally, dietary constituents and pharmaceutical agents are unlikely to interfere with fecal DNA testing.

Early investigations assessing single DNA markers (usually K-*ras*) demonstrated that the mutations present in tumor tissue can be detected in stool obtained from the same patient. However, because colorectal neoplasms are known to be genetically heterogeneous, no single universally expressed mutation has yet been identified. For example, mutant K-*ras* appears to be present in fewer than half of all large bowel tumors, which would restrict its maximum sensitivity for CRC detection to less than 50% if used as the sole analyte in a stool screening assay.

Early data suggest that the diagnostic yield is increased using multitarget stool assays directed at a spectrum of DNA alterations associated with CRC. Findings to date further suggest that fecal DNA screening may also detect supracolonic aerodigestive cancers at sensitivities comparable to those observed with colorectal neoplasia. As such, stool screening with DNA markers could have cancer control benefits beyond just the colorectum alone. However, it will be important to evaluate the implications of these preliminary results on other relevant program parameters, such as screening cost-effectiveness, and corroborate performance characteristics in large representative populations.

Computed Tomography Colonography

CT colonography represents a new minimally invasive alternative to conventional colorectal imaging that incorporates virtual reality technology and rapid CT scanners to yield detailed two and three-dimensional views of the entire colorectal surface. After a CT scan in the supine and prone positions, each obtained with a single breath-hold, diagnostic interrogation is performed on the virtual image rather than on the patient. Early studies by some indicate that cathartic bowel cleansing may be obviated, as stool can be subtracted digitally from the image, and such virtual preparation may represent an important incentive for compliance. CT colonography appears to detect colorectal neoplasms >1 cm at sensitivity rates of 70–95% with specificities of 85–95%, based on early observations in selected patient populations. Performance characteristics in large screening populations have not yet been determined.

Based on modeling using performance assumptions to date, CT colonography may not be cost-effective relative to screening colonoscopy unless it is substantially less expensive than colonoscopy and compliance is much higher. Technical refinements with CT colonography will certainly continue.

CHEMOPREVENTION

Chemoprevention can be defined as the use of chemical compounds to prevent, inhibit, or reverse carcinogenesis prior to the point when dysplastic epithelial cells invade across the basement membrane. In its broadest sense, chemoprevention includes the use of either nutritional or pharmaceutical agents. A variety of nutritional interventions have been described above (see Environmental Factors). The following section highlights three pharmaceutical agents with potential application to CRC chemoprevention.

Nonsteroidal Anti-Inflammatory Drugs

Extensive epidemiologic data suggest that regular use of nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce CRC risk by approximately 40–60%. The chemopreventive effects of NSAIDs are thought to result from cyclooxygenase-2 (COX-2) inhibition. Recently, agents that selectively block the COX-2 enzyme isoform (for example, celecoxib and rofecoxib) have been developed. These drugs are being actively investigated among

high-risk CRC patients to determine whether they afford an improved risk : benefit profile.

Exogenous Estrogens

Estrogen compounds decrease hepatic bile acid synthesis, with a consequent lowering of secondary bile acid concentrations within the colorectal lumen. The estrogen receptor also appears to be functionally important in growth regulation in the large bowel mucosa, although the specific cellular pathways involved have yet to be defined. Based on a recent meta-analysis of 28 observational studies, ever use of estrogen compounds appears to decrease CRC risk by approximately 20%.

Ursodeoxycholic Acid

Ursodeoxycholic acid (UDCA) is a hydrophilic epimer of chenodeoxycholate. This compound is noncytotoxic, stimulates the expression of major histocompatibility complex antigens, and may serve to beneficially modulate cellular growth and differentiation through a protein kinase C-mediated pathway. When used to treat patients with liver disease, UDCA has been found to have an excellent safety profile. Impressive chemopreventive potential has been demonstrated in animal models of CRC. Two randomized, clinical trials among patients with a history of colorectal adenomas are currently under way. These data should provide strong evidence regarding the chemopreventive efficacy of UDCA.

TREATMENT

Surgery

Surgical excision is the mainstay of CRC treatment, especially when a curative outcome may be potentially achievable. The type of operation and extent of resection are dependent on multiple factors, including tumor location, size, and preoperative stage. In general, right hemicolectomy is performed for CRCs arising from the cecum, ascending colon, or hepatic flexure. The transverse colon and both flexures are typically removed when cancers originate from anywhere between the ascending colon and the descending colon. For distal colon cancers, left hemicolectomy is usually the procedure of choice. For any cancers above the rectum, at least a 5 cm margin of grossly uninvolved tissue should be obtained and regional lymph nodes should be aggressively sampled. Most colonic lesions can be resected with a primary anastomosis. Adenocarcinomas in the middle and upper rectum are usually removed by anterior resection. Cancers in the lower rectum (0–5 cm above the anal verge) may require preoperative chemoradiation therapy and/or abdominoperineal resection with a permanent colostomy.

Adjuvant Therapy

Although specific dosages and delivery methods may differ slightly across institutions, adjuvant chemotherapy is usually given to stage III colon cancer patients and typically includes 5-fluorouracil (5-FU) and leucovorin. A subset of stage II colon cancer patients may benefit from this regimen as well. Chemotherapy is often begun 3–5 weeks after surgery and is administered for a duration of 6 months. Common toxicities include stomatitis, diarrhea, and neutropenia. For rectal cancer patients, adjuvant therapy may be recommended for stage II or stage III disease. A combination of 5-FU and radiation therapy (preoperatively, postoperatively, or both) is used at most centers in the United States. Investigational agents such as irinotecan (CPT-11) and oxaliplatin have shown considerable promise in early clinical trials and may become part of standard chemotherapy regimens in the near future.

colorectal adenocarcinoma Malignant neoplasm of the colon or rectum (colorectal cancer).

colorectal adenoma Benign neoplasm of the colon or rectum with malignant potential.

colorectal polyp Growth protruding from the mucosal surface into the bowel lumen.

ureterosigmoidostomy Surgical implantation of the ureters into the sigmoid colon.

Colorectal cancer is the second most common cause of cancer-related death in males and females in the United States. In 2003, it is estimated there will be 147,500 new cases of colorectal cancer and 57,100 deaths from the disease. Almost all colorectal cancers arise from adenomas, which are benign neoplasms. Adenomas that are removed cannot progress to become cancers. Screening for adenomas and their removal are, therefore, now a major part of colorectal cancer screening programs.

INTRODUCTION

Colorectal polyps are raised growths that protrude into the bowel lumen. They are described by their shape (sessile or pedunculated), size, and histological type. The common histological types are inflammatory, hyperplastic, hamartomatous, and adenomatous polyps. It is only adenomatous polyps (adenomas) that are neoplastic and therefore have malignant potential. Colorectal adenomas are classified histologically as tubular, tubulovillous, or villous. The epithelium of all adenomas is dysplastic, which is categorized as low or high grade. Advanced adenomas have the greatest potential for malignant transformation and are defined as adenomas of diameter ≥ 1 cm, or those of any size with villous histology or high-grade dysplasia. Advanced colorectal neoplasms are composed of colorectal adenocarcinomas and advanced adenomas. Adenomas are readily detected endoscopically using a sigmoidoscope or colonoscope and most can also be completely removed during the same examination by the procedure of polypectomy.

EPIDEMIOLOGY

Prevalence

Adenomas are uncommon before the age of 50 years in individuals at average risk for colorectal cancer. Prevalence rates from autopsy studies are higher than those in comparable groups determined colonoscopically. Adenoma prevalence is over 40% in subjects undergoing first colonoscopy in the seventh decade and approaches 60% in autopsy studies of subjects over the age of 65.

Distribution

Approximately 50% of adenomas diagnosed at colonoscopy are located distal to the splenic flexure (distal adenomas). The proportion of adenomas on the right side of the colon (proximal adenomas) increases with age and the proportion of all adenomas located on the right side of the colon has increased in recent decades. Individuals with a distal adenoma are more likely than those without a distal adenoma to have proximal adenomas, but approximately 50% of patients with advanced proximal adenomas do not have distal adenomas.

Conditions Associated with Adenomas

There are three conditions typically associated with adenomas:

1. Ureterosigmoidostomy. Up to 29% of patients with a ureterosigmoidostomy develop adenomas or even CRC at the ureterosigmoidostomy site. The latency period is long, with an average of 20 years, but shorter periods have been reported. Nitrosamines generated from the diverted urine are thought to be important etiologic factors.
2. Acromegaly. The risk for developing colorectal adenomas and CRC is sixfold higher in acromegalics than in control subjects. A family history of CRC further compounds this excess risk.
3. *Streptococcus* infection. *Streptococcus bovis* bacteremia and endocarditis have been associated with simple adenomas, adenomatous polyposis coli, and colon cancer. Colonoscopy has therefore been recommended for such patients. A similar association has also been reported with *Streptococcus agalactiae* infection.

ETIOLOGY

Hereditary

Individuals with the autosomally dominant hereditary conditions of familial adenomatosis polyposis (FAP) or hereditary nonpolyposis colorectal carcinoma (HNPCC) are at greatly increased risk for CRC. However, a large majority of colorectal neoplasms, termed sporadic, arise outside the context of FAP or HNPCC. Individuals with first-degree relatives (parent, sibling, or child) who have had colorectal adenomas or CRC are at increased risk for colorectal adenomas and CRC. The risk for individuals in this category is greatest for those with a first-degree relative diagnosed with CRC or adenomas at age <60 years. Individuals with no first-degree relatives diagnosed with colorectal neoplasms are deemed at "average risk" for colorectal adenomas and cancer.

Diet

Dietary factors are considered the most important determinants of risk for developing colorectal adenomas in average-risk individuals. Wide geographic variations in the prevalence of colorectal adenomas and cancer are attributed to differences in diet. Although the "Western" diet that is high in animal fat and low in fruit, vegetables, and fiber has been widely incriminated for the high prevalence of colorectal neoplasms in developed countries, definitive proof for a causal association between a Western diet and adenoma or CRC development is largely lacking. Recent randomized prospective clinical trials in individuals who had recently undergone colonoscopic polypectomy (removal of adenomas) failed to show any reduction of adenoma recurrence rates following consumption of diets low in animal fat or high in fruit and vegetable servings and fiber. There is reliable evidence that high levels of folate consumption and calcium supplements can reduce the risk for developing colorectal neoplasms.

Other Factors

Aspirin is a nonsteroidal antiinflammatory drug (NSAID) that acts by inhibiting the cyclooxygenase (COX) enzymes, COX-1 and -2. Daily aspirin ingestion over a period of years can reduce mortality from CRC by up to 50% and aspirin has recently been shown to reduce the rate of adenoma recurrence following polypectomy. The antineoplastic actions of aspirin are attributed to inhibition of COX-2 rather than COX-1, and COX-2 levels are increased in colorectal neoplasms. The serious and potentially life-threatening complications of aspirin are due largely to inhibition of COX-1. Selective NSAIDs that inhibit only COX-2 are now available. A number of large trials are currently in progress to determine whether the colorectal antineoplastic actions of the selective COX-2 inhibitor NSAIDs are equivalent to those of aspirin.

THE ADENOMA–CARCINOMA SEQUENCE

Abundant evidence indicates that almost all CRCs develop from benign adenomas. The neoplastic changes in adenomas constitute histological dysplasia and are confined to the epithelial cell layer. An adenoma progresses to become a CRC when dysplastic cells

transgress the muscularis mucosae to invade the bowel wall. Several lines of evidence support the concept of a colorectal adenoma–carcinoma sequence.

Epidemiology

The prevalence of both adenomas and CRC increases with age, but the prevalence of adenomas peaks 5 to 10 years earlier than the peak prevalence for CRC. This applies to sporadic adenomas and the adenomas of subjects with FAP.

Clinical

Subsequent incidence of CRC is profoundly reduced in subjects who have undergone adenoma polypectomy.

Morphologic

Large adenomas sometimes harbor adenocarcinomatous foci and adenomatous remnants are sometimes seen immediately adjacent to invasive cancer, implying a histological continuum from benign to malignant colorectal neoplasms. However, small foci of adenocarcinoma surrounded by normal mucosa are encountered very rarely.

Genetic

The progression from formation of the earliest adenoma to advanced adenoma and invasive cancer is driven by accumulation of genetic mutations in the neoplastic tissue (these are somatic mutations as opposed to the germ-line mutations of FAP and HNPCC). In the commonest mutational pathway, formation of the initial adenoma is heralded by mutations of both copies of the adenomatous polyposis coli (APC) gene in the colorectal epithelial cells that form the adenoma. In those adenomas that grow and have an aggressive phenotype, transition from a benign adenoma to an invasive cancer is marked by sequential mutations to both copies of the p53 gene. Mutations or silencing of a number of other genes are required for the adenoma–carcinoma sequence to be completed. The accumulated molecular genetic events that are the hallmark of colorectal carcinogenesis provide strong direct evidence linking benign and malignant colorectal neoplasms through the adenoma–carcinoma sequence.

NATURAL HISTORY OF COLORECTAL ADENOMAS

With adenoma prevalence rates as high as 50% or more in older populations, it is clear that only a small minority of adenomas progress to CRC. The most common adenoma is a diminutive (diameter $\leq$5 mm) tubular adenoma with low-grade dysplasia. Fewer than 10% of adenomas progress to become advanced adenomas and CRC. Advanced adenomas are those most likely to progress. When it occurs, progression from adenoma, most of which are of diameter $<$10 mm, to CRC is estimated to take at least 10 years on average. However, there have been very few studies in which adenomas have been identified and observed over a period of years rather than being removed when first diagnosed. In one radiological study using barium enema examinations, the time period for adenomas $>$10 mm in diameter to progress to become CRCs was from 2 to 5 years.

CLINICAL MANIFESTATIONS

A majority of adenomas are asymptomatic. A minority of large polyps may bleed sufficiently for an occult blood test to be positive without frank blood being visible in the stool. Frank bleeding from even large polyps is rare. Altered bowel habit and pain from colorectal neoplasia almost always signify CRC rather than an adenoma.

DIAGNOSIS

Because most adenomas are asymptomatic, they are usually detected by screening tests or as incidental findings in the course of investigations for unrelated symptoms. Screening of all subjects for colorectal neoplasms is now recommended, starting from the age of 50. Several modalities are available.

Fecal Occult Blood Testing

The surface epithelium of adenomas is intact so that bleeding is infrequent and intermittent. Therefore, the sensitivity of fecal occult blood testing (FOBT) for detection of adenomas is extremely poor and a majority remain undiagnosed if FOBT is the only screening tool. To improve sensitivity, it is recommended that flexible sigmoidoscopy be combined with FOBT.

Flexible Sigmoidoscopy

The 60-cm flexible sigmoidoscope has replaced the 25-cm rigid sigmoidoscope. Among asymptomatic individuals undergoing screening flexible sigmoidoscopy, 10–15% are found to have adenomas. The major limitation of flexible sigmoidoscopy as a screening tool is the inaccessibility of proximal colonic lesions to the flexible sigmoidoscope. The prevalence

of distal colorectal adenomas is higher in subjects who have a proximal advanced neoplasm than in those who do not. Nonetheless, approximately one-half of subjects with an asymptomatic proximal advanced neoplasm will have a negative flexible sigmoidoscopy. The proximal advanced neoplasms will, therefore, go undiagnosed if FOBT and flexible sigmoidoscopy are negative.

Double-Contrast Barium Enema

The sensitivity of double-contrast barium enema (DCBE) for detecting adenomas $\geq$6 mm in diameter is approximately 50%. It is an unreliable modality for detecting smaller adenomas. Flexible sigmoidoscopy should always be combined with DCBE because lesions in the distal rectum are often not visualized by DCBE.

Colonoscopy

Colonoscopy is indicated for all subjects with a positive FOBT or adenoma(s) diagnosed by flexible sigmoidoscopy. It is also increasingly being advocated as the primary screening tool for colorectal neoplasms. The sensitivity of colonoscopy for detection of advanced adenomas is >90% and somewhat lower for small adenomas. Colonoscopy, however, has several drawbacks as the primary screening tool for colorectal neoplasms in average-risk subjects. Colonic perforations of 1 per 1000 to 2000 have been reported, although recent studies suggest this may overestimate their frequency. The costs of colonoscopy are considerable. It is highly doubtful whether sufficient skilled colonoscopists could be trained in the foreseeable future to be able to provide screening colonoscopy for the entire United States population aged 50 years and older. Nonetheless, colonoscopy is regarded as the "gold standard" screening technique for colorectal adenomas and CRC.

Other Techniques

Virtual colonoscopy is another diagnostic tool, although the diagnostic accuracy of this procedure is not well established. After a short bowel preparation, patients undergo computed tomography with colonic insufflation. Mucosal images are reconstructed to identify adenomas and other mass lesions. Colonoscopy is indicated for all subjects with a mass lesion on virtual colonoscopy. Virtual colonoscopy has not yet been adequately tested outside the research setting and should not, therefore, be used for routine screening purposes.

In another procedure, fecal DNA from exfoliated cells can be extracted from stool and amplified by polymerase chain reaction. In this way, it is possible to detect somatic mutations and other abnormalities in DNA deriving from the exfoliated cells of asymptomatic colorectal neoplasms. Studies are in progress to determine the sensitivity and specificity of this approach to screening.

TREATMENT

Colonoscopy

All patients with a positive FOBT, flexible sigmoidoscopy, or DCBE should undergo a colonoscopy. Because most colon cancers arise from adenomas and visual examination of a polyp does not reliably differentiate adenomatous from nonadenomatous polyps, all polyps should be removed or at least biopsied and submitted for histological examination. The histological type determines subsequent management. Small adenomas are removed using cold or hot biopsies whereas larger polyps are removed using a snare with or without cautery. Very large or broad-based sessile polyps are removed piecemeal and any remnant polyp tissue can be ablated by a variety of thermal devices.

Endoscopic polypectomy is safe and carries a less than 1% risk of perforation or bleeding. This risk is increased when removing multiple polyps, very large polyps, and lesions in the cecum or ascending colon, which have a thinner wall.

Surgery

Surgical resection is needed for lesions that cannot be adequately removed endoscopically. Polyps found to harbor foci of carcinoma warrant special consideration. If the cancer cells are intramucosal and do not traverse the muscularis mucosae, they are considered to be noninvasive malignant polyps and polypectomy alone is curative. When the cancer cells have invaded beyond the muscularis mucosa, the polyp is considered to be a malignant polyp. Polypectomy alone of a malignant polyp carries a 10% risk of having cancer cells remaining in the bowel wall or surrounding lymph nodes. Several unfavorable factors have been identified, the presence of which increase the risk for an adverse outcome. These include poorly differentiated carcinomas, evidence of vascular or lymphatic invasion, involvement of resection margins, and involvement of the submucosa of the

bowel wall, which is likely in sessile malignant polyps. Surgical resection is indicated if any one of these unfavorable features is present.

Postpolypectomy Followup

Up to 50% of patients will develop recurrent adenomas following initial polypectomy. The annual rate of adenoma recurrence following polypectomy is from 10 to 15%. The likelihood of recurrence is greatest with multiple adenomas, large polyps, villous histology, and severe dysplasia. The optimal time period between examinations depends on the initial findings. Following an adequate examination and complete resection of all adenomas, surveillance colonoscopy should be performed in 3 to 5 years, depending on characteristics of the initial adenoma(s). If recurrent adenoma(s) are found at the first surveillance exam, colonoscopy should be repeated in 3 years. In the absence of recurrent adenomas, the surveillance interval can be extended to 5 years.

addition, risk factors that have been noted to be associated with colorectal cancer development include obesity, physical inactivity, excess caloric intake, and centrally deposited adipose tissue.

INTRODUCTION

The stage at which colorectal cancer is diagnosed relates to patient survival. Screening for the malignancy has the potential to detect premalignant lesions and early cancers such that curative intervention can be initiated.

RISK STRATIFICATION

The initial step in colorectal cancer screening is the determination of an individual's risk status. Risk stratification determines when screening should be initiated and what tests should be performed. Guidelines by the United States Multisociety Task Force on Colorectal Cancer note that risk stratification can be accomplished by inquiring about several issues. It should be determined if the patient has had colorectal cancer or adenomatous polyps, if the patient has an illness that predisposes to colorectal cancer, or if the patient has a family member who has had an adenomatous polyp or colorectal cancer. The relationship of the affected family member to the individual and the age at which polyps or colorectal cancer developed in the relative should be determined.

If a person is asymptomatic and without a personal or family history that predisposes to colorectal cancer, the individual is considered to be of average risk and should begin colorectal cancer screening at 50 years of age. If a person has a first-degree relative or two or more second-degree relatives who have had adenomatous polyps or colorectal cancer at ≥ 60 years of age, they should be considered to be at average risk, but can begin screening at 40 years of age. If a person has a first-degree relative with colorectal cancer or adenomatous polyps at <60 years of age or two or more second-degree relatives with colorectal cancer at any age, they are considered to be at increased risk for colorectal cancer and screening should begin at age 40 years, or 10 years younger than the age at which the earliest diagnosis was made. If a person has a family history of familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer, the patient is considered to be at increased risk and screening is initiated based on the particular condition.

RECOMMENDATIONS FOR AVERAGE-RISK INDIVIDUALS

Guidelines for colorectal cancer screening include fecal occult blood testing and endoscopic (flexible sigmoidoscopy or colonoscopy) or radiologic evaluation of the colon.

Fecal Occult Blood Testing

Fecal occult blood testing (FOBT), using a guaiac-based test, should be started at age 50 years and should be performed annually. FOBT is performed on three consecutive stools without hydration. There have been three randomized controlled studies that reported that FOBT reduces the risk of death from colorectal cancer. Screening is most effective when performed annually, as opposed to every 2 years. Dietary and medication restrictions are commonly recommended to reduce the false positive rate for the sensitive guaiac-based tests. It is recommended that individuals avoid red meat for 3 days, as well as avoiding radishes, broccoli, turnips, nonsteroidal antiinflammatory drugs, and vitamin C for 2 days prior to performing the test. It is recommended not to rehydrate the samples prior to FOBT despite the increased sensitivity, because it decreases the specificity of the testing.

Flexible Sigmoidoscopy

A flexible sigmoidoscopy allows for visualization of the distal portion of the colon. The current recommendation is that flexible sigmoidoscopy should be offered every 5 years. The performance of a flexible sigmoidoscopy can reduce colorectal cancer mortality by up to two-thirds for lesions that are within the view of the instrument. Additionally, a case-control study has demonstrated that the use of a rigid sigmoidoscopy for screening reduces mortality from distal colorectal cancer by 59%. If a polyp detected by sigmoidoscopy is ≥ 1 cm in size, it should be assumed to be adenomatous. A polyp <1 cm in size should be evaluated to determine if it is hyperplastic or adenomatous. Sigmoidoscopies detecting adenomatous polyps, when followed by a colonoscopy with removal of all polyps, have been associated with an 80% reduction in the incidence of colorectal cancer.

Barium Enema

A barium enema, performed every 5 years, is an alternative to the use of endoscopic examinations for colorectal cancer screening. This radiologic examination results in the visualization of the entire colon and can detect the presence of most large polyps. However, there have been no randomized controlled studies that demonstrate a reduction of mortality from colorectal cancer in individuals at average risk for the disease. Additionally, the barium enema does not allow for biopsies of suspicious lesions or removal of polyps.

This procedure is an option for those individuals who have a contraindication to or are unable to undergo endoscopic evaluation.

Colonoscopy

The colonoscopy is the most effective tool for the early detection of precancerous and cancerous lesions and can be performed every 10 years for colorectal cancer screening. The colonoscopy allows for the visualization of the entire colon and the biopsy or removal of colonic lesions. Two cohort studies have demonstrated that the colonoscopy can reduce the incidence of colorectal cancer in individuals with adenomatous polyps. Disadvantages for the colonoscopy include the increased cost, risk of perforation, and greater degree of invasiveness. The recommended 10-year interval between screenings is based on the rate at which adenomatous polyps can convert to cancer. It has been estimated that it may take >10 years for an adenomatous polyp to develop and convert to cancer. In a study of asymptomatic average-risk individuals with negative screening colonoscopies, a second colonoscopy 5 years later had a <1% incidence of advanced neoplasm.

RECOMMENDATIONS FOR HIGH-RISK PATIENTS

Family History of Adenomatous Polyp or Cancer

Any person with a first-degree relative with adenomatous polyps or colon cancer diagnosed at age <60 years or two first-degree relatives with colorectal cancer should have a colonoscopy at age 40 years, or 10 years before the earliest diagnosis in their family. The colonoscopy should be repeated every 5 years. In an individual who has a first-degree relative with colon cancer or adenomatous polyps at age ≥60 years or two second-degree relatives with colorectal cancer, screening should begin at age 40 years and should occur at intervals similar to those for individuals at average risk for cancer. Individuals with one second-degree or third-degree relative with colorectal cancer should be screened as an average-risk individual.

Family History of Familial Adenomatous Polyposis

Individuals with familial adenomatous polyposis (FAP) or those who are at risk for having FAP should have an annual endoscopic screening starting at age 10–12 years. FAP is an autosomal dominant disorder with adenomas appearing at an average age of 16 years. The cause of FAP is a mutation in the adenomatous polyposis coli gene (*APC*). The current recommendations suggest that in addition to endoscopic screening, genetic testing should be considered in individuals with FAP and relatives who are at risk for the disorder.

Hereditary Nonpolyposis Colorectal Cancer

Individuals with hereditary nonpolyposis colorectal cancer (HNPCC) or those at increased risk for HNPCC should have a colonoscopy every 1–2 years beginning at the age of 20–25 years, or 10 years earlier than the earliest cancer diagnosis in the family. The genetic testing for HNPCC should be offered to first-degree relatives of those patients with a known mismatch repair gene mutation. If the individual meets clinical criteria for HNPCC, genetic testing should also be performed.

Inflammatory Bowel Disease

It has been suggested that individuals with inflammatory bowel disease for >10 years are at increased risk for colon cancer development and should have a colonoscopy with surveillance biopsies every 1–2 years.

Personal History of a Polyp or Colon Cancer

Patients who have had a malignant adenoma, multiple adenomas, or a large sessile adenoma should have a followup colonoscopy within a short period of time. The interval of time for repeat screening is typically 1 year, but is based upon the physician's clinical judgment. If an individual has had less than three adenomas, the repeat colonoscopy can be performed in 3 years. If the individuals has one to two small adenomas, the followup colonoscopy can be done in 5 years. An individual's specific followup regimen is based on the number of polyps and the pathology of the polyps.

Colostomy

DOUGLAS W. WILMORE

Harvard Medical School and Brigham and Women's Hospital

ostomate Individual undergoing an ostomy, usually an ileostomy or colostomy.

ostomy Operation to create an artificial opening through which body wastes may exit.

A colostomy is a surgically created passage between the colon and the skin of the abdominal wall, culminating in an opening, or stoma. The purpose of a colostomy is to divert the fecal stream from the colon distal to the site of the colostomy or to prevent or avoid use of the rectum for fecal elimination. An individual with a colostomy wears a bag or appliance that collects the fecal material expelled from the stoma. A person with a colostomy is referred to as an ostomate, and it is estimated that approximately 1 million individuals in the United States have undergone ostomies. To help patients deal with difficulties, ostomy organizations share information and collectively purchase supplies in bulk. Highly trained nurses in this field of gastroenterology teach patients about dealing with their colostomies and aid in the care of the stoma. Patients with colostomies are active, productive individuals and are generally unaffected by the colostomy, but may have life changes because of the disease that prompted this operation.

INDICATIONS

There are numerous indications for a colostomy. Diversion of the fecal stream may be necessary because of a distal bowel resection that has resulted in an anastomosis. A proximal colostomy to divert feces from the operative site may be required if a surgeon feel that a suture line in the colon is too fragile to receive intestinal contents. Often, colon obstruction and distension with fluid and gas is resolved by a colostomy proximal to the obstruction so that all the contents can be expelled, which allows the colon to decompress. At a later time, the patient undergoes an operation to allow more definitive repair of the obstructing site. A proximal colostomy is often formed when the colon perforates, either from diverticulitis, inflammatory bowel disease, cancer, or secondary to pelvic or abdominal trauma, to allow inflammation to subside; final resection and repair can be performed under more ideal operative

conditions. Finally, when a patient has complete resection of the rectum, or on some occasions the most distal colon, a colostomy is performed because the sphincter mechanisms of the rectum have been removed and controlled evacuation through this distal portal is not possible. This situation usually occurs because the patient has cancer in the distal bowel and the entire area is resected.

TYPES OF COLOSTOMIES

There are three general types of colostomies: temporary, permanent, and reservoir. Temporary colostomies are the most common and are usually performed because of an acute need, such as colonic obstruction, perforation, and/or abdominal sepsis. This type of colostomy is created by making a small puncture incision in the abdominal wall and pulling a loop of bowel through the incision. The bowel is not transected or opened at this time. A plastic rod is passed through the mesentery and under the loop to keep the colon above the skin surface and the bowel is covered with a nonadhesive dressing. Over the next several days this loop of bowel undergoes an inflammatory reaction and becomes adherent to the abdominal wall. When this seal is formed, the colon is opened and the gas and fluid contents are evacuated. In several days, a colostomy bag is placed over the stoma, and with time the bowel contracts and resides just above the surface of the abdominal skin. This series of events may be quite frightening to the patient, who has just undergone a major emergency operation. However, the one positive point is that the ostomy is only temporary, and in 3–6 months, depending on the patient's condition, the colostomy will be closed and the patient will be able to evacuate in a normal manner.

The second type of colostomy is permanent. It is formed in patients with cancer of the most distal bowel or with a rectum that has been resected. Because the sphincter muscles have been removed, fecal countenance is not possible, requiring a colostomy. In this type of colostomy (an end colostomy), the end of the bowel is pulled through a small incision in the abdominal wall, the lumen is opened, and the outer and inner lining of the colon is everted and sewn to the skin. The bowel is also attached to the inner layers of the abdominal wall. When this procedure is finished, the colostomy looks much like a rosebud, with the luminal mucosa visible, and is generally at the level or only slightly above the level of the abdominal skin. Patients frequently leave the operating room with a bag placed over this colostomy. Alternatively, the colostomy may have a temporary clamp placed transversely across the distal colon and in several days the bowel seals with the abdominal wall. The clamp is then removed, the bowel is opened, and a bag is applied.

The third type of colostomy is rarely utilized, and was conceived by surgeons who wanted to create a sphincterlike mechanism for the distal colon. A pouch, or reservoir, is created with two loops of bowel and a nipple valve is fashioned in the distal colon, just at the level of the abdominal wall. The patient can then insert a tube through the valve and evacuate the contents of the reservoir. This bypasses the need to wear a bag. Although the initial concept was appropriate, the reservoir colostomy valves rarely worked correctly and many of the pouches had to be revised and the more standard type of colostomy formed. Few if any surgeons perform the procedure at this time.

COLOSTOMY FUNCTION

One of the main functions of the colon is to dehydrate the fecal contents by absorbing water and sodium. This occurs gradually along the length of the colon, so that stool in the right (proximal) side of the colon is more liquid than that in the left (distal) side of the colon. This is important, because colostomies may be created in the transverse (middle) colon or in the descending (left) colon. Stool from the midcolon may be more liquid than that produced from a more distal site, such as the left lower colon.

A colostomy does not have a sphincter mechanism, and hence peristaltic movements of the bowel, which are not under voluntary control, cause stool evacuation. Thus, a patient with a colostomy must wear a bag at all times to collect the extruded feces. Two schools of thought exist in terms of regulating a colostomy. One group of physicians, primarily found in Europe, believes that the colon should function on its own, and hence a small amount of stool is evacuated from the stoma three to seven times a day. The patient empties the colostomy bag when convenient or when indicated. In the United States, patients are usually instructed to irrigate their colostomy once a day. This is a process similar to having an enema; fluid is instilled via a tube inserted into the colostomy and this stimulates peristalsis, which results in evacuation. Following this procedure, there is usually no additional evacuation from the stoma for the next 24 hours.

Patients with colostomies wear a bag, and the proper attachment of the bag to the abdominal skin is a process usually learned from an ostomy (stoma) nurse. The more chronic attachment devices use a soft rubber doughnut-shaped disk or wafer that fits closely around the stoma and is fixed to the skin. A flange is attached to

the disk or wafer and the flange accepts a plastic ring that is part of a specially constructed ostomy bag. This generally provides a watertight seal. The bag can thus be removed without disturbing the apparatus attachment to the skin. Only occasionally is the disk changed, which protects the skin surrounding the stoma.

A temporary approach uses a light plastic bag that has adhesive fixed to a portion of the outer surface around an appropriately sized hole.. This allows direct application of the bag to the skin around the stoma. The attached bag must be removed from the underlying skin each time the bag is changed, which causes undesirable irritation to the skin. Hence, this approach is only a temporary short-term solution to ostomy collection.

The ostomate should generally be able to live a near-normal life. Bathing and showering will not harm the stoma. Physical activity should not be limited and diet should be tailored to food preferences. Sexual activity is not prohibited. Most health insurance policies, including Medicare and Medicaid, cover the cost of equipment and supplies.

COMPLICATIONS

Early complications include wound infections, intestinal obstruction, prolapse of the bowel through the incision in the abdominal wall or through the stoma, bleeding from the exposed bowel, and excoriation of the skin around the stoma.

Long-term complications are similar to those that occur in the short term but, most often relate to bag attachment problems. Bag leakage and spillage result in soilage of clothing, creating social embarrassments. If the disk around the ostomy is not well fitted, skin excoriation can occur, and this is an annoying and painful problem. Ostomy nurses are specialists in dealing with these problems and have a variety of solutions for these mechanical complications. The colon ferments fiber and produces gas, which is often entrapped in the bag and on occasion causes odors. Dietary modification and some pharmacological approaches are often useful to solve these problems. Adequate hydration is necessary to ensure that a semisoft stool is present and can be evacuated without difficulty. Injury to the exposed mucosa occasionally occurs, resulting in bleeding. This is usually minor and self-limiting but may necessitate surgical care if the bleeding is prolonged. Stenosis and herniation of the colostomy are additional complications that require consultation with a physician.

COLOSTOMY CLOSURE

Individuals with temporary colostomies will be admitted to the hospital 3–6 months later for colostomy closure. Although this may seem like a minor procedure when compared to the colon resection, this operation involves opening the abdomen, resecting a small portion of bowel, and connecting the portions of colon distal and proximal to the colostomy. Some time in the hospital may be required and complications may occur. Wound infections are frequent, and ileus and poor food tolerance are initially the most common complications observed. Rehabilitation associated with normal bowel action usually progresses without incident.

Complementary and Alternative Medicine

JUDITH K. SHABERT
Harvard Medical School

holistic Describes therapies based on information about the "whole person," including spiritual, physical, mental, emotional, environmental, and social health.

placebo An inactive substance given to a participant in a research study as part of a test of the effects of another substance or treatment.

Over the past decade, there has been a growing interest in complementary and alternative medicine (CAM), a field that encompasses a wide variety of approaches ranging from herbal medicines to massage and from macrobiotics to magnet therapy. The therapies that are proven safe and effective gradually become incorporated into mainstream practices and thus the list of practices is continually changing. The National Center for Complementary and Alternative Medicine, a component of the National Institutes of Health, defines CAM as "those healthcare and medical practices that are not currently an integral part of conventional medicine." Using these criteria, CAM practices can be grouped in five major domains: alternative medical systems; mind–body interventions; biologically based treatments; manipulative and body-based methods; and energy therapies. Common to most of these practices is the concept of vitalism or the transfer of energy to the individual to support the healing process. This point will be emphasized in the following descriptions of this wide range of practices.

MAJOR DOMAINS OF CAM

Alternative Medical Systems

Alternative medical systems involve complete systems of theory and practice that have evolved independent of and often prior to the conventional biomedical approaches. These systems include shamanism and traditional healing in cultures throughout the world. Some systems originated 5000–6000 years ago includingAyurveda from India and traditional Oriental medicine originating in China and practiced throughout Asia.

Traditional Chinese Medicine

In Asia, the full complement of traditional Chinese medicine (TCM) treatment incorporates diet, acupuncture, and Chinese herbal preparations for each individual patient for optimal results. In Western cultures, acupuncture is often given in isolation from diet and herbal preparations.

Acupuncture is based on the concept of vital energy channels or qi (pronounced chee), which flows through the body and is essential for health. Vital energy channels are known as meridians; disruption or imbalance of qi results in illness. Two other concepts are central to TCM: Yin–Yang describes the polarity of nature, and the concept of Five Elements (earth, water, air, fire, and metal) describes the interrelatedness of the body's organs and energy flow.

There are 12 meridians in the body that flow close to the skin's surface with more than 450 acupuncture sites. Acupuncture sites are stimulated, depending on the specific ailment, by needles that penetrate the skin. The duration and frequency of the treatments are determined by the practitioner and by the response of the patient to treatment. Recommended conditions appropriate for acupuncture are found in Table I.

Ayurveda

Ayurveda is a 6000-year-old system that utilizes energetic forces (doshas) to guide healing and maintain health. This system believes in a strong connection between the mind and the body and utilizes the Laws of Nature to create health and maintain balance of the body, senses, mind, and soul. Ayurveda, like TCM, views a person as being composed of five primary elements including air, fire, water, and earth. Ether is the fifth element in Ayurveda versus metal in TCM.

The Ayurveda medical system incorporates three energetic forces or Tridoshas. Vata dosha is the most important of the three doshas and drives the other two doshas, Pitta dosha and Kapha dosha. Vata dosha controls body movement (mental and physical), eliminates waste, transmits sensory input to the brain, and assists in aspects of metabolism. When Vata dosha is the dominant dosha, its imbalance is powerful enough to upset the Pitta and Kapha doshas.

Pitta dosha represents fire or heat and is located at sites of transformation such as digestion and

TABLE I Conditions Appropriate for Acupuncture Therapy

Digestive	Emotional	Eye–Ear–Nose–Throat	Gynecological
Abdominal panic	Anxiety	Cataracts	Infertility
Constipation	Depression	Gingivitis	Menopausal symptoms
Diarrhea	Insomnia	Poor vision	Premenstrual syndrome
Hyperacidity	Nervousness	Tinnitis	
Indigestion	Neurosis	Toothache	
Miscellaneous	**Musculoskeletal**	**Neurological**	**Respiratory**
Addiction control	Arthritis	Headaches	Asthma
Athletic performance	Back pain	Migraines	Bronchitis
Blood pressure regulation	Muscle cramping	Neurogenic bladder dysfunction	Common cold
Chronic fatigue	Muscle pain/weakness	Parkinson's disease	Sinusitis
Immune system tonification	Neck pain	Postoperative pain	Smoking cessation
Stress reduction	Sciatica	Stroke	Tonsillitis

Source: World Health Organization (1979). "Viewpoint on Acupuncture." World Health Organization, Geneva, Switzerland.

metabolism, appetite, vision, regulation of body temperature, skin, comprehension, and bravery. Kappa dosha is the heaviest of the doshas and it provides structure and lubrication to the body. It is associated with bodily strength, fertility, and stability of mind and body.

An Ayurvedic practitioner assesses a person's body type and determines their dosha by feeling the pulse. When it is determined that one of the doshas is underactive or, more significantly, overactive, a diet that is specific to one of the doshas is prescribed to rebalance the doshas and remedy the disease. Herbs and aromatherapy are also utilized.

Homeopathy

Homeopathy is a medical system based on the concept of "Laws of Similars" and it incorporates tinctures produced from natural sources such as plants, animals, and minerals. Dr. Samuel Hahnemann developed homeopathy in the early 1800s.

Dr. Hahnemann discovered that when the bark of the cinchona tree, which was used to treat swamp fever (malaria), was given to healthy individuals, symptoms of swamp fever were elicited. This experiment led Hahnemann to test thousands of substances on healthy individuals. When a specific symptom occurred in a healthy person given a certain substance, this substance was then used to treat people who had this specific symptom.

The process of preparing homeopathic remedies incorporates potentization and succussion. The substance being prepared as a remedy is successively diluted with water (potentization) and shaken (succussion). When the final product is produced, it is unlikely that even one molecule of the original substance remains and that is the goal of homeopathic preparations. This phenomenon is called the Principle of Infinitesimal Dose.

Drops of a preparation are usually given every 3–4 h for each symptom of an illness. For example, if a person has insomnia due to fright, one type of preparation is given. If insomnia is due to exhaustion, another preparation is suggested.

Naturopathic Medicine

Naturopathic medicine is a system of medical care based on a number of different modalities. A basic tenet of naturopathy is the belief that the body has an innate ability to heal itself utilizing treatments that include clinical nutrition, homeopathy, herbal medicine, light therapy, therapeutic counseling, TCM, mechanical manipulation, and hydrotherapy. The interdependent parts of an individual including mind, body, spirit, and emotion are considered in formulating a treatment plan and in providing care to an individual.

Naturopathic medicine is not considered a solitary system of care and naturopaths work with other practitioners, including allopathic caregivers, to provide optimal care for the patient. Although naturopaths do treat patients, their emphasis is on patient education and preventive care.

Mind–Body Interventions

Herbert Benson, a cardiologist at Harvard Medical School, and John Kabat-Zinn, from the University of Massachusetts, were the first to research and prove the benefit of mind–body medicine. Relaxation exercises, visual imaging, and particularly biofeedback are the basis of this approach that is used for the treatment of many chronic health conditions. Most mind–body interventions developed or proven effective by Benson and Kabat-Zinn are now an integral part of mainstream medicine. Other forms of mind–body interventions

include art, dance, and music therapy, intuitive healing, prayer, and meditation.

Biofeedback

Biofeedback is a technique that trains the individual to alter brain activity and therefore modify blood pressure, muscle tension, heart rate, and other bodily functions that are ordinarily under autonomic (nonvoluntary) control. The training initially utilizes a device that triggers a flashing light or activates a beeper when an appropriate response is elicited. Thus, one can think about increasing blood flow to the hands, and a small temperature probe attached to a finger will indicate when this is accomplished. Such signals "teach" people to improve their health and performance by controlling bodily functions. Other signal systems respond to changes in blood pressure, heart rate, muscle tension, sweat activity, and activity of the brain waves.

Some of the conditions that are treated by this technique include migraine headaches, chronic pain, high blood pressure, cardiac arrhythmias, Raynaud's phenomena, and some seizure disorders.

Transcendental Meditation

Many forms of meditation are used to promote healing. In North America, the most institutionalized form is transcendental meditation (TM), brought to the Western world by Maharishi Mahesh Yogi. Followers of TM meditate twice a day on a mantra provided to them by a TM instructor following two weekends of instruction on its techniques.

Art, Dance, and Sound Therapy

All of these therapies have a psychological directive and art and dance therapies are also useful for individuals with physical disabilities. It is believed that the expression of self though body movement, the creation of art work, and listening to sound and music are therapeutic for improving self-esteem, recovery from abuse and trauma, and enhancement of social integration, to name a few benefits.

Biological-Based Therapies

This grouping of CAM practices is based on interventions using natural or biological substances. Examples include the practice of orthomolecular medicine, the provision of nutritional supplements (vitamins, minerals, herbs, hormones, and other products), special diets (macrobiotic, Atkins, The Zone), and chelation therapy.

Orthomolecular Medicine

Linus Pauling first used the term "orthomolecular" in an article in *Science* in the 1960s. The term describes the practice of preventing and treating disease by providing natural nutrients to the body in optimal amounts specific for each person. It is based on the concept of genetic individuality. Just as each person has a different skin color that determines tolerance to the sun, each person has unique biochemical needs based upon their genetic make-up that determines nutrient requirements. Orthomolecular medicine supports the use of megadose vitamins for physical and mental conditions (for example, the use of large doses of vitamin C to treat the common cold).

Herbal Medicine

Herbs are the oldest form of medical therapy and they are used throughout the world to treat a variety of conditions. In Europe, herbs are prescribed by allopathic physicians as frequently as are pharmaceutical drugs. Herbs can be provided as teas, tinctures, and capsules both internally and externally. Extensive research is being conducted on the effectiveness of herbs to treat a variety of conditions. A list of commonly used herbs is presented in Table II.

Macrobiotics

The use of the macrobiotic diet and the philosophy surrounding it were developed and promoted by Michio Kushi.

The macrobiotic diet is based loosely on the traditional Japanese diet and it also supports a healthy lifestyle. Brown rice, vegetable soup, vegetables, beans, and sea vegetables are the staples of the diet. Occasionally, fruit, nuts, and seeds are allowed. The diet eliminates most animal products but fish is occasionally permitted. The most restrictive form of the diet can result in vitamin B12 deficiency.

Chelation Therapy

The intravenous infusion of a chelation substance was initiated in the 1940s to treat individuals with heavy metal exposure by chelating the metal and facilitating its elimination from the body.

Today ethylenediaminetetraacetic acid (EDTA) chelation therapy is being utilized by some CAM physicians to treat patients with atherosclerotic and peripheral vascular disease.

Proponents believe that chelation therapy binds toxic metals such as lead, mercury, cadmium, copper, calcium, iron, arsenic, nickel, and aluminum. By chelating calcium from cholesterol-laden plaques in

TABLE II Commonly Used Herbs

Name	Use	Pharmacologal Effects	Potential side effects
Echinacea, purple cone flower root	Treatment of infectious diseases, particularly those of the respiratory tract	Immunostimulation, immunosuppression	Allergic reactions, immunosuppression with long-term use
Ephedra, ma huang	Promote weight loss, increase energy, treat asthma	Contains alkaloids including ephedrine; increases heart rate and blood pressure	Myocardial infarction, stroke, interaction with monoamine, oxidase inhibitors
Garlic, ajo	Decrease risk of atherosclerosis, decrease serum lipids	Inhibit platelet aggregation	Potential risk of bleeding
Ginkgo, duck foot tree	Use for cognitive disorders and peripheral vascular disease	Inhibits platelet-activating factor	Potential risk of bleeding
Ginseng	Protects body against stress	Lowers blood glucose, inhibits platelet aggregation	Hypoglycemia, increased risk of bleeding, interaction with warafin
Kava, awa	Reduces anxiety; used as a sedative	Sedation	Potential to increase sedative effects of other drugs
St. John's wort, amber, goat weed	Treatment of mild to moderate depression	Inhibit neurotransmitter reuptake	Affects a variety of drugs by altering liver metabolism
Valerian, all-heal	Treatment of insomnia	Sedation	Increases potency of other sedative drugs

vessels throughout the body, atherosclerotic tissue damage is resolved and vessel integrity is improved. Usually a patient is treated one to three times per week over several months. The intravenous solution containing EDTA is also supplemented with vitamins and minerals that replace nutrients eliminated through the urine during therapy and megadoses of antioxidant nutrients are also provided.

The Food and Drug Administration and numerous medical groups such as the American Medical Association are opposed to this therapy as a means of treating atherosclerosis because the double-blind studies testing chelation therapy have not shown benefit.

Light Therapy

Some individuals experience depression only in the winter months when the hours of sunlight are reduced. This is referred to as seasonal affective disorder. Light therapy utilizes lamps with the full spectrum of ultraviolet light. Exposure to these lamps for 1−2 h/day is effective is resolving depression is some of these individuals.

Hydrotherapy

Hydrotherapy is a general term that refers to treatments that use water for the relief of symptoms arising from various diseases or injuries. The therapy may vary by the temperature of the water (hot versus cold) or it may use water under pressure in the form of jets, whirlpools, or aerated bubbles. This form of therapy is often used for complaints related to the musculoskeletal system or the joints.

Internal hydrotherapy includes colonic irrigations and enemas to eliminate toxins and steam baths or steam inhalation to relieve respiratory congestion.

Environmental Medicine

Practitioners of environmental medicine support a holistic approach to the patient and believe that the thousands of artificial chemicals in the environment are related to ill health and allergies. Chronic exposure to environmental toxics leads to chronic health conditions that affect not only physical health but mental and emotional health as well. Treatment approaches in environmental medicine focus on decreasing exposure to environmental toxins and allergies and detoxification programs that may include chelation therapy and megavitamin therapy.

Manipulative and Body-Based Methods

All forms of massage and body manipulation performed by chiropractors and osteopaths are included in this grouping.

Massage Therapy

Massage therapy has been practiced for at least 4000 years. The goal of massage is to manipulate the soft tissues of the body to normalize those tissues. It is estimated that 7% of the population has at least one massage annually. Massage is being used to provide

relief from injury, stress, pain, and other acute and chronic conditions. The types of massage therapy are too numerous to list but include Swedish, deep tissue, hot stone, neonatal, and sports massage.

Oriental massage techniques such as Shiatsu, Amma, acupressure, and Tibetan point holding are based on the concept of qi and focus on the 12 meridians of the body.

Osteopathic Medicine

Osteopathic medicine is a system of health care based on the premise that disease is the result of structural and anatomical abnormalities. Treatment aims to rebalance the interrelationship of structure and function. Osteopaths undergo an educational program similar to that for medical doctors including residency training in all of the major medical specialties including surgery.

Osteopathic physicians differ from conventionally trained physicians because, in addition to the use of all allopathic practices, they use manipulative techniques to diagnose and treat illness. An extensive body of work supports the use of osteopathic techniques for musculoskeletal and nonmusculoskeletal problems.

Chiropractic

Chiropractic care is based on spinal manipulation and includes adjustment and manipulation of the articulations and adjacent tissues of the body. The practice is drug- and surgery-free. There are more than 50,000 chiropractic practitioners in the United States. In addition to spinal manipulation, many practitioners provide advice on and dispense herbs, books and videos, healthcare products, and nutritional supplements.

The National Guideline Clearinghouse provides information on chiropractic quality assurance and practice parameters.

Energy Therapies

Energy therapies are concerned with energy originating from within the body or energy applied to the body from outside sources such as magnet therapy. Many practices and systems of health care discussed previously incorporate the concept of energy therapy, such as acupuncture, Ayurveda, Shiatsu, and qi gong.

Therapeutic Touch

This method claims to assist the natural healing process by redirecting and rebalancing the energy fields of the body. The practitioner places his or her hands on or over certain parts of the body to redistribute the patient's energy or transfer his or her own energy to the patient.

This therapy is said to reduce pain and anxiety, promote relaxation, and stimulate the body's natural healing process.

VALIDATING THE EFFECTIVENESS OF CAM

Much of both allopathic and alternative medicine is based on anecdotal evidence or experiences; that is, a particular approach appeared to work for one patient so the practitioner institutes the same or a similar therapy on the next patient. Providers and payers are now asking for the "evidence" that therapies are effective, not only for allopathic treatments but also for CAM approaches. Within the past 15 years, the field of "evidence-based" medicine has grown starting with a group of investigators at Oxford University. Levels of evidence are used to evaluate information concerning various therapies. In the opinion of the Oxford group, the strongest evidence for a particular therapy is based on prospective, randomized, blinded, clinical trials and the weakest recommendations are based on case series or expert opinion without explicit clinical appraisal.

Some CAM treatments, particularly herbal therapies and nutritional supplements, can be evaluated by using conventional clinical trial techniques like those that are used to test new drugs. Difficulty arises in designing an appropriate study when a specific procedure involves physical manipulation such as with acupuncture, therapeutic touch, and chiropractic adjustments.

Another approach to evaluating the effectiveness of CAM is to gather a group of experts and review the evidence published on a specific topic. The experts then offer a final opinion or consensus on a topic and this information is made available in periodicals or on the Internet. An individual seeking allopathic or CAM treatment should be made aware of the available evidence concerning a particular therapy before embarking on a course of treatment.

Other research on CAM treatments is being supported by the National Institutes of Health and/or other funding sources such as industry.

RISKS ASSOCIATED WITH CAM

In addition to understanding the benefits of a particular therapy, an individual should appreciate the risks involved. This is particularly true of side effects associated with the ingestion of herbs or supplements (Table III). Because patients rarely inform their allopathic providers

TABLE III Some of the CAM Substances Associated with Specific Side Effects

Product	Common name	Toxin(s)	Side effects
Aconite	Monkshood, wolfbane	Aconite, hypaconitine	Nausea, vomiting, neuromuscular weakness, seizures, coma, cardiac effects (bradycardia, arrhythmia, and hypotension)
Chaparral tea			Liver failure
Chomper			May be contaminated with digitalis
Comfrey	Bruisewort, knitbone	Pyrrolizidine	Veno-occlusive disease, vomiting, hepatomegaly, hepatic necrosis
Jin bu huan			Sedative, hepatitis, bradycardia
Lobella			Vomiting, coma, tachycardia, respiratory distress
Ma huang	Ephedra	Ephedrine, pseudoephedrine	Hypertension, heart attack stroke, arrhythmias, headaches, seizures, tremors, anxiety, hallucinations
Pennyroyal		Pulegone	Liver and renal failure, nausea, vomiting, abdominal pain, shock, alterations in mental status (delirium, confusion, agitation, seizures)
Plantain leaf			May be contaminated with digitalis
Yohimbe			Seizures, renal failure

Adapted from Cassileth, B. R. (1998). "The Alternative Medicine Handbook: The Complete Reference Guide to Alternative and Complementary Therapies." W. W. Norton & Co., New York, and Mack, R. B. (1998). "Something wicked this way comes"—Herbs even witches should avoid. *Contemp. Pediatr.* **15**(6), 49–64, with permission.

of their use of CAM therapies—or alternatively allopathic providers rarely ask a patient or are knowledgeable about such therapies—there is concern that deleterious herb–supplement–drug interactions may occur. This concern has prompted anesthesiologists to advise patients to discontinue all herbal medicines for 1–7 days before an operation in order to prevent relevant side effects from interactions of herbal products and anesthetic agents.

There is also concern that a patient with a specific disease will avoid a conventional therapy that could potentially cure the disease and choose a CAM treatment that may have variable or negligible effects on the disease. High-risk patients, such as those with cancer or autoimmune deficiency syndrome, may be more likely to pursue such a course. A variety of information databases are available to help individuals in this decision-making process.

TRENDS IN THE USE OF CAM

Over the past decade, the use of CAM has grown rapidly in the United States, Japan, Australia, and Europe. In 1990, approximately 33% of Americans used an alternative therapy and that percentage increased to approximately 42% by 1997. Individuals spent more than $27 billion on these therapies and such expenditures were in the most part not covered by insurance and were paid for out-of-pocket.

Allopathic physicians are increasingly participating in CAM therapies, although the inclusion of CAM instruction as required curriculum in medical schools is quite variable. One survey reported that 60% of physicians from a wide range of specialties recommended alternative therapy to their patients at least once and almost one-half of the physicians surveyed had used alternative therapies themselves.

A variety of reasons are offered for the recent success of CAM. Some suggest that the popularity reflects a failing in our present medical system and relates to problems in care delivery (the growth of health maintenance organizations and the 10-min patient visit). Others suggest that this trend reflects an issue related to patient control and choice, which usually are not associated with present methods of allopathic care. Finally, most of the CAM approaches are holistic and are seen by the patient as being more "natural" than allopathic treatments. Whatever the reasons, it is quite clear that CAM will play a greater role in medical care in the future.

Computed Tomography (CT)

RICHARD M. GORE, VAHID YAGHMAI, GERALDINE M. NEWMARK, JONATHAN W. BERLIN, AND FRANK H. MILLER

Northwestern University and Evanston Northwestern Healthcare

computed tomography (CT)-colonography Multidetector CT acquires a volume data set of the abdomen. With computer software, a virtual, volume-rendered display of the colon is created, permitting detection of polyps and cancer.

contrast-enhanced computed tomography images obtained with intravascular and intralumenal contrast material. This is the preferred scanning protocol for most intra-abdominal pathology.

helical computed tomography (CT) CT technology that acquires a volume of data rather than acquiring data slice by slice as in older technology.

intralumenal contrast A dilute solution (2%) of barium or gatrografin is ingested to distend and opacify the hollow abdominal viscera. This is helpful in differentiating the gut from masses, lymph nodes, and abscesses.

intravascular contrast Iodinated contrast material is injected into an antecubital fossa vein to assess bowel wall enhancement, to identify and characterize focal lesions in the liver, spleen, pancreas, adrenal glands, kidneys, and bladder, and to perform computed tomography–angiography. Usually, 150 cc of contrast is injected at a rate of 2–5 cc/s.

multidetector computed tomography (CT) An advancement in helical CT in which multiple detectors, rather than a single detector, are employed to acquire the data. This technology allows for extremely rapid scans, optimizing intravenous contrast levels.

mural stratification Computed tomography visualization of all three layers of the gut: mucosa, submucosa, and muscularis propria. Most benign causes of gastrointestinal pathology result in mural thickening of the gut with preservation of mural stratification. Malignant disorders generally cause wall thickening with loss of mural stratification.

noncontrast computed tomography (CT) scans Images obtained on CT without intravascular or intralumenal contrast material. It is a good technique for evaluating kidney and ureter stones but limits the sensitivity in detecting gastrointestinal pathology.

The noninvasive evaluation of gastrointestinal disorders has been revolutionized over the past 20 years by technical advances in cross-sectional imaging techniques: ultrasound, computed tomography (CT), and magnetic resonance imaging. CT has evolved as the premier imaging examination in most clinical situations. It has earned this role by virtue of its ability to provide a global perspective of the gut, solid abdominal and pelvic organs, mesenteries, omenta, peritoneum, retroperitoneum, extraperitoneum, and subperitoneum, uninhibited by the presence of bowel gas, fat, or surgical wounds. The advent of multidetector CT has further advanced the clinical utility of CT by permitting thinner contiguous images to be obtained without respiratory misregistration and allowing multiple data acquisitions to be made during different phases of a single intravenous contrast bolus injection. This advance has also shortened examination times and the acquired data set can be displayed as angiographic renderings, multiplanar reformatted images, and surface- or volume-rendered images of the abdominal viscera or lumen without exposing the patient to additional radiation. In this article, the CT features of the most common gastrointestinal disorders are discussed and the utility of CT is placed in a clinical perspective.

THE SOLID ABDOMINAL ORGANS

Liver

Diffuse Disease

Cirrhosis The computed tomography (CT) findings in cirrhosis are varied and depend on the cause and duration of the hepatic injury. Typically, the liver has an irregular nodular appearance with inhomogenous contrast enhancement. There is widening of the fissures and gallbladder fossa, a notch in the posterior aspect of the right hepatic lobe, atrophy of the right lobe with hypertrophy of the caudate lobe (Fig. 1) and lateral segment of the left lobe. In the later stages of cirrhosis, the overall liver volume is diminished. Whereas all patients pathologically demonstrate regenerating nodules, these are infrequently demonstrated on CT. Siderotic nodules have higher attenuation than liver and other soft tissue organs and are readily apparent on unenhanced CT. Because of the insensitivity of CT to depicting regenerating nodules, it cannot reliably identify the transformation process of regenerative nodules to dysplastic nodules.

The gallbladder, hepatic flexure of the colon, and greater omentum often become more superficial in location due to atrophy of the right hepatic lobe and thus are at risk for injury during liver biopsy. Patients with immune-mediated liver disease, such as chronic active hepatitis and sclerosing cholangitis, often have

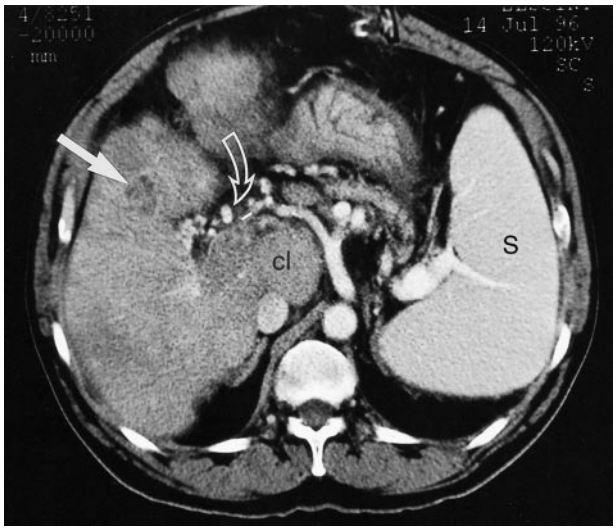

FIGURE 1 Cirrhosis of the liver with a hypovascular hepatoma (straight arrow). The liver has a nodular contour with enlargement of the caudate lobe (cl) and there is cavernous transformation of the main portal vein (curved arrow). Note the splenomegaly (s).

enlarged lymph nodes in the porta hepatis. CT is also helpful in showing signs of portal hypertension: varices, ascites, splenomegaly, and increased density of mesenteric and omental fat.

Steatosis There is an excellent correlation between hepatic parenchymal CT attenuation and the amount of hepatic triglycerides found on liver biopsy specimens. Intracellular fat lowers the CT attenuation of the liver, so that the liver is less dense than the spleen (Fig. 2). Normally the CT density of the liver is equal to or greater than that of the spleen.

FIGURE 2 Diffuse hepatic steatosis in a patient with alcoholic gastritis. The density of the liver is diffuse low, contrasting with the hepatic vessels. The thickened rugal folds of the stomach (arrows) attest to the gastritis.

When fat deposition is focal, it can be confused with a hepatic mass. Focal fat, however, does not displace adjacent blood vessels or cause focal contour abnormalities and may change its appearance rapidly. In questionable cases, the diagnosis of focal fat can be confirmed by magnetic resonance imaging (MRI).

Iron overload Hemosiderosis and hemochromatosis increase the density of the liver on CT. Indeed, there is a linear relationship between CT attenuation values and hepatic iron content. CT can therefore establish the diagnosis, quantitate the amount of iron in the liver, and follow the efficacy of phlebotomy therapy. High hepatic parenchymal attenuation can also be seen in patients receiving amiodarone or gold therapy, glycogen storage disease, calcification from shock liver, and previous exposure to thorotrast.

Hepatitis The primary role of CT in patients with hepatitis is to exclude focal masses or a hepatocellular carcinoma. CT findings in hepatitis are usually nonspecific. Hepatomegaly, gallbladder wall thickening, and hepatic periportal lucency are the major CT findings in patients with acute viral hepatitis. This lucency is due to fluid and lymphedema surrounding the portal veins and has also been reported in patients with acquired immunodeficiency syndrome (AIDS), trauma, neoplasm, liver transplants, liver transplant rejection, and congestive heart failure. Early in the disease, multiple regenerating nodules may be seen in an atrophied liver. CT has shown that hepatic necrosis is repaired by hypertrophy of regenerating nodules rather than by an increase in the number of nodules. These nodules give rise to the macronodular pattern of postnecrotic cirrhosis. Rarely, the nodules may be hypodense and simulate metastases on CT.

In patients with chronic active hepatitis, lymphadenopathy can be found in the porta hepatis, gastrohepatic ligament, and retroperitoneum in 65% of cases and may be the only CT abnormality in a patient with severe hepatic dysfunction. CT can also follow the course of immunosuppression by observing the reduction of lymph node size with therapy.

Focal Hepatic Lesions

Malignant neoplasms

Metastases Liver metastases are the most common malignant tumor of the liver and CT is preferred over MRI as the initial screening test because of its shorter examination time, greater ability to detect extrahepatic disease, lower cost, and greater availability. On noncontrast scans, metastases most commonly appear hypodense relative to normal liver. Metastases can occasionally appear hyperdense due to hemorrhage, calcification, or fatty infiltration of the liver.

The appearance of metastatic lesions following the intravenous administration of contrast is dependent on the intrinsic vascularity of the lesion (hypovascular versus hypervascular) and the timing of scanning following contrast administration. During the hepatic arterial phase of contrast enhancement, hypervascular metastases either appear uniformly hyperdense or contain a hyperdense ring relative to the surrounding liver. Hypovascular lesions appear hypodense when compared to adjacent hepatic parenchyma during the arterial phase. During the portal venous phase of contrast enhancement, most metastatic lesions will appear hypodense compared to normal hepatic parenchyma (Fig. 3). Hypervascular metastases include renal cell carcinoma, islet cell tumors, leiomyosarcoma, and thyroid carcinoma. Metastases may also show a complete peripheral ring of contrast enhancement. The CT findings of metastases are not pathognomonic and can be simulated by hepatomas, abscesses, hematomas, and complicated cysts.

Hepatocellular carcinoma Hepatocellular carcinoma (HCC) is the most common primary liver malignancy and the most common type of cancer worldwide. Since nearly 90% of these tumors occur in patients with cirrhosis or chronic viral infection, detection can be obscured by the hepatic morphologic changes that attend these disorders. On noncontrast scans, HCC presents as a single hypodense or isodense hepatic mass or as multiple masses. In patients with fatty infiltration, however, the lesions can appear hyperdense. Calcifications are present in nearly 7% of lesions. HCC is most commonly hyperdense (Fig. 4) during arterial-phase imaging and becomes hypodense during the portal

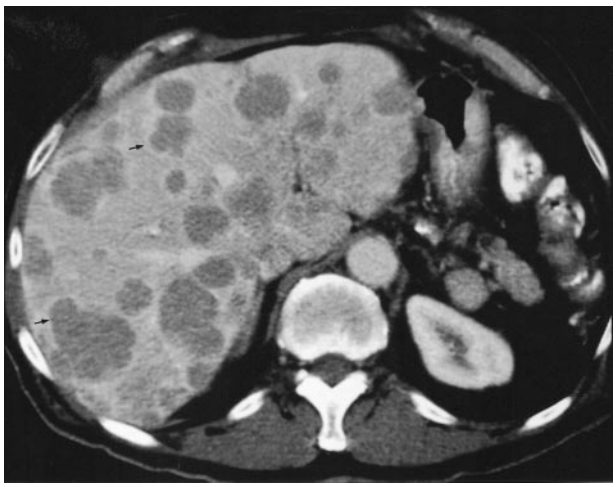

FIGURE 3 Liver metastases from colon cancer. Multiple low-attenuation masses are identified, showing a thin peripheral rim of enhancement (thin small arrows).

FIGURE 4 Hepatocellular carcinoma. There is a large peripherally hypervascular mass in the lateral segment of the left lobe of the liver (H). Necrosis is present centrally.

venous phase. On CT, HCC can appear as a focal, solitary mass, as a multifocal process, or as a diffuse, infiltrating process. Encapsulated HCC will demonstrate a hypodense rim on contrast-enhanced CT and demonstrate delayed contrast fill-in.

Cholangiocarcinoma Cholangiocarcinoma is the second most common primary malignant liver tumor. On noncontrast CT scans, cholangiocarcinomas appear as an irregular round or oval hypodense mass. Initial contrast enhancement is limited and may be peripheral or septated. The majority of these lesions demonstrate homogenous delayed contrast enhancement on scans performed 6 to 30 min following contrast administration.

Benign neoplasms

Hemangiomas Hemangiomas are the most common benign liver tumors and are usually less than 5 cm in size. Helical CT can definitively establish the diagnosis in more than 90% of cases by using the following criteria: peripheral globular or nodular enhancement, a lack of continuity of enhancing tissue, isodense or hyperdense enhancement relative to the aorta (Fig. 5), and centripetal "fill-in" of the lesion. When globular enhancement is demonstrated in CT, no further work-up is needed.

Focal nodular hyperplasia Focal nodular hyperplasia (FNH) is the second most common benign hepatic neoplasm. This lesion contains a central scar and is characteristically subcapsular in location. On noncontrast CT scans, FNH is typically a well-defined lesion that is isodense or hypodense compared to normal hepatic parenchyma. After contrast administration, FNH characteristically shows robust enhancement that washes out quickly. The central stellate scar is initially hypodense, but will accrete the contrast material on delayed images.

Adenomas Adenomas typically occur in young women taking oral contraceptives, athletes abusing anabolic steroids, and patients with glycogen storage disease. Adenomas have a propensity to bleed, which significantly affects their imaging appearance. These lesions may appear hypodense or hyperdense on noncontrast CT scans depending on the presence (see Fig. 5) or absence of hemorrhage. These lesions enhance rapidly on CT due to the predominantly hepatic arterial supply of the tumor. Hepatic adenomas tend to appear well defined due to the presence of a tumor capsule.

Vascular Disorders

Passive hepatic congestion Passive hepatic congestion is caused by stasis of blood within the liver parenchyma due to compromise of hepatic venous drainage. It is a common complication of congestive heart failure and constrictive pericarditis, wherein elevated central venous pressure is directly transmitted from the right atrium to the hepatic veins because of their close anatomic relationship. The liver becomes tensely swollen as the hepatic sinusoids engorge and dilate with blood. The CT findings of passive hepatic congestion include dilation of the inferior vena cava and the hepatic veins. The elevated central venous pressure permits retrograde opacification and enhancement of the inferior vena cava and hepatic veins following contrast injection (Fig. 6). Contrast-enhanced CT scans may show an inhomogenous,

FIGURE 5 Hepatic adenoma and hemangioma. Globular peripheral enhancement, isodense with the aorta, is diagnostic of hepatic hemangioma (H). The adenoma (A) shows central hemorrhage (curved arrows) and inhomogenous enhancement.

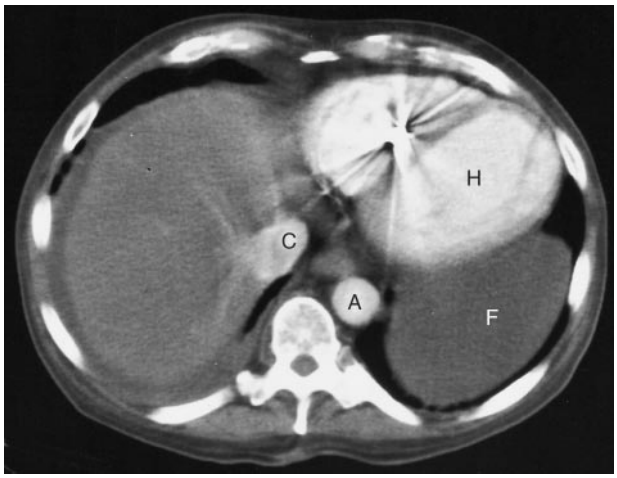

FIGURE 6 Passive hepatic congestion. The heart (H), aorta (A), and inferior vena cava (C) should not enhance to this degree so early after contrast administration, indicating reflux of contrast through the failing right heart. Note ascites (F).

mottled, reticulated-mosaic pattern of parenchymal contrast enhancement. Ancillary findings include cardiomegaly, hepatomegaly, intrahepatic periportal lucency due to perivascular lymphedema, pleural effusions, ascites, and pericardial effusions.

Budd–Chiari syndrome Budd–Chiari syndrome comprises a diverse group of conditions associated with hepatic venous outflow obstruction, at the level of either the large hepatic veins or the suprahepatic segment of the inferior vena cava. Diagnosis of this disorder is frequently difficult because of its protean causes and clinical manifestations. On noncontrast CT scans, diffuse hepatic hypodensity is associated with global liver enlargement and ascites. Hyperdense thrombus may be seen in the inferior vena cava and hepatic veins. Rarely, a calcified caval membrane is identified. After the injection of contrast material, the liver typically shows patchy enhancement. This is due to the hepatic congestion, which causes portal and sinusoidal stasis. In most patients, however, the central regions of the liver, including the caudate and part of the left lobe, may enhance normally and appear hyperdense compared with the more peripheral parts of the liver, which show decreased enhancement (Fig. 7). Later, a classic "flip-flop" pattern may develop, in which the contrast material from the normally enhanced central liver washes out so that this region becomes relatively hypodense compared with the peripheral zones, which are slowly accreting contrast material. The subcapsular portions of the liver may enhance normally, as they have independent venous drainage through systemic subcapsular veins. Intravascular thrombus is best seen in the acute phase of the Budd-Chiari syndrome, as a low-density mass in the lumen of the hepatic veins and inferior vena cava. Portal vein thrombus may be seen in up to 20% of cases. Compression of the inferior vena cava is also demonstrated.

Portal vein thrombosis Portal vein thrombosis is the leading cause of presinusoidal hypertension in the United States. Portal vein thrombosis appears as a low-density central zone surrounded by an intensely enhanced periphery on contrast-enhanced scans (Fig. 8). There is also transient inhomogenous enhancement of the periportal hepatic parenchyma. Enlargement of the occluded vein increases the likelihood of the presence of tumor thrombus. Streaky enhancement of the clot can be seen in tumor thrombus. On precontrast scans, the portal vein contents may be hyperdense due to the high protein content of concentrated red blood cells.

Biliary Tract

Inflammatory Diseases

The CT findings of sclerosing cholangitis (Fig. 9) include the following: intrahepatic duct stenoses, dilated peripheral ducts with no apparent connection to the central ducts, irregular intrahepatic duct dilation with a beaded appearance, and mural thickening, irregularity, and abnormal enhancement of the common bile duct.

Acute cholangitis is usually seen in the clinical setting of biliary obstruction and CT shows dilation of the intrahepatic bile ducts, high-attenuation debris in the duct lumen, and thickening and abnormal enhancement of the bile duct wall. Frank liver abscesses that manifest

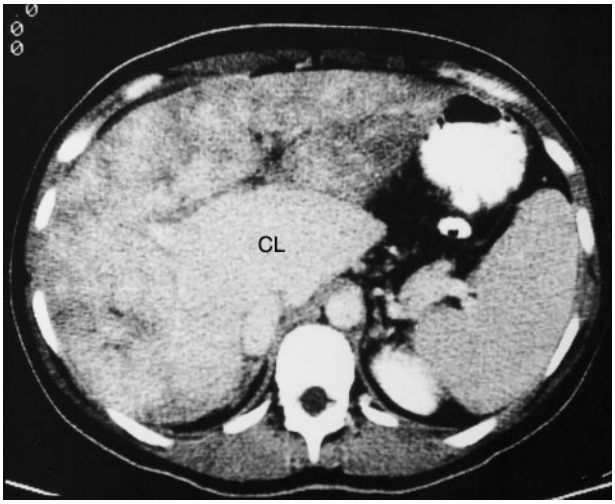

FIGURE 7 Budd-Chiari syndrome. Note the enlarged, enhancing caudate lobe (CL) and hypodense hepatic periphery with mottled enhancement.

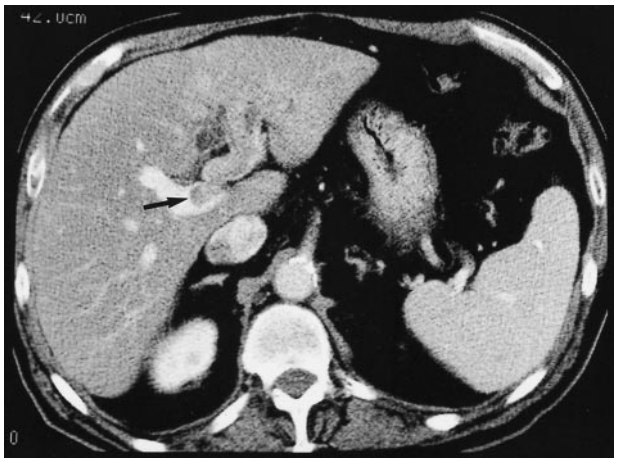

FIGURE 8 Portal vein thrombosis. Low-density tumor thrombus (arrow) is present within the left portal vein in this patient with hepatoma.

as low-attenuation areas in contiguity with the biliary tract may result from acute suppurative cholangitis.

Cholangiocarcinoma

Cholangiocarcinoma of the extrahepatic bile ducts is usually infiltrating, causing stenosis of the duct, but may appear exophytic or intralumenal. Characteristically, the tumor is hypodense early after contrast administration and later shows retention of contrast on delayed images.

Gallbladder

Gallstones

CT is less sensitive in the detection of gallstones than ultrasound: 75% compared to 98%. The CT appearance of gallstones is variable, depending on their composition, pattern of calcification, and the presence of lamination, fissuring, or gas. Stones with a high cholesterol content are difficult to see because they are isodense with the surrounding bile. Well-calcified stones are easily detected on CT. Stones that are denser than bile may be seen due to a rim or nidus of calcification. The CT attenuation of gallstones correlates more closely with the cholesterol content of the stones than with the calcium content. On CT, gallstones can be simulated by the enhancing mucosa of a contracted gallbladder wall or neck, which often fold upon themselves.

Acute Cholecystitis

Although ultrasound is the preferred method for diagnosing acute cholecystitis, CT is frequently the initial examination ordered because the diagnosis is unclear. Mural thickening greater than 3 mm in the setting of a distended gallbladder and enhancement of the inflamed wall are the most sensitive helical CT findings of acute cholecystitis (Fig. 10). Transient focal increased attenuation of the liver may develop adjacent to the inflamed gallbladder as a result of hepatic arterial hyperemia and early venous drainage. Less specific signs include pericholecystic fluid, haziness of the pericholecystic fat, and increased attenuation of the gallbladder bile. Helical CT can also depict the complications of acute cholecystitis, such as perforation and gangrene. Intramural or intralumenal gas is present in emphysematous cholecystitis.

Choledocholithiasis

Patients with choledocholithiasis typically present with acute right upper quadrant pain, fever, jaundice, and pancreatitis. Thin collimation (3 mm) scans are

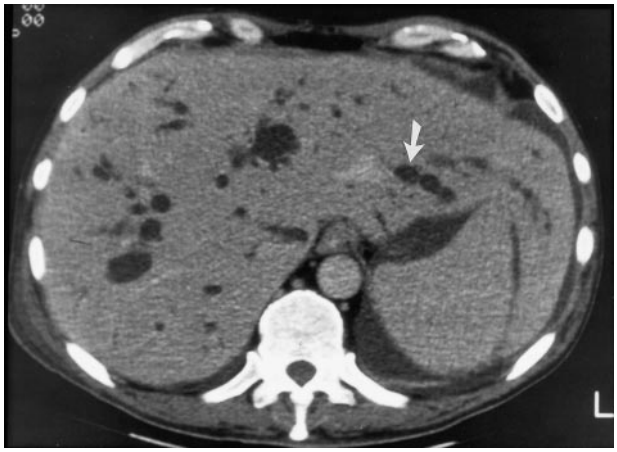

FIGURE 9 Sclerosing cholangitis. Multiple areas of heading of focally ectatic intrahepatic (arrow) are evident.

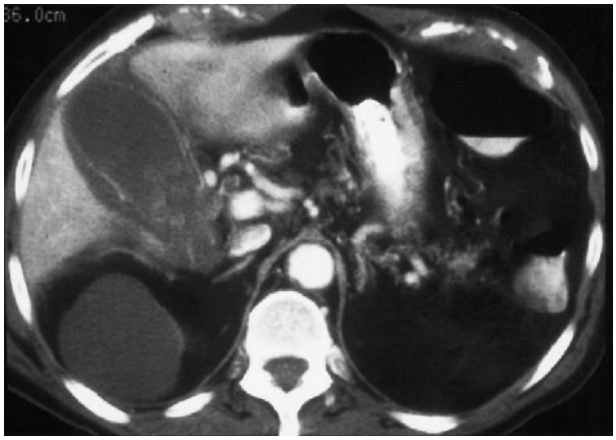

FIGURE 10 Acute cholecystitis. The gallbladder wall is thickened and shows mural edema. Multiple stones are also evident.

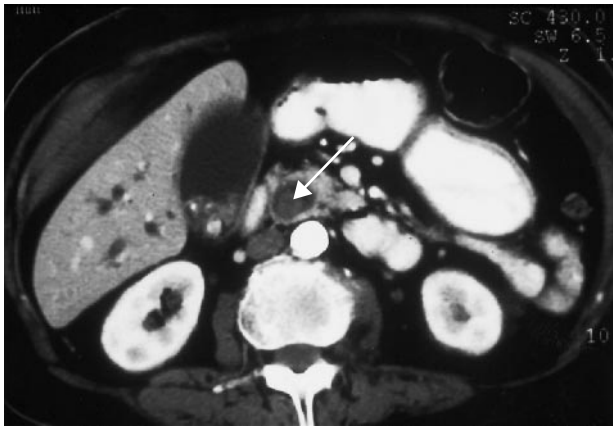

FIGURE 11 Choledocholithiasis. A high-density stone is present within the lumen of a dilated common bile duct (arrow).

needed to optimize the detection of stones on CT. A high-density nidus may be visualized within the duct or alternating low- and high-density rings of mixed cholesterol–calcium stones may be seen (Fig. 11). Biliary dilation may be evident proximally. Helical CT has a sensitivity of 88%, a specificity of 97%, and an accuracy of 94% in the detection of choledocholithiasis. Positive intralumenal and intravascular contrast material can obscure the detection of peripherally calcified stone, however.

Neoplasms

Carcinoma of the gallbladder is the fifth most common malignancy of the gastrointestinal tract, responsible for nearly 7000 deaths annually in the United States. This neoplasm has three major patterns of presentation pathologically and on CT: (1) focal or diffuse mural thickening; (2) an intralumenal polypoid mass (Fig. 12), usually larger than 2 cm, originating in the gallbladder wall; and (3) most commonly (45–65%), a subhepatic mass replacing or obscuring the gallbladder, often invading adjacent liver.

FIGURE 12 Gallbladder carcinoma. This neoplasm manifests as an enhancing mass (arrow) in the gallbladder lumen.

Pancreas

Neoplasms

Adenocarcinoma On CT, most adenocarcinomas present as a focal hypodense (Fig. 13) mass on contrast-enhanced scans. Atrophy of the pancreas and dilation of the pancreatic duct are often seen upstream of the neoplasm. Helical CT is also quite useful in assessing resectability of the tumor. Liver metastases, vascular encasement, and involvement of adjacent lymph nodes suggest unresectability.

Islet cell tumors Most islet cell tumors are strikingly hypervascular lesions and consequently enhance robustly following contrast administration. Most are less than 2 cm in size.

Cystic pancreatic neoplasm Serous, microcystic cystadenomas have small ($\leq$1 cm), often innumerable cysts interspersed within a dense fibrous honeycomb. Central calcifications occur in 30% of these usually benign tumors. Mucinous cystadenomas and cystadenocarcinomas present as macrocystic ($\geq$2 cm) unilocular cysts or as intraductal neoplasms. Calcification is rare and mural nodules may be present. On the basis of CT findings, it is difficult to differentiate benign from malignant mucinous tumors.

Pancreatitis

Acute pancreatitis Helical CT plays a vital role in the clinical management and staging of patients with acute pancreatitis. CT can establish the presence of hemorrhage or necrosis within the gland itself and identify the extension of the inflammatory process into adjacent organs. The CT findings of acute pancreatitis reflect edema of the gland and surrounding fat and may be normal in up to 28% of mild cases. The entire gland may become diffusely enlarged with an irregular contour. In mild cases, the peripancreatic fat contains wisps of high attenuation, the vascular margins are cuffed, and the fascial planes are thickened. Mild peripancreatic inflammation may be present around an otherwise normal appearing gland. Segmental pancreatitis occurs in 10–18% of patients and is usually associated with stone disease. Typically, the gland shows uniform enhancement.

In more advanced cases, intraglandular intravasation of pancreatic fluid leads to the formation of multiple, small, intrapancreatic fluid collections. In

FIGURE 13 Pancreatic adenocarcinoma. CT shows a hypodense mass that encases the splenic artery (open arrow). Note the upstream dilation of the pancreatic duct and parenchymal atrophy (curved arrow).

necrotizing pancreatitis, the gland becomes enlarged and is often enveloped by high-attenuation exudates. Necrotic parenchyma shows decreased or no enhancement that is sharply demarcated from normally enhancing viable tissue (Fig. 14). The body and tail are usually involved; the head is spared because of its rich collateral vascular network. Enhancing islands of viable tissue may be scattered throughout the gland. The poorly

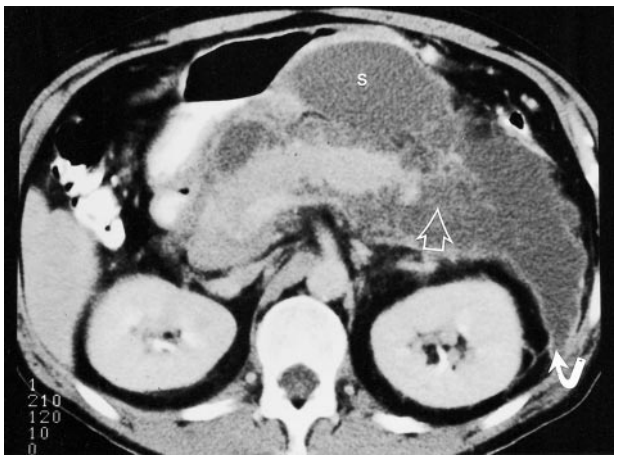

FIGURE 14 Necrotizing pancreatitis. There is poor enhancement of the pancreatic tail (open arrow), suggesting necrosis. Note the large fluid collections in the lesser sac (S) and the anterior interfascial plane (curved arrow).

defined peripancreatic exudates obliterate the peripancreatic fat, dissect fascial planes, and penetrate through fascial and peritoneal boundaries and ligaments. These collections typically accumulate in the lesser sac, anterior pararenal space, and anterior interfascial space. Helical CT is also useful in demonstrating vascular complications, such as pseudoaneurysms and splenic and portal vein thrombosis. Delineation of necrosis by helical CT can help predict patient outcome.

Chronic pancreatitis The CT features of chronic pancreatitis include the following: dilation of the main pancreatic duct, parenchymal atrophy, pancreatic calcifications, intra- and peripancreatic fluid collections, focal pancreatic enlargement, and biliary tract dilation. It is often difficult to differentiate focal mass-like chronic pancreatitis from adenocarcinoma on the basis of CT features alone.

HOLLOW ABDOMINAL VISCERA

Esophagus

Neoplasms

On CT, esophageal carcinoma produces either concentric mural thickening or a focal, asymmetric soft tissue mass arising from the wall. CT is useful for tumor staging, assessing response to therapy, and diagnosing complications of surgery. Tumor invasion of the aorta is unlikely if the tumor involves the aortic circumference by $\leq 45°$; contact $\geq 90°$ is highly suggestive of invasion and contact in the range of 45° to 90° is indeterminate. Aortic invasion is also predicted when the small triangular deposit of fat between the esophagus, aorta, and spine is obliterated. The preoperative identification of tracheobronchial invasion is important because it may make tumor resection, particularly by the transhiatal route, more difficult or even impossible. The demonstration of a tracheobronchial fistula or extension of the tumor into the airway lumen is a specific sign of invasion. Tracheobronchial invasion should be suspected if an esophageal tumor either causes inward bowing of the posterior tracheal or bronchial wall or displaces the trachea and/or bronchi away from the spine.

Varices

The complete extent of esophageal and abdominal varices is well depicted on CT. Varices produce thickening of the esophageal wall, a scalloped contour, and enhancing intralumenal protrusions following intravenous contrast injection.

Stomach

Neoplasms

Malignant tumors

Adenocarcinoma Gastric carcinomas on CT appear as a region of focal, inhomogenous mural thickening (Fig. 15). Scirrhous and polypoid forms, with or without ulceration, are typically seen. Gastric carcinoma typically spreads to the liver, lymph nodes, pancreas, duodenum, transverse mesocolon, and peritoneal cavity. Direct extension of proximal tumors can occur via the gastrohepatic ligament to the porta hepatis and left lobe of the liver. The transverse colon may be involved by tumor spread through the gastrocolic ligament and splenic involvement may be seen from gastrosplenic ligament invasion. Direct extension may be seen into the pancreas and duodenum. The use of helical CT techniques that optimize intravenous contrast levels and minimize respiratory misregistration helps to identify lymph node involvement and vascular encasement. Carcinomatosis with diffuse peritoneal seeding, malignant ascites, and adnexal and pelvic metastases are well depicted by CT.

Lymphoma On CT, gastric lymphomas tend to produce significantly greater wall thickening than adenocarcinoma. Lymphomas also tend to be more homogenous and more diffusely involve the stomach than adenocarcinomas.

Leiomyosarcomas On CT, these lesions tend to be large and inhomogenous, to ulcerate, and to have a greater degree of extragastric growth than leiomyomas.

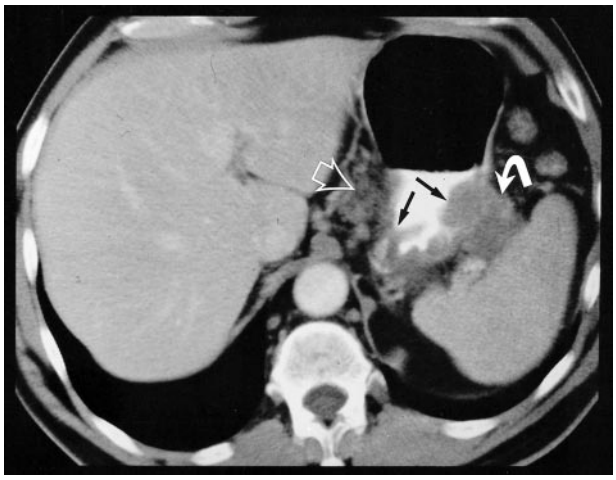

FIGURE 15 Gastric cancer. There is mural thickening with polypoid folds of the proximal gastric body (black arrows). There is tumor spread into the gastrohepatic ligament (open arrow) and gastrosplenic ligament (curved arrow).

FIGURE 16 Gastric leiomyoma. A large, ulcerating (arrow), endophytic mass is present near the cardia of the stomach.

Benign tumors

Leiomyomas These lesions tend to be less than 4 cm in size, are homogenous, and show endolumenal growth as on CT (Fig. 16). Differentiation from leiomyosarcomas may be impossible.

Lipomas These well-circumscribed lesions have fat (low) attenuation on CT.

Gastritis

On CT, gastritis manifests as mural thickening, often with submucosal edema. CT has no role in the primary evaluation of gastritis but can be useful in showing complications of peptic ulcer disease, e.g., perforation (Fig. 17) or fistula.

Small Bowel

Crohn's Disease

Crohn's disease is manifested on CT by bowel wall thickening ranging between 1 and 2 cm. During the acute, noncicatrizing phase of Crohn's disease, the small bowel and colon maintain mural stratification and often have a target or double-halo appearance. There is a soft-tissue-density ring (corresponding to mucosa), which is surrounded by a low-density ring with an attenuation near water or fat (corresponding to submucosal edema or fat infiltration, respectively), which in turn is surrounded by a higher-density ring (muscularis propria). Inflamed mucosa and serosa may show significant contrast enhancement following bolus intravenous contrast administration and the intensity of enhancement correlates with the clinical activity of disease (Fig. 18).

The CT demonstration of mural stratification, i.e., the ability to visualize distinct mucosal, submucosal,

FIGURE 17 Penetrating benign gastric ulcer. A large benign gastric ulcer (white arrow) is seen penetrating into the gastrohepatic ligament. The thick gastric folds (black arrows) attest to the gastritis.

and muscularis propria layers, indicates that transmural fibrosis has not occurred and that medical therapy may be successful in ameliorating lumen compromise. The edema and inflammation of the bowel wall that cause mural thickening and lumen obstruction are reversible to some extent. A modest decrease in wall thickness often produces a dramatic increase in lumen cross-sectional area and resolution of the patient's obstructive symptoms.

In patients with long-standing Crohn's disease and transmural fibrosis, mural stratification is lost so that the affected bowel wall typically has homogenous attenuation on CT. Homogenous attenuation of the thickened bowel wall in the presence of good intravascular contrast-medium levels and thin-section scanning suggests irreversible fibrosis so that anti-inflammatory agents may not provide a significant reduction in bowel wall thickness. If these segments become sufficiently narrow, surgery or stricturoplasty may be necessary to relieve the patient's obstruction.

CT can readily differentiate the extralumenal manifestations of Crohn's disease. Fibrofatty proliferation, also known as "creeping fat" of the mesentery, is the most common cause of separation of bowel loops seen on small bowel series in patients with Crohn's disease. On CT, the sharp interface between bowel and mesentery is lost and the attenuation value of the fat is elevated by 20 to 60 housefield units (HU) due to the influx of inflammatory cells and fluid. Mesenteric adenopathy with lymph nodes ranging in size between 3 and 8 mm may also be present. Contrast-enhanced CT scans often show hypervascularity of the involved mesentery manifesting as vascular dilation, tortuousity, prominence, and wide spacing of the vasa recta. These distinctive vascular changes have been called "vascular jejunization of the ileum" or the "comb sign." Identification of this hypervascularity should suggest active disease and may be useful in differentiating Crohn's disease from lymphoma or metastases, which tend to be hypovascular lesions. On CT, a phlegmon produces loss of definition of the surrounding organs and a "smudgy" or "streaky" appearance of the adjacent mesenteric or omental fat. Initially, abscesses appear as a mass of soft tissue attenuation due to the influx of inflammatory cells. With maturation, the abscess undergoes liquefactive necrosis centrally and highly vascularized connective tissue develops peripherally. As a result, this lesion has a low-attenuation center with an enhancing rim (Fig. 19).

FIGURE 18 Crohn's disease. (A) There is marked mural thickening and abnormal enhancement of the distal ileum. Note the inflammation of the adjacent mesentery (arrows). (B) Note the dramatic mural and mesenteric improvement following medical therapy.

FIGURE 19 Crohn's disease with mesenteric abscess. There is mural thickening of the distal ileum (black arrows), which has an adjacent mesentery that contains engorged vasa recta. Note the gas-containing abscess (A) that has a thick, enhancing wall.

Bowel Obstruction

Small and large bowel obstruction accounts for approximately 20% of acute abdominal surgical conditions. Helical CT has replaced conventional contrast studies in these patients because it can more reliably answer the following questions:

1. Is an obstruction present?
2. What is the level of obstruction?
3. What is the cause of the obstruction?
4. What is the severity of the obstruction?
5. Is the obstruction simple or is it a closed loop?
6. Is strangulation or ischemia present?

It is important to differentiate between simple versus closed-loop obstruction since the former can be managed conservatively, whereas the latter requires prompt surgical intervention. Scans in these patients are best obtained without oral contrast material because intralumenal fluid and gas serve as a natural contrast agent. Intravenous contrast is important in assessing intestinal perfusion and ischemia as well as delineating the size, configuration, and patency of the mesenteric vessels.

Demonstration of a transition zone between dilated and decompressed bowel is the CT hallmark of bowel obstruction. Careful inspection of the transition zone and lumenal contents will often demonstrate the underlying etiology of the obstruction. CT is most helpful in patients with internal and external hernias, neoplasms, gallstone ileus, various forms of enteroenteric intussusception and afferent loop obstruction following a Billroth II gastrectomy. If no mass, hernia, intussusception, stone (Fig. 20), abscess, or inflammatory thickenings are present, then adhesion is the most likely diagnosis. The typical adhesion has a beak-like narrowing and the affected gut may be difficult to appreciate depending on the orientation of the loop relative to the axial plane.

An incarcerated or closed-loop obstruction manifests as a loop-shaped, fluid-filled structure, causing the proximal segments to dilate with gas and fluid. The mesenteric vessels have a radial distribution as they become stretched and converge toward the U- or C-shaped loop. There are typically two adjacent collapsed round/oval/triangular segments that represent the afferent and efferent entry points or the torsion site. The mesenteric vasculature may have an unusual course. When ischemia develops, the bowel wall may be thickened and have a target appearance due to submucosal edema. Additionally, there may be poor or delayed enhancement of the involved bowel wall. Fluid and hemorrhage may collect in the mesentery, bowel wall, and/or lumen of the involved segment. The mesentery becomes hazy in appearance and ascites may develop.

In patients with high-grade small bowel obstruction, CT has a reported sensitivity of 90–96%, a specificity of 91–96%, and an accuracy of 90–95%. CT is less accurate in patients with low-grade obstruction.

Neoplasms

Small bowel lymphoma may demonstrate a large homogenous mass or a large ulcerating mass, often with associated enlargement of mesenteric and retroperitoneal lymph nodes (Fig. 21). Carcinoid tumors classically manifest as a variably calcified mass with radially oriented linear densities in the perienteric fat. Resulting desmoplasia causes bowel loops to be drawn in toward the mass.

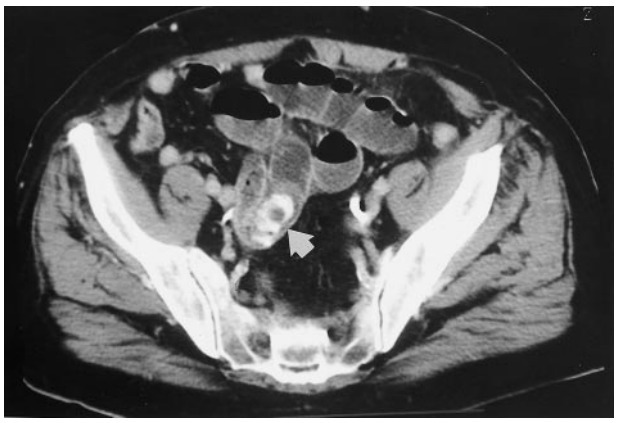

FIGURE 20 Gallstone ileus. A calcified gallstone (arrow) is causing small bowel obstruction

FIGURE 21 Small bowel lymphoma. There is a large cavitating mass (M) in the ileum.

Colon

Ulcerative Colitis

In acute, fulminant ulcerative colitis (Fig. 22), deep ulcerations may be identified associated with increased intralumenal fluid. Mural thickening and lumen narrowing are common CT features of subacute and chronic ulcerative colitis. The mucosa becomes thickened due to hypertrophy of the muscularis mucosae in chronic ulcerative colitis. Additionally, the lamina propria is thickened due to round cell infiltration in both acute and chronic ulcerative colitis. The submucosa becomes thickened due to the deposition of fat (Fig. 23) or, in acute and subacute cases, edema. Submucosal thickening further contributes to lumenal narrowing.

FIGURE 22 Acute ulcerative colitis. Large areas of ulceration leave inflammatory pseudopolyps (arrows) in their wake. The increased lumenal fluid (F) attests to the copious diarrhea. Note the ascites (A).

On CT, these mural changes produce a target or halo appearance when axially imaged: the lumen is surrounded by a ring of soft tissue density (mucosa, lamina propria, hypertrophied muscularis mucosae), which is surrounded by a low-density ring (edema or fatty infiltration of the submucosa), which in turn is surrounded by a ring of soft tissue density (muscularis propria). This mural stratification is not specific and can also be seen in Crohn's disease, infectious enterocolitis, pseudomembranous colitis, ischemic and radiation enterocolitis, mesenteric venous thrombosis, bowel edema, and graft-versus-host disease.

Diverticulitis

Diverticulitis occurs in 10–25% of patients with known diverticulosis. Clinical misdiagnosis rates ranging from 34 to 67% have been reported. The role of CT in these patients is to confirm the diagnosis, establish the presence of complications (e.g., abscess), provide a road map for percutaneous or surgical therapy, and suggest alternative diagnoses in patients in whom diverticulitis has been excluded.

Inflammatory change in the pericolic fat is the CT hallmark of diverticulitis (Fig. 24), seen in 98% of patients. In mild cases, there is only minimal haziness of the adjacent fat. Small fluid collections, fine linear strands, and extralumenal gas bubbles may be visualized. In more severe cases, phlegmon or frank abscess formation can occur. Diverticula are evident in >80% of cases and symmetric mural thickening in excess of 4 mm is seen in approximately 70% of patients. In some cases, contrast material collects in an arrowhead shape adjacent to the inflamed colonic diverticulum—the arrowhead sign. The offending inflamed diverticulum may appear as a rounded, paracolic out-pouching centered within the paracolic inflammation with soft tissue, calcium, barium, or air attenuation.

Appendicitis

Acute appendicitis is the most common abdominal surgical emergency, affecting approximately 250,000 people annually in the United States. Although the correct diagnosis can be made in most patients on the basis of history, physical examination, and laboratory tests, diagnosis is uncertain in the 20–33% of patients who present with atypical features. The diagnosis is most

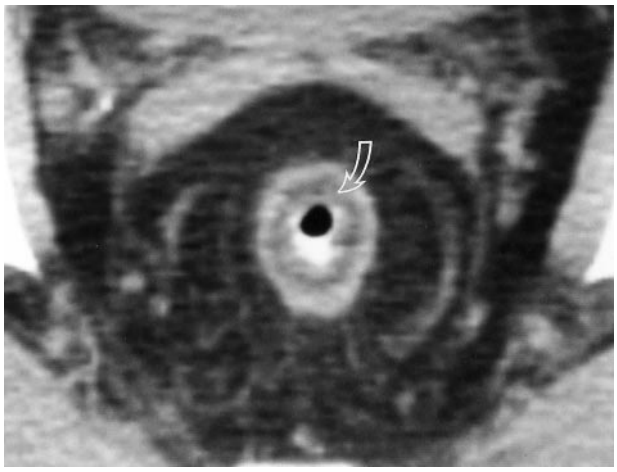

FIGURE 23 Chronic ulcerative colitis. CT scan of the rectum shows mural thickening and submucosal fat deposition (arrow).

difficult to establish in infants and young children, the elderly, and women of reproductive age. In the past, an average negative laparotomy rate of 20% was acceptable. The widespread use of helical CT in patients with suspected appendicitis has been shown to positively affect patient outcome and increase the number of positive laparotomies. Studies evaluating the efficacy of helical CT show sensitivities of 90–100%, specificities of 83–97%, and accuracies of 93–98% for the diagnosis of acute appendicitis.

The CT findings in acute appendicitis reflect the extent and severity of inflammation. In mild disease, the appendix appears as a distended (6–15 mm diameter) fluid-filled structure that shows circumferential, symmetric mural thickening (Fig. 25). Homogenous

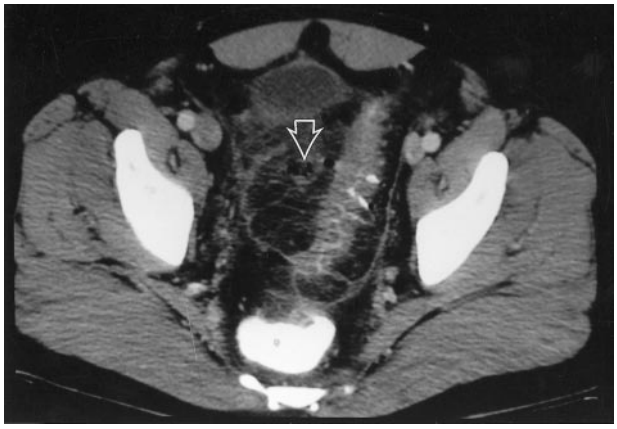

FIGURE 24 Diverticulitis. There is mural thickening of the sigmoid colon associated with inflammatory change and gas bubbles (arrow) in the sigmoid mesocolon.

dense contrast enhancement of the wall is typical but a target sign may be seen when the appendix is axially viewed. Periappendiceal inflammation manifests as slight haziness of the fat of the mesoappendix. A calcified appendicolith is more reliably demonstrated on CT than on plain films.

With disease progression and perforation, the appendix becomes fragmented, destroyed, and replaced by a phlegmon or abscess. There may be associated mural thickening of the adjacent distal ileum and cecum. In these cases, the specific diagnosis of appendicitis can be made if an appendicolith is seen within the abscess or phlegmon.

Epiploic Appendagitis

This unusual condition occurs when an epiploic appendage of the colon develops inflammation, torsion, or ischemia. Epiploic appendagitis can simulate appendicitis and right- and left-sided diverticulitis both clinically and on CT scans. The inflamed appendage presents as a small fat attenuation mass with a hyperattenuating rim that abuts the serosal surface of the colon (Fig. 26). At the center of the lesion, a small round or linear hyperdense focus may be seen and is thought to represent vascular thrombosis. Epiploic appendagitis also produces mass effect and focal thickening of the adjacent bowel, infiltration of the mesenteric fat, and focal thickening of the surrounding peritoneum.

Other Colitides

Infectious enterocolitides Gastroenteritis and the infectious enterocolitides are responsible for nearly 70% of emergency room visits prompted by abdominal pain. Most cases are self-limited and do not require imaging. In atypical cases, colicky abdominal pain rather than diarrhea may be the predominant symptom. The CT scan may be normal or show nonspecific mural thickening in more severe cases of *Shigella*, invasive *Escherichia coli*, *Salmonella*, *Yersinia*, and *Entamoeba*.

In pseudomembranous colitis, potent antibiotics disrupt the normal bacterial flora of the colon, leading to overgrowth of *Clostridium difficile*. The release of its enterotoxins causes mucosal inflammation and the development of pseudomembranes consisting of mucous and inflammatory debris. On CT, there is mural thickening averaging 15–20 mm, with a target or halo pattern due to submucosal edema (Fig. 27). Contrast material caught between thick haustra may simulate deep ulcerations and produce an accordion-like appearance. The lumen may be completely effaced as well. Ascites and pericolic inflammatory changes accompany these features.

FIGURE 25 Appendicitis. There is dilation of the appendix with increased mural enhancement (open arrow). There is reactive thickening of the adjacent cecum (black arrow).

Helical CT is most useful in differentiating the panoply of inflammatory, infectious, and neoplastic disorders that can cause the acute abdomen in AIDS patients. Infections such as cryptosporidiosis (Fig. 28) and cytomegalovirus produce thickening of the gut wall with edema of the submucosa and increased enhancement of the mucosa.

Typhlitis Neutropenic colitis is an acute inflammatory and necrotizing process that affects the cecum of immunocompromised patients with profound neutropenia. In this disorder, there is ulceration of the mucosa followed by bacterial and fungal invasion. The CT features are nonspecific and include segmental mural thickening of the cecum (Fig. 29), intramural regions of edema or necrosis, pericolic fluid, and perienteric stranding. In advanced cases, pneumatosis intestinalis and frank perforation may develop.

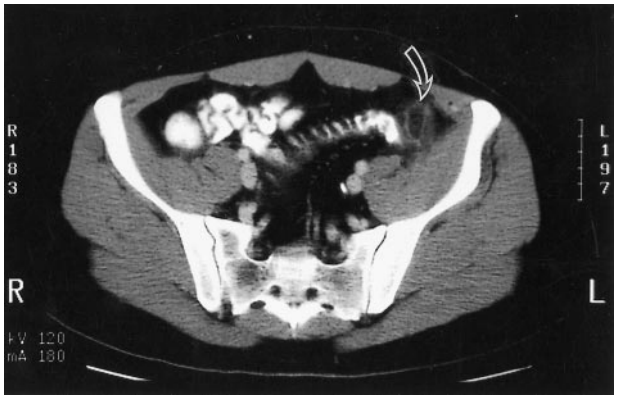

FIGURE 26 Epiploic appendagitis. The fat-density epiploic appendage is surrounded by high-density inflammatory changes (curved arrow).

Neoplasms

Colorectal cancer (CRC) is usually diagnosed by barium studies, colonoscopy, or sigmoidoscopy. Although these techniques provide superb visualization of the mucosa, they cannot determine the depth of mural invasion by the tumor or the extent of metastatic involvement. Preoperative staging aims to accurately assess tumor extent in order to individualize patient therapy, facilitate evaluation of treatment results, assess risk of disease recurrence, and determine prognosis. By virtue of their cross-sectional imaging format and ability to demonstrate the extent of wall invasion, extralumenal tumor spread, and lymph node and distant metastases, CT has become the primary means for radiologic staging of CRC (Fig. 30).

The preoperative accuracy of CT in staging CRC is limited, with reported sensitivity rates of only 48–77%. This is due to the inability of CT to accurately assess the degree of mural invasion and the difficulty in differentiating reactive from malignant lymph nodes. Despite these limitations, preoperative CT is commonly used to provide a baseline exam for comparison with postoperative imaging studies and to help detect metastatic lesions prior to surgery. Additional indications for preoperative CT include suspected contiguous organ invasion by tumor and unusual tumor histology, such as lymphoma.

FIGURE 27 Pseudomembranous colitis. There is a proctosigmoiditis associated with diffuse mural thickening (arrows) and submucosa edema. A, ascites.

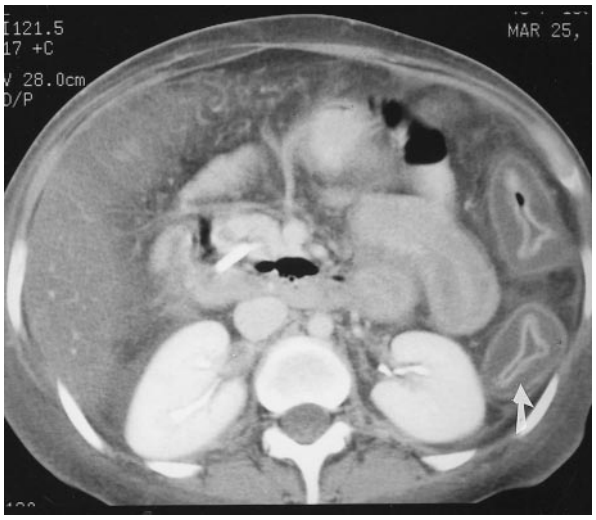

FIGURE 28 Cryptosporidial colitis. There is marked submucosal edema (arrow) evident in the region of the distal transverse and proximal descending colon in this AIDS patient with a CD4 lymphocyte count <50. Note the enhancing mucosal and muscularis propria layers.

The sensitivity of conventional CT approaches 75% in the detection of the initial colorectal tumor. Lesions less than 3 to 5 mm are usually not detectable. This is probably not clinically significant in most cases, since the risk of malignancy in a polyp less than 1 cm in diameter is less than 1%. Most often, the inability to detect small lesions of the colon and rectum on CT is due to incomplete bowel distension and difficulty in the differentiation of adherent fecal material from true colonic polyps.

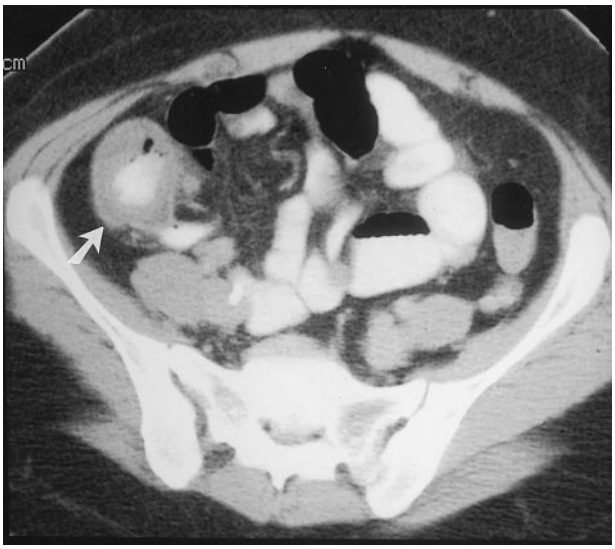

FIGURE 29 Typhlitis. There is focal mural thickening of the cecum (arrow) in this patient with leukemia and profound neutropenia.

Detection of colonic tumors on CT can be optimized by using a scanning protocol that acquires thin-section images (3–5 mm) obtained during peak enhancement of a rapidly delivered contrast bolus ($\geq$3 ml/s). Some authors advocate scanning from the symphysis pubis cephalad to the iliac crests to maximize visualization of mural enhancement. Certain centers also perform pelvic CT in both supine and prone positions to minimize adherent fecal material. Other techniques used to maximize tumor detection include instilling air into the rectum with a Foley catheter to increase distension of the colon and rectum. Helical CT scanning with breath-holding should be used if possible to minimize respiratory motion artifacts and spatial misregistration. Images should be displayed in soft tissue, liver, and bone windows to maximize lesion conspicuity.

CRC on CT most commonly manifests as a soft tissue mass that narrows the colonic lumen. The mass, if large enough, may undergo central necrosis, causing low attenuation. Mucinous primary adenocarcinomas may rarely contain calcium, although this more commonly occurs with hepatic metastasis than in the primary tumor. Occasionally, necrotic tumor masses may contain gas and perforate into adjacent structures. In such cases, differentiation from an abscess may be difficult. Another relatively common appearance of primary tumors of the colon is focal wall thickening. The normal, distended colonic wall should not measure more than 3 mm in thickness on CT. Wall thickness between 3 and 6 mm is considered indeterminate but concerning for neoplasia and measurements greater than 6 mm are abnormal. Malignant wall thickening most often has a nodular appearance and is associated with lumenal narrowing. However, the thickening can occasionally appear symmetric and involve the entire circumference of the bowel wall. In such cases, malignancy can be difficult to differentiate from benign causes of wall thickening including inflammation and mural edema.

The pericolonic and perirectal fat should appear uniformly low in density without soft tissue stranding on CT. Invasion beyond the bowel wall should be suspected if a focal mass deforms the contour of the outer colonic wall, with or without soft tissue stranding into the adjacent fat. Extramural invasion may be present when there is loss of fat planes between the colon and adjacent muscles such as the levator ani, piriform, obturator, and gluteal muscles. Unfortunately, the loss of fat planes is a nonspecific sign in cross-sectional imaging and can also be seen with cachexia and lymphatic or vascular obstruction. Therefore, the diagnosis of

extramural tumor extension should be made with caution. Additionally, patients with microinvasion through the bowel often demonstrate normal-appearing pericolonic and perirectal fat on CT, leading to understaging of the tumor.

CT detection of malignant lymphadenopathy has traditionally been based on size criteria. Lymph nodes greater than 1 cm in size are considered abnormal, except in the perirectal fat, where any lymphadenopathy is considered pathologic. Unfortunately, size criteria are based only on statistical probability. In reality, many nodes smaller than 1 cm are malignant and nodes larger than 1 cm are caused by reaction to a number of benign inflammatory conditions. As a result, true differentiation of benign from malignant lymphadenopathy can be achieved only with biopsy.

Gross tumor invasion into the adjacent pelvic musculature is manifested by muscle enlargement and occasionally an enhancing intramuscular mass. Bladder invasion with rectovesical fistula should be considered in patients with gas in the bladder and no history of Foley catheterization.

CT virtual colonography (Fig. 31) takes the detection of CRC and polyps one step further. In this technique, CT data are displayed with a two- and three-dimensional format. Viewing these images at a rate of 15–30 per second creates the illusion of viewing the colon endolumenally. The bowel preparation for cross-sectional colonography is similar to that for colonoscopy and barium enema. Colonic distension prior to virtual colonography is accomplished with CO_2 or room air. To minimize motion artifacts, data are obtained during a single helical CT acquisition. The sensitivity for detection of polyps greater than 1 cm in size has been reported to be as high as 75% with a specificity greater than 90%. Virtual colonography also offers the advantage of allowing visualization of the colon proximal to a distal obstructing tumor, an area that is inaccessible endoscopically. This is particularly valuable, because the rate of a second synchronous CRC is between 1.5 and 9.0% and the rate of multiple coexistent adenomatous polyps is between 27 and 55%. This advantage suggests that virtual colonography will likely play a larger role in the radiographic staging of colon carcinoma.

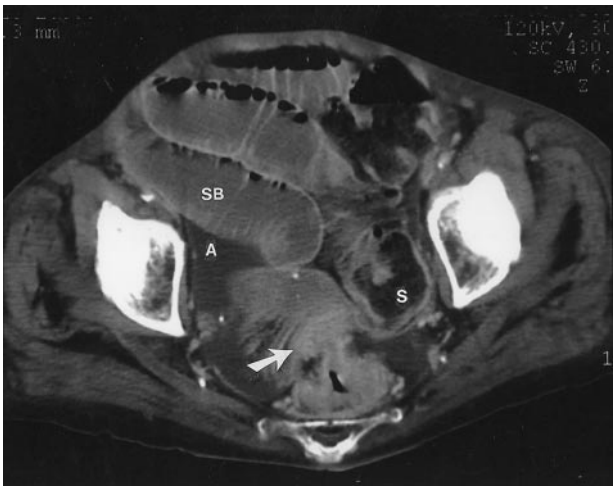

FIGURE 30 Annular constricting rectal cancer (arrow) causing large and small bowel obstruction. SB, dilated fluid-filled small bowel; S, dilated sigmoid colon; A, ascites.

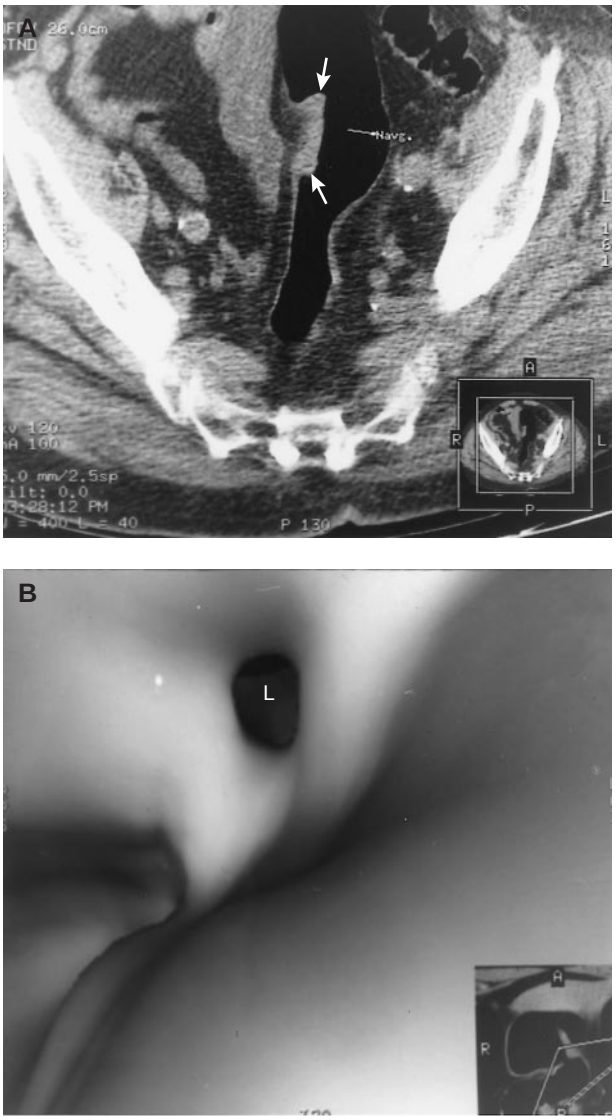

FIGURE 31 Flat distal sigmoid cancer. (A) Tumor (arrows) visualized on conventional axial image. (B) Lumen (L) narrowing as depicted on 3D virtual colonographic view.

Hepatic metastases from CRC on CT most commonly appear as low-attenuation lesions on noncontrast images. Surgical resection of hepatic metastasis is attempted if only one lobe of the liver is involved with less than four lesions, the remaining hepatic lobe has a normal appearance and function, and no focal adenopathy or distant spread of tumor is present. Patients undergoing hepatic lobectomy for metastatic disease should also have intraoperative ultrasound, as this is the most sensitive imaging technique for detection of hepatic metastases.

Peritoneal carcinomatosis, caused by spread of tumor over peritoneal surfaces, is usually well demonstrated by CT and appears as linear or nodular peritoneal thickening that enhances with contrast. Adrenal metastases on CT appear as low-density masses in the adrenal gland and osseous metastases on CT are most commonly lytic and associated with cortical disruption.

Overall sensitivity rates in the detection of recurrent colon cancer are similar with CT and MRI. For detecting the recurrence of rectal tumors, TRUS and MRI appear to have better detection rates. Despite this, however, the radiographic evaluation for recurrent tumor is most commonly performed with CT. With easy access to CT scanners, overall sensitivity rates of 69–95%, and relative speed in completing the procedure, CT will likely remain the imaging modality of choice for detecting tumor recurrence in the near future. Limitations of CT for detection of postoperative recurrence are similar to those of preoperative studies and primarily consist of difficulty in distinguishing malignant adenopathy and microinvasive spread of tumor into pericolonic and perirectal fat. Detection of tumor recurrence is further complicated by several benign entities that can simulate recurrence on cross-sectional imaging studies. The most important of these are postradiation changes, including radiation colitis and radiation fibrosis. Additionally, patients receiving chemotherapy are often more susceptible to inflammatory conditions, which can mimic tumor recurrence as well.

Constipation

ARNOLD WALD
University of Pittsburgh Medical Center

colonic transit Measurement of the time it takes for inert markers to pass through the colon and anorectum, traditionally measured while the subject consumes a high-fiber diet and uses no laxatives.

dietary fiber That portion of plant food that escapes digestion and which is composed of either insoluble or soluble components. Insoluble fiber retains water within the cellular structures whereas soluble fiber stimulates growth of colonic bacteria; both actions increase fecal mass.

laxative Substance that acts to promote the passage of stools modestly and without violent action.

pelvic floor dyssynergia Condition in which normal defecation is impeded by the unconscious contraction of the puborectalis and external anal sphincter muscles.

In the United States, there are at least 2.5 million visits to medical facilities per year for constipation, mostly to physicians in general and family practice. Eighty-five percent of patients receive at least one prescription, with laxatives being the most frequently prescribed. For both sexes, visits increase with increasing age but there is a higher frequency of visits for women. Over $800 million was spent in the United States for laxatives in 1994. Additional costs for diagnostic testing and surgical procedures for constipation are unknown. For a small but clinically important subset of individuals, constipation appears to be refractory to conventional treatment.

INTRODUCTION

The definition of constipation has often been based on a stool frequency of less than three per week. Yet only 6% of individuals who self-report constipation have infrequent bowel movements. Constipated individuals more frequently complain of defecatory straining or a sense of incomplete defecation. An international working committee has recommended that the definition of constipation should include either two or more of the following complaints that are present for at least 3 months (not necessarily consecutive), in the previous 12 months:

1. Straining with at least 25% of bowel movements.
2. Sensation of incomplete evacuation after at least 25% of bowel movements.
3. Hard or lumpy stools with at least 25% of bowel movements following laxatives.
4. Stools less frequent than three per week.
5. Sensation of anorectal obstruction on at least 25% of defecations.
6. Manual maneuvers to facilitate defecation on at least 25% of attempts.

There are two important implications of this definition: infrequent defecation alone is insufficient for the diagnosis of chronic constipation and defecatory difficulty in the absence of infrequent defecation is sufficient for and comprises the majority of patients who complain of chronic constipation.

CAUSES

Constipation is a heterogeneous disorder that often is hypothesized to be associated with disordered movement through the large intestine, the anorectum, or both. Constipation has been associated with a large number of diseases or as a side effect of many drugs (Tables I and II). Diseases may produce constipation by having a direct effect on gastrointestinal function or may result in physical or mental impairments that produce or exacerbate constipation. An example of the latter is physical immobility, which can lead to fecal retention. The most devastating disorders are neurologic diseases, which may have direct effects on the large intestine, produce generalized weakness or voluntary muscle dysfunction, and lead to inanition or physical and emotional impairments.

TABLE I Some Diseases Associated with Chronic Constipation

Neurogenic disorders	Nonneurogenic disorders
Autonomic neuropathy	Hypothyroidism
Diabetes mellitus	Hypercalcemia
Hirschsprung's disease	Systemic sclerosis
Intestinal pseudo-obstruction	
Multiple sclerosis	
Parkinson's disease	
Spinal cord injury

TABLE II Some Drugs Associated with Constipation

Anticholinergics	Diuretics
Anticonvulsants	5-HT3 antagonists
Antihypertensives	Granisetron
Anti-Parkinson drugs	Ondansetron
Calcium channel blockers	Opiates
Cation-containing agents	Tricyclic antidepressants
Aluminum (antacids, sucralfate)	
Bismuth	
Iron supplements	

PATHOPHYSIOLOGY

Most constipated patients have no obvious cause to explain their symptoms. Contrary to a commonly held belief, there is no established relationship to decreased dietary fiber or fluid intake, although fiber supplements are often effective when treating some individuals with constipation. Several studies do suggest that colonic transit is affected by decreased calorie intake.

One approach to assessing idiopathic constipation is to classify patients according to patterns of colonic transit.

1. Normal colonic transit: Patients with infrequent defecation and normal transit constipation may misperceive bowel frequency and often exhibit increased psychosocial distress. Alternatively, they complain about difficult or unsatisfactory defecation, which is not identified using colonic transit assessment techniques. The patients experiencing difficult or unsatisfactory defecation may have disorders of anorectal function or outlet dysfunction, but identification of such abnormalities is not universal in these patients.
2. Slow colonic transit: Slow colonic transit can result from decreased propulsion (hypomotility) or may be associated with increased distal motility (hypermotility) and retropulsion of markers. The term "colonic inertia" should be reserved for cases in which transit in the proximal colon is delayed without evidence of outlet delay.

In most patients with colonic inertia, there is little or no increase of colonic motor activity after meals or following administration of bisacodyl and cholinergic agents. Such findings suggest abnormalities of the enteric nerve plexus; this is supported by the recent demonstration of decreased interstitial cells of Cajal, which serve as intestinal pacemakers in the colon of patients with colonic inertia. Other studies have shown decreased numbers of serotonin-containing cells. In some patients, colonic slowing may be secondary to anorectal dysfunction, and colonic motor activity is normal.

Another form of slow colonic transit is thought to occur in some patients with irritable bowel syndrome, in which nonpropulsive segmenting contractions are more pronounced and result in retarded movement of colon contents though the left colon.

Outlet Dysfunction

Several anorectal disorders may contribute to disordered defecation. These include megarectum, failure of internal anal sphincter relaxation associated with congenital aganglionosis (Hirschsprung's disease), some large rectoceles in which there is misdirection of stool into a pouch (associated with weakness of the rectovaginal septum), and pelvic floor dyssynergia, in which ineffective defecation is associated with failure to relax, or inappropriate contraction of, the puborectalis and external anal sphincter muscles.

A diagnosis of outlet dysfunction should be considered when there is impaired expulsion of a water-filled balloon from the rectum (patients are asked to attempt this in privacy). The diagnosis may then be confirmed by at least two of the following studies: anorectal manometry, anal sphincter electromyelogram (EMG), and defecography. If studies are not diagnostic, other causes for ineffective expulsion should be considered.

TREATMENT OF UNCOMPLICATED CONSTIPATION

The initial management of functional chronic constipation includes patient education, behavior modification, dietary changes, and laxatives or enemas. Patient education should include reassurance and an explanation as to normal bowel habits. Efforts are made to reduce excessive use of laxatives and cathartics, increase fluid and fiber intake, and utilize postprandial increases in colonic motility by instructing patients to attempt to defecate after certain meals. Dietary fiber and bulk laxatives such as psyllium or methylcellulose are the most physiologic approaches. Cereal fiber cell walls generally resist digestion and retain water within their cellular structures, whereas citrus fruit and legume fibers stimulate the growth of colonic flora, which increases fecal mass. Wheat bran is one of the most effective fiber laxatives, and there is a clear dose response to fiber with respect to fecal output. Particle size appears to be crucially important and the large particle size of cereal products appears to enhance fecal bulking effects.

TABLE III Types of Laxatives and Their Effects

Softening of formed stools (1–3 days)	Soft–semifluid stools (6–12 hours)
Bulk agent	**Saline laxatives (low dose)**
Dietary fiber	Milk of magnesia
Psyllium	Magnesium sulfate
Methylcellulose	**Diphenylmethanes**
Calcium polycarbophil	Bisacodyl (oral)
Nonabsorbed substances	**Anthraquinones**
Polyethylene glycol[a]	Senna (oral)
Lactulose[a]	Cascara sagrada
Sorbitol[a]	Aloe

[a] Available by prescription only.

Those patients who respond poorly or who do not tolerate fiber may require other laxatives. In general, bulk agents, nonabsorbed substances, and mineral oil are used daily in varying doses, whereas saline laxatives, diphenylmethanes, and anthraquinones are used no more than two to three times weekly (Table III).

OTHER TREATMENTS OF CONSTIPATION

Behavioral Approaches

Habit training has been successfully employed in children with severe constipation. A modified program may also be effective in many adults with neurogenic constipation, dementia, or physical impairment. Initially, patients should be disimpacted if necessary and the colon evacuated. This can be accomplished with enemas followed by drinking a solution containing polyethylene glycol until cleansing is complete. After bowel cleansing, osmotic laxatives are given to produce one stool at least every other day. The patient is instructed to use the bathroom after eating breakfast to take advantage of meal-stimulated increases in colonic motility. An enema or bisacodyl suppository is administered if there is no defecation after 2 days to prevent recurrence of fecal impaction.

A modified program may be used in demented or bedridden patients with fecal impactions. After disimpaction and bowel cleansing with enemas or polyethylene glycol-containing solutions, a fiber-restricted diet together with cleansing enemas once or twice per week will assist nursing management by decreasing buildup of stool and recurrence of fecal impaction.

Another behavioral approach is biofeedback. This is used to correct inappropriate contraction of the pelvic floor muscles and the external anal sphincter during defecation in patients with pelvic floor dyssynergia.

Pharmacologic Approaches

Misoprostol, a prostaglandin analogue, has been used with some success in patients with severe constipation but is not a good choice in young women because of its abortifacient properties. Oral colchicine has been reported to be effective in several small studies. Prokinetics such as metoclopramide and erythromycin have little effect on colonic motility. There is enthusiasm for serotonin (or 5-hydroxytryptamine) receptor agonists, and these are being tested.

5-Hydroxytryptamine (5-HT) is found throughout the body, but a majority of the receptors are located along the gastrointestinal tract. The 5-HT subtype 4 (5-HT4) agonists selectively stimulate colonic propulsive activity and increase stool frequency. A selective 5-HT4 agonist is currently being tested after having been shown to accelerate large bowel transit and improve symptoms associated with constipation-predominant irritable bowel syndrome (IBS).

Surgical Approaches

Surgery to treat constipation remains controversial. Subtotal colectomy with ileorectal anastomosis can dramatically ameliorate incapacitating constipation in carefully selected patients. If surgery is undertaken, at least three criteria should be met: (1) the patient has chronic, severe, and disabling symptoms from constipation that are unresponsive to medical therapy; (2) the patient has slow colonic transit of the inertia pattern; and (3) the patient does not have intestinal or anorectal dysmotility, as demonstrated by radiologic or manometric studies. Many studies have documented that greater than 90% of carefully studied patients have satisfactory long-term results. However, this operation is associated with significant morbidity and some mortality. A common cause of morbidity is small bowel obstruction, and many patients require laparotomy at some stage. Some patients appear to develop intestinal pseudo-obstruction despite normal preoperative studies. Finally, abdominal pain and bloating are a problem in many patients who have been followed for long periods of time. The selection of that subset of constipated patients who benefit greatly from this surgery remains a key issue. The presence of abdominal pain that is not relieved with bowel cleansing should lead to extreme caution in operating on such patients.

constipation In infants and children, constipation can be defined by a stool frequency of less than 3 per week, but the passage of painful, hard or lumpy stools and stool retention are symptoms of constipation even when the defecation frequency is 3 or more per week.

encopresis The voluntary or involuntary passage of a normal bowel movement in the underwear (or other unorthodox locations), after the age of 4 years, occurring on a regular basis without any organic cause.

soiling The involuntary seepage of feces that is frequently associated with fecal impaction and which reflects staining of the underwear.

Many caretakers regard constipation and encopresis as trivial symptoms, which will eventually disappear. However, constipation in childhood is not always simple to treat and often requires prolonged follow-up after a comprehensive explanation and demystification of its pathophysiology and appropriate medical treatment. Long-term follow-up studies show that more than 40% of the children have persistent complaints even after 5 years of intensive medical and behavioral treatment. Moreover, in approximately 30% of the patients, childhood constipation proceeds into adulthood constipation. Importantly, apart from shame and fear of discovery, it often leads to social withdrawal, low self-esteem, and depression. The etiology of chronic constipation remains poorly understood although our understanding has increased in all areas relevant to this condition such as epidemiology, clinical classification, psychological disturbance, changes in motility, and abnormalities in enteric neurochemistry.

DEFINITION

One of the problems in correctly defining constipation is that constipation is a symptom rather than a disease. Furthermore, constipation is often differently interpreted by patients and their caretakers and physicians. Physicians often define constipation on the basis of defecation frequency, whereas healthy subjects and patients define constipation in terms of function (straining) and consistency (hard stools). Recently, a group of experts in the field of pediatric gastroenterology categorized defecation disorders using symptom-based diagnostic criteria. These criteria have provided clinicians with a method for standardizing their manner of defining clinical disorders and have allowed researchers from various fields to study the physiology and treatment of the same disorders. Disorders of defecation in children include infant dyschezia, functional constipation, and functional retention (Table I).

TABLE I Childhood Functional Defecation Disorders: ROME II—Criteria

	Diagnostic criteria
Infant dyschezia	At least 10 min of straining and crying before successful passage of soft stools in an otherwise healthy child
Functional constipation	In infants and preschool children at least 2 weeks of: 1. Scybalous, pebble-like, hard stools for a majority of stools; or 2. Firm stools $\leq$2 times/week; and 3. No evidence of structural, endocrine, or metabolic disease
Functional fecal retention	From infancy to 16 years old, a history of at least 12 weeks of: 1. Passage of large-diameter stools at intervals $<$2 times/week 2. Retentive poisturing, avoiding defecation by contracting pelvic floor and gluteal muscles

Adapted from Rasquin-Weber, *et al.* (1999).

EPIDEMIOLOGY

Constipation represents the chief complaint in 3% of pediatric outpatient visits and 10 to 25% of pediatric gastroenterology visits in the United States. Constipation is reported in 26 to 74% of children with cerebral palsy. In the Netherlands, 1% of children ages 0–4 years, but hardly any in the range 4–15 years, visit the general practitioner for complaints of constipation. American and British parents reported constipation in 16 and 34% of toddlers, respectively. In contrast to constipation in adults, constipation in childhood seems to be more common in boys than in girls (2 : 1), although a 1 : 1 ratio is also described.

PHYSIOLOGY

Defecation is elicited by the presence of fecal material in the rectum due to peristaltic propagation of colonic motility. Consequently, sensory stimuli in the anal canal provoke a sudden drop in the tone of the internal anal sphincter. By voluntary control, defecation starts with relaxation of the puborectalis and the levator. The distension of the rectum evokes a wave of contractions of the rectum and defecation can be completed by a voluntary increase in intra-abdominal pressure. The act of defecation depends on maturational control, a process that can be trained when the child slowly discovers the ability to control the pelvic muscles. First, the child feels the satisfaction and gains approval from parents by using the potty chair. Later, toileting changes to something that is done for self-approval and comfort. Before the age of 4 years, most children acquire autonomy, and defecation becomes a private, hardly thought about activity.

Normally, a decline in stool frequency from more than four stools per day during the first week of life to one to two per day at 4 years of age is observed, with a corresponding increase in stool size. Approximately 97% of 1- to 4-year-old children pass stool three times daily to once every other day.

CLINICAL PRESENTATION

The most important complaint of constipated children is a combination of a low defecation frequency and the involuntary loss of feces (Table II). Soiling often happens several times a day, and in the case of severe constipation and fecal retention, it occurs even at night. Often, once a week to once a month, a very large amount of stool is produced, which may clog the toilet. Preceding this often painful and difficult evacuation of feces, soiling frequency increases and the children complain of

TABLE II Common Clinical Presentation of Constipation

Feature	Percentage (%)
Soiling/encopresis	75–90
Defecation frequency $<$3/week	75
Large stools	75
Straining during defecation	35
Pain during defecation	50–80
Retentive posturing	35–45
Abdominal pain	10–70
Abdominal distension	20–40
Anorexia	10–25
Vomiting	10
Poor appetite	25
Enuresis/urinary tract infection	30
"Psychological problems"	20
Physical examination	
Abdominal mass	30–50
Anal prolapse	3
Fissures/hemorrhoids	5–25
Fecal impaction	40–100

abdominal pain and poor appetite. These symptoms disappear immediately after the production of this large amount of stool. In approximately 30% of constipated children, there are complaints of urinary tract infections and enuresis. Most constipated children do have abdominal and/or rectal fecal impaction upon physical examination.

PATHOPHYSIOLOGY

In 90 to 95% of constipated children, no obvious cause can be identified. In some babies, an acute episode of constipation may occur associated with a change in diet (i.e., changing from human milk to cow's milk). This results in the passage of dry hard stools, sometimes with traces of fresh blood, often the consequence of anal fissures. The pain caused by the anal fissures leads to understandable motivation of the child to avoid defecation and induces the persistence of this cycle of problems. In "infant dyschezia," it is speculated that neonates fail to coordinate increased intra-abdominal pressure with relaxation of the pelvic floor. Parents need to be reassured that this condition is part of the child's learning process for which no intervention is indicated.

"Retentive posturing" is a hallmark of the development and/or persistence of constipation in children. When the child experiences an urge to defecate, he or she assumes an erect posture and holds the legs stiffly together to forcefully contract the pelvic and gluteal muscles. Consequently, the rectum accommodates to its content and the urge to defecate disappears. The retained stools become progressively more difficult to evacuate, leading to a vicious cycle in which the rectum is increasingly distended by abnormally firm and large fecal contents. Finally, chronic rectal distention may cause overflow soiling, loss of rectal sensitivity, and eventually loss of the urge to defecate. This aberrant behavior might lead to the unconscious contraction of the external sphincter during defecation, better known as anal sphincter dyssynergy. More than 50% of children with fecal retention show this abnormal defecation pattern. For a long time, this paradoxical contraction of the anal sphincter complex was thought to be the major pathophysiological mechanism in childhood constipation. However, normalization of this pattern with biofeedback training did not correlate with successful treatment.

In a minority of patients, a deficiency in dietary fiber and/or insufficient fluid intake may also cause constipation.

There are rare organic causes of constipation such as anatomical, neurological, endocrine, and metabolic disorders (Table III). Hirschsprung's disease is characterized by the absence of ganglion cells from the distal rectum to a variable length up to the duodenum and must be considered in any child of any age with severe constipation.

DIAGNOSTIC TOOLS

A careful medical history together with a thorough physical examination is the cornerstone of the diagnostic work-up of children with constipation. Adjunctive procedures are available, such as an abdominal X ray, barium enema, anorectal and colonic manometry, rectal biopsies, and magnetic resonance imaging of the spine. However, the value of these tests is limited and often not necessary to make a correct diagnosis. They should be reserved for appropriate clinical indications.

The medical history of children with constipation should include questions about the age of onset of bowel problems, stool frequency, consistency and size of stools, painful defecation, and retentive posturing. Furthermore, information about the encopresis frequency, the amount of feces lost in the underwear, the time of occurrence (day and/or night), and the situation in which encopresis occurs (while sitting at the computer, during play outside) is of major importance. Other questions should focus on abdominal pain, loss of appetite, urinary tract problems, neuromuscular development, and psychological or behavioral problems. Finally, medical treatment and previous treatment strategies in relationship to the defecation problems should be discussed. In addition, it is essential to ask for possible contributing events, such as a death in the family, the birth of a sibling, school problems, and sexual abuse.

After the history is obtained, a complete physical (and neurological) examination should be performed. Abdominal examination gives information concerning the accumulation of gas or feces. Perianal inspection provides information about the position of the anus, perianal feces, erythema, fissures, hemorrhoids, and scars (sexual abuse). Anorectal digital examination is essential to define sphincter pressure, the amount and consistency of stool in the rectum, and the voluntary contraction and relaxation of the anal sphincter. Neurological exam may suggest problems that were previously unappreciated (such as tethered cord).

TREATMENT

Despite the high prevalence of childhood constipation, large randomized controlled therapeutic trials are lacking. The treatment of constipation is therefore mainly based on experience and a small number of clinical trials. The treatment of constipation in childhood is

TABLE III Conditions Associated with Childhood Constipation

Anal stenosis
Anorectal malformation (imperforate anus, anteriorly located anus)
Aganglionosis and/or abnormal myenteric plexus
1. Hirschsprung's disease
2. Acquired Chagas' disease
3. Chronic intestinal pseudo-obstruction
Spina bifida
Meningomyelocele
Spinal cord tumor
Hypothyroidism
Hypercalcemia
Diabetes mellitus? diabetes insipidus
Infantile renal acidosis
Anesthetics
Antidepressant agents
Hemantinics (iron)
Opiates
Vincristine

based on four important phases: (1) education, (2) disimpaction, (3) prevention of reaccummulation of feces, and (4) follow-up.

It is important to treat constipation early in childhood. Large studies in the United States and Great Britain showed that constipated children <2 years of age responded better to treatment than children >2 years of age. Early treatment is important to prevent development of severe constipation, fecal soiling, or both.

The first essential in treatment is to gain the family's confidence and explain the mechanism of the symptoms. It is crucial for both the child and the parent that the physician alleviate guilt, make the child and parents comfortable talking about the loss of feces, explain that soiling is a consequence of the full rectum, and decrease feelings of shame. A positive nonaccusatory approach is almost invariably accepted with relief by the child and parents. Furthermore, it should be explained that the treatment is often of long duration and marked by periods of improvement alternating with periods of deterioration.

Treatment of severe fecal impaction in the rectum should begin by administering enemas for 3 consecutive days. Once disimpaction has been achieved, it is essential to begin an oral daily laxative immediately and continue this treatment for months, or longer if necessary, to prevent reaccumulation of retained stools and overcome stool withholding if present. The correct dose is that which produces daily soft stool without side effects. In the United States, milk of magnesia is often used as oral laxative, whereas in Europe, the most common laxative drug prescribed is lactulose. Recently, good results using polyethylene glycol have been obtained in children with constipation. However, the success of this compound in these children was 50 to 60%, which was not significantly better than that obtained with older laxatives.

A combination of oral laxatives and regular toilet training (sitting on the toilet for 5 to 10 min within 30 min after each meal) combined with parental praise and reward is more successful than oral laxatives alone. Moreover, long-term success is higher in children who are able to maintain regular toileting.

The role of biofeedback training in constipated children with paradoxical sphincter contraction and/or diminished rectal sensation is limited. Two large randomized trials in such children showed that biofeedback training could change the abnormal sphincter pattern but was not more effective than laxative treatment.

Psychological referral is indicated in children who fail intensive medical treatment and in those with severe emotional problems or serious family problems. In these patients, a combination of psychiatric and pediatric treatment strategies is preferred.

Frequent follow-up in these patients is of major importance since relapse of symptoms occurs in 50% of the children. After 3 months, the use of laxatives can be reduced, provided that a normal bowel habit is maintained. Approximately 50% of children with chronic constipation require treatment and close follow-up for at least 6 to 12 months.

Cow Milk Protein Allergy

GLENN T. FURUTA

Children's Hospital Boston and Harvard Medical University

Cow milk, egg, peanut, soy, wheat, and fish antigens account for 90% of food allergic reactions. This article will focus on clinical syndromes associated with allergic reactions to cow milk proteins. Cow milk is not only a very common food product but also a potent allergen that has the capacity to induce a wide variety of different clinical reactions that affect both children and adults. In addition, the severity of the reactions ranges from systemic anaphylaxis to benign milk protein allergy of infancy; this diverse spectrum of clinical syndromes suggests different pathogenetic pathways for a common antigen.

INTRODUCTION

A wide spectrum of immunoglobulin E (IgE)-mediated and non-IgE-mediated food responses exist. For instance, the classical food allergic reaction to peanuts offers the best example of an IgE-mediated hypersensitivity reaction. Upon ingestion of or contact with peanuts, patients can develop the rapid onset of anaphylactic symptoms. Further evaluation shows elevated radioimmunosorbent test (RAST) for peanut IgE and abnormal skin prick testing. In contrast, many patients with food allergic responses, characterized by delayed reactions and intestinal mucosal pathology, often do not have abnormal RAST or positive skin testing for specific antigens. For instance, patients with cow milk protein colitis of infancy develop rectal bleeding and often no elevation of RAST for milk; further evaluation reveals eosinophilia of the rectosigmoid mucosa. A new era is dawning in the field of food allergic reactions as clinicians and scientists begin to define the clinical and pathophysiological features of the ever-broadening spectrum of food allergic reactions.

DEFINITIONS

Food Intolerance and Food Allergic/ Hypersensitivity Responses

Adverse food reactions refer to undesirable physical responses to an ingested food product. These reactions can be divided into two subcategories, food intolerances and food hypersensitivity/allergic reactions. Food intolerances are reflective of digestive deficiencies (i.e., lactose intolerance), toxins (i.e., bacterial toxins derived from infected foods such as from *Shigella* or *Campylobacter*), or biochemical properties of the food (i.e., monosodium glutamate, caffeine). Three features characterize food allergic/hypersensitivity reactions. First, they are reproducible reactions to a specific food product. Second, and often the more difficult part of the immunological response should be characterized in the diagnosis, clinic setting or with laboratory analysis. For instance, currently the availability of accurate tests is limited to RAST, skin prick testing, and double-blind placebo control food challenge. In

For instance, the classical food allergic reaction to peanuts offers the best example of an IgE-mediated hypersensitivity reaction. Upon ingestion of or contact with peanuts, patients can develop the rapid onset of anaphylactic symptoms. Further evaluation shows elevated radioimmunosorbent test (RAST) for peanut IgE and abnormal skin prick testing. In contrast, many patients with food allergic responses, characterized by delayed reactions and intestinal mucosal pathology, often do not have abnormal RAST or positive skin testing for specific antigens. For instance, patients with cow milk protein colitis of infancy develop rectal bleeding and often no elevation of RAST for milk; further evaluation reveals eosinophilia of the rectosigmoid mucosa. A new era is dawning in the field of food allergic reactions as clinicians and scientists begin to define the clinical and pathophysiological features of the ever-broadening spectrum of food allergic reactions.

DEFINITIONS

Food Intolerance and Food Allergic/ Hypersensitivity Responses

Adverse food reactions refer to undesirable physical responses to an ingested food product. These reactions can be divided into two subcategories, food intolerances and food hypersensitivity/allergic reactions. Food intolerances are reflective of digestive deficiencies (i.e., lactose intolerance), toxins (i.e., bacterial toxins derived from infected foods such as from *Shigella* or *Campylobacter*), or biochemical properties of the food (i.e., monosodium glutamate, caffeine). Three features characterize food allergic/hypersensitivity reactions. First, they are reproducible reactions to a specific food product. Second, and often the more difficult part of the immunological response should be characterized in the diagnosis, clinic setting or with laboratory analysis. For instance, currently the availability of accurate tests is limited to RAST, skin prick testing, and double-blind placebo control food challenge. In

 Copyright 2004, Elsevier (USA). All rights reserved.

certain circumstances, intestinal endoscopy may offer clues to the presence of an allergic reaction but offer no benefit in identifying the etiology. Last, symptoms and intestinal pathology normalize with removal of the food antigen.

SYNDROMES ASSOCIATED WITH COW MILK PROTEINS

Esophagitis

A variety of upper intestinal symptoms, including vomiting, dysphagia, food impaction, heartburn, chest pain, irritability, and failure to thrive, can be seen in milk protein allergic responses. Two different allergic diseases leading to esophagitis have been recently defined. First, eosinophilic esophagitis (EE) is characterized by upper gastrointestinal symptoms (as noted above) that do not respond to acid-blocking medications, specific histological features with large numbers of eosinophils in the squamous epithelium, and normal pH probe monitoring of the distal esophagus. EE occurs in children over 1 year of age and throughout adulthood. Studies to date indicate that as many as three-quarters of patients have a personal or family history of allergic diseases. Physical examination usually reveals evidence of atopic diseases, including eczema, asthma, or allergic rhinitis/conjunctivitis. As many as 60% of reported patients with EE have abnormal RAST or skin prick testing for cow milk or soy proteins, suggesting evidence of an IgE-mediated reaction, but removal of these proteins does not always bring about remission. Diagnostic endoscopy reveals esophageal eosinophilic inflammation affecting both the proximal and distal esophagus, but not the stomach or duodenum. Some studies have demonstrated therapeutic success with the elimination of cow milk protein from the diet. Others have induced remission with an elemental formula or systemic or topical corticosteroids. The pathogenesis for this EE is not certain but murine studies demonstrate the importance of interleukin-5 (IL-5), an eosinotropic cytokine. The incidence of long-term complications from EE is unknown but esophageal strictures have been identified in both adults and children.

Another group of patients with upper gastrointestinal symptoms related to allergies are infants who have gastroesophageal reflux disease and cow milk protein allergy. These babies present with symptoms of vomiting and irritability. Mucosal biopsy of the esophagus demonstrates mild eosinophilic inflammation of the esophagus and gastric or duodenal abnormalities. pH probe monitoring of the distal esophagus is often abnormal. RAST and skin testing demonstrate sensitization to cow milk protein. Removal of the protein from the diet leads to clinical improvement. Children outgrow this condition and do not have further complications.

Allergic Gastritis

Milk proteins can induce symptoms associated with gastritis including abdominal pain, vomiting, nausea, early satiety, failure to thrive, gastrointestinal bleeding, and obstruction. Patients with milk protein allergy-induced gastritis can present at any age from the neonatal period to adolescence. As many as half of patients who develop the physical reactions to milk proteins demonstrate normal RAST and lack peripheral eosinophilia. When endoscopy is performed, mucosal biopsies show dense eosinophilic infiltration primarily affecting the gastric antrum. Removal of cow milk will relieve symptoms within a few days to weeks. It has been a longstanding belief that the majority of infants affected with cow milk protein are also affected with soy protein allergy. This finding has led to the practice of switching to a protein hydrolysate-based formula as the initial treatment. In fact, recent evidence suggests that less than 15% of infants develop soy allergy and therefore soy formulas are a reasonable, less costly initial therapeutic alternative.

Allergic Eosinophilic Gastroenteritis

Eosinophilic infiltration of the mucosa, muscular, or serosal layer of the stomach, small intestine or colon characterizes this disease. This anatomic classification system assists in explaining the wide variety of upper and lower intestinal symptoms occurring in this condition. For instance, mucosal disease can present with diarrhea, failure to thrive, bleeding and abdominal pain; muscular disease can present with symptoms of obstruction and serosal disease can manifest with eosinophilic ascites. While this classification system offers a convenient way to identify patients, clinical overlap certainly exists. Laboratory analysis often reveals anemia, peripheral eosinophilia, hypoalbuminemia, and, in a minority of patients, increased IgE antibodies to specific foods including milk proteins. Treatment with a diet restricted in the identified food allergen can lead to remission in 50% of patients. In those not responding, the use of protein hydrolysate formulas, elemental formulas, or systemic corticosteroids is indicated. Typically, patients have a prolonged course with intermittent exacerbations and remissions.

Food Protein-Induced Enterocolitis Syndrome

Food allergic responses sometimes involve the small and large intestine, leading to symptoms including severe abdominal pain, vomiting, diarrhea with bleeding, and hypotension. This constellation of symptoms presents in the first year of life and is associated with a non-IgE-mediated reaction to cow milk or soy proteins. At challenge, children develop vomiting and diarrhea within several hours. Villous atrophy and colonic inflammation characterize the histological features. Over 80% of patients respond quickly to a protein hydrolysate formula and the remainder require amino acid-based preparations. In rare circumstances, intravenous nutrition is required. The majority of patients outgrow this illness by 3 years of age; if the allergen is soy protein, a longer course can be expected.

Allergic Proctitis

The best characterized clinical syndrome associated with the ingestion of cow milk proteins is allergic proctitis of infancy. Well-appearing, thriving infants develop loose, mucousy, bloody stools upon the ingestion of cow milk or breast milk of mothers consuming milk and milk products. Interestingly, over half of affected infants are reported to be allergic to breast milk. Bloody stools begin within the first 3 months of life but can occur as early as the first week. Stool cultures are negative for pathogens and stool analysis may reveal eosinophils or evidence of degranulation with Charcot Leyden crystal proteins. Flexible sigmoidoscopic examination shows focal eosinophilic colitis and affected infants respond to a formula free of the offending protein. If the mother desires to continue breast-feeding, cow milk and milk products should be eliminated from her diet. The pathogenesis of allergic colitis is unknown. Recent evidence has identified increased numbers of T lymphocytes within the affected mucosa, increased production of IL-5, and decreased production of interferon-γ, a cytokine associated with the development of oral tolerance. Long-term prognosis is good and most infants outgrow the allergy by 1 year of age.

Constipation Associated with Cow Milk Allergy

In contrast to the bloody diarrhea associated with allergic proctitis of infancy or food protein-induced enterocolitis syndrome, several studies suggest that cow milk protein allergy may be associated with constipation through an immunologically mediated response. Children typically present during the first few years of life with symptoms of constipation or partial obstruction soon after beginning cow milk. In the initial report of this condition, over three-quarters of the subjects showed evidence of IgE sensitization to cow milk. Endoscopic evaluation of the distal rectal mucosa revealed mild eosinophilic inflammation without crypt invasion. Removal of cow milk increased the number of stools and reintroduction led to a decline in the number of stools per day.

Crohn's Disease

WILLIAM S. MOW AND MARIA T. ABREU
University of California, Los Angeles and Cedars-Sinai Medical Center

anti-*Saccharomyces cerevesiae* An antibody that recognizes *Saccharomyces cerevesiae* (baker's yeast). It is thought that this antibody represents an altered immune response to bacteria that share cross-reacting epitopes with oligomannosidic cell wall epitopes on baker's yeast. This antibody is seen in 60% of CD patients.

azathioprine (AZA) Pro-drug of 6-mercaptopurine (6-MP). AZA is metabolized to make 6-MP. AZA is commonly used in the treatment of Crohn's disease and works by interfering with DNA replication and cell proliferation.

Crohn's disease A disorder of chronic intestinal inflammation of unclear etiology and no known cure.

cyclosporin A calcineurin inhibitor that suppresses T helper cell responses to interleukin-1 (IL-1), thus blocking the immune response via its effect on calcineurin-mediated IL-2 mRNA transcription and production.

extraintestinal manifestations Areas with disease involvement outside of the intestinal tract in patients with Crohn's disease. They can affect any organ, mucosal, or epithelial surface.

fissure A tear in the anal canal associated with Crohn's disease.

fistula A connection between the gastrointestinal tract and other organs resulting from ongoing inflammation or obstructive stricturing. Fistulas can be entero-entero, entero-vesicular, entero-renal, entero-cutaneous, recto-vaginal, peri-anal, etc.

granulomas An uncommon finding in Crohn's disease (CD), but when found they are highly specific for this diagnosis. The granulomas seen in CD are of the noncaseating epitheliod form.

IBD1 The first gene locus identified in inflammatory bowel disease. It is located in the peri-centromeric region of chromosome 16 and contains the NOD2 gene.

infliximab A humanized monoclonal antibody directed toward tumor necrosis factor α that has shown great efficacy in the therapy of Crohn's disease.

6-mercaptopurine Anti-metabolic drug used commonly in treatment of Crohn's disease; it works by interfering with in DNA replication and cell proliferation.

methotrexate (MTX) A dihydrofolate reductase inhibitor. MTX and its metabolites inhibit the enzymes responsible for folate metabolism that result in anti-proliferative and cytotoxic effects on hematopoietic cells. This drug has been used with some efficacy in Crohn's disease.

NOD2 A gene within the IBD1 locus that has been associated with Crohn's disease. It codes for a protein involved in the innate immune response to bacteria products.

perinuclear anti-neutrophil cytoplasmic antibody A distinct form of anti-neutrophil cytoplasmic antibody seen in inflammatory bowel disease. It is characterized by a perinuclear staining pattern and is seen in up to 65% of ulcerative colitis patients.

probiotics Therapies involving ingestion of bacteria that are thought to have anti-inflammatory properties.

stricture or stenosis A narrowed area of the gut lumen commonly seen in Crohn's disease, usually secondary to scarring or inflammation.

tacrolimus A potent drug that works similarly to cyclosporin by blocking T-cell reactivity to interleukin-1 (IL-1) and therefore T-cell production of IL-2.

tumor necrosis factor α A cytokine that is important in the inflammation seen in Crohn's disease and rheumatoid arthritis secondary to its effect on T helper 1 immune responses.

Crohn's disease (CD) is a chronic disorder characterized by patchy transmural inflammation that may affect any portion of the gastrointestinal tract, but most commonly involves the ileum and colon. In addition to transmural inflammation, 10–28% of biopsy specimens demonstrate noncaseating epitheliod granulomas that are pathognomonic of this disorder. Patients with this disease suffer from chronic abdominal pain, malnutrition, and diarrhea. Therefore, CD may result in great morbidity and increased health care costs. Although the exact etiology is still under investigation, the current paradigm is that genetically susceptible individuals develop aberrant T-cell-mediated inflammation in response to lumenal bacteria. The incidence of CD appears to be on the rise in Westernized countries, with an incidence of between 3.1 and 14.6 per 100,000 person–years and an overall prevalence of between 0.1 and 0.5%. Because CD is a chronic disorder, it must be assessed and treated appropriately to minimize morbidity and health care costs in these patients. New and established therapies for CD have resulted in dramatic improvements in the quality of life for patients with CD.

PATHOGENESIS

There is strong evidence that Crohn's disease (CD) is a genetically based disorder in which individuals with a predisposition for this disease develop an abnormal

 Copyright 2004, Elsevier (USA). All rights reserved.

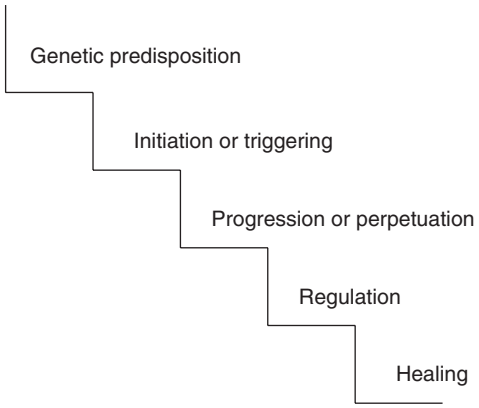

FIGURE 1 Steps in the development of Crohn's disease.

mucosal immune response to environmental triggers (Figs. 1 and 2). Although there is a strong genetic role in this disease, environmental factors also play a role in the pathogenesis of CD.

Environmental Triggers

Environmental triggers in CD may consist of bacteria, viruses, or food antigens. In humans, the exact relationship between CD and bacteria is less clear than in animal models. There are over 10^{10} bacteria per milliliter of stool residing in the human colon. Although this disease can affect any part of the gastrointestinal tract, a majority of patients have disease in the areas of the bowel with the highest bacterial load, the ileum, cecum, and colon. Studies have shown that diversion of the fecal stream can ameliorate disease. Additionally, there is literature supporting the use of therapies that can alter the bacterial flora, such as probiotics or antibiotics, for treatment of this disease. Animal models of inflammatory bowel disease (IBD) have provided much insight

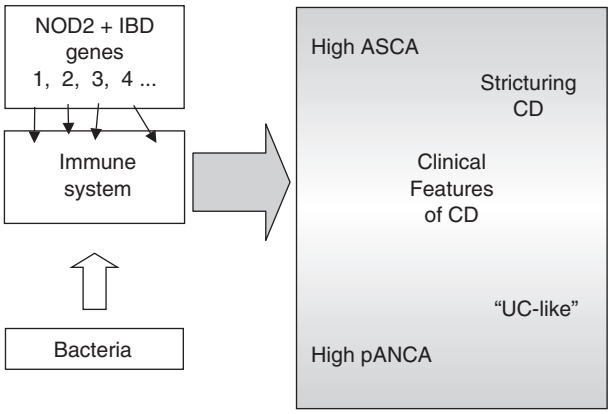

FIGURE 2 Influence of genes and bacteria in the clinical manifestations of Crohn's disease.

into the pathogenesis of CD in humans. These models have supported the knowledge that numerous genes can create the same clinical disease, that bacterial flora are key for the expression of the disease, that disease-specific effector lymphocytes can transfer disease to immune-deficient mice, that T helper 1 (T_H1) cytokines such as tumor necrosis factor-α (TNF-α), interleukin-12 (IL-12), and interferon-γ (IFN-γ) mediate disease, and that regulation of mucosal inflammation is controlled by T cells.

Many papers that both support and refute the role of a specific microbial pathogen as the etiologic cause of CD have been published. Most of this research has been directed toward *Mycobacterium paratuberculosis* and the measles virus but has been inconclusive. Evidence in animal models of IBD supports the concept that lumenal bacteria play a key role in the initiation of inflammation in the mucosa. More recently, a unique bacterial DNA sequence has been identified within lamina propria mononuclear cells in CD patients. This DNA sequence is present in the affected colonic mucosa, but not in uninvolved CD mucosa, in ulcerative colitis (UC) patients, or in normal controls. This DNA codes for a peptide termed I2. This peptide can function as a T-cell superantigen, a protein that can induce a T-cell response in a non-major histocompatibility complex (MHC)-restricted fashion. This strong immunologic response is credited to specific, direct reactivity of I2 and the MHC class II protein. Further research has identified the organism expressing the I2-containing gene as *Pseudomonas fluorescens*. *P. fluorescens* is part of the normal human intestinal flora and is usually found within the terminal ileum and colon. It is possible that this organism may play a role in initiating mucosal inflammation in some CD patients or may colonize the intestine of CD patients as a result of treatment.

Although the exact role of bacteria in the pathogenesis of Crohn's disease is unclear, considerable research exists to support the role of microorganisms in IBD. Much of this research has been performed on animal models of CD in which researchers can control the bacteria in the environment, creating the ability to associate specific bacteria with the onset and progression of disease. Current evidence supports the concept that bacteria are important for the development of the mucosal immune system and colonization with bacteria is important to the development of disease in many animal models. For example, two mouse models, the IL-$10^{-/-}$ and the Gαi$2^{-/-}$ mice, have several similarities to human CD, such as a predominant T_H1 response of $CD4^+$ T cells and transmural inflammation. In these models, disease does not develop if the mice are raised in germ-free or specific microorganism-free environments, supporting

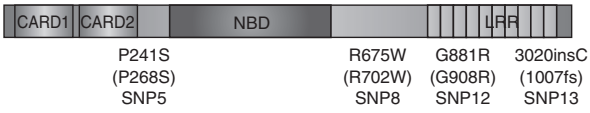
the role of bacteria in these animal models. In the C3H/HeJBir murine colitis model, animals develop a spontaneous colitis characterized by $CD4^+$ T cells that have specific reactivity to bacterial antigens. In addition, these bacteria-reactive $CD4^+$ T cells can transfer disease to recipient mice with severe combined immunodeficiency. These studies demonstrate that genetically susceptible hosts require intestinal flora and the subsequent development of bacterial-reactive T cells for intestinal inflammation.

An increasing incidence of CD in Westernized nations has led to theories that environmental changes that occur with industrialization may contain the environmental triggers for CD. A delicate balance between the gut microflora and the mucosal immune response may be disrupted with alteration in the bacterial flora secondary to refrigeration and improved sanitation. Literature supports the role of helminthic parasites in the suppression of CD. A decline in the incidence of helminthic infections is seen in industrialized societies. Helminth infections are associated with a T helper 2-type response that may counteract a robust T helper 1-type response that is associated with CD.

Genetics

CD is most prevalent in people of Northern European and Jewish descent. Genetic disorders such as Turner's syndrome and Hermansky-Pudlak syndrome are associated with CD. Those suffering from other disorders, e.g., glycogen storage disease type 1b patients, have a predisposition to "CD-like" disease characterized by chronic colonic inflammation, which at times can involve circumferential ulcerations. First-degree relatives of patients with CD have 15 times the normal risk of developing IBD. Approximately 44% of monozygotic twins share the diagnosis of CD, compared with only 3.8% of dizygotic twins, indicating that genetics plays an important role in this disease. Heredity, however, is not the only factor that dictates whether or not a genetically predisposed person develops disease.

It is likely that many genes are involved in the development of Crohn's disease. Extensive research on families with IBD has identified linkage regions on five chromosomes for these disorders. The identified regions are IBD1 on chromosome 16 (NOD2 region), IBD2 on chromosome 12, IBD3 on chromosome 6 (the human leukocyte antigen region), IBD4, which is another linkage area at chromosome 14q11−q12, and IBD5 at chromosome 5q31, which is a dense area of cytokine genes. In the pericentromeric region of IBD1, a gene called NOD2, which confers susceptibility to development of Crohn's disease, was recently described.



- Carriage of NOD2 allelic variants:
  - Crohn's disease 27– 39% (49% of all DCMs)
  - Control population 14–16% (22.5% of all DCMs)
  - UC population 12–14% (12%)
- 27 rare mutations account for 19% of disease-causing mutations

FIGURE 3 Allelic variants of NOD2 are associated with Crohn's disease. Data from Hugot, J. P. *et al.* (2001). *Nature* **411**, 599; Ogura, Y., *et al.* (2001). *Nature* **411**, 603; Hampe, J., *et al.* (2001). *Lancet* **357**, 1925; Lesage, S. *et al.* (2002). *Am. J. Hum. Genet.* **70**, 845; Cuthbert, A. P., *et al.* (2002). *Gastroenterology* **122**, 867; Ahmad, T., *et al.* (2002). *Gastroenterology* **122**, 854.

This NOD2 gene is specific for CD and is not associated with UC (Fig. 3). Its protein product is expressed by monocytes and activates nuclear factor κB (NF-κB), an important factor that is involved in the mucosal immune response to bacterial products such as lipopolysaccharides. The exact mechanism by which mutations in NOD2 confer susceptibility to CD is not yet understood. The mutations that occur in NOD2 result in diminished activation of NF-κB in response to bacterial products. CD patients with NOD2 mutations are characterized by having a fibrostenosing disease phenotype predominantly of the small bowel.

Mucosal Immunology

The mucosal immune system of the gut must achieve a delicate balance between tolerance to the lumenal flora and defense against pathogenic bacteria that may gain access through the oral route. Below the epithelial layer, naive, undifferentiated T cells await stimulation from antigen-presenting cells to activate them and provide guidance with respect to which type of T cell they will become. Interaction between co-stimulatory molecules on the surface of T cells, e.g., CD40 ligand (CD40L or CD154), and their cognate receptors on antigen-presenting cells, e.g. CD40, is required for full T-cell activation. Because T cells are the principal directors of the immune response, the characterization of the immune response is based on the pattern of cytokines or the surface markers expressed by mature T cells, e.g., T_H1, T_H2, T_H3, or T regulatory 1(Tr1). T_H1 and T_H2 cytokines are effector cytokines that may have important roles in determining the clinical manifestations associated with CD or ulcerative colitis. Antigen-presenting cells, such as dendritic cells and macrophages, also play a critical role in shaping the immune response through secretion of cytokines that

guide the differentiation of T cells. IL-12, a macrophage-derived cytokine, and IL-18, a macrophage- and epithelium-derived cytokine, shift the immune response toward a T_H1-type response and are elevated in the mucosa of patients with CD (Fig. 4). As a result, T_H1 cytokines such as IFN-γ, IL-2, and TNF-α are frequently elevated in the mucosa of CD patients. In animal models, mice lacking the IL-10 gene (IL-10 knockout mice) develop a Crohn's disease-like inflammatory bowel disease. In these mice, IFN-γ and IL-12 levels peak coincident with the onset of the inflammation at week 10.

Transforming growth factor-β (TGF-β) and IL-10 are secreted by Th3 and Tr1 cells, respectively. In several animal models, delivery of TGF-β or IL-10 can ameliorate colitis. Because these cytokines appear to have beneficial effects, attempts have been made to harness the power of Tr1 and Th3 cells. Studies have been hampered by an inability to isolate these cell populations. In addition, TGF-β is associated with increased fibrosis and is unlikely to be tolerated systemically. Likewise, studies using recombinant human IL-10 to treat CD have been associated with flu-like symptoms and little clinical benefit. In contrast, the TNF-α antagonist infliximab has been dramatically effective in the treatment of CD. Studies have demonstrated that infliximab results in apoptosis of TNF-α-expressing T cells in the mucosa. However, in clinical practice, cytokine measurements are not currently used to make decisions about patient care as they are cumbersome and are not sufficiently specific because of the broad range of normal and abnormal cytokine levels.

DIAGNOSIS

The diagnosis of CD is based on a combination of clinical, endoscopic, and radiologic findings. Serologic and pathologic findings and genetic testing are available and may be used as adjuncts to diagnosis and management. Most patients will present with abdominal pain, weight loss, fever, diarrhea, bloody stools, and poor growth (in pediatric patients). The differential diagnosis includes infectious diarrhea (viral, bacterial, mycobacterial, or parasitic), ulcerative colitis, collagenous or microscopic colitis, colorectal carcinoma, polyposis, nonsteroidal anti-inflammatory drug- or medication-related gastrointestinal inflammation, diverticulitis, human immunodeficiency virus, immunodeficiency, and celiac disease.

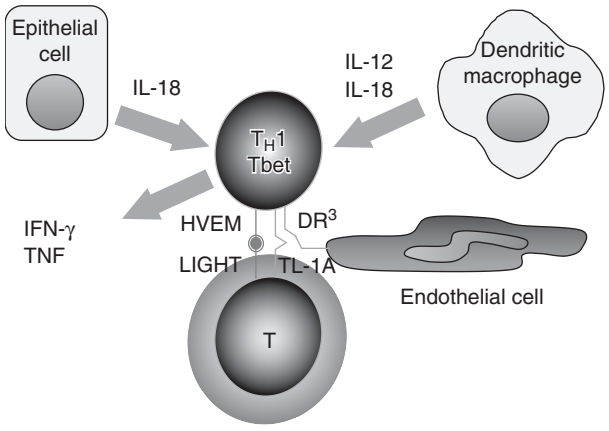


FIGURE 4 T_H1 development in Crohn's disease.

The work-up for a patient suspected to have CD includes basic laboratory tests including electrolytes, liver function tests (including albumin), complete blood count with differential and platelet count, C-reactive protein, and erythrocyte sedimentation rate. These tests point to problems associated with CD, such as anemia, malnutrition, and active inflammatory disease. An upper gastrointestinal series with small bowel follow-through (UGI-SBFT) should be performed to assess for areas of disease involvement. Small-bowel enteroclysis provides similar information and in general is not thought to be more sensitive than UGI-SBFT. In select cases, however, CD may be missed with UGI-SBFT and seen with enteroclysis and vice versa.

Colonoscopy with ileal intubation and biopsies is generally necessary to confirm the diagnosis of CD. Endoscopic lesions seen in CD include linear ulcers, stellate ulcers, aphthous ulcers, inflammation, polyps, erosions, strictures, fistulae, and bleeding/friability. In contrast to UC, the inflammation may be both microscopically and macroscopically patchy. It is important that the endoscopist define areas of disease involvement during the colonoscopy. Ideally, endoscopy should include intubation of the ileum for evaluation and biopsies, as this area is frequently affected in CD. Video capsule enteroscopy is a new method of assessing the small bowel of patients with CD and offers the ability to visually assess the small bowel in its entirety. At present, capsule studies are contraindicated in patients with CD-related strictures or stenosis.

Since CD can affect any part of the gastrointestinal tract, the disease has diverse manifestations. The most common area of disease is the ileum and ileocecal area. Up to 40% of CD patients have involvement of this area and present with abdominal pain and diarrhea, but they may also have fever, abdominal mass, and weight loss (Fig. 5). Some patients presenting with right lower quadrant pain are diagnosed with appendicitis and the diagnosis of CD is made at the time of surgery. Approximately 30% of CD patients have disease limited to the small bowel. These patients also present with

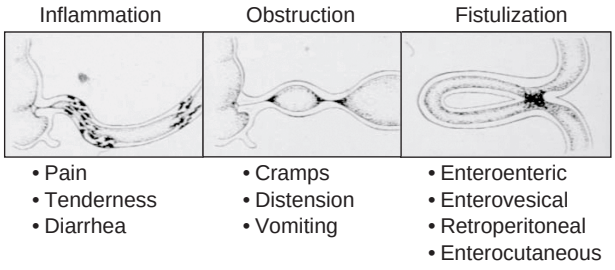

FIGURE 5 Clinical presentations of Crohn's disease.

diarrhea, abdominal pain, fever, and abdominal mass, but they may have more severe problems with malabsorption, steatorrhea, weight loss, and malnutrition, depending on the extent of small-bowel involvement. In 25–30% of CD patients, inflammation is limited to the colon. These patients can be difficult to distinguish from UC because of similarity of symptoms, including bloody diarrhea, weight loss, abdominal pain, urgency, and tenesmus. Endoscopic features, such as skip lesions, rectal sparing, and right-sided colonic disease, are supportive of the diagnosis of CD colitis.

Approximately 18% of patients will have perianal disease at the time of presentation. The spectrum of perianal disease ranges from hemorrhoids and skin tags to perianal fistula and abscesses. In addition, CD patients may have extraintestinal symptoms including, but not limited to, arthralgias, episcleritis, nodular scleritis, eythema nodosum, pyoderma gangrenosum, and psoriasis.

SEROLOGIC TESTS

In recent years, serologic tests have been used with increased frequency to help diagnose and define disease. These blood tests are moderately specific and sensitive for detecting IBD, but are generally insufficient as the sole diagnostic or screening tool. If there is a high level of suspicion for CD, diagnosis should be made by endoscopy with biopsies of the diseased areas. The main antibody tests used in IBD are anti-neutrophil cytoplasmic antibody (ANCA) and anti-*Saccharomyces cerevisiae* antibody (ASCA). These antibodies are directed toward self-antigens and microbial antigens, supporting the hypothesis that these disorders represent a loss of tolerance to self or to commensal organisms.

Distinct from ANCA in Wegener's granulomatosis, ANCA in IBD is characterized by a perinuclear staining pattern, hence the term pANCA. Of the serologic markers, pANCA is most prevalent in IBD. pANCA is positive in 15% of CD patients, 65% of UC patients, and less than 5% of non-IBD controls. This autoantibody is strongly associated with UC. In CD, patients expressing pANCA have "UC-like" features, such as left-sided colitis and pan-colitis. CD patients expressing pANCA tend to have isolated colonic disease and it has been shown that these patients have a blunted clinical response to therapy with anti-tumor necrosis factor therapies, such as infliximab.

ASCA is an antibody that recognizes *S. cerevesiae* (baker's yeast). It is thought that this antibody represents an altered immune response to bacteria that share cross-reacting epitopes with oligomannosidic cell wall epitopes on baker's yeast. This antibody is seen in 60% of CD patients, 5% of UC patients, and less than 5% of non-IBD patients. High levels of ASCA expression have been associated with younger age of onset, fibrostenosis, internal-penetrating phenotype, and an increased risk for multiple surgeries.

In addition to pANCA and ASCA, antibodies to I2 and *Escherichia coli* outer membrane porin C (OmpC) are also used to assist in diagnosis. Serum reactivity to I2 is seen in up to 54% of CD patients. The exact role of antibodies to OmpC has not been defined, but serum reactivity to this bacterial antigen is seen in up to 55% of CD patients. Further research on serologic responses to ANCA, ASCA, I2, and OmpC has indicated that CD patients can be grouped into four categories based on these serologic responses. ASCA and pANCA have been shown to play a role in the work-up of chronic abdominal pain in pediatric patients when used as a tool to determine whether invasive tests are necessary. Pancreatic autoantibodies have also been found in up to 27% of CD patients, but they are absent in healthy controls and ulcerative colitis patients. In addition to these serologies, there are many other tests being developed that show promise in helping to diagnose IBD and predict disease prognosis and course in attempts to better direct therapy and minimize morbidity.

PATHOLOGY

CD is characterized by acute and chronic transmural inflammation of any part of the gastrointestinal tract. The typical pathologic features include acute and chronic inflammation (esophagitis, ileitis, colitis), ulcerations, and crypt abscesses. Noncaseating granulomas are typical of CD, but can also be seen in gastrointestinal infections such as *Yersinia enterorolitica*, *Chlamydia trachomatis*, and fungal infections. The presence of caseating granulomas should always raise suspicion for tuberculosis. When present, noncaseating granulomas are useful in helping to diagnose CD. However, they are rarely seen on biopsy specimens and the absence of granulomas does not rule out the diagnosis of CD. The

location from which biopsy specimens are taken is essential to help differentiate CD from UC. Many colonic biopsy specimens from UC and CD patients are indistinguishable unless there are granulomas present and thus the endoscopic description of disease extent is essential for the diagnosis. Patchy microscopic inflammation is suspicious for CD.

TREATMENT

Treatments for CD can be broadly defined as those directed toward protection of the epithelium, those directed at the mucosal immune response, and those directed at modifying the lumenal contents. These therapies are generally delivered in a tiered approach depending on symptoms and the phase of disease (Fig. 6).

Epithelial Protection

Numerous studies on aminosalicylate-containing products, including sulfasalazine and mesalamine (5-ASA) products, have been performed. These drugs are known to inhibit cyclooxygenase and 5-lipoxygenase pathways and may have other functions that help in the treatment of IBD including suppression of antibody secretion and action as oxygen radical scavengers. Recent studies have found that mesalamine inhibits activation of NF-κB and thus may exert its anti-inflammatory effect through this mechanism. Sulfasalazine at a dose of 4–6 g/day has been evaluated in four double-blind studies, of which three studies demonstrated the drug to be better than placebo in achieving remission. This drug seems to have its best effect in mild to moderately active colonic CD and not in small-bowel CD. This drug has not been demonstrated to maintain remission; however, these studies were not performed using high doses and it is likely that patients who achieve remission on sulfasalazine can be maintained in remission on this drug as well.

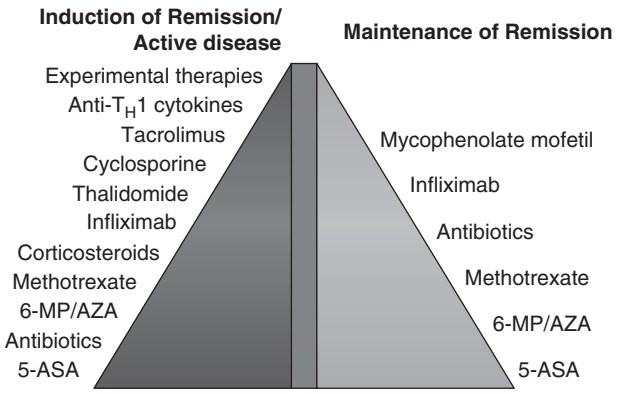

FIGURE 6 Therapeutic pyramid for Crohn's disease.

Non-sulfa-containing 5-aminosalicylate formulations are widely used for treatment of UC and CD. Many studies have been performed to evaluate the ability of these drugs to achieve remission in CD patients. The largest of these studies examined a dose range of ethyl-cellulose-coated granules of mesalamine (1, 2, and 4 g/day) and found that only the high-dose treatment group had a statistically significant reduction in Crohn's disease activity index (CDAI). The conclusions that can be made from studies on mesalamine are that it is effective in mildly to moderately active CD at doses greater than 3.2 g/day. Studies to evaluate maintenance of remission suggest a role for higher doses (>3 g/day). However, meta-analysis of these studies failed to show significant efficacy in the prevention of recurrence following medical remission. Studies on postoperative prophylaxis for CD are more promising than those on treatment of active disease. High-dose mesalamine demonstrated a trend toward reduction of recurrence at ileocolic anastomoses. It is likely there are subgroups of CD patients who are responsive to 5-ASA products, but it is not yet possible to identify these patients.

IL-11, a cytokine produced by mesenchymal cells, has a strong effect on thrombopoiesis and also acts to enhance the intestinal mucosal barrier. Recombinant human IL-11 has been evaluated in trials of CD patients. Phase IIa dose–response studies were performed but showed no overall benefit. However, there was a trend toward improvement in the 16 μg/kg per dose group. In phase IIb/III trials, 148 patients with active CD were enrolled and received subcutaneous doses of 15 μg/kg weekly or 7.5 μg/kg twice weekly. The rate of remission in the 15 μg/kg weekly group at 6 weeks of therapy was significantly higher than that observed in the placebo group, but was not very high (40% versus 16%). Patients in this trial also had dose-related increases in platelet counts. Although no thrombotic events occurred in this trial, it is possible that with continued therapy patients may experience these complications.

Growth hormone (GH) has been investigated for use in CD with the rationale that GH may reverse the catabolic effects of chronic intestinal inflammation. A randomized, placebo-controlled trial using human recombinant growth hormone in 37 CD patients with active disease was conducted. GH-treated patients had a statistically significant decrease in their CDAI compared with placebo-treated patients. However, this study did not report remission rates and therefore additional studies are needed before recommendations on GH use can be made. The dose of GH used in this study

was very high [5 mg administered subcutaneously (sc) the first day followed by 1.5 mg sc daily] and in the range used for catabolism cited with acquired immune deficiency syndrome. There were two patients who were found to have a tumor during the study. The long-term risks may therefore be unacceptable.

Immunomodulators

Inhibition of Trafficking as a Strategy to Treat CD

Glucocorticoids have multiple effects on inflammation including diminished production of cytokines, apoptosis of lymphocytes, and reduced expression of adhesion molecules that regulate leukocyte trafficking to sites of inflammation. Glucocorticoids have a definite role in inducing remission in CD patients with moderate to severe symptoms. Prednisone and prednisolone have been studied extensively, but the use of these drugs is complicated by side effects, such as adrenal suppression, Cushingoid features, hypertension, diabetes, and infection. Although these drugs have potent effects on moderate to severe CD, they have little long-term efficacy. Two large trials, the National Cooperative Crohn's Disease Study in 1979 and the European Cooperative Crohn's Disease Study in 1984, demonstrated that prednisone at doses greater than 40 mg was better than placebo in achieving remission in acute disease. Greater than 80% of CD patients apparently respond to glucocorticoids and patients with high disease activity as measured by CDAI, previous surgeries, and perianal disease were less likely to respond. Another corticosteroid, budesonide CIR (controlled ileal release), is formulated to allow for delivery to the ileal and cecal areas because it is coated with a methacylic acid copolymer (Eudragit), which dissolves at a pH of 5.5 or higher. It is a more potent steroid than prednisone and has fewer systemic side effects secondary to a high first-pass metabolism in the liver. Placebo-controlled trials have supported the role of this drug in mild to moderate ileal–colonic CD. In one of the first studies, a dose of 9 mg daily for 8 weeks was superior to other doses and to placebo in achieving remission. In other studies, budesonide at 9 mg once daily has been compared to 40 mg of prednisone daily. After 8 weeks of treatment, remission rates for daily budesonide and prednisone were similar, 53–66%. In addition to providing good results in induction of remission in mild to moderate CD, budesonide has been effective in maintaining remission. In a placebo-controlled 1-year study, it was demonstrated that time to relapse in the group given 6 mg daily of budesonide was longer (>250 days) than in the placebo group (<100 days). The prolonged use of these medications has indicated that their efficacy may wane after a year of continuous treatment. Long-term follow-up studies on CD patients treated with budesonide, prednisone, and non-steroid-based therapies for over 2 years indicated that budesonide does not spare patients the osteoporotic effects of other systemic glucocorticoids. In fact, budesonide-treated patients in some trials had a greater decrease in bone mineral density than patients treated with prednisone. Results of a prospective study comparing budesonide to prednisone for active CD demonstrate, however, that budesonide is not as harmful to bone as prednisone.

A new therapy, natalizumab, currently in phase III trials, is a humanized monoclonal antibody to $\alpha 4$ integrin. It inhibits lymphocyte binding to the mucosal addressin cell adhesion molecule expressed on high endothelial venules in the intestine by blocking the $\alpha 4$ receptor on lymphocytes. Studies on humans and animals indicate that these $\alpha 4$ integrins play a key role in the migration of lymphocytes to the gut. $\alpha 4$ integrin blockade for the therapy of IBD was first used on cotton-topped tamarinds with spontaneous colitis. These animals had complete resolution of their symptoms with treatment. In a human trial of natalizumab, patients with mildly to moderately active CD had a statistically significant decrease in CDAI and many achieved remission by week 2. Further studies are being performed using higher doses of natalizumab and examining rates of response and remission. Studies on this drug show that it holds promise in the treatment of CD, but it has not yet been approved by the Food and Drug Administration and more studies are needed.

Antimetabolites

Since the initial trials of 6-mercaptopurine (6-MP) and azathioprine (AZA), these drugs have become the mainstays of maintenance therapy for CD. Studies have been both supportive and contradictory, but 6-MP and AZA remain the primary medications used for maintenance of remission. The benchmark study on this drug was a double-blind placebo-controlled crossover study, which showed that 6-MP at a dose of up to 1.5 mg/kg/day was effective in producing a clinical response in active CD in up to 72% of patients compared to 14% for placebo. In addition, 75% of the 6-MP-treated patients were able to wean or discontinue steroids compared to $<40\%$ of placebo-treated patients. Fistulas closed in 36% of 6-MP-treated patients compared to 6% of placebo-treated patients. Finally, it was observed that the mean time to clinical response was approximately 3 months. In many cases, however, 3 months was the earliest time point at which patients were seen. This study solidified the role of 6-MP in treatment

of active CD with the goals of minimizing steroids, inducing remission, and treating active fistulas.

AZA has been also evaluated for maintenance of remission. Meta-analysis of numerous controlled studies evaluating the role of AZA in maintenance of remission supports its use. Overall, 67% of patients had continued clinical response compared with an odds ratio of 3.09 (95% confidence interval CI, 2.45 to 3.91), favoring response in patients treated with 6-MP/AZA. Although this study did not reach statistical significance, there is a wealth of long-term clinical experience supporting the use of AZA. However, studies have failed to establish the length of time required to achieve and to maintain remission. Studies have addressed whether AZA withdrawal after several years is safe in CD patients in long-term remission. Although initial studies suggested that >4 years of AZA use was associated with maintenance of remission before drug withdrawal, more recent studies have found that AZA withdrawal is associated with a greater number of relapses than continued use of the drug. Studies have failed to conclusively determine the duration of therapy that is adequate for permanent remission of disease. Most studies seem to indicate that those patients that are taken off of 6-MP or AZA tend to relapse, whereas those that are maintained on one of these medicines continue to do well. In addition, the long-term use of these drugs has been associated with an increased risk of malignancy. Treatment of fistulas has also been evaluated in controlled trials and has been summarized in a meta-analysis that showed that approximately half of patients with fistulas had a favorable response to 6-MP/AZA, whereas only approximately 20% of controls showed improvement. Finally, its role in postoperative prophylaxis has also been evaluated and results from a few studies are very promising.

More recently, research has focused on the metabolism of 6-MP by an enzyme called thiopurine methyltransferase (TPMT) (Fig. 7). It appears that this enzyme is responsible for methylation of the drug and production of 6-methylmercaptopurine (6-MMP), the blood level of which appears to correlate with the hepatotoxic effects of the drug. There has also been much research directed at 6-thioguanine (6-TG), which has been correlated with clinical response to 6-MP/AZA (Fig. 8). Methods for measurement of TPMT activity and determination of genotype are now commercially available and may help to minimize toxicity. Less than 1% of patients have an absence of TPMT activity, 10% of patients have intermediate activity, and the remainder have normal activity. Many patients with normal TPMT activity will have preferential

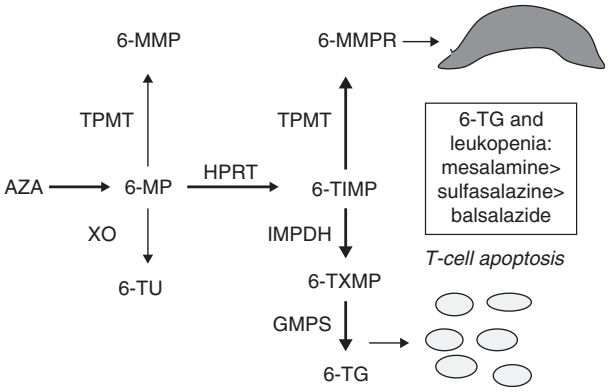

FIGURE 7 6-MP/AZA mechanism of action. From Lowry *et al*. (2001). *Gut*, with permission.

metabolism of 6-MP toward 6-methylmercaptopurine, which has a stronger association with hepatotoxicity than 6-TG.

Methotrexate (MTX) is a dihydrofolate reductase inhibitor. MTX and its metabolites inhibit the enzymes responsible for folate metabolism that result in antiproliferative and cytotoxic effects on hematopoietic cells. This drug has been studied in CD patients with chronic active disease and steroid dependence for over 3 months. Patients were randomized to receive 25 mg intramuscularly of methotrexate weekly or placebo injections. After 16 weeks of therapy, more patients treated with methotrexate were in remission and off steroids than those given the placebo. Although this drug is effective for maintenance of remission, it does carry significant risks for hepatotoxicity, teratogenicity, bone marrow toxicity, and other side effects.

Calcineurin Inhibitors

Cyclosporine (CSA) is potent drug that has revolutionized organ transplantation. It is a cyclic protein derived from the fungus *Tolypocladium inflatum*. Cyclosporine is a calcineurin inhibitor that suppresses T helper cell responses to IL-1, thus blocking the immune response via its effect on calcineurin-mediated IL-2 mRNA transcription and production. There have been several trials on the use of cyclosporine in Crohn's disease. Many of these reports have yielded promising results, with the main risks being the side effects of the drug. The first demonstration of efficacy of oral CSA (5–7 mg/kg/day) was in active steroid-refractory CD, where it was superior to placebo. Several uncontrolled series have suggested that CSA can be used in active CD as a bridge to anti-metabolite therapy. One of the major advantages of this medication is its prompt onset of action. Response rates to cyclosporine are high (>60%) and the benefits of cyclosporine are generally noticeable within 2 weeks of starting therapy. However, few patients who achieve a response to this medication maintain the benefit for prolonged periods of time. Thus, although a high proportion of inflammatory and fistulizing CD patients remained in remission while on oral cyclosporine, almost all of the patients relapsed when cyclosporine was discontinued. Moreover, this medication has several side effects and toxicities that make continuous intravenous infusion risky if done incorrectly. Significant side effects include neurotoxicity and renal toxicity; thus, patients taking this medication should be followed closely with laboratory tests and cyclosporine levels should be monitored carefully. The standard oral dose of cyclosporine is 5–10 mg/kg/day divided twice daily. All patients on cyclosporine have an increased risk of opportunistic infections and should receive antibiotic prophylaxis for *Pneumocystis carinii* pneumonia and prompt evaluation for infection-related symptoms.

Tacrolimus is a newer agent with actions similar to those of cyclosporine, but with improved oral absorption compared to its older relative. There have been a handful of reports on the use of this drug in active inflammatory and fistulizing CD. A high percentage of pediatric patients (>60%) with steroid-refractory UC or CD colitis responded to therapy and were discharged. The drug was discontinued, however, after 2–3 months and a majority of patients underwent colectomy within 1 year of receiving tacrolimus. This drug has also been used for short-term treatment of CD patients as well as CD patients with fistulizing disease with some beneficial effects. Despite these promising reports, there remains a need for a good prospective study to evaluate the use of this drug in CD. Moreover, tacrolimus-treated patients reportedly have a high frequency of side effects, such as paresthesias, insomnia, tremor, and headache. As with cyclosporine, patients treated with tacrolimus are at risk for opportunistic infections and similar side effects, such as renal, neurologic, and bone marrow toxicity, can occur. It is essential to monitor drug levels and follow patients with laboratory tests.

T-Cell Regulation

Tumor Necrosis Factor-α-Modulating Drugs

T-cell activation is a central event in the pathogenesis of Crohn's disease. Because T-cell activation results in cytokine secretion and because certain cytokines may be detrimental when overexpressed, biologists and clinicians have examined the effect of cytokine blockade in patients with CD.

TNF-α is a potent pro-inflammatory cytokine that plays an important role in the mucosal inflammation seen in CD. There are many different drugs aimed at blocking the function of this pro-inflammatory protein (Fig. 9). Infliximab is a chimeric monoclonal antibody with human constant regions and murine variable regions. It is approximately 25% murine-derived protein. CDP 571 is a humanized version of a murine antibody toward TNF-α. This drug has human IgG4 constant regions and κ light chains in which specific murine protein residues were inserted to confer reactivity to TNF-α. This drug is reported to be 90% less immunogenic than murine antibodies. Finally, etanercept is a soluble TNF-α receptor fusion protein that has been used extensively for rheumatoid arthritis.

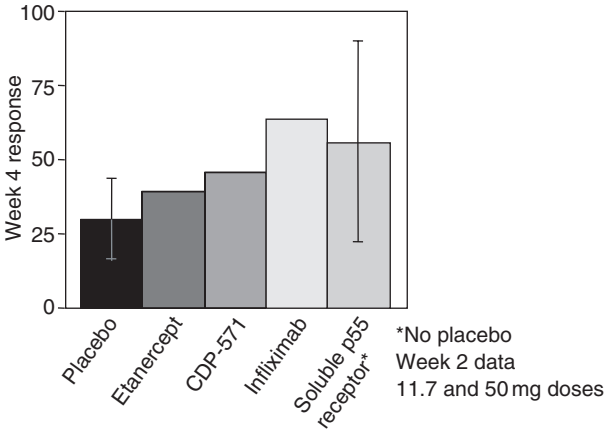

FIGURE 9 Comparison of anti-TNF-α strategies for Crohn's disease.

The initial trials on infliximab showed that it had great efficacy in patients with severe refractory CD. More than 70% of patients will respond within 2 weeks of the first infusion of this drug at a dose of 5 mg/kg given intravenously. Further studies have confirmed that infliximab has a role in the maintenance of remission in CD that is refractory to traditional therapies. A recent study demonstrated that CD patients can achieve long-term remission with repeated dosing. In addition, infliximab has shown efficacy in perianal fistulas, with fistula closures in greater than 50% of patients.

The genetically engineered human monoclonal antibody to TNF-α, CDP571, has also been studied. For reasons that have yet to be determined, clinical response to this medication is less than that for infliximab. Infusion reactions and other side effects that were associated with infliximab were also seen with CDP571. This drug may have a role in the therapy of CD, but it must be compared with the superior efficacy of infliximab. Differences may be accounted for by the fact that infliximab induces apoptosis of activated lymphocytes and binds more avidly to TNF-α. Etanercept has also been studied in a double-blinded placebo-controlled trial at a dose similar to that used for rheumatoid arthritis. Rates of remission for etanercept and placebo were similar. Thus, this drug seems to have the least anti-TNF-α activity of the medications discussed thus far.

Therapy with murine-derived anti-TNF-α agents is not without risks. Patients may develop acute IgE-mediated reactions to infusions of these agents as a result of the immunogenic murine portions of these drugs. Acute hypersensitivity reactions are characterized by symptoms of anaphylaxis, hypotension, urticaria, angioedema, and respiratory difficulty. Other patients may have a T-cell-mediated delayed-type hypersensitivity reaction characterized by gradual onset of arthralgias, myalgias, fever, and acute respiratory distress. Because TNF-α is required to contain infections by intracellular pathogens, therapy with anti-TNF-α agents has also resulted in opportunistic infections such as tuberculosis, histoplasmosis, aspergillosis, coccidiomycosis, and listeriosis. Due to increased infections by tuberculosis, all patients must receive a purified protein derivative skin test prior to their first infusion. Physicians treating patients with anti-TNF-α medications should have a low threshold to thoroughly evaluate symptoms of fever, night sweats, productive cough, etc. Other side effects include exacerbation of multiple sclerosis symptoms, lupus-like reactions, and autoimmune antibody formation. The effects of these drugs on a patient's risk for malignancy are not known. Regardless of the risks, infliximab has changed the face of treatment of CD and is the first effective biological therapy for this chronic disorder.

Thalidomide is another agent used in the therapy of CD. Thalidomide reduces TNF-α mRNA stability and has been found to reduce TNF-α and IL-12 levels in CD patients. Two open-label trials have addressed the use of this medication in CD. A high rate of response, comparable to that obtained with infliximab, was observed. Patients who completed this trial were able to reduce their steroid dosage by at least 50%. In these open-label studies, thalidomide also seems to provide therapeutic benefit for perianal fistulas. Since this medication has effects on TNF-α production, it has also been studied in patients who have achieved remission following infusions of infliximab. In this study, over 80% of patients were able to maintain remission for almost a year. Despite the promising effects of thalidomide in these trials, the teratogenic effects of this drug continue to haunt users and prescribing doctors. It is recommended that all patients (both male and female) receiving this medication be made aware of its teratogenic effects and use effective contraception. In addition, this medication has frequent side effects such as drowsiness, peripheral neuropathy, edema, and dermatitis. Because of the efficacy of thalidomide, newer agents called selective cytokine inhibitory drugs are being developed with the hopes of harnessing the TNF-α suppressive effects while reducing the side effects and teratogenicity. CC-1088 is the first of these drugs and is currently in clinical trials for use in CD.

SURGERY AND POSTOPERATIVE RECURRENCES

Despite advances in knowledge about the pathogenesis of CD and the development of new potent biologic therapies for this disorder, many CD patients will fail the above outlined medical therapies or have advanced disease at the time of presentation. In these cases, it is important for these patients to be evaluated by an experienced surgeon with expertise in IBD. Many of these patients have had surgeries previously and are at risk for intra- and postoperative complications. Surgery is not curative in CD (unlike ulcerative colitis) and therefore it is usually considered predominantly in patients with complications such as abscesses, perforation, obstruction, hemorrhage, medically refractory disease, cancer, fulminant colitis, toxic megacolon, sepsis, and certain fistulas. It is estimated that up to 80% of CD patients with ileal disease will need surgical intervention for

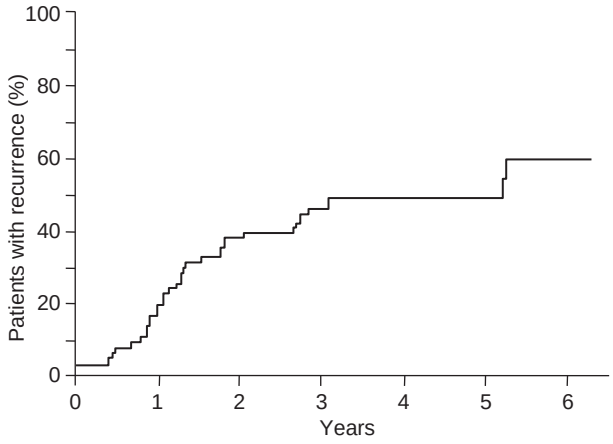

FIGURE 10 Recurrence of Crohn's disease symptoms after surgery. Reprinted from McLeod, R. S., *et al.* (1997). *Gastroenterology* **113**, 1823, with permission from Elsevier.

their disease at some time in their life. The overall goal of surgery for CD is to relieve the symptoms while sparing the bowel. Twenty-two percent of operations on patients with CD are secondary to obstruction. Obstruction in CD is secondary to strictures of the small intestines necessitating either small-bowel resection or stricturoplasties in cases in which bowel length must be preserved.

Because surgery is not curative, select patients should be placed on therapy to prevent a postoperative recurrence. As many as 50% of CD patients will have recurrence following surgical resection and need further surgical intervention (Fig. 10). There have been limited studies on 6-MP/AZA and mesalamine examining postoperative prophylaxis. It is generally believed that patients with severe recurrent surgical disease should be placed on stronger postoperative medications such as 6-MP/AZA, whereas those patients with their first surgery may be placed on mesalamine products alone. Postoperative recurrence rates in patients who were placed on mesalamine were somewhat lower than those for patients placed on placebo. Similar results have been found with the anaerobic antibiotic metronidazole.

EXTRAINTESTINAL MANIFESTATIONS

It is not uncommon for patients with Crohn's disease to have manifestations of this disorder in organs distant to the intestinal tract. These manifestations are not always associated with clinical disease activity, but often the aim of therapy revolves around increased medical therapy for the underlying chronic inflammatory bowel disease. These manifestations are thought to be a consequence of ongoing inflammation in the intestines and can affect any organ, mucosal, or serosal surface. Some of the more common extraintestinal manifestations include pyoderma gangrenosum, erythema nodosum, arthritis, primary sclerosing cholangitis, uveitis, episcleritis, anklylosing spondylitis, thrombosis, pancreatitis, thrombosis, autoimmune hepatitis, diabetes, and osteoporosis.

SUMMARY

The exact etiopathogenesis of CD is unknown but knowledge of the genes and immune effectors playing a role in this disease has dramatically increased. The next few years will witness the identification of more disease susceptibility genes and bacterial factors resulting in CD. This should permit improved treatment for CD that targets specific steps in the inflammatory cascade.

Crohn's disease Inflammatory disease of the intestine; may affect any portion of the intestinal tract from the mouth to the anus.

inflammatory bowel disease Refers to the two chronic inflammatory disorders of the gastrointestinal tract, ulcerative colitis and Crohn's disease.

ulcerative colitis Inflammatory disease of the colon and rectum.

Crohn's disease is an immune-mediated inflammatory disease of the intestine that may affect any portion of the intestinal tract from the mouth to the anus. The hallmarks of Crohn's disease that distinguish it from ulcerative colitis are transmural intestinal inflammation, fistulizing disease, and noncaseating granulomas in the bowel. The disease is usually localized and focal, most commonly affecting the ileum alone, the ileum and the cecum, or the ileum and the entire colon. Gastritis and upper intestinal tract inflammation are present in 30% of cases. Although 20% of Crohn's disease cases are diagnosed in patients under age 18 years, the disease is rare in children under age 5 years. Diagnosis is established by barium radiography, colonoscopy, and upper endoscopy with multiple biopsies. Treatment of the child and adolescent with the disease involves a combination of medical therapy, nutritional supplementation, properly timed surgery, and psychological support.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Although the exact pathophysiology of Crohn's disease (CD, regional enteritis) has not been fully defined, there is both a genetic and an environmental component. Evidence supporting a genetic component includes the increased risk of developing CD among first-degree relatives of an index case (approximately 5–10%) and the high concordance for CD among monozygotic twins (approximately 50%). Mutations in the human macrophage *NOD2* gene, which regulates the immune response to bacterial lipopolysaccharide, are present in 25% of patients with CD. An individual inheriting one mutant *NOD2* allele has a 2.6-fold increase in risk of developing CD, and an individual inheriting two mutant *NOD2* alleles has a 40-fold increase in risk. Mutations in the *NOD2* gene are most commonly identified in patients who develop ileal disease and

Treatment of the child and adolescent with the disease involves a combination of medical therapy, nutritional supplementation, properly timed surgery, and psychological support.

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Although the exact pathophysiology of Crohn's disease (CD, regional enteritis) has not been fully defined, there is both a genetic and an environmental component. Evidence supporting a genetic component includes the increased risk of developing CD among first-degree relatives of an index case (approximately 5–10%) and the high concordance for CD among monozygotic twins (approximately 50%). Mutations in the human macrophage *NOD2* gene, which regulates the immune response to bacterial lipopolysaccharide, are present in 25% of patients with CD. An individual inheriting one mutant *NOD2* allele has a 2.6-fold increase in risk of developing CD, and an individual inheriting two mutant *NOD2* alleles has a 40-fold increase in risk. Mutations in the *NOD2* gene are most commonly identified in patients who develop ileal disease and

fibrostenosing disease. Genetic linkage studies have identified several other candidate genes, including a locus on chromosome 5 (5q31–q33) associated with early-onset CD. Otherwise, genotype–phenotype correlations have not yet been demonstrated in the other candidate loci.

Although genetic loci transmit risk for the disease, environmental factors appear to influence the development of disease. Environmental triggers influencing the onset of disease include dietary factors, exogenous microbial pathogens such as atypical mycobacteria, the host's endogenous bacterial flora, medications (nonsteroidal antiinflammatory drugs and oral contraceptives), and other environmental toxins (tobacco smoke). Studies have failed to identify any consistent environmental triggers that promote the onset of CD, although use of nonsteroidal antiinflammatory drugs may be a risk factor for relapse.

Interaction of the predisposed individual with the environment leads to an activated mucosal immune system characterized by a predominance of CD4+ T helper (Th) cells of the Th1 phenotype, and by activated macrophages. Proinflammatory cytokines such as tumor necrosis factor α, interleukin-1, interleukin-6, and interleukin-12 are present in the intestinal mucosa. The activated immune cells then recruit additional leukocytes, with the end result being the production of a wide variety of inflammatory mediators of granulomatous inflammation and tissue ulceration.

The incidence of Crohn's disease is approximately 5–10 new cases/100,000 individuals per year, and is similar in children and adults. Epidemiologic studies from Sweden suggest a doubling of disease incidence in the past decade. The disease incidence is higher in northern latitudes (e.g., North America and Scandinavia), and in individuals of Jewish descent. Genetic syndromes associated with CD in children include Hermansky–Pudlak syndrome, glycogen storage disease type 1b, and Turner's syndrome. It is unclear whether the diseases seen in these syndromes are genetically similar to idiopathic CD.

DIAGNOSIS AND EVALUATION

The child or adolescent with Crohn's disease will typically present in one of two ways. Occasionally, children present acutely with bloody diarrhea or severe abdominal pain from severe ileitis, intestinal stricture, or abdominal abscess. Given that the most common area of abdominal tenderness in patients with CD is the right lower quadrant, patients with CD presenting in emergency room settings are often thought to have acute appendicitis. More commonly, children present with a chronic history of low-grade abdominal pain, fever, weight loss, recurrent perianal infections, or growth failure. Up to 50% of children with Crohn's disease will have a decrease in rate of growth (height) prior to the onset of any intestinal symptoms. The general physical examination may reveal an underweight child with poorly localized abdominal tenderness. Perianal skin tags, fissures, or fistulae will be identified in 30% of patients. Other physical findings identified may include eye inflammation, mouth ulcers, erythema nodosum, digital clubbing, and arthritis, but these are seen in fewer than 10% of patients at presentation. Laboratory studies of children with CD will commonly demonstrate a microcytic anemia, hypoalbuminemia, or an elevated erythrocyte sedimentation rate or C-reactive protein. Antibodies to neutrophilic and microbial antigens, including perinuclear antineutrophil cytoplasmic antibodies (pANCAs) and anti-*Saccharomyces cerevisiae* antibodies (ASCAs) can be utilized as a serologic "screen" for inflammatory bowel disease (IBD) in children, but use of these tests is limited by their 10% false positive rate. Although a positive result for antibody to *S. cerevisiae* is found in only 40–50% of children with Crohn's disease, this antibody is highly specific (95–98%) for CD.

When CD is suspected, other conditions causing similar symptoms should be ruled out. In some children, it may be difficult to distinguish CD from ulcerative colitis (UC), and these children are given the diagnosis of indeterminate colitis. Other illnesses that may present with rectal bleeding can be excluded by obtaining stool cultures for enteric pathogens and *Clostridium difficile*, and by considering other diagnoses, such as Henoch–Schonlein purpura, Behcet's disease, or vasculitis. Localized right lower quadrant or ileal disease can be caused by *Yersinia* infection, intestinal tuberculosis, appendicitis, or lymphoma. The differential diagnosis of an abdominal abscess includes a perforated appendix, vasculitic perforation, malignant typhilitis, or trauma. In adolescent females, gynecologic disease must be considered.

The definitive diagnosis of Crohn's disease and the localization of the disease are established with radiography and endoscopy. A barium upper gastrointestinal (GI) exam with small bowel follow through may identify mucosal nodularity, ileal and cecal narrowing, enteric fistula, or obstruction. In children, it is recommended that both colonoscopy and upper endoscopy with multiple biopsies be performed under general anesthesia as part of the initial evaluation. Crohn's disease in the colon is characterized by discontinuous colitis with normal intervening areas (skip areas), as well as superficial and deep ulcers. Endoscopy of the terminal

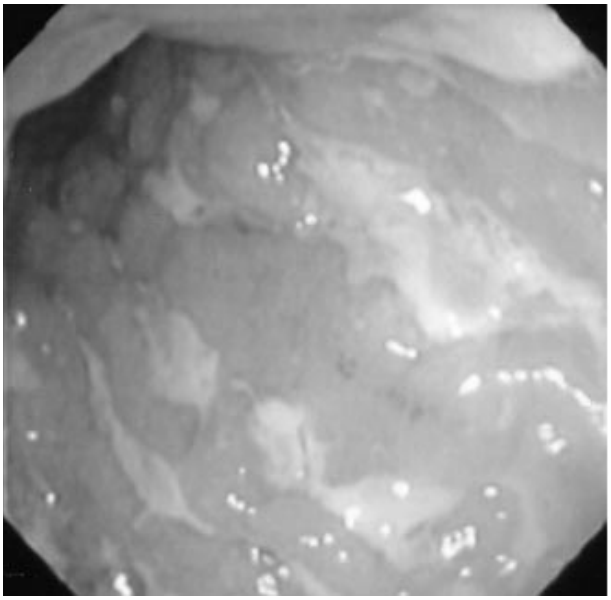

FIGURE 1 Severe ileitis with linear ulcerations and nodularity in a child with newly diagnosed Crohn's disease.

ileum may identify linear ulcerations with nodularity (cobblestoning) or ileal stenosis (Fig. 1). In patients with CD of the upper GI tract, esophagogastroduodenoscopy will identify duodenal erosions ("moth-eaten" folds) in children with duodenitis, or gastric erythema, nodularity, and aphthous lesions in those with gastritis. Histology of biopsy specimens can show nonspecific inflammation (neutrophilic colitis and gastritis), but will identify noncaseating granulomas in 25% of patients. The most reliable findings that differentiate CD from UC are the presence of small bowel involvement, perianal fistulizing disease, or granulomas on endoscopic biopsy. In 10% of cases, the patient may be given a diagnosis of "indeterminate colitis" if the clinician cannot differentiate CD from UC after complete evaluation.

Once diagnosis and disease location have been established, the child should be evaluated for other conditions associated with Crohn's disease. These may include dermatologic conditions (erythema nodosum and pyoderma gangrenosum), ocular involvement (uveitis and episcleritis), osteoporosis, and arthritis. Arthritis in CD is typically nonerosive, asymmetric, and affects large joints, including the hips, knees, and wrists. Abnormal liver function tests are most often caused by medications used to treat CD (e.g., 6-mercaptopurine) or hepatic steatosis. However, primary sclerosing cholangitis, an immune-mediated disease causing scarring and stenosis of the biliary tree, is present in 1–2% of patients with CD.

TREATMENT

Therapy for inflammatory bowel disease (ulcerative colitis and Crohn's disease) is indicated for induction of remission of disease activity, maintenance of remission, and prevention of relapse. In children and adolescents with IBD, the aim of therapy should include the eradication of abdominal symptoms, normalization of laboratory parameters such as hematocrit and sedimentation rate, and establishment of normal growth and pubertal development. Because the disease has a potential for long-term impact on physical growth and psychosocial development, psychosocial support is a necessary component of the treatment program. The unique therapeutic features of pediatric-onset inflammatory bowel disease are listed in Table I.

The three primary treatment modalities for pediatric Crohn's disease are medication, enteral nutrition, and surgery. In general, initial treatment consists of medication combined with nutritional treatment or supplementation. Nutritional therapy may be used as the primary initial treatment in active Crohn's disease in children or as an adjunct to medical therapy in the management of weight loss or growth failure. If the disease is medically refractory, surgery of a limited segment of bowel may eradicate all symptoms and facilitate catch-up growth during puberty.

Medication

Few clinical trials have focused on children with CD, and medical practice is mostly based on evidence from studies of adult CD patients. Dosages are extrapolated from adult dosages and adjusted according to body weight or body surface area. In addition, the duration of treatment is largely determined by empiric assessment of response and from adult studies.

There are five categories of current drug treatment options: aminosalicylates, corticosteroids, antibiotics, immunomodulators (azathioprine/6-mercaptopurine), and monoclonal antibodies (infliximab). The choice of treatment depends on the disease activity and behavior, and whether induction or maintenance of remission is the goal. Typically, induction of remission involves medications with greater efficacy and a more rapid onset of action, but a less favorable side-effect profile. In contrast, maintenance therapy involves long-term treatment with medications that have a slower onset, but fewer side effects. Table I lists indications, dosing information and efficacy rates for the medications that are commonly used.

TABLE I Medication Used in Pediatric Crohn's Disease

Treatment	Dose	Clinical response
Induction of remission		
Salicylates	Mesalazine, oral and/or rectal, 50–75 mg/kg/day in two to four divided doses, maximum 6 g/day	40–60% remission
	Sulfasalazine, oral and/or rectal, 50–100 mg/kg/day in three to four divided doses, maximum 4–6 g/day	40–60% remission
Steroids	Predniso(lo)ne, intravenously if needed, then oral, 1–2 mg/kg/day in one to two divided doses, maximum 40–60 mg/day, 2–4 weeks, then taper to zero slowly using oral agents	60–80% remission
	Budesonide, oral, 9 mg/day in one dose, 8 weeks, then taper to zero	50% remission
Antibiotics	Metronidazole, oral, 15–30 mg/kg/day in three to four divided doses, maximum 1500 mg/day	Not well studied
	Ciprofloxacin, oral, 20 mg/kg/day in two divided doses	Not well studied
Immunomodulator	Infliximab (anti-TNF), infusion, 5 mg/kg (specific protocol must be followed)	60–80% remission
Maintenance of remission		
Immunomodulator	Azathioprine, oral 1.5–2.5 mg/kg/day	60–80% maintenance of remission without steroids
	6-Mercaptopurine, oral, 1–2 mg/kg/day	60–80% maintenance of remission without steroids
	Methotrexate, subcutaneously, 10–15 mg/m^2/week, increase if necessary, maximum 25 mg/week	40% maintenance of remission without steroids
	Infliximab (anti-TNF), infusion, 5 mg/kg, every 8 weeks or on individual basis; fistulae, repeat weeks 2 and 6 (specific protocol must be followed)	Not well studied

Induction of Remission

In moderate to severely active disease and in hospitalized patients, medium-dose systemic corticosteroids will rapidly reduce pain and diarrhea and bring about weight gain. Prednisone or prednisolone treatment can generally be given orally, but in ill patients requiring hospitalization, methylprednisolone is preferred. Approximately 70–80% of patients will experience improvement of symptoms on prednisone therapy, usually within 2–4 weeks after therapy is started. However, corticosteroid side effects, including hypertension, hyperglycemia, infection, moon face, mood changes, osteopenia, and growth arrest, limit the duration of prednisone usage. In addition, many patients will experience a recurrence of symptoms once prednisone administration is stopped. For these reasons, corticosteroid use should ideally be limited to short-term induction of remission, and a medication useful for maintenance of remission should be started simultaneously. Budesonide is a locally acting corticosteroid that has minimal systemic bioavailability. Budesonide induces a remission in approximately 60% of children with mild to moderate Crohn's disease located in the ileum, cecum, and/or ascending colon, with fewer side effects than conventional corticosteroids. As with prednisone, maintenance budesonide treatment is not indicated because of the potential for impairment of linear growth and osteopenia.

Aminosalicylates and Antibiotics

Because these agents have a favorable safety profile with few side effects, physicians have utilized them for both induction and maintenance therapy. Aminosalicylates utilized in the treatment of ulcerative colitis include mesalamine, sulfasalazine, and balsalazide. Although all of these have been studied and have received United States Food and Drug Administration (FDA) approval for ulcerative colitis, they may also be effective in the treatment of Crohn's colitis. In addition, two formulations of mesalamine (Pentasa and Asacol) release drug into the distal small bowel and have been studied as induction therapies in Crohn's disease. In mild disease, the aminosalicylates may induce remission, but the results of meta-analyses in adults indicate that this occurs at a rate only slightly greater than that of placebo. Side effects of aminosalicylates, although rare, include proteinuria, skin rashes, headaches, and pancreatitis. Similarly, although open-label series and a few randomized

trials suggest a role for ciprofloxacin or metronidazole in treatment of small bowel or colonic Crohn's disease, the efficacy of antibiotic treatment is limited. One important role for antibiotic treatment is in the therapy of acute abdominal infections or chronic perianal fistulae. The principal side effects of metronidazole therapy include nausea, vomiting, a disulfiram-like reaction if the drug is taken with alcohol, and peripheral neuropathy with long-term use.

Enteral Nutrition

Enteral nutrition (as a 6-week course of exclusive elemental or polymeric formula, ingested orally or by nasogastric tube) can induce remission in 60–80% of children with CD. With enteral feeding, the patient gains weight, micronutrient deficiencies are corrected, and growth and pubertal development are promoted, while avoiding the systemic toxicity of corticosteroid therapy. Disadvantages with use of enteral feeds as primary induction therapy include the relapse of disease once patients start eating again, the poor palatability of these formulas (making oral ingestion difficult), and the discomfort and social stigma associated with nasogastric tube feeding. Elemental diet administration via nasogastric tube is commonly utilized as induction therapy for children with Crohn's disease in Europe; in contrast, corticosteroids are more commonly used as primary induction therapy in the United States.

Infliximab

Infliximab, a chimeric antibody to tumor necrosis factor, is very effective in inducing clinical remission within 1–2 weeks. Treatment is given in the hospital by intravenous infusion. This biologic agent has now been evaluated in several open-label noncontrolled studies of children and adolescents with severe, treatment-resistant Crohn's disease. Efficacy seems to be similar in children and adults, with remission rates of approximately 65–80% after a single infusion. In patients who respond, remission can be maintained by administration of repeat infusions, and a commonly utilized treatment protocol involves the administration of three initial infusions at 0, 2, and 6 weeks, followed by infusions every 2 months. In children with perianal fistulae refractory to antibiotics and 6-mercaptopurine, infliximab therapy may result in cessation of fistulous drainage with closure of the tract. Adverse effects include severe infusion reactions (e.g., chest pain, rashes, or anaphylaxis) and increased risk of infections (herpes zoster or tuberculosis). At the present time, infliximab treatment is primarily reserved for cases of refractory disease in patients who have persistently active disease despite therapy with aminosalicylates, corticosteroids, azathioprine, or 6-mercaptopurine.

MAINTENANCE OF REMISSION

The majority of patients with Crohn's disease located in the terminal ileum or colon, aminosalicylates may be effective in inducing and subsequently maintaining remission. Meta-analysis of a large series of controlled randomized trials suggests a slight superiority over placebo. High doses of aminosalicylates (up to 80 mg/kg/day) may be required to see this effect.

In patients who continue to have active disease or growth failure, early introduction of azathioprine (AZA) or its metabolite 6-mercaptopurine (6-MP) is advocated as maintenance treatment. These medications inhibit lymphocyte proliferation, may induce antiinflammatory cytokine production, and promote mucosal healing. Studies suggest that 6-MP and AZA are effective steroid sparing agents in approximately 65–75% of adults and children with steroid-refractory or steroid-dependent disease. In addition, a randomized placebo-controlled trial of 6-MP in children with newly diagnosed Crohn's disease demonstrated clear efficacy in relapse prevention and reduction of cumulative corticosteroid dose. However, the efficacy of AZA or 6-MP may not be seen until 3–6 months after the institution of therapy. For this reason, these drugs are not effective induction therapies, and must be combined with some other treatment in the acutely ill patient. Measurement of erythrocyte 6-thioguanine (6-TG) levels may help optimize treatment. In addition, *a priori* determination of thiopurine methyltransferase (the principal enzyme metabolizing 6-MP) activity prior to the institution of therapy may help guide dosing and minimize the risk of myelosuppression.

Adverse effects of 6-MP/AZA, although infrequent, are potentially serious. Mild gastrointestinal side effects may occur in 20–30% of pediatric patients, and hypersensitivity reactions (pancreatitis, high fevers, rash, and arthralgia) may develop in 5–10% in the first weeks of therapy. Aminotransferase elevation (more than twice normal) can be found in almost 15% of patients and is associated with high levels of 6-methylmercaptopurine, the principal inactive metabolite of 6-MP. Bone marrow suppression and hepatotoxicity are reversible with dose reduction, but require frequent blood monitoring, especially during the early phases of treatment. Opportunistic infections such as varicella or herpes zoster may occur. In adults, continuation of maintenance treatment has been shown to be useful even after 4 years. Whether AZA and 6-MP will be associated with an increase in malignancy in pediatric patients who undergo

long-term therapy is unknown, but most adult studies suggest little if any increase in risk.

If azathioprine/6-MP treatment fails, in case of steroid dependency or toxicity, repeat infliximab infusions are indicated. AZA or 6-MP treatment is generally continued as maintenance treatment. In children with refractory Crohn's disease of short (less than 2 years) duration, the clinical response to one infusion of infliximab (5 mg/kg) lasts longer than it does in patients with "late" Crohn's disease. An alternative to repeated infliximab infusions for refractory patients is conversion to therapy with methotrexate.

OTHER MEDICATIONS FOR REFRACTORY DISEASE

In Crohn's disease, methotrexate (MTX) may serve as an alternative to azathioprine and 6-MP, if these drugs are not tolerated or are ineffective. Experience and literature are limited for application to Crohn's disease in children, but controlled trials with adults demonstrate superiority of MTX over placebo both in induction and maintenance of remission. Parenteral administration is preferred, because gastrointestinal absorption is variable in IBD patients. MTX is a folate antagonist, thus concomitant administration of folic acid is advised. Side effects include oral ulcers, myelosuppression, and increased risk of infection. Two potential concerns related to chronic methotrexate use are pulmonary fibrosis and hepatoxicity with fibrosis (or even cirrhosis). However, experience with long-term MTX therapy for rheumatoid arthritis patients indicates that severe hepatotoxicity is rare.

Thalidomide is an inhibitor of tumor necrosis factor α (TNFα) production and of angiogenesis. Small open-label trials suggest efficacy in adults and children with steroid-dependent Crohn's disease, including children with refractory oral aphthous ulcers. Side effects include drowsiness, leukopenia, and peripheral neuropathy. Use of this drug is restricted because of the enormous risk of birth defects if the drug is ingested by pregnant women.

Cyclosporine may serve as a rescue treatment in children with treatment-resistant colitis, with rapid onset of action within 1–2 weeks during high-dose intravenous administration. A placebo-controlled trial has demonstrated efficacy of high-dose cyclosporine as an induction agent, but subsequent controlled trials demonstrated that low-dose cyclosporine does not maintain remission. Tacrolimus (FK-506), a drug with a mechanism of action similar to that of cyclosporine, is well absorbed after oral dosing. Topical tacrolimus has been utilized in the treatment of perianal disease, and oral tacrolimus has been utilized in the treatment of severe colitis and fistulizing perianal Crohn's disease. The use of cyclosporine or tacrolimus is limited by their side-effect profile, which includes nephrotoxicity, myalgia, headache, hyperglycemia, and risk of infection.

NUTRITIONAL MANAGEMENT AND SUPPORT

Growth failure represents a common, serious complication unique to the pediatric age group of IBD patients. Nutritional deficiencies, caused by inadequate dietary intake in relation to overall nutrient requirements, appear to be a major factor related to growth failure in children and adolescents with Crohn's disease. In addition to its positive effect on growth, nutritional therapy has been advocated as primary therapy for disease activity in these children. Continuation of enteral nutrition in a nocturnal regimen may promote maintenance of remission. There is no consensus on whether elemental or polymeric liquid formulas are preferred in induction of remission. Although the exact mechanism of the beneficial effect of nutrition on CD is unknown, proposed actions include restoration of anabolism, decreased gut motility, reduction of antigenic load, and changes in bowel flora. In addition, the liquid nature of the diet (and its ease of transport through the diseased and/or narrowed small bowel) may be responsible for the effect. In severely painful perianal disease, elemental feeding can minimize fecal output while maintaining good nutritional status.

When used as primary treatment of active disease, the elemental or polymeric formula is administered either orally or by nasogastric tube for 6 weeks. Calorie and protein intake should equal 150% or more of the required daily intake. If this is not tolerated, a semielemental (oligomeric) formula may provide relief. Except for clear liquids, no other food or drink is allowed. The child can receive nutritional treatment at home and is able to attend school. After 6 weeks, a normal diet is reintroduced while nocturnal formula administration is continued; the recommended regimen is 5 nights per week, because this may prolong the duration of remission.

NUTRITIONAL THERAPY OF NONMALNOURISHED OUTPATIENTS

Many adults and children with CD feel well on medical therapy, do not require nasogastric tube feeding, and are either normal weight or slightly underweight. Although

clinically asymptomatic, they remain at risk for nutritional complications of IBD and benefit from dietary counseling. There is no specific diet universally recommended for patients with CD and UC. Low-residue, low-fiber diets may be palliative for patients with narrowed regions of bowel (i.e., CD patients with inflammatory or fibrotic strictures). Fish oil capsules may have some efficacy in the prevention of relapse, because they may inhibit release of leukotrienes in the bowel. Patients should take a multivitamin because of reports of vitamin A, D, and E deficiencies. Patients on maintenance sulfasalazine should receive at least 1 mg of folic acid per day, because sulfasalazine interferes with luminal folate absorption. Adolescents should ingest 1200−1500 mg of total daily calcium, either through their diet or as supplements.

SURGERY

Surgery is primarily reserved for Crohn's disease patients who do not respond to medications or who develop complications (abscess, fistula, or stricture) that can only be treated surgically. In one study of 204 children with Crohn's disease from 1968 to 1994, 46% of patients with CD required surgery for complications within 3 years after diagnosis. The primary indications for surgery were medically refractory disease, intestinal abscess, or stricture. Surgery is most effective in patients with a limited region of disease (e.g., terminal ileal or ileocecal Crohn's disease) and usually involves resection of a diseased bowel segment and anastomosis. In some patients with multiple small bowel strictures, strictureplasty (widening of the strictured area) may eliminate the need for bowel resection. In patients with extensive Crohn's colitis, full colonic resection and permanent end-ileostomy may be necessary. After a bowel resection and anastomosis, Crohn's disease recurs in approximately 50% of patients within 5 years, with the most common site of disease resection being at the anastomosis. Postoperative prophylactic therapy, especially with 6-mercaptopurine, may delay the onset of disease recurrence; mesalamine and metronidazole may have some short-term efficiency as well.

PSYCHOSOCIAL SUPPORT

The chronic relapsing nature of CD and its profound effects on body appearance and image may lead to anxiety, depression, and psychosocial dysfunction in a subset of patients. Children with CD may be shorter than their classmates in high school because of growth failure and pubertal delay. The presence of surgical scars, nasogastric tubes, or ostomies may also lead to estrangement from their peers. Many children and teenagers develop "medication fatigue" from taking over 10 pills a day for several years. Family conflicts may arise over a child's poor appetite, especially if parents do not recognize that the disease is causing a child's anorexia. Although psychological counseling is often beneficial, many teenagers are either "too busy" or are reluctant to undergo counseling. Thus, the pediatrician and pediatric gastroenterologist need to address the above issues openly during outpatient visits. Discussion groups and summer camp programs provided by organizations such as the Crohn's and Colitis Foundation of America (**www.ccfa.org**) may help restore a child's self-esteem and provide support from adults and peers with the disease.

CANCER RISK

Patients with ulcerative and Crohn's colitis are at increased risk for the development of colon cancer. In general, the risk is minimal in patients who have had their disease for less than 10 years. However, rare cases of colon cancer have been reported in adolescents with inflammatory bowel disease. Therefore, children with Crohn's colitis involving the majority of the colon should probably be enrolled in colon cancer surveillance programs no later than 10 years after the onset of disease.

Cryptosporidium

DEREK A. MOSIER
Kansas State University

anthroponosis A cycle of infection characterized by transmission between humans.
monoxenous Requires only one host to complete the entire life cycle.
zoonosis A cycle of infection characterized by transmission between animals and humans.

Cryptosporidiosis is a diarrheal disease caused by the protozoan *Cryptosporidium*. The most common manifestation of infection is transient diarrhea in immunocompetent infants and adults. However, infection in immunosuppressed persons can cause persistent and life-threatening disease.

ETIOLOGY AND EPIDEMIOLOGY

Cryptosporidium parvum is the most common etiology of mammalian cryptosporidiosis. An anthroponotic genotype is responsible for most human cases (Fig. 1). However, zoonotic genotypes also cause disease in humans and various other species, particularly cattle. The *Cryptosporidium* life cycle is similar to that of other monoxenous coccidia, with the added features of recycling and amplification of asexual stages, production of autoinfective thin-walled oocysts, and the lack of a requirement for sporulation of oocysts in the environment (Fig. 1). Therefore, small numbers of oocysts (as few as 10–100) can induce severe infection and shedding of large numbers of oocysts. Sporadic disease occurs by contact with infected persons or animals, such as in daycare centers or animal facilities. Disease outbreaks are most often associated with drinking contaminated water. The incidence of infection in the general population is approximately 1–2%, with a seroprevalence rate of 25–35%. Approximately 3–5% of immunosuppressed populations, particularly persons with acquired immunodeficiency syndrome (AIDS), are infected. Cryptosporidiosis occurs with greatest prevalence in less developed countries. Incidence rates of 8–9% in infants and up to 50% in AIDS patients are common in these countries.

CLINICAL FEATURES

First described in 1976, human cryptosporidiosis is now recognized worldwide as an important cause of diarrhea. Infection is most common in 1- to 5-year-old infants, but can occur in persons of any age. Following an approximately 5- to 7-day incubation, there is watery diarrhea, often accompanied by fever, nausea, vomiting, abdominal cramps, weight loss, and anorexia. Symptoms subside spontaneously after 1–2 weeks; however, asymptomatic shedding of oocyts can continue for several more weeks.

In AIDS patients and other immunosuppressed individuals, diarrhea can be intractable and contribute to fatality due to dehydration and cachexia. The stool may contain over 10^{10} oocysts and fluid loss often exceeds 10 liters daily. Spontaneous remission in immunosuppressed persons is rare.

Sporadic disease occurs by contact with infected persons or animals, such as in daycare centers or animal facilities. Disease outbreaks are most often associated with drinking contaminated water. The incidence of infection in the general population is approximately 1–2%, with a seroprevalence rate of 25–35%. Approximately 3–5% of immunosuppressed populations, particularly persons with acquired immunodeficiency syndrome (AIDS), are infected. Cryptosporidiosis occurs with greatest prevalence in less developed countries. Incidence rates of 8–9% in infants and up to 50% in AIDS patients are common in these countries.

CLINICAL FEATURES

First described in 1976, human cryptosporidiosis is now recognized worldwide as an important cause of diarrhea. Infection is most common in 1- to 5-year-old infants, but can occur in persons of any age. Following an approximately 5- to 7-day incubation, there is watery diarrhea, often accompanied by fever, nausea, vomiting, abdominal cramps, weight loss, and anorexia. Symptoms subside spontaneously after 1–2 weeks; however, asymptomatic shedding of oocyts can continue for several more weeks.

In AIDS patients and other immunosuppressed individuals, diarrhea can be intractable and contribute to fatality due to dehydration and cachexia. The stool may contain over 10^{10} oocysts and fluid loss often exceeds 10 liters daily. Spontaneous remission in immunosuppressed persons is rare.

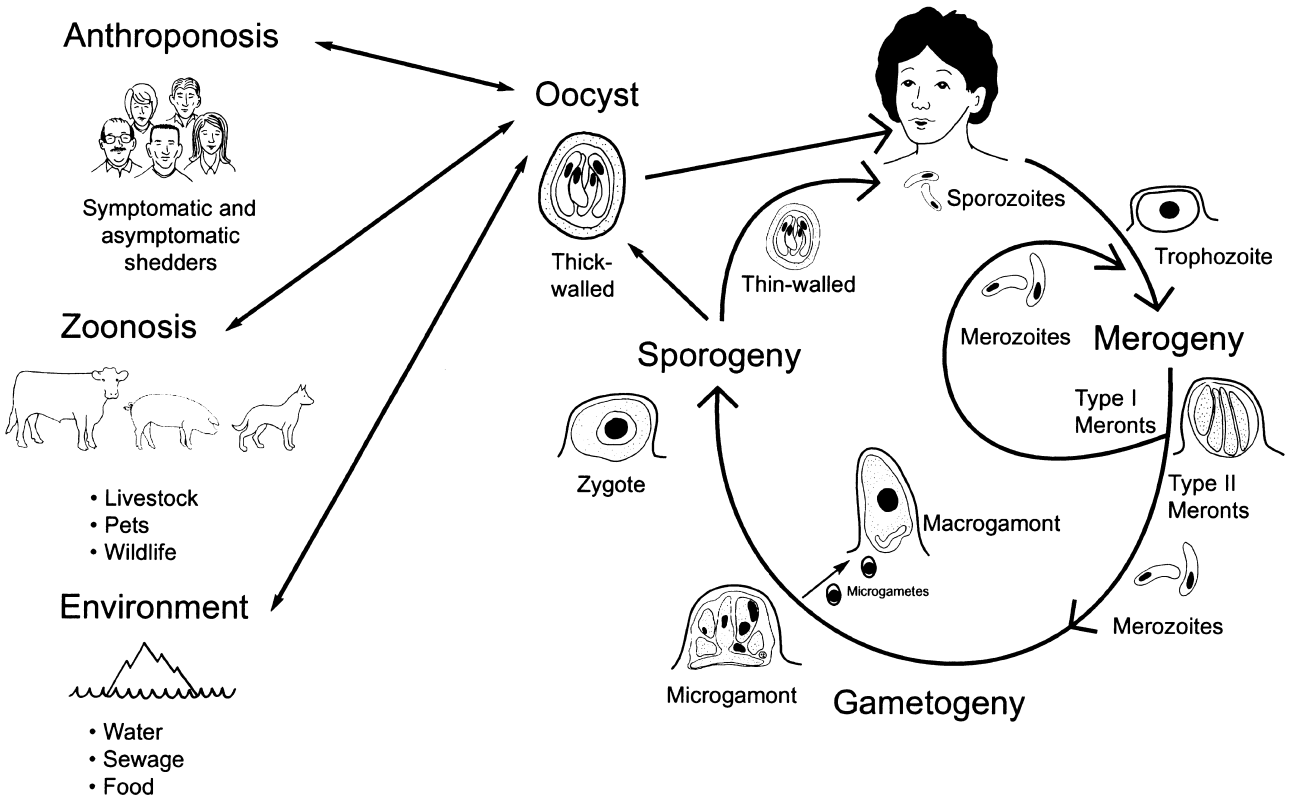

FIGURE 1 Sources of infection (left) and the life cycle of *Cryptosporidium* within an infected host (right). Important features of the life cycle include the amplification of infection by recycling of type I merozoites to produce additional type I meronts and the production of an autoinfective thin-walled oocyst in addition to the excreted thick-walled oocyst.

PATHOGENESIS AND IMMUNITY

Cryptosporidium are intracellular, extracytoplasmic epithelial cell parasites. Enteric infection causes villous atrophy with minimal inflammation in the lower jejunum and ileum. Diarrhea results from the decreased absorptive area and prostaglandin-induced inhibition of NaCl absorption in the villi accompanied by increased Cl^- secretion in the crypts. Gastrointestinal infection in immunosuppressed persons can affect the entire tract from the esophagus to the colon, including the biliary and pancreatic duct systems.

Cell-mediated responses are critical for preventing or resolving *Cryptosporidium* infection. Th-1 type $CD4^+$ T cells activate macrophages and cytotoxic $CD8^+$ T cells that help mediate protection. $CD4^+$ T cells may also interact with infected enterocytes to induce apoptosis and nitric oxide production. Interferon-γ prevents epithelial invasion and may inhibit intracellular development of *Cryptosporidium* stages. It also up-regulates the expression of various epithelial receptors that can interact with cytotoxic effector cells.

Humoral immune responses are less important, but neutralizing antibodies may inhibit autoinfection by intralumenal stages of the organism. Variable resistance to initial infection can be provided by preexisting maternal antibodies or from antibodies induced by prior exposure.

SIGNIFICANCE

Over 100 different therapeutic agents for cryptosporidiosis have been investigated *in vivo*, yet there is no consistently effective and safe, or approved, treatment. Oocysts are frequently present in lakes, rivers, and other surface waters due to contamination by human, domestic animal, or wildlife waste. Treated water supplies are also often contaminated. Organisms are notably resistant to many disinfectants, including chlorine, and its size (4–6 μ) allows it to pass through many filtration systems. The relative resistance of oocysts allows them to remain infectious in water or the environment for months. Therefore, waterborne infection is a considerable public health concern due to the potentially fatal consequences in immunosuppressed persons and the possibility of high morbidity in the general population. In less developed countries with inadequate sanitation

systems, this concern is even greater due to higher rates of exposure and the contributing effects of malnutrition and concurrent disease.

pancreatic insufficiency Decreased secretion of digestive enzymes or insulin to the extent that malabsorption or diabetes mellitus appears. Malabsorption typically manifests with steatorrhea, the presence of more than 7% of dietary fat in the stool.

Cystic fibrosis is the most common lethal genetic defect in the Caucasian population. This autosomal recessive disorder affects between 1 in 200 and 1 in 4500 newborns in different ethnic groups. A defect in the CF transmembrane conductance regulator causes the disease. The conductance regulator localizes to the apical membrane of epithelial cells in a variety of organs, including pancreas, lung, liver, and intestine, where it regulates chloride conductance and water flow and may function in the transport of other ions.

INTRODUCTION

Cystic fibrosis (CF) can be caused by over 900 different mutations in the cystic fibrosis transmembrane conductance regulator (CFTR). The most common mutation, ΔF508, which is a 3-base-pair deletion, affects about 70% of CF genes. Approximately 50% of patients with CF are homozygous for this mutation and have classical CF with pulmonary and pancreatic dysfunction. CFTR mutations fall into five major classes. Mutations designated as classes I, II, and III result in complete loss of CFTR function because of defective protein production, abnormal protein processing, and abnormal regulation of chloride conductance, respectively. In general, these mutations cause more severe disease manifestations. Mutations designated as classes IV and V produce milder symptoms and produce mutant CFTRs with decreased conductance properties or cause decreased synthesis of normally active CFTRs. Individuals with CF may be homozygous for one genetic mutation or heterozygous for two different mutations.

The degree of organ dysfunction caused by a CFTR mutation depends on the properties of the CFTR and on the physiology of the involved organ. More severe mutations of the CFTR (classes I, II, and III) produce greater organ dysfunction and damage than do milder mutations (classes IV and V). Damage is generally

more extensive in organs with a high level of CFTR expression or in organs in which the CFTR regulates other ion channels or operates in parallel with other anion exchangers. In organs with ion transporters that have overlapping functions with the CFTR, damage may depend on the ability of these transporters to compensate for the lack of functioning CFTRs.

Decreased or absent CFTR function results in diminished secretion of electrolytes and water by the ductular epithelium. Consequently, the concentration of macromolecules in the lumen of the affected duct increases significantly, causing proteins to precipitate and form plugs that further slow duct flow and produce duct obstruction. Thus, organs that have levels of secretions with high protein concentration and slow flow through ducts are most susceptible to damage from mutant CFTRs. The epididymis and vas deferens, the pancreas, and, to a lesser extent, the bile ducts represent vulnerable organs. In the lung, macromolecules move through narrow passages at an air–fluid interface and any decrease in water content of pulmonary secretions, such as occurs with a defective CFTR, causes precipitation of macromolecules in small airways. The increased tenacity of pulmonary secretions and small airway plugging inhibit clearance of pathogens from the airways. Recurrent or chronic infection then contributes to the pulmonary damage. In contrast, the sweat gland has abnormal electrolyte and fluid flux, but does not sustain any histological damage. Presumably, the low protein concentration and high flow rates of their secretions protect sweat glands from damaging precipitates.

TABLE I Clinical Manifestations of Cystic Fibrosis

Respiratory
- Sinusitis
- Nasal polyps
- Atelectasis
- Emphysema
- Bronchiectasis
- Recurrent Infections

Gastrointestinal
- Meconium ileus
- Jejunoileal atresia
- Meconium peritonitis
- Distal intestinal obstruction syndrome
- Rectal prolapse

Pancreas
- Pancreatic insufficiency
  - Malnutrition
  - Vitamin deficiencies
  - Steatorrhea
- Diabetes
- Acute pancreatitis

Skeletal
- Delayed bone age
- Osteopenia
- Hypertrophic pulmonary osteoarthopathy

Hepatobiliary
- Gallstones
- Focal biliary cirrhosis
- Neonatal cholestasis
- Cirrhosis
- Portal hypertension

Reproductive System
- Females
  - Decreased fertility
- Males
  - Sterility
  - Absent vas deferens, epididymis, and seminal vesicles

Eye
- Venous engorgement
- Retinal hemorrhage

Other
- Salt depletion
- Heat stroke
- Hypertrophy of the apocrine glands

CLINICAL PICTURE

Because many cell types express mutant CFTRs and these cells have variable degrees of dysfunction, the clinical manifestations of CF are myriad (Table I). Most patients with CF are diagnosed within the first months of life and 80% are diagnosed before age 6 years (Fig. 1). Infants typically have protracted cough, wheezing, and tachypnea. Toddlers and school-aged children exhibit refractory wheezing or recurrent pneumonia and may have milder respiratory problems such as recurrent sinusitis or nasal polyps.

Most CF patients have exocrine pancreatic insufficiency, resulting in maldigestion and malabsorption. Stool complaints are common, ranging from bulky and frequent stools to diarrhea. At times, oil may separate from the stools. In infancy, weight gain is often poor or absent because of altered digestion and absorption. The severity and progression of CF vary considerably. Some patients deteriorate rapidly and die within the first year. Most patients have milder courses and with appropriate therapy can reach adulthood (Fig. 2). A few have mild disease or monosymptomatic disease and do well over a long period of time. Progressive pulmonary disease often dominates the

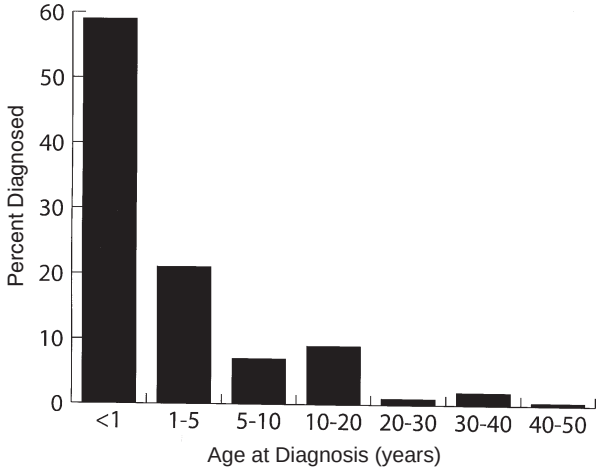

FIGURE 1 Age at diagnosis of cystic fibrosis. Data are from the National Cystic Fibrosis Registry.

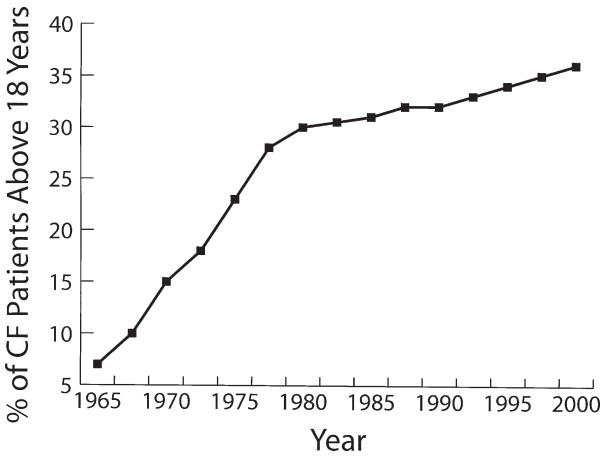

FIGURE 2 The percentage of cystic fibrosis patients older than 18 years, from 1965 to 2000. Data are from the National Cystic Fibrosis Registry.

clinical course, although a variety of gastrointestinal manifestations may predate pulmonary symptoms and may even be more problematic than the pulmonary disease. The only clinical manifestation that correlates with genotype is pancreatic function. Patients with pancreatic insufficiency generally carry two class I, II, or III mutations. In contrast, patients with pancreatic sufficiency generally carry at least one class IV or V mutation.

DIAGNOSIS

The diagnosis of CF depends primarily on measuring the concentration of electrolytes in sweat stimulated by pilocarpine iontophoresis. Patients with CF have abnormal sweat tests from birth. The sodium and chloride concentrations are elevated above 60 mEq/liter in at least 98% of patients with CF. Levels below 40 mEq/liter are normal. Levels between 40 and 60 mEq/liter are indeterminate and not diagnostic. Generally, the sweat chloride concentration exceeds the sodium concentration, particularly in infants. Several situations can produce misleading sweat test results. False negative sweat tests can occur in malnourished or edematous infants with CF. Other disorders besides CF can cause elevated sweat electrolyte concentrations (Table II). Steroids, diuretics, and the amount of sodium in the diet can affect the results. Accurate sweat collection and analysis require experience and expertise, and either negative or positive results can stem from improperly performed sweat tests. To avoid these pitfalls, an initial positive sweat test should be confirmed by testing at a CF center.

Genetic testing for CFTR mutations can aid in diagnosis, but current methods may not be adequate in many populations. The large number of disease-causing mutations in the CFTR gene and the marked variation in the distribution and frequency of mutations within geographic regions and ethnic groups make clinical testing for mutated alleles particularly difficult. In a handful of populations, 98–100% of the mutated alleles have been identified, and suspected patients can be screened for these mutations. Such certainty is impossible in the genetically heterogeneous populations residing in many geographic regions, and testing in these populations relies on commercially available panels that screen for the 70 most common mutations. Less common or unique mutant alleles will not be identified unless broader screening procedures become available. New techniques, such as denaturing ion-pair reverse-phase high-performance liquid chromatography, show promise for rapidly analyzing the complete coding sequence of the CFTR gene. In the near future, rapid and complete screening of the CFTR gene for mutations will be possible.

These new genetic tools create the potential for prenatal diagnosis and genetic counseling. In 1997, a consensus panel convened by the National Institutes of Health offered recommendations for genetic testing in families at risk for CF and for the general population. The panel concluded that genetic testing for CF should be offered to adults with a positive family history of CF, to partners of people with CF, to couples currently planning a pregnancy, and to couples seeking prenatal care, provided that adequate education and appropriate genetic testing and counseling services are available to all persons being tested. Effective counseling depends on extensive and thorough review of the implications, potential results, and possible outcomes of mutated alleles. For some CFTR mutations, a thorough discussion may not be possible because the effect of the mutation on CFTR function is unknown.

Environmental deprivation syndrome

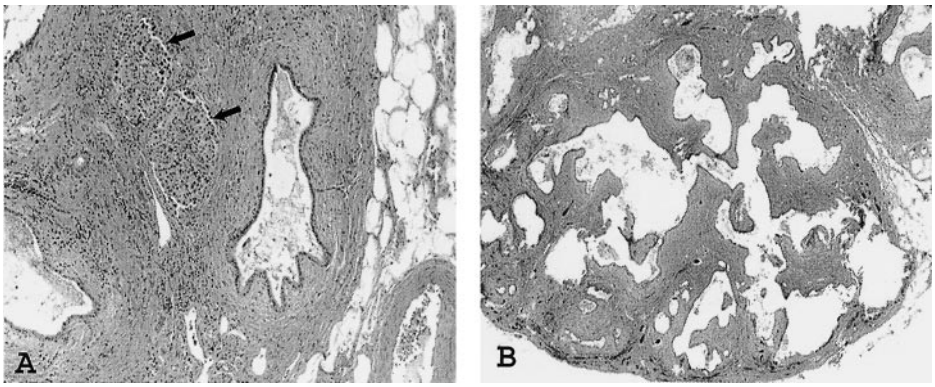

FIGURE 3 The histology of the pancreas in CF. (A) A section of pancreas with two preserved islets (black arrows) also includes a cystic region containing inspissated material. The cyst is surrounded by fibrous tissue. Fatty change is apparent on the left side of the section. (B) A lower power view of the same pancreas section illustrates the marked cystic changes typical of the CF pancreas. No normal acinar tissue is apparent.

PANCREATIC DYSFUNCTION

From 85 to 90% of CF patients have exocrine pancreatic insufficiency with malabsorption of fat and protein and decreased bicarbonate and fluid production. Pancreatic function is often deficient at or shortly after birth. In some individuals with CF, pancreatic function deteriorates over years before exocrine pancreatic insufficiency develops. A minority of patients who remain pancreatic sufficient still secrete lower than normal amounts of digestive enzymes, fluid, and bicarbonate.

Pathology of the Pancreas

Like the clinical course, the histopathology of the pancreas in CF varies considerably (Fig. 3). Patients with mild disease can have a normal pancreas. Severely affected patients have a shrunken, cystic, and fibrotic pancreas with fatty changes. In these patients, the gland may be difficult to identify at postmortem. Pancreatic damage results from obstruction of small ducts by precipitated proteins and cellular debris. Involvement of large ducts, usually stenosis, is much less common. Cystic spaces filled with eosinophilic, calcium-containing concretions develop secondary to duct blockage and acinar cell damage. Mild inflammatory changes and fibrosis develop around damaged acini. Even as fibrosis progresses, the islets of Langerhans are spared until later in life.

Radiographic imaging studies are usually not helpful in diagnosing or in predicting the degree of pancreatic insufficiency. Computer tomography (CT) and magnetic resonance imaging provide the most information about the extent of pancreatic damage. CT delineates fatty replacement and small pancreatic volume (Fig. 4). Magnetic resonance imaging reveals fat deposition as increased signal on T1-weighted images and identifies

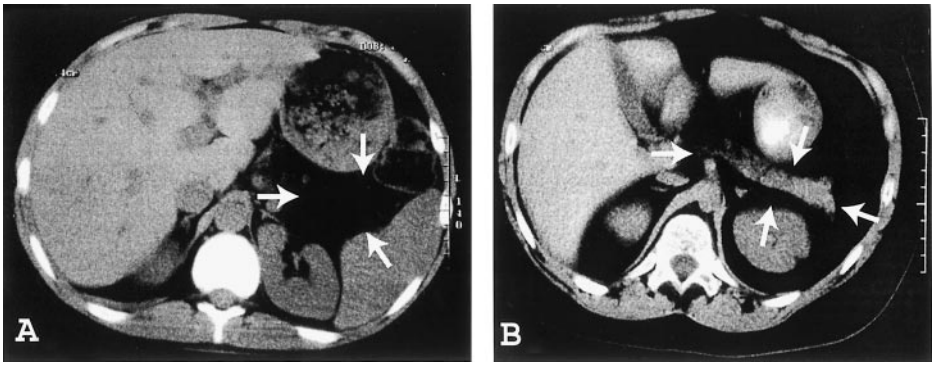

FIGURE 4 Computer tomography scan of the abdomen of a patient with CF. (A) The pancreas is replaced with fat. The arrows delineate the region of the pancreas. (B) The arrows identify an atrophic, fatty pancreas.

pancreatic fibrosis as low-signal intensity on both T1- and T2-weighted images, and may show cystic changes. Occasionally, both modalities reveal abnormalities of the main pancreatic duct.

Exocrine Dysfunction

When the secretion of lipase and trypsin falls below 2% of normal, pancreatic insufficiency results. At this level, 60% or more of ingested fat and around 50% of ingested protein are not digested or absorbed. A nonpancreatic lipase, gastric lipase, probably accounts for the residual lipolysis, and a compensatory increase in gastric lipase activity may occur. An estimated 85–90% of CF patients have pancreatic insufficiency.

Infants are most severely affected by the malabsorption that results from exocrine pancreatic insufficiency. Infants from 2 to 4 months old may present with hypoalbuminemia, edema, and severe normochromic, normocytic anemia. Fat-soluble vitamin deficiencies are most common in infancy prior to diagnosis. Vitamin A deficiency may produce pseudotumor cerebri with sixth nerve palsy and poor feeding, or xerophthalmia. Coagulopathy from vitamin K deficiency is common. Biochemical deficiencies of vitamin E and vitamin D can be detected, but clinical symptoms from either are infrequent.

Tests of Pancreatic Function

The direct measurement of enzyme activities in pancreatic juice collected from the duodenum after stimulation with cholecystokinin and secretin represents the standard for establishing pancreatic insufficiency. This testing provides quantitative results and can reliably detect patients with decreased pancreatic function who do not yet have pancreatic insufficiency. Because this test is invasive and is not widely available, other tests of pancreatic function have been proposed. Usually, protein absorption is measured by indirect tests such as the bentiromide test. In this test, *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid, a chymotrypsin substrate, is given orally and the liberated *p*-aminobenzoic acid is measured in the urine. A modification of this test using a radiolabeled substrate is not suitable for children. The pancreolauryl test is based on another oral substrate, fluorescein dilaurate, which is cleaved by esterases to release fluorescein. The fluorescein is then measured in the urine. Both methods have been tested in CF patients and have good sensitivity and specificity in patients with advanced pancreatic failure. Most other tests are measures of fat malabsorption. Qualitative Sudan stain on stools can be helpful in identifying patients with severe steatorrhea, but it performs poorly in identifying patients with moderate fat loss. The [^{14}C]triolein breath test has been advocated as a method for identifying fat malabsorption, but is not universally available. Even when available, interpretation of the results can be difficult because many factors affect the data. Altered metabolism of triolein, slow intestinal transit, and impaired secretion of CO_2 (which occurs in chronic lung disease) all affect the results. Many centers use the 72-hour fecal fat collection to determine fat malabsorption. Like all of the tests for pancreatic function, fecal fat collection has drawbacks. The fecal collection is cumbersome and is often distasteful for the families to perform. The results are affected by the level of dietary fat intake and by the kind of fat ingested, making an accurate dietary history mandatory to determine the percentage of fat absorbed accurately. Mineral oils and dietary medium-chain triglycerides may cause errors in fat measurement. Finally, fecal fat collections do not distinguish between pancreatic and nonpancreatic causes of fat malabsorption. Most often, infants and others who consume an *ad libitum* diet and are undernourished, and who also have a diagnostic sweat test result or mutant CFTR alleles by genetic testing, are presumed to have pancreatic insufficiency.

Treatment of Pancreatic Insufficiency

Standard treatment for pancreatic insufficiency begins with pancreatic enzyme replacement with extracts from porcine pancreas. Over the years, these preparations have evolved from powders to enteric-coated, encapsulated beads that dissolve at pH 5 to 6, allowing the release of the supplemental enzymes in the proximal small bowel where they are most effective. Importantly, the introduction of enteric-coated capsules has decreased the number of capsules taken per meal, improved the stool pattern, and decreased the abdominal complaints. Still, some treated patients continue to have steatorrhea and azotorrhea even with the enteric-coated preparations.

Several hypotheses attempt to explain the decreased effectiveness of enzyme replacement in some patients. Common to multiple theories is the effect of pH. An acidic pH dramatically slows the release of enzymes from the enteric-coated beads. Even the small difference between pH 5.5 and 5.2 can delay enzyme release up to threefold. A pH below 6.0 may decrease the activity of pancreatic lipase, the predominant lipase in pancreatic extracts, and a pH below 5.0 will irreversibly inactivate pancreatic lipase. Low pH will cause many bile salts to precipitate. The decreased bile acid concentration limits

the formation of mixed micelles of bile acids and fatty acids. Because mixed micelles are required for efficient absorption of fatty acids, steatorrhea results. Several studies document lower than normal pH in the duodenum of CF patients, presumably due to decreased secretion of pancreatic bicarbonate to neutralize gastric acid. Based on this information, agents that suppress gastric acid production, such as omeprazole or lansoprazole, are often prescribed in conjunction with pancreatic enzymes. Although there are no studies of the long-term effectiveness of this approach to increase duodenal pH, some patients benefit from acid suppression over the short term.

CF patients should consume age-appropriate diets. Dietary fat should not be restricted. To prevent deficiencies, all patients should receive multivitamins in addition to daily oral fat-soluble vitamin supplementation. Increased doses of multivitamins may provide adequate amounts of vitamins A and D, but vitamins E and K may require individual supplementation. The efficacy of treatment is judged by the presence of normal growth, by the absence of abdominal complaints, and by biochemical measurements of fat-soluble vitamins in serum. If the patient has slow weight gain or growth, the intake of energy-producing foods and protein should be determined because inadequate nutrient intake is the main cause of poor growth even in patients with undertreated steatorrhea. Low levels of food intake can result from complications of the disease, such as vomiting, anorexia, abdominal pain, and psychosomatic problems such as depression, fatigue, and altered body image.

Nutritional therapy should first aim to increase voluntary oral intake and to maximize fat absorption. The patient should be advised to eat meals and snacks with high caloric content. Some patients may accept fortified milkshakes or powders. Fat absorption may be improved by changing to a different enzyme preparation, by altering the timing of enzyme intake in relation to the meal, or by starting a histamine-2 (H2) receptor antagonist or a proton pump inhibitor. In patients who do still not grow appropriately, nocturnal nasogastric tube or gastrostomy feedings of a defined formula may improve growth. A minority of patients will require parenteral nutrition for acute support until adequate enteral nutrition can be tolerated.

Endocrine Dysfunction

As CF individuals survive into adulthood, progressive damage to the islets of Langerhans reduces insulin secretion, producing glucose intolerance and diabetes mellitus. Although diabetes can develop in young children, the mean age of onset is around age 20. The prevalence of diabetes mellitus increases at a rate of about 5% per year, and by 30 years of age 50% of patients are diabetic. The reasons that some patients develop diabetes are not fully understood. Generally, diabetes develops in patients with class I, II, or III mutations. These patients have impaired insulin secretion and increased insulin clearance rates, leading to insulinopenia. Because the development of diabetes in CF patients is often insidious, the diagnosis should be considered whenever there is a change in growth or pulmonary function, particularly in older patients. Adequate therapy can improve both growth and pulmonary function. Renal, ophthalmologic, and autonomic complications of diabetes can arise in CF patients.

Acute Pancreatitis

Approximately 1% of CF patients suffer recurrent episodes of acute pancreatitis and pancreatitis may be the presenting manifestation of CF. Acute pancreatitis occurs in patients who have pancreatic sufficiency. In such patients, the diagnosis of CF may be delayed because the patients lack other symptoms of CF. CF pancreatitis presents with typical symptoms of abdominal pain and vomiting. Elevations of serum lipase and amylase are present. In one series, patients averaged 3.5 attacks, with a range of one to seven. As with other types of acute pancreatitis, treatment is supportive. The usual course of the acute illness is 3 to 5 days. Complications occur infrequently.

HEPATOBILIARY DISEASE

Damage to the liver and biliary tree in patients with CF was originally described in 1938. Since then, various reports have identified an association of CF with biliary cirrhosis, portal hypertension, cholelithiasis, and bile duct abnormalities. Because the more severe fibrotic hepatic disorders develop insidiously over more than a decade, the impact of CF-related liver disease has become apparent only as the life expectancy of CF patients has improved, and the symptoms and complications of chronic liver disease now affect more CF patients. No marker reliably identifies patients with early liver disease and no specific therapy ameliorates the progression to severe disease.

Pathogenesis of Hepatobiliary Disease

In the human liver, the CFTR localizes to the apical domain of the epithelial cells of the intrahepatic and extrahepatic bile ducts and the gallbladder. Hepatocytes and other liver cells do not express detectable levels of

CFTRs. Presumably, the abnormal biliary secretions present in patients with CF result from the ability of CFTRs to secrete chloride through a low-conductance channel. Most likely, this chloride conductance creates a negative potential and osmotic gradient in the duct lumen. Together, these forces drive sodium and water into the duct lumen. Additionally, CFTRs may regulate anion exchanger activity in cholangiocytes and affect HCO_3^- flux across the cell and increase the secretion of chondroitin sulfate in CF biliary epithelium, which would further increase the viscosity of bile.

In this model, defective CFTR function alters the composition, viscosity, flow, and alkalinity of bile. The increased viscosity, decreased flow, and increased concentrations of macromolecules encourage precipitation of biliary components. The resultant obstruction of small biliary ductules and the accumulation of potentially cytotoxic bile acids damage hepatocytes and bile duct epithelial cells, causing the release of proinflammatory cytokines, growth factors, or free radicals. These factors activate hepatic stellate cells to synthesize and secrete collagen and attract neutrophils, macrophages, and lymphocytes to the damaged regions. Further cytokine release from the inflammatory cells recruits additional stellate cells into the developing lesion, and they add to the developing fibrosis. Over years to decades, the focal damage and fibrosis progress to bridging fibrosis and to multilobular, macronodular cirrhosis and portal hypertension.

Although decreased or absent CFTR function must contribute to the liver disease in CF, significant liver disease does not develop in most patients. Autopsy series show that the majority of older patients have focal biliary cirrhosis. Yet, few CF individuals manifest clinical liver disease. Other modifying factors, such as genetic predisposition or environmental agents, must influence the onset and severity of liver disease. Potentially, specific CFTR mutations could affect the progression to liver disease, but no obvious correlation exists between the CFTR genotype and the development of liver disease. Other possible explanations include differences in how the epithelial cells degrade mutant CFTRs, differences in how well other chloride conductance pathways compensate for the secretory defect, and differences in the immune response. A recent study did find a correlation between liver disease and the human leukocyte antigen (HLA) haplotype B7-DR15-DQ6 in male CF patients, suggesting that the immune response may indeed predispose to liver disease in some CF individuals. An additional study identified mutations in the glutathione transferase gene as a predisposing factor in CF-related liver disease.

Other types of liver disease, specifically neonatal cholestasis and hepatic steatosis, can affect CF patients. The abnormal biliary secretions and flow probably contribute to the pathophysiology of neonatal cholestasis because inspissated, eosinophilic secretions in bile canaliculi and intrahepatic bile ducts represent the predominant pathological changes in the liver. Factors apart from abnormal biliary secretions and flow probably underlie the pathogenesis of hepatic steatosis. Protein calorie malnutrition strongly associates with hepatic steatosis, and nutritional deficiencies such as essential fatty acid deficiency may produce fatty change in the liver of many CF patients. Additional mechanisms, such as increased levels of cytokines and ethanol ingestion, have been proposed as the basis for steatosis in well-nourished patients. It is unclear if steatosis is a precursor for permanent liver damage in CF patients.

Prevalence of Hepatobiliary Disease

The lack of diagnostic markers for CF liver disease makes the identification of all CF patients with liver disease virtually impossible, a problem that complicates any determination of prevalence and incidence of hepatobiliary disease in CF patients. Consequently, all studies probably underestimate the true risk for CF liver disease. An evaluation of voluntary reporting from CF centers in the United States to the CF Foundation National Cystic Fibrosis Registry indicated a prevalence rate of only 1% for hepatic cirrhosis, but found that liver disease accounted for 2.3% of deaths. Several large studies evaluated liver disease prospectively with biochemical markers and imaging criteria and found evidence for liver disease in 18–37% of CF patients.

Clinical Features of Liver Disease in CF

Neonatal Cholestasis

Fewer than 2% of infants with CF develop cholestasis. Half of those infants have meconium ileus compared to 15% of the total CF population. Biochemical studies, clinical findings, and liver histology are not specific and may suggest other disorders. Total and direct bilirubin levels are elevated and hepatomegaly is sometimes present. Acholic stools and a liver biopsy showing bile duct proliferation can occur and suggest biliary atresia. Giant cell transformation and intrahepatic paucity of bile ducts are also described. Most infants with neonatal liver disease do well. The cholestasis can continue for up to 8 months, but usually clears sooner. Hepatic fibrosis may develop and persist, but progression to chronic liver disease is unlikely.

Hepatic Steatosis

Diffuse hepatic steatosis occurs in up to 60% of CF patients. Most patients are identified by the detection of hepatomegaly on physical exam. Splenomegaly and other symptoms of liver disease are absent. Frequently, such patients are malnourished. Serum transaminases may be modestly elevated, but biochemical indicators of liver function are normal. The presence of steatosis does not correlate with the development of chronic liver disease or with worsening of pulmonary function.

Elevation of Serum Transaminases or of Alkaline Phosphatase

Asymptomatic elevations of serum transaminases or alkaline phosphatase are commonly found in CF patients. The frequency of elevated transaminases varies with age. Over 50% of patients below 1 year of age have elevated transaminases. By 2 years of age, the percentage drops to around 40% and continues to drop until it reaches about 10% by age 8 years. Similarly, 30–40% of patients less than 1 year of age have elevated serum alkaline phosphatase. The percentage decreases to approximately 5% by 8 years of age. Most patients have elevations of serum enzymes less than 1.5 times the upper limit of normal. Elevated serum transaminases or alkaline phosphatase or both are more common in patients with the ΔF508 mutation (class I). Of 267 patients who were homozygous for the ΔF508 mutation, 45% had enzyme elevations compared to only 20% in 25 pancreatic sufficient patients with class IV or V mutations. The prevalence rates for other genotypes ranged from 34 to 60%. The magnitude of the enzyme elevation does not predict the development of chronic liver disease.

Cirrhosis

Autopsy series estimate the prevalence of focal biliary cirrhosis at 10% in infants with CF within 3 months of birth, at 25% in children 1 year of age, and at 70% in adults. The available data are old and life expectancies have increased significantly since the publication of the last study in 1979. Consequently, the prevalence rate may be considerably different in CF patients at this time. Most patients with focal biliary cirrhosis do not progress to multilobular cirrhosis, which has a prevalence between 5 and 15%.

Because multilobular cirrhosis and portal hypertension develop insidiously, chronic liver disease is frequently first suspected on palpation of a hard-edged irregular liver and an enlarged spleen at a scheduled office visit. Other physical signs of chronic liver disease, such as dilated and prominent superficial abdominal veins or spider hemangiomas, may be present. Digital clubbing and oxygen desaturation can occur with cirrhosis even in patients without significant pulmonary disease. Impaired bile flow can decrease fat absorption, resulting in steatorrhea, weight loss, and clinical signs of fat-soluble vitamin deficiency. Serum transaminases and alkaline phosphatase are mildly elevated or normal. Initially, liver synthetic function is preserved and, although synthetic function can deteriorate, the complications of portal hypertension, variceal bleeding, and intractable ascites most often threaten the health of the CF patient. Recurrent hemorrhage from varices, intractable ascites, and hepatic synthetic failure most commonly provide the impetus for liver transplantation (Fig. 5).

Diagnostic Evaluation of Liver Disease

Even though a large proportion of CF patients have hepatomegaly or elevated serum transaminases, only a small fraction will develop hepatobiliary disease to an extent that alters their clinical course. To identify these individuals, there should be regular patient history reviews for bruising or bleeding, abdominal swelling, change in stool pattern, weight loss, and fatigue. Careful palpation and percussion of the liver and spleen and examination for cutaneous manifestations of chronic

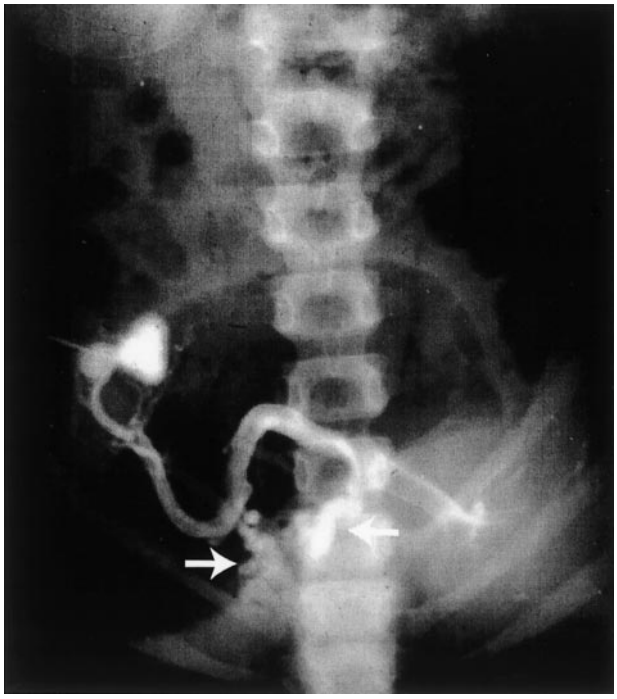

FIGURE 5 A venogram after a splenic injection shows varices (arrows) in a patient with both CF and cirrhosis.

liver disease and of nutritional deficiencies are required. Laboratory studies should include serum transaminase levels, total and direct bilirubin, alkaline phosphatase, γ-glutamyl transferase (GGT), total protein, serum albumin, prothrombin time, and a complete blood count. If significant liver involvement is suspected, then other potential causes of liver disease should be evaluated by specific testing. Multiple reports have documented the coexistence of CF-related liver disease with other causes of liver disease. α1-antitrypsin deficiency, chronic viral hepatitis, Wilson's disease, autoimmune hepatitis, hemochromatosis, sclerosing cholangitis, and drug-induced liver injury have all been reported in CF patients with liver disease.

Imaging studies and endoscopy have variable utility in CF-related liver disease. Ultrasonography of the liver, biliary tree, and hepatic vasculature can provide critical information in evaluating patients with newly suspected liver disease. Ultrasound coupled with Doppler ultrasound can assess the patient for gallstones, ascites, bile duct dilatation, and abnormal flow in the hepatic vessels. Computer tomography can exclude mass lesions or suggest steatosis. Magnetic resonance imaging is quite sensitive for fatty changes. Upper endoscopy is the most sensitive method for detecting esophageal or gastric varices and should always be employed in CF patients with upper gastrointestinal bleeding. Early detection of esophageal varices in patients with evidence of portal hypertension may allow prophylactic use of beta-blocker therapy to prevent variceal bleeding. This approach must be weighed against the potential effects of beta-blockers on airway function.

Liver biopsies are done infrequently in CF patients for several reasons. The heterogeneous nature of the hepatic lesion increases sampling error. Histology does not predict the likely clinical course nor does the type of lesion dictate therapy. Liver biopsy can differentiate between steatosis and focal biliary cirrhosis and may detect diffuse fibrosis or cirrhosis (Fig. 6). At times, this information may influence clinical decisions. If a liver biopsy is required, a prebiopsy ultrasound can direct the biopsy away from dilated hepatic veins and the often hyperexpanded right lower lobe of the lung.

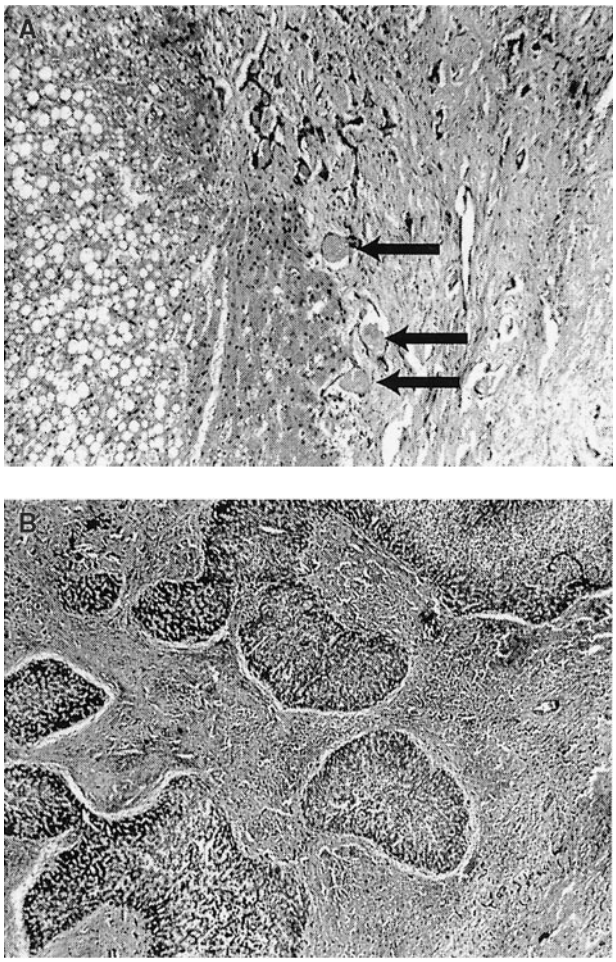

FIGURE 6 Histology of multilobular cirrhosis. (A) Fibrosis and fatty change are present. The arrows mark inspissated material in sinusoids. (B) Marked fibrosis and nodular regeneration are present.

Medical Therapy of CF-Related Liver Disease

The treatment of hepatic steatosis centers on improving the patient's nutritional status. The goal is to maximize the intake of energy-producing foods, protein, and fat-soluble vitamins. A thorough evaluation by a nutritionist can suggest ways to improve nutrition. Fat malabsorption can be quantitated and pancreatic enzyme supplements can be adjusted to optimize fat absorption. Deficiencies of fat-soluble vitamins and essential fatty acids can be determined by biochemical measurements and corrected as indicated. Older patients and well-nourished patients should be questioned about alcohol ingestion and drug use. New-onset diabetes mellitus should be considered.

The treatment of patients with disease characterized by fibrosis or cirrhosis centers on preventing and treating the complications of portal hypertension and cirrhosis. No therapy alters the progression to cirrhosis. Improvements in the biochemical indices of liver injury, in the symptom of pruritus, and in essential fatty acid status have been reported in uncontrolled trials of urosodeoxycholic acid (UDCA) therapy in CF patients with liver disease. UDCA is a potent choleretic and may

protect hepatocytes from injury by displacing toxic bile acids in the enterohepatic circulation and by increasing bile flow as determined by hepatobiliary scintigraphy. No study has shown that UDCA changes the course or outcome in CF-related liver disease or that UDCA prevents the development of liver disease in patients with little or no evidence of liver abnormalities. Despite this lack of evidence, many researchers still recommend UDCA treatment of all patients with fibrosis or cirrhosis.

For patients with life-threatening complications of portal hypertension, with severe synthetic dysfunction, or with growth failure on a background of severe liver disease, liver transplantation offers the only therapeutic option. Because wait times for a donor liver can be long, patients should be referred for transplant evaluation before they are desperately ill. The 1-year survival is about 80% and many patients show improvement in lung function. The outcome is much poorer in patients who require combined organ transplants.

Prevalence and Clinical Features of Biliary Disease in CF

Microgallbladder

Asymptomatic microgallbladder is the most common biliary tract abnormality in CF patients. It is found in about 30% of patients. The contents of the gallbladder are thick and colorless and the submucosa contains mucus-filled cysts. The cystic duct may be undersized or obstructed. Associated abnormalities in the hepatic or common bile ducts have not been described.

Cholelithiasis and Cholecystitis

The prevalence of gallstones and cholecystitis is 1–10% in patients with CF. The frequency may increase with age, but this correlation requires additional confirmation. Although the gallstones are radiolucent, they do not contain cholesterol. Instead, the stones in CF patients are composed of calcium bilirubinate and protein. Comparison of the biliary lipid concentrations between bile from CF patients with and without gallstones shows no differences that might explain why only some CF patients develop stones. When symptomatic, patients have right upper quadrant abdominal pain that may radiate to the right shoulder. Sometimes vague or diffuse abdominal pain is the only complaint in CF patients. Jaundice, nausea and vomiting, and pruritus are less commonly present. Laboratory studies may be normal or show elevated alkaline phosphatase or bilirubin.

Bile Duct Disorders

Abnormalities of the extrahepatic or intrahepatic bile ducts occur in less than 2% of patients. Structural changes in the larger intrahepatic bile ducts similar to the strictures and beading typical of sclerosing cholangitis can be present, particularly in adult patients. The interpretation of these duct abnormalities is complicated in CF patients because of the high probability that these patients have biliary cirrhosis and inspissated thickened biliary secretions. Still, these patients may have the same clinical manifestations found in sclerosing cholangitis, including hepatomegaly and pruritus associated with elevated alkaline phosphatase and GGT. Another abnormality, stenosis of the intrapancreatic common bile duct by compression from pancreatic fibrosis, has also been reported in a few CF patients.

Diagnosis of Biliary Disease

Various imaging studies aid in the identification of biliary disease. Ultrasonography and computer tomography reveal gallstones and duct dilatation. Endoscopic retrograde cholangiopancreatography (ERCP) discloses anatomic abnormalities of bile ducts and identifies gallstones. Because it is an invasive procedure, ERCP should be reserved for diagnosis in selected patients. Magnetic resonance cholangiopancreatography has revealed cholelithiasis and strictures and dilatation of the extrahepatic and intrahepatic bile ducts in a series of CF patients and may provide a noninvasive alternative to ERCP.

Treatment of Biliary Disease

ERCP provides a therapeutic option to laparotomy for treating biliary disease. Impacted gallstones can be removed, strictures can be dilated, and biliary stents can be placed through the endoscope. Because UDCA does not dissolve the gallstones in CF patients, patients with symptomatic gallbladder disease require laparoscopic or surgical cholecystectomy for treatment.

INTESTINAL DISORDERS IN CYSTIC FIBROSIS

The expression of mRNA encoding CFTRs occurs at high levels in the duodenal mucosa and decreases steadily throughout the length of the small intestine. A decreasing gradient of expression also occurs along the axis from the crypt to villus tip in both the small intestine and the colon. Other high-expressing cells reside in the Brunner's glands of the duodenum and are

scattered sparingly throughout the duodenum and jejunum. The consequence of abnormal CFTRs in the intestine is decreased chloride, sodium, and water secretion into the intestinal lumen by the crypt cells. The decreased water content results in thickened intestinal secretions that have abnormal mucus composition and concentrations. The CF intestine contains more mucus than normal intestine and the secreted CF mucus has abnormal biochemical properties with increased fucosylation and sulfation and decreased sialylation. Together, the decreased water content and abnormal mucus account for the increased viscosity of intestinal secretions in CF patients and predispose CF patients to intestinal obstruction.

Viscous secretions generate many of the histological and radiological findings in the intestine of CF patients. Variable quantities of inspissated secretions reside within the lumen of the mucosal glands of the small intestine. Brunner's glands are often dilated and have flattening of the epithelial cells lining the lumen. Thickened small bowel folds, nodular filling defects, and variable dilatation of small bowel loops are radiographic findings in upper gastrointestinal barium studies in CF patients. In the colon, collections of mucus frequently dilate the colonic crypts. Proximal colonic wall thickening without stricture, pericolonic fat proliferation, or mesenteric infiltration can be seen by computer tomography of the abdomen in many CF patients. The appendix also shows changes that suggest the diagnosis of CF. In the appendix, mucus-filled goblet cells line dilated crypts and eosinophilic casts of the crypts appear in the lumen of the appendix.

Meconium Ileus

About 10–15% of newborns with CF present with neonatal meconium ileus or its complications. In these infants, the meconium contains greatly decreased water and high calcium content. Other salts and minerals, such as sodium, potassium, copper, and zinc, are decreased. The development of meconium ileus does not correlate with the presence or absence of pancreatic insufficiency or with any genotype.

Pathology of Meconium Ileus

Viscous inspissated meconium produces distal small bowel obstruction. Typically, the distal ileum is narrow and the colon beyond the obstruction is small (a microcolon). Small bowel ischemia and perforation can occur antenatally. Leakage of meconium into the peritoneum causes an intense inflammatory reaction and can produce meconium cysts, meconium ascites, adhesions, or intraabdominal calcifications. In some infants, the intrauterine perforation seals spontaneously and restores intestinal continuity. Volvulus can occur in the fetus or in the newborn. Fetal volvulus can cause intestinal atresia.

Clinical Features of Meconium Ileus

Most infants with uncomplicated meconium ileus present with signs of intestinal obstruction, abdominal distension, and bilious vomiting within 48 hours of birth. These infants generally appear well at birth. In contrast, infants with complicated meconium ileus present earlier and often appear ill at birth or shortly after birth. Dilated, firm loops of bowel may be visible or palpable, frequently in the right lower quadrant.

Plain X-ray films of the abdomen characteristically show distended loops of bowel with few or no air–fluid levels. Gas trapped in the thick meconium may be found throughout the ileum. Calcifications indicate meconium peritonitis, and mass effect from a meconium pseudocyst may be appreciated. A contrast enema is diagnostic and often therapeutic (Fig. 7). During the enema, contrast fills the microcolon, refluxes into the small bowel, and outlines filling defects caused by the inspissated meconium, establishing the diagnosis. The hypertonicity and mild mucosal irritation of the contrast media may draw fluid into the

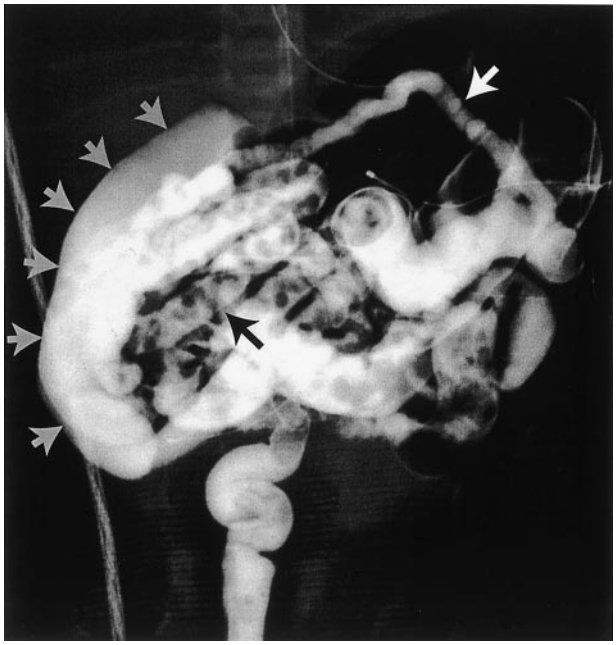

FIGURE 7 Barium enema in a patient with CF and meconium ileus. The white arrow identifies the microcolon. The black arrow shows filling defects in the distal small bowel. The gray arrows mark a dilated loop of more proximal small bowel.

meconium and, along with the mechanical action of the enema, mobilize the obstruction in 50–75% of affected infants.

Additional treatment options include other irrigating solutions and surgery. *N*-Acetylcysteine (Mucomyst) cleaves disulfide bonds in the mucoproteins and reduces the viscosity of the meconium. Surgery is required in infants who fail to respond to irrigation or who have complicated meconium ileus. In these cases, bowel resection with primary anastomosis or stoma formation is generally performed. Improvements in treatment have increased survival of infants with meconium ileus to over 95%.

All infants with meconium ileus, meconium peritonitis, jejunoileal atresia, or volvulus should have a sweat test done; 80% or more of infants with meconium ileus will have CF, as will 30–50% of infants with meconium peritonitis. The presence of jejunoileal atresia increases the risk that the patient has CF 210-fold. Another meconium obstruction syndrome, meconium plug syndrome, carries a much lower risk for CF. Meconium plug syndrome presents with signs and symptoms of bowel obstruction like meconium ileus, but the contrast enema reveals a normal caliber colon and obstruction of the colon with mucus plugs. As in meconium ileus, the enema frequently relieves the obstruction.

Distal Intestinal Obstruction Syndrome

Small bowel obstruction also presents problems in 15% of older CF patients. In the late 1960s, a published report described patients with distal small bowel obstruction secondary to inspissated intestinal contents in the terminal ileum. Originally named "meconium ileus equivalent," the term "distal intestinal obstruction syndrome" (DIOS) is preferred today.

Pathogenesis of DIOS

Multiple mechanisms probably contribute to DIOS. The presence of steatorrhea, either from noncompliance with enzyme therapy or ineffective enzyme therapy, is associated with DIOS. Slowing of intestinal motility, perhaps by the release of neurotensin or by narcotic pain relievers, may allow the accumulation of partially digested food residues in the ileum. Other potential factors include bowel dilatation, previous laparotomy, or inherent dysmotility. Occasionally, the syndrome appears in patients who have no obvious inciting factors.

Clinical Features of DIOS

DIOS presents with acute or chronic symptoms of partial or complete bowel obstruction. Rarely does the

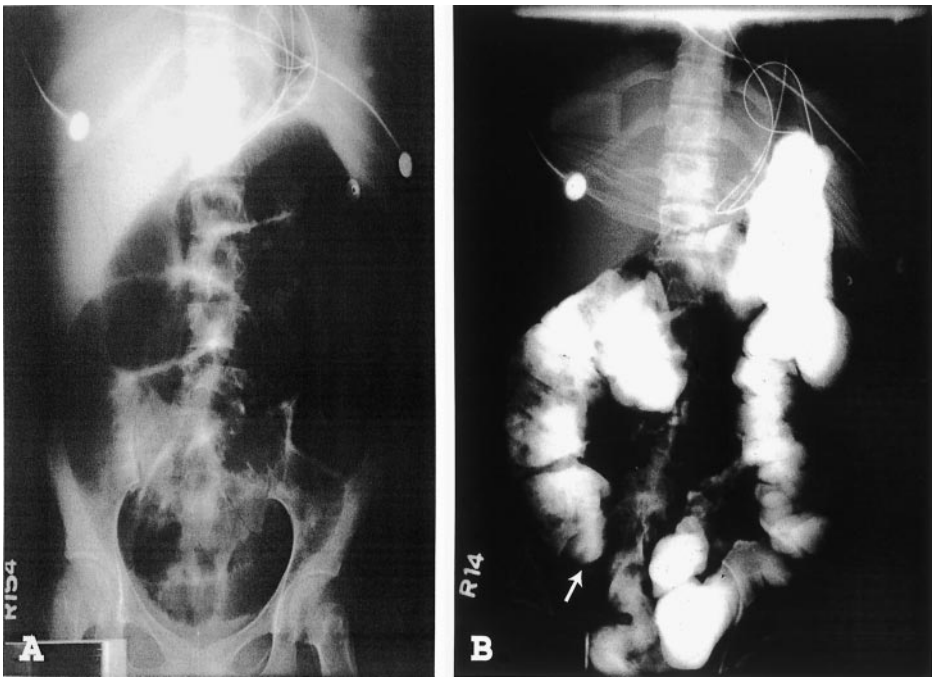

FIGURE 8 Radiography of distal intestinal obstruction syndrome. (A) An older patient with markedly dilated bowel loops. (B) A water-soluble contrast study identifies an obstruction (white arrow).

syndrome occur in patients younger than 5 years and most cases occur in patients older than 15 years. The cardinal features include crampy abdominal pain in the right lower quadrant or lower abdomen, a palpable abdominal mass, and decreased frequency of defecation. In about 10% of patients, abdominal distension and bilious vomiting predominate. Pain is the most common complaint in the chronic form of DIOS. Often, meals trigger the pain and anorexia develops as the patients try to avoid pain episodes. The pain may remit for weeks or months only to return at a later time. In both forms of DIOS, abdominal plain films identify bubbly fecal material in the right lower quadrant with or without bowel dilatation (Fig. 8). Other causes of partial or complete small bowel obstruction, such as intussusception, appendicitis, postoperative adhesions, Crohn's disease, or fibrosing colonopathy, may exist in patients who lack the typical history, physical findings, and radiological findings of DIOS.

The treatment of DIOS focuses on nonoperative relief of the distal small bowel obstruction. A hypertonic, water-soluble contrast enema confirms the diagnosis and may dislodge the impaction from the distal ileum. Patient distress may limit the ability to reflux contrast into the proximal small bowel and thus may thwart therapeutic efforts. In that case, patients without complete bowel obstruction can be treated by intestinal lavage with a balanced electrolyte solution such as Golytely. The lavage should be given orally or by nasogastric tube until the rectal effluent is almost clear. Lavage can also treat chronic DIOS. Some patients will have recurrent episodes of DIOS and may benefit from intermittent oral intake of intestinal lavage solution in addition to regular oral doses of pancreatic enzymes.

Rectal Prolapse

Rectal prolapse was seen in about 20% of patients with CF in early studies. More recent data from the Cystic Fibrosis Registry estimate that this complication now happens in fewer than 2% of CF individuals. Still, CF patients account for about 10% of all patients presenting with rectal prolapse, most presenting in the first year of life and experiencing recurrent episodes. Adequate pancreatic enzyme supplementation almost always stops the prolapse. A few patients require surgery.

Fibrosing Colonopathy

Fibrosing colonopathy, first reported in 1994, is a disorder associated with the administration of high doses of pancreatic enzymes. The colon characteristically has dense submucosal fibrosis and may be foreshortened or strictured. Histologically, eosinophilia, mild cryptitis, regenerative epithelium, and disruption of the muscularis mucosa are seen. Most commonly, patients present with a distended abdomen and abdominal pain. In addition to high-dose administration of pancreatic enzymes, predisposing factors may include young age, prior intestinal surgery, and DIOS. The withdrawal of all high-dose formulations of pancreatic enzymes from the market has been associated with a decreased prevalence of this complication.

Cytochrome P450

CLARK R. GREGG
Veterans Affairs North Texas Health Care System and University of Texas Southwestern Medical School, Dallas

oxidative metabolizing enzymes Render drugs and other xenobiotics both less biologically active and more water soluble for renal or biliary excretion. The principal enzymes involved in this process are the microsomal mixed-function oxidases of the cytochrome P450 system, so named because of their absorbance maximum at 450 nm under laboratory conditions.

P450 induction Increased synthesis of P450 enzymes following extended exposure to certain drugs or substances, resulting in accelerated metabolism of other drugs.

P450 inhibition Specific inhibition of cytochrome P450 enzymes by certain drugs or foods; delays the metabolism and augments the pharmacologic effects of other drugs that are substrates of the same enzyme.

The cytochrome P450 enzymes are pivotally important in the biotransformation of drugs and are the most important mediators of drug–drug interactions. The clinical relevance of pharmacokinetic P450 drug interactions may not always be apparent, but the adverse effects may occasionally be severe. Inhibitory P450 interactions can in some situations be purposely used for pharmacologic benefit.

ENZYMATIC BIOTRANSFORMATION OF DRUGS

More than 30 distinguishable cytochrome P450 enzymes have been described. They are found in highest concentration in the liver and, in the case of certain subfamilies, in the small intestinal mucosal enterocytes and other organs. Many P450 enzymes have versatile substrate specificities and can metabolize drugs, toxins, and carcinogens as well as normal endogenous compounds. Cytochrome P450 enzymes are assigned a distinctive nomenclature and are grouped into families, with subgrouping (e.g., CYP 1A2, CYP 3A4) according to biochemical relatedness. The human P450 enzymes that are most important in drug metabolism are CYP 1A2, the CYP 2C family, CYP 2D6, and CYP 3A4. These isoenzymes differ in their pharmacogenetics, substrate specificities, inducibility, and susceptibility to inhibition by competing substrate drugs. In the intestine and liver, CYP 3A4 shares with the P-glycoprotein efflux transporter an important role in the presystemic metabolism and elimination of many commonly used drugs.

CYTOCHROME P450 AND DRUG INTERACTIONS

Exposure to certain drugs and other substances can induce the synthesis of some P450 enzymes, which accelerates the metabolism of other drugs that are substrates of these enzymes. The most important inducers of P450 enzymes are anticonvulsants, the antimicrobial drug rifampin, chronic alcohol consumption, and cigarette smoking. Following P450 induction, the enhanced metabolism of other drugs will diminish their pharmacologic activity. These effects may persist for weeks following cessation of the inducing drug.

Certain drugs can inhibit specific P450 isoenzyme-mediated metabolism of other (object) drugs in a dose-dependent fashion. This inhibition may result in an immediate decrease in the metabolism of the object drugs, resulting in their accumulation and possible toxicity. Because a range of variation in different P450 activities exists among individuals in a population, the clinical significance of this inhibition may be difficult to predict in a particular person. Commonly used drugs that, by inhibiting specific P450 enzymes, may cause clinically significant drug interactions include cimetidine, amiodarone, selective serotonin reuptake inhibitors (SSRIs), and a variety of antimicrobials (e.g., macrolides, sulfonamides, azole antifungals, and the HIV-1 protease inhibitors, especially ritonavir). The potent P450 inhibition by ritonavir is intentionally used to advantage in combination drug regimens for the treatment of HIV-1 infection.

Object drugs for which clinically important toxicity has resulted from these inhibitory cytochrome P450-mediated drug interactions include theophylline, warfarin, carbamazepine, phenytoin, benzodiazepines, psychotropic drugs, cyclosporine, tacrolimus, terfenadine, cisapride, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, calcium channel

blockers, and ergotamine. Furanocoumarins in grapefruit juice irreversibly inhibit CYP 3A4 in the intestinal mucosa, which may markedly enhance the bioavailability and pharmacologic effects of coadministered drugs that are substrates of this particular enzyme.

highly active antiretroviral therapy Combination of three or more anti-human immunodeficiency virus agents, usually including a protease inhibitor.

inflammatory bowel disease Idiopathic inflammatory condition of the bowel.

Human cytomegalovirus is a β herpesvirus that produces a characteristic cytopathology on biopsy. Approximately 50% of individuals in the developed world are seropositive for cytomegalovirus antibodies by adulthood. Primary infection is often mild or asymptomatic but may be responsible for an infectious mononucleosis syndrome. In immunocompromised individuals, primary infection or reactivation of latent cytomegalovirus infection may cause a range of severe clinical manifestations throughout the body, including the gastrointestinal tract, eye, respiratory tract, and central nervous system. Groups at risk include individuals with primary or secondary immunodeficiencies, particularly patients with human immunodeficiency virus, patients undergoing transplant with immunosuppression, oncology patients receiving chemotherapy, and congenitally infected neonates.

GASTROINTESTINAL INFECTION IN THE IMMUNOCOMPROMISED

Cytomegalovirus (CMV) gastrointestinal tract infections in patients with human immunodeficiency virus (HIV) were common in the era preceding use of highly active antiretroviral therapy (HAART); affected patients usually had CD4 cell counts below 100 cells/μl. CMV infection in allogeneic transplant patients has also been well described. In this group of patients, interstitial pneumonitis is the predominant problem, but gastrointestinal (GI) disease is well recognized and anti-CMV prophylaxis for patients with CMV viremia substantially reduces end organ disease.

Clinical Features

Gastrointestinal infection of the esophagus, stomach, small bowel, and colon occurs in 5–15% of patients during the course of HIV infection. Although CMV may infect any part of the GI tract, the most common site of infection is the colon. There is a wide spectrum of symptoms associated with CMV colitis. Chronic or

inflammatory bowel disease Idiopathic inflammatory condition of the bowel.

Human cytomegalovirus is a β herpesvirus that produces a characteristic cytopathology on biopsy. Approximately 50% of individuals in the developed world are seropositive for cytomegalovirus antibodies by adulthood. Primary infection is often mild or asymptomatic but may be responsible for an infectious mononucleosis syndrome. In immunocompromised individuals, primary infection or reactivation of latent cytomegalovirus infection may cause a range of severe clinical manifestations throughout the body, including the gastrointestinal tract, eye, respiratory tract, and central nervous system. Groups at risk include individuals with primary or secondary immunodeficiencies, particularly patients with human immunodeficiency virus, patients undergoing transplant with immunosuppression, oncology patients receiving chemotherapy, and congenitally infected neonates.

GASTROINTESTINAL INFECTION IN THE IMMUNOCOMPROMISED

Cytomegalovirus (CMV) gastrointestinal tract infections in patients with human immunodeficiency virus (HIV) were common in the era preceding use of highly active antiretroviral therapy (HAART); affected patients usually had CD4 cell counts below 100 cells/μl. CMV infection in allogeneic transplant patients has also been well described. In this group of patients, interstitial pneumonitis is the predominant problem, but gastrointestinal (GI) disease is well recognized and anti-CMV prophylaxis for patients with CMV viremia substantially reduces end organ disease.

Clinical Features

Gastrointestinal infection of the esophagus, stomach, small bowel, and colon occurs in 5–15% of patients during the course of HIV infection. Although CMV may infect any part of the GI tract, the most common site of infection is the colon. There is a wide spectrum of symptoms associated with CMV colitis. Chronic or

Copyright 2004, Elsevier (USA). All rights reserved.

intermittent diarrhea in association with abdominal pain is the most common manifestation of colonic infection. Colonic infection may present with mild or severe rectal bleeding, or abdominal pain without diarrhea and fever. Pain may precede the development of toxic megacolon and intestinal perforation, which is a rare but life-threatening occurrence. CMV infection of the colon may occur in association with infection elsewhere in the GI tract. Such sites include the esophagus, usually resulting in dysphagia and odynophagia, and the pancreatico-biliary tree, manifesting as pain in the upper abdomen that results from acquired immunodeficiency syndrome (AIDS)-related pancreatico-cholangiopathy or pancreatitis. Importantly, GI infection may also herald CMV retinitis, and careful retinal assessment is therefore essential in this group of patients.

Diagnosis

Definitive diagnosis of CMV enterocolitis requires intestinal biopsy. A spectrum of both upper and lower GI manifestations of CMV infection has been described. In a prospective study of HIV patients with CMV colitis, chronic diarrhea and abdominal pain occurred in 80 and 50% of patients, respectively; 9% presented with lower GI bleeding with a previous history of diarrhea. Endoscopic appearances were heterogeneous. Three main categories were identified: colitis associated with ulceration (40%), ulceration alone (40%), or colitis alone (20%). Subepithelial hemorrhage was a common manifestation in all groups; 9% of patients had disease proximal to the splenic flexure without distal involvement.

The histological diagnosis of CMV enterocolitis is largely dependent on identifying characteristic cytomegalovirus inclusion bodies, and these are best seen in biopsies obtained from the base of CMV ulcers. In addition, specific immunoperoxidase staining for CMV is also useful in identifying GI disease. Positive staining is more likely at the edge of ulcers and some clinicians claim greater sensitivity using immunostaining compared to conventional histology. The value of viral culture and the polymerase chain reaction in evaluating intestinal biopsies is limited because of the lack of specificity. Monitoring CMV antigenemia or CMV DNA levels during treatment indicates that levels broadly correspond to the clinical response.

Treatment

Treatment of CMV enterocolitis requires parenteral therapy with either ganciclovir (5 mg/kg, twice daily) or foscarnet (90 mg/kg, twice daily), both of which may be associated with severe side effects. Ganciclovir may cause severe bone marrow depression with resultant anemia and neutropenia. Foscarnet may cause severe renal impairment, although a concomitant normal saline infusion largely seems to diminish the risk of renal damage. In an open-label randomized study comparing a 2-week course of ganciclovir with foscarnet, at doses of 5 and 90 mg/kg, twice daily, respectively, no significant difference in response of GI CMV disease was found between the two therapies. Around 75% of patients had good clinical and endoscopic responses, with disappearance of inclusion bodies. Relapse occurs in at least 50% of patients within around 10 weeks, and survival without HAART in HIV-infected patients is around 20 weeks. Encouragingly, the advent of HAART has led to a marked reduction in mortality and morbidity associated with opportunistic infection among HIV patients, including CMV. HAART results in a reconstitution of anti-CMV immunity, with a resultant significant and progressive decline in CMV viremia in the absence of specific anti-CMV treatment.

GASTROINTESTINAL INFECTION IN THE IMMUNOCOMPETENT

CMV colitis may rarely occur in the immunocompetent individual and has been associated with significant morbidity (hemorrhage and perforation) and occasionally mortality. Patients with inflammatory bowel disease treated with immunomodulatory drugs such as azathioprine or cyclosporine are at increased risk of CMV colitis, which may contribute to the course of seemingly refractory severe colitis in these patients.

biofeedback A training technique by which an individual is taught to gain control over an important body function using information received from an instrument to guide their response.

enteric nervous system The nerve cell bodies and their processes that are found in the wall of the gastrointestinal tract and that act to influence motor activity and other important gut functions.

outlet dysfunction A constellation of disorders in which normal defecation is disturbed by organic or functional abnormalities of the anorectum.

pelvic floor dyssynergia A condition in which normal defecation is impeded by the unconscious contraction of the puborectalis and external anal sphincter muscles.

In humans, the colon and rectum function to store fecal material and to expel it when appropriate. As fecal material passes through the colon, water is removed from it so that a semisolid to solid stool is formed by the time it reaches the distal colon. The critical mechanisms that control defecation are examined in this article.

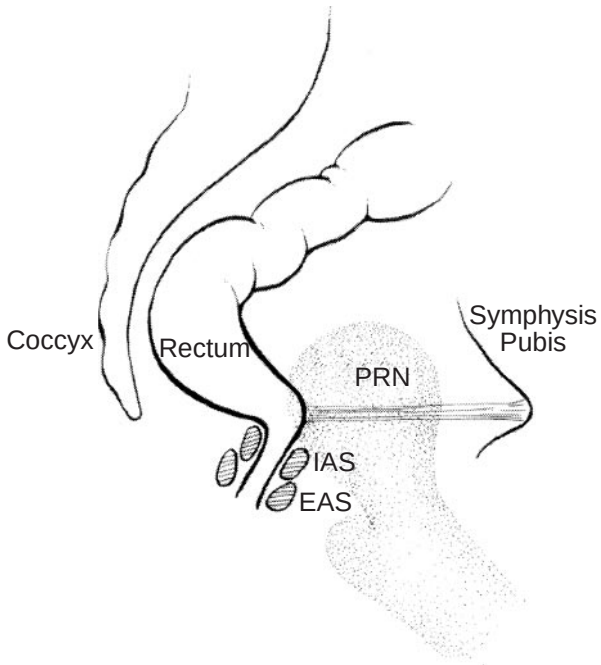

FIGURE 1 Sagittal view of the anorectum at rest. PRM, puborectalis muscle; IAS, internal anal sphincter; EAS, external anal sphincter. The anorectal angle is formed by the tone of the puborectalis muscle. Anal canal pressure is the sum of the IAS and EAS.

INTRODUCTION

The main functions of the colon and rectum in humans are to store fecal material and to expel it when socially appropriate. During the passage of fecal material through the colon, dehydration occurs so that stool is semisolid to solid and formed by the time it arrives at the distal colon. In addition to the volume, consistency, and speed with which stool arrives at the distal colon and rectum, the critical mechanisms that control continence and defecation include the reservoir function of the rectum, the anorectal angle created by the puborectalis sling muscle, and the internal and external anal sphincters, which help to regulate the passage of fecal wastes through the anal canal (Fig. 1).

The stimulus to initiate defecation appears to be distension of the rectum, which normally occurs when colonic peristaltic contractions propel stool into the rectum. Whether defecation occurs is the result of a variety of factors. The nature of rectal contents can generally be distinguished by epithelial nerve endings in the rectum and anal canal. Rectal distension is perceived via sensory afferents in the perirectal spaces and perhaps in the rectal wall itself. In most cases, defecation may be suppressed or allowed through complex cortical influences on anorectal components.

NORMAL DEFECATION

Normally, rectal distension induces relaxation of the internal anal sphincter. This is associated with transient contraction of the external anal sphincter to maintain continence and allow sampling of rectal contents by anal sensory nerves to distinguish gas, liquids, and solids. If the decision to defecate is made, the subjects assume the squatting position, which helps to straighten the

 Copyright 2004, Elsevier (USA). All rights reserved.

alignment between the rectum and anal canal. Rectal contraction increases intralumenal pressures and contraction of the rectus abdominus muscles and diaphragm during the performance of the Valsalva maneuver increases intra-abdominal pressures to provide a propulsive force. The pelvic floor descends and relaxation of the puborectalis muscle and external anal sphincter decreases resistance to the passage of the fecal mass through the anal canal (Fig. 2). After defecation, there is rebound contraction of the puborectalis and external anal sphincter (EAS) and the anal canal is closed (Fig. 1). In most healthy subjects, there is substantial emptying of the left colon as well as the rectum.

In contrast to defecation, expulsion of flatus is not associated with straightening of the anorectal angle. In this circumstance, propulsive forces move intralumenal gas past the anorectal angle and through the anal canal.

ABNORMAL DEFECATION (OUTLET DYSFUNCTION)

In certain individuals, behavioral or physiologic factors may produce defecatory dysfunction with resultant constipation. This constellation of disorders is known as outlet dysfunction, which may be divided into various subtypes.

FIGURE 2 During normal defecation, the puborectalis muscle is relaxed to widen the anorectal angle while relaxation of the EAS reduces resistance pressures in the anal canal (arrows).

Neurologic Disorders

Neurologic disorders that affect the anorectum may impair the act of defecation in a variety of ways. Defecation is triggered by an urge to defecate, a sensory signal that activates the sequence of voluntary and involuntary movements in the anorectum and pelvic floor. The sensory stimulus may be lacking when sensory fibers from the pelvic floor and anorectum are disconnected from the higher cortical centers; these diseases may occur anywhere from the peripheral nerves to the cerebral cortex.

The voluntary and coordinated activation of the thoracoabdominal muscles, the levator/puborectalis muscles, and the EAS may be impaired or absent in the presence of spinal cord lesions or bilateral cortical damage. Lesions above T10 invariably affect all three muscle groups but in lesions below T10, thoracic and abdominal muscle activity is preserved, thus allowing defecation to occur, although perhaps with some delay.

Normally, the resting activity of the puborectalis muscle and EAS is maintained by spinal sacral reflexes that are inhibited during the act of defecation. In neurologic diseases that affect the suprasacral spinal cord but with intact spinal sacral reflexes, the descending inhibition of these muscles is lost or impaired, which in turn may interfere with defecation.

Enteric Nervous System Disorders

The prime example in this group is Hirschsprung's disease, which is characterized by the congenital absence of ganglion cells in the submucosal and myenteric plexus, beginning at the internal anal sphincter and extending proximally for varying distances. At least seven different genes are associated with this disorder, but with variable penetrance, which influences the expression of the disorder.

The loss of intrinsic innervation in the distal colon results in loss of the inhibiting neurotransmitter nitric oxide and overexpression of extrinsic parasympathetic nerves. This results in unopposed contraction of the aganglionic segment. As a result of this functional obstruction, the normal innervated bowel proximally becomes dilated.

Pelvic Floor Dyssynergia

Normal defecation involves the coordinated relaxation of the puborectalis and external anal sphincter muscles together with increased intra-abdominal pressure and inhibition of colonic segmenting activity. In patients with pelvic floor dyssynergia, ineffective defecation is associated with failure to relax, or

FIGURE 3 In pelvic floor dyssynergia, there is unconscious contraction of the PRM and EAS during attempted defecation. This narrows the anorectal angle and increases anal canal pressures (arrows) to impede defecation.

inappropriate contraction of the puborectalis and external anal sphincter muscles. This narrows the anorectal angle and increases pressure of the anal canal so that evacuation is less effective (Fig. 3). Because relaxation of these muscles involves cortical inhibition of the spinal reflex during defecation, this pattern may represent a conscious or unconscious act.

The diagnosis of pelvic floor dyssynergia is generally established by diagnostic testing in a laboratory facility using techniques that attempt to duplicate normal defecation. There is recent evidence that pelvic floor dyssynergia is often an artifact of laboratory testing and may be overdiagnosed. In one study, 80% of patients who exhibited dyssynergia in the laboratory showed appropriate sphincter relaxation when tested at home. Others have demonstrated dyssynergia in approximately 25% of controls and a similar percentage of patients with fecal incontinence. Thus, more rigorous criteria for the diagnosis are required in clinical practice and for clinical trials.

A diagnosis of pelvic floor dyssynergia should be suspected only when there is impaired expulsion of a water-filled balloon or artificial stool from the rectum when attempted in privacy. It should then be confirmed by at least two of the following studies: anorectal manometry, anal sphincter electromyography (EMG), and defecography.

Weak Expulsion Forces

In this condition, expulsion forces are inadequate to expel stool from the rectum. This occurs in several scenarios such as neuromuscular disorders, painful conditions that inhibit the Valsalva maneuver, lax rectus abdominus muscles, and megarectum, which disperses expulsion forces into a capacious rectum rather than toward the anal canal.

Misdirection of Expulsion Forces

Rarely, a large rectocele (anterior in women, posterior in men) will cause misdirection of expulsion forces as stool is directed toward areas of less resistance rather than through the anal canal. However, the large majority of rectoceles are of no physiologic significance and constipation may be caused by other mechanisms such as dyssynergia.

Unexplained Rectal Dysfunction

Unexplained rectal dysfunction is characterized by difficulty expelling rectal contents in the absence of a demonstrable mechanism. This diagnosis should be made only if there is considerable delay or inability to expel an artificial stool in the absence of demonstrable organic or functional abnormalities. It should be emphasized that the expulsion of artificial stool does not mimic exactly normal defecation as the latter is associated with propulsive contractions of the distal colon.

TREATMENT OF ABNORMAL DEFECATION

Ideally, treatment for patients with outlet dysfunction should be based on presumed pathophysiologic mechanisms. Broadly speaking, treatments include stimulant and osmotic laxatives and enemas, behavioral approaches such as biofeedback, and surgery in highly selected patients.

Behavioral Approaches

One behavioral approach is the use of biofeedback training to modify striated muscle activity during simulated defecation, in the laboratory or at home. A second approach is practicing simulated defecation of a water-filled or air-filled balloon or other substances that are used as artificial stool. The last has been combined with diaphragmatic muscle training by some investigators.

Biofeedback is performed with an EMG sensor or manometry catheter, which is placed into the anorectum. The patient watches a visual display of pressure traces or EMG activity. The patient is instructed to squeeze to produce an increase in pressure or EMG activity and then is asked to strain as if to expel the catheter from the rectum. The patient is shown what a normal response is and then is asked to normalize his (her) recording using trial and error efforts. Biofeedback sessions continue until normal defecation efforts are consistently made. The patient is instructed to use these techniques when attempting to defecate at home and may be given a home trainer to practice. Therapeutic endpoints are subjective and objective (frequency, straining, sense of complete evacuation, etc.). The ideal target population is made up of adult patients with pelvic floor dyssynergia.

A modification of the biofeedback technique is simulated defecation in which a balloon attached to a catheter is inserted into the rectum and inflated with 20 cc of air or water. The patient is asked to push the balloon out slowly without straining. Relaxation of the external anal sphincter is necessary to do this easily. The process is repeated with the patient straining; the ease with which this is done is the feedback for the patient, as squeezing the EAS will make it more difficult. Phases 2 and 3 are identical to the biofeedback program above.

Surgical Approaches

In Hirschsprung's disease, surgical resection of the aganglionic bowel with anastomosis of the normal colon to the anal canal is the optimal approach. In patients with short segment disease, internal sphincterotomy with extension to the normal rectum may be effective.

Rectocele repairs should be restricted to those occasions when a rectocele is believed to be of physiologic importance. Surgery should be preceded by behavioral correction of functional abnormalities of defecation, if present.

Pharmacologic Approaches

Botulinum toxin is a potent neurotoxin that binds to presynaptic cholinergic nerve terminals to inhibit the release of acetylcholine at the neuromuscular junction. When injected into muscle, paralysis occurs for several months until there is axonal regeneration and formation of new nerve terminals. Some studies suggest that botulinum toxin injected into the puborectalis muscle may be helpful in patients with pelvic floor dyssynergia who fail to respond to behavioral treatments.

Development, Overview

ROBERT K. MONTGOMERY
Children's Hospital Boston

endoderm One of the three germ layers formed by the process of gastrulation. Gives rise to the epithelial lining of the gastrointestinal tract and its derivatives.

epithelial/mesenchymal interaction Fundamental process in development. Interaction may occur via soluble factors, produced by either cell type, binding to receptors on the surface of the other, via direct cell–cell contact, or via the basal lamina produced between the cell layers, to which the epithelial cells are attached.

forkhead-related proteins Family of transcription factors structurally similar to the product of the *Drosophila forkhead* gene. Also known as "winged helix" factors because of their three-dimensional structure. In mice and humans, the family has multiple members. It is now systematically known as the Fox family.

GATA factors Family of transcription factors that bind to DNA on the nucleic acid sequence -G-A-T-A-.

mesoderm One of the three germ layers formed by the process of gastrulation. Mesodermal cells give rise to mesenchymal tissue and the muscle layers of the gastrointestinal tract.

sonic hedgehog One member of a family of signaling proteins originally described in *Drosophila*. Sonic and Indian hedgehog proteins are key regulators of gastrointestinal morphogenesis.

Gastrulation, during which the axes of the embryo are determined and formation of the gastrointestinal tract is initiated, is an essential early step in development of all multicellular organisms. The endoderm layer generated during gastrulation gives rise to the epithelial lining of the gastrointestinal tract. Initially, the endoderm forms a simple tube surrounded by mesoderm. Regionalization and development of specialized organs along the tube appear early in evolution, suggesting that the mechanisms regulating gut tube formation are likely to be very early evolutionary developments and are similar in most organisms. Current research suggests that the mechanisms governing these processes are indeed highly conserved throughout evolution. Therefore, data from model organisms are directly relevant to human development.

INTRODUCTION

There are three major developmental milestones in formation of the gastrointestinal tract. First is the initial specification of the endoderm. Second is formation and patterning of the gut tube, which establishes the anterior–posterior axis and the boundaries between different organs. Third is the initiation of formation of organs that are outgrowths of the gut tube, such as liver and pancreas. Experiments in model organisms have identified families of genes involved in endoderm specification that are highly conserved in evolution, whereas other genes appear to be specific to vertebrate gut development. Conservation of form and function is supported by experiments in which mouse genes substitute for the homologous genes in frogs and fruit flies. Morphogenesis and functional development have been well described in other texts and reviews. The focus here is on current understanding of the molecular basis of the major milestones in gastrointestinal development and the roles of the best understood genes.

SPECIFICATION OF THE ENDODERM

Specification of the endoderm can be traced to the earliest stages of embryo formation. Classical experiments demonstrated that explants of chick embryos prior to gastrulation were capable of gastrointestinal development, indicating that their fate had already been specified. Evidence is accumulating in support of the hypothesis that the original patterning of the endoderm is cell autonomous, but that full development of the organs requires a reciprocal interaction between the endoderm and mesoderm. Six gene families that act to specify endoderm have now been identified in a number of model organisms. One class of genes encodes transcription factors that directly activate target genes. A second class encodes signaling molecules that mediate cellular interactions. At least some of the transcription factors involved in specification of the endoderm continue to be expressed in the gastrointestinal (GI) tract throughout development, such as the forkhead-related factors. Signaling pathways, such as hedgehog/bone morphogenetic protein (BMP), act at different times and in different locations to regulate GI development.

From its earliest stages, the endoderm is in close apposition to mesoderm throughout the GI tract. Tissue

 Copyright 2004, Elsevier (USA). All rights reserved.

recombination experiments have shown that patterning of the endoderm and its differentiation into separate organs result from signaling between the mesoderm and the endoderm. The earliest identified step in anterior/posterior patterning in mouse endoderm requires signaling from mesoderm to endoderm by fibroblast growth factor-4 (FGF-4). Other members of the FGF family and their receptors are critical in liver development. Three other important gene families mediating mesoderm/endoderm signaling are sonic hedgehog, the BMPs, and the *hox* genes.

It remains unclear if a single "master gene" initiates the formation of the endoderm, setting in motion the process of gastrointestinal development. In some of the model systems, genes have been identified that appear to be both necessary and sufficient to specify endoderm. In others, genes have been identified that are necessary, but may not be sufficient.

Two GATA transcription factor genes are essential in specification of the cells that give rise to the intestinal epithelium of *Caenorhabditis elegans*, and a *Drosophila* GATA factor is encoded by the gene *serpent*, previously demonstrated to be required for differentiation of gut endoderm. Three members of the GATA family, initially discovered as key regulators of erythroid differentiation, are expressed in vertebrate intestine. Distinct functions for GATA-4, -5, and -6 in intestinal epithelial cell proliferation and differentiation have been suggested, but their role in early development remains unclear. In addition to the GATA factors, members of the forkhead-related (Fox) family and members of the wnt/Tcf signaling pathway are regulators of endoderm formation. In addition to these factors, members of the transforming growth factor-β (TGF-β) superfamily critical in the initiation of endoderm formation have been identified in vertebrates. One of the effector molecules in this pathway, Smad2, has also been shown to be critical for endoderm formation. The evidence indicates that elimination of the genes for these factors blocks endoderm formation, whereas ectopic expression induces formation of endoderm from cells that would not normally do so.

Many transcription factors initially identified as liver specific have key roles in the intestine. When analyzed in model systems, several of these transcription factors have been found to be expressed in patterns suggesting that they may also regulate intestinal development. For example, hepatic nuclear factor 3β (HNF3β; now designated FoxA2) has been shown to be critical for the earliest differentiation of the gastrointestinal tract. Furthermore, it continues to be expressed in the adult progeny of the endoderm. Homozygous null mutants of HNF3β do not form a normal primitive streak, which gives rise to the gut tube and other structures. HNF3β is critical to formation of the foregut and midgut, but not the hindgut. Multiple members of this family have been identified, some of which display intestine-enriched or intestine-specific expression. One of the family members, normally expressed in the intestinal mesoderm, is a critical mediator of epithelial/mesenchymal interactions. Its elimination leads to abnormal epithelial cell proliferation and aberrant intestinal development. Thus, it appears likely that during intestinal development, multiple members of the HNF3β/forkhead family interact in a complex mechanism that remains to be elucidated.

Several mouse homeobox genes related to *Drosophila caudal* are expressed specifically in the intestine. One, *Cdx-1*, is restricted to the adult intestine but is expressed widely in the developing embryo. Another caudal-related gene, *Cdx-2*, is expressed in visceral endoderm of the early embryo but is restricted to the intestine at later stages. Forced expression of *Cdx-2* will induce differentiation in an intestinal cell line that does not normally differentiate. *Cdx-2* is clearly a critical intestine-specific differentiation factor, but its role in early development of the intestine remains unclear.

FORMATION OF THE GUT TUBE

Formation of the gut tube follows specification of the endoderm. In frogs, completion of gastrulation produces the primitive gut tube. In birds and mammals, the gut tube is formed from a layer of endoderm by a process of folding that begins at the anterior and posterior ends of the embryo. Reciprocal signaling between endoderm and mesoderm continue to be critical to the developmental process.

A key mechanism that has emerged as a mediator of endoderm/mesoderm interactions in the organization of the gastrointestinal tract involves the sonic hedgehog (Shh) and Indian hedgehog (Ihh) signaling proteins. Both Shh and Ihh play critical roles in anterior/posterior patterning and concentric patterning of the developing GI tract, at least in part through their role in development of muscle from the mesoderm. One target of this signaling pathway is a second family of signaling molecules, the bone morphogenetic proteins, members of the TGF-β superfamily.

Shh is first detectable in the primitive endoderm of the embryo, later in the endoderm of the anterior and posterior intestinal portals, and subsequently throughout the gut endoderm and in the adult crypt region. BMP-4 is expressed in the mesoderm adjacent to the intestinal portals and can be induced ectopically in the visceral mesoderm by Shh protein. The endoderm

of the intestinal portals is the source of Shh; the portal regions can act as polarizing centers if transplanted. Shh also induces the expression of *hox* genes. Knockout of a forkhead family member producing abnormal epithelial cell proliferation later in development likely has its effect through reduced expression of BMP-2 and BMP-4. Null mice display foregut anomalies such as esophageal atresia and tracheoesophageal fistula and hindgut anomalies such as persistent cloaca, indicating that Shh is a critical regulator of both foregut and hindgut development.

ORGAN DEVELOPMENT

Patterning

In *Drosophila*, the large family of homeotic genes is expressed in the body in a precise anterior to posterior order. The homeotic genes encode transcription factors, incorporating a conserved homeobox sequence, that regulate segmentation and pattern formation. Vertebrates have homologous *hox* genes that play important roles in the formation of distinctly delineated regions of the brain and skeleton. The four copies of the set of vertebrate genes, *hoxa*, *hoxb*, *hoxc*, and *hoxd*, form groups of paralogues, e.g., *hoxa-1*, *hoxb-1*, and *hoxd-1*. Within each group, the genes are expressed in the embryo in an anterior to posterior sequence of regions with overlapping boundaries, e.g., *hoxa-1* in the occipital vertebrae to *hoxa-11* in the caudal vertebrae.

A detailed study of the developing chick hindgut has demonstrated a correlation between the boundaries of expression of *hoxa-9*, *hoxa-10*, *hoxa-11*, and *hoxa-13* in the mesoderm and the location of morphologic boundaries. Regional differences in expression of homeobox genes in the developing mouse intestine have also been demonstrated. Interference with the expression of specific *hox* genes produces organ-specific gastrointestinal defects. Disruption of *hoxc-4* gives rise to esophageal obstruction due to abnormal epithelial cell proliferation and abnormal muscle development. Alteration of the expression pattern of *hox 3.1* (now *hoxc-8*) to a more anterior location causes distorted development of the gastric epithelium. Mice with disrupted *hoxd-12* and *hoxd-13* genes display defects in formation of the anal musculature. Expression of the human homologues of a number of homeobox genes has also been shown to be region specific. These data indicate that the *hox* genes are critical early regulators of proximal-to-distal, organ-specific patterning in gastrointestinal development. The *caudal* genes are members of a divergent homeobox gene family and regulate the anterior margins of *hox* gene expression as well as having GI-specific roles.

Regional Specification

Organs such as the stomach are first identifiable by thickening in the mesodermal layer. Early in the process of patterning, BMP-4 is expressed throughout the mesoderm. Sonic hedgehog is expressed in the endoderm and is an upstream regulator of BMP-4. The patterning of BMP-4 expression in the mesoderm regulates growth of the stomach mesoderm and determines the sidedness of the stomach. Location of the pyloric sphincter is dependent on the interaction of BMP-4 expression and inhibitors of that expression. Patterning of the concentric muscle layer structure is dependent on Shh signaling that induces formation of lamina propria and submucosa, while inhibiting smooth muscle and enteric neuron development near the endoderm.

Development of Organs from Outgrowths

Liver

The liver diverticulum emerges from the most caudal portion of the foregut just distal to the stomach. It is first detectable as a thickening in the endoderm of the ventral duodenum. Hepatogenesis is initiated through an instructive induction of ventral foregut endoderm by cardiac mesoderm. A series of elegant experiments have identified a number of signaling pathways involved in the complex process of development of the liver. The immediate signal is provided by cardiac mesoderm fibroblast growth factors that bind to specific receptors in the endoderm. The appearance of mRNA for the liver-specific protein albumin in endodermal cells of the liver diverticulum is one of the earliest indications of hepatocyte induction. Endothelial precursor cells provide another critical factor for hepatogenesis. After formation of the liver bud, hepatocyte growth factor (HGF) is required for continued hepatocyte proliferation. The hepatic diverticulum grows into the septum transversum and gives rise to the liver cords, which become the hepatocytes. During this process, a combination of signals from the cells of the septum transversum, including BMP, is necessary for liver development.

Pancreas

Development of the pancreas has provided one of the classic examples of epithelial–mesenchymal interactions. Previous investigations have shown that growth and differentiation of the pancreas requires the presence of mesenchyme, although both endocrine and exocrine cells develop from the foregut endoderm. Analysis of the development of separated endoderm and mesenchyme under different conditions indicates that the "default pathway" of pancreatic differentiation leads

to endocrine cells, whereas combinations of extracellular matrix and mesenchymal factors are required for complete organogenesis.

The dorsal pancreatic bud arises in an area where Shh expression is repressed by factors from the notochord. One of the earliest signs of pancreas development is expression of the *pdx-1* gene in cells of the pancreatic bud. This gene is a homeobox gene, related to the *Drosophila* gene *antennapedia*. The encoded protein has been found to be expressed in the epithelium of the duodenum immediately surrounding the pancreatic buds, as well as in the epithelium of the buds. Examination of an initial *pdx-1* knockout mouse indicates that, although development of the rest of the gastrointestinal tract and the rest of the animal is normal, the pancreas does not develop. A second study by another group of researchers, who independently made a *pdx-1* null mouse, found that the dorsal pancreas bud does form, but its development is arrested. The defect due to the *pdx* knockout is restricted to the epithelium, as indicated by the maintenance of normal developmental potential by the mesenchymal cells. In addition, the most proximal part of the duodenum in the null mice is abnormal, forming a vesicle-like structure lined with cuboidal epithelium, rather than villi lined by columnar cells, indicating that *pdx-1* influences the differentiation of cells in an area larger than that giving rise to the pancreas, consistent with the earlier delineated domain of expression. A case of human congenital pancreatic agenesis has been demonstrated to result from a single nucleotide deletion in the human *pdx-1* gene.

CONCLUSION

Key regulators of gastrointestinal development have been identified. Some of the genes critical in epithelial/mesenchymal interaction, long known to be a fundamental developmental process, are now known. Analysis of the expression pattern of the *hox* genes suggests that they act to pattern the gastrointestinal tract. The hedgehog proteins mediate several aspects of early development, but inhibition experiments suggest that after organ formation, their role is largely complete. Targeted disruption of several genes that regulate intestinal growth indicate that bone morphogenetic protein secretion has a key developmental role in cell proliferation and villus morphology. Most of the signaling pathways identified are short range. With the exception of epidermal growth factor (EGF), there is little compelling evidence for a role of any circulating or luminal growth factor in the development of the intestine.

Microarray analysis of gene expression profiles indicates that the organs of the adult gastrointestinal tract display distinct patterns. Furthermore, the analysis identifies common regulatory elements, including those for HNF1 and GATA factors, in the 5′ flanking sequences of groups of genes expressed in specific regions, suggesting organ-specific regulation. A combination of work on critical individual genes with examination of cell-and organ-specific developmental gene expression profiles should provide a deeper understanding of the regulation of gastrointestinal development.

Diabetes Mellitus

MANISHA CHANDALIA AND NICOLA ABATE
University of Texas Southwestern Medical Center, Dallas

diabetes ketoacidosis A syndrome consisting of hyperglycemia, ketosis, and acidemia (an arterial pH <7.3, a bicarbonate value <15 mEq/liter, and a blood glucose level >250 mg/dl with a variable degree of ketonemia and ketonuria).

hyperglycemia The state of having a higher than normal plasma glucose concentration. Normal values of plasma glucose differ depending on the whether the subject is in the fasting or fed state.

hypoglycemia The state in which plasma glucose concentration is decreased sufficiently to produce symptoms, which improve with restoration of normal plasma glucose.

insulin resistance Inability of insulin to lower plasma glucose effectively, with resultant higher plasma insulin levels.

insulin secretagogues Drugs that improve insulin secretion: sulfonylurea and metiglinides.

insulin sensitizers Drugs that improve insulin action: biguanides (metformin) and thiazolidinediones (rosiglitazone and pioglitazone).

nonketotic hyperosmolar state A syndrome associated with little or no ketoacid accumulation in blood, hyperglycemia (plasma glucose often exceeding 1000 mg/dl), increased plasma osmolality (as high as 400 mosm/kg), and neurological abnormality.

Diabetes mellitus is a complex metabolic disorder characterized by hyperglycemia and long-term complications affecting the heart, kidney, eyes, and other organs including the gastrointestinal tract. The main metabolic feature of diabetes mellitus consists of a relative or absolute impairment of insulin secretion, along with varying degrees of peripheral resistance to the biological activity of insulin. This is a pathophysiologically heterogeneous group of disorders, with the common denominator being hyperglycemia. The symptoms, manifestations, and management options vary depending on the underlying pathogenesis and type of disease.

CLASSIFICATION

The American Diabetes Association (ADA) revised its classification of diabetes mellitus in 1997 according to etiologic differences and to move away from descriptions based upon age at onset or type of treatment (Table I).

In its classic form, two common types of diabetes are recognized: type 1 (formerly called insulin-dependent diabetes mellitus) and type 2 (formerly called non-insulin-dependent diabetes mellitus). The majority of patients with type 1 diabetes have autoimmune destruction of the pancreatic beta cells as the underlying cause, have an absolute requirement for insulin therapy, and will develop diabetic ketoacidosis if not given insulin. Type 2 diabetes, on the other hand, is characterized by association with obesity and absence of an absolute dependence on insulin. In addition to these two primary types of diabetes and gestational diabetes, a final group includes a large number of conditions with either secondary forms of diabetes or those associated with specific known gene mutations and is classified as diabetes of other types.

DIAGNOSIS

The diagnosis of diabetes mellitus is easy to establish when a patient presents with classic symptoms of hyperglycemia (polydipsia, polyuria, weight loss, visual blurring) and has a fasting blood glucose concentration of at least 126 mg/dl (7.0 mmol/liter) or a random value of at least 200 mg/dl (11.1 mmol/liter), confirmed on another occasion. The American Diabetes Association revised the criteria for diagnosis of diabetes in 1997 (Table II). The new diagnostic criteria strongly suggest that the diagnosis of diabetes be made on the basis of fasting blood glucose only. The blood glucose criteria for the diagnosis of gestational diabetes are lower and include values 1, 2, and 3 h after 100 g of oral glucose (Table II). The use of glycosylated hemoglobin values for screening and identification of diabetes is also considered by many investigators. Though a sensitive means of assessing glycemic control in patients with diabetes, since the assays for glycosylated hemoglobin are not yet standardized, the diagnosis of diabetes mellitus should not be made on the basis of glycosylated hemoglobin values alone. One other caution is that the values mentioned in Table II are for venous plasma. Capillary whole-blood values normally measured by patients at home are lower in the basal state and are considered abnormal if they exceed 120 mg/dl.

PATHOGENESIS

Type 1 Diabetes

Type 1 diabetes mellitus results from autoimmune destruction of the insulin-producing beta cells in the islets of Langerhans in the pancreas. This process occurs in genetically susceptible subjects, is triggered by one or more environmental agents, and usually progresses over many months or years. Genes in both the major histocompatibility complex and elsewhere in the genome appear to be involved. The lifelong risk of type 1 diabetes is markedly increased in close relatives of patients with type 1 diabetes, averaging approximately 6% in offspring, 5% in siblings, and 30% in identical twins (versus 0.4% in subjects with no family history). The major susceptibility gene for type 1 diabetes is in the human leukocyte antigen (HLA) region on chromosome 6p and appears to account for approximately 40% of familial clustering of type 1 diabetes. In particular, more than 90% of patients with type 1 diabetes carry HLA-DR3,DQB1*0201 or -DR4,DQB1*0302 and approximately 30% carry both haplotypes, which confers the greatest susceptibility. On the other hand, the HLA allele DQB1*0602 confers protection against the development of type 1 diabetes.

The lack of 100% concordance of type 1 diabetes in monozygotic twins underscores the importance of environmental factors, such as viruses, as triggers in the development of the disease. One such virus is congenital rubella. Other viral infections (coxsackie virus, Epstein-Barr virus, mumps, or cytomegalovirus) and other exposures, such as to cow's milk protein and certain drugs, have been suggested as triggers but no conclusive data are available at this time.

Cytoplasmic islet cell antibodies are identified by immunofluorescence in 70 to 80% of patients with newly diagnosed type 1 diabetes and in prediabetic subjects. The presence of islet cell antibodies can precede the development of overt diabetes by more than a decade and can be used to identify persons at high risk. Several autoantigens have been recognized within the pancreatic beta cells that may play important roles in the initiation or progression of autoimmune islet injury. One of the first and most important autoantigens against which antibodies are detected is the enzyme glutamic acid decarboxylase (GAD) and antibodies to GAD are found in approximately 70% of patients with type 1 diabetes at the time of diagnosis.

Type 2 Diabetes

Type 2 diabetes is the most prevalent endocrine disease. It is estimated to affect more than 15 million

TABLE II Diagnosis of Diabetes Mellitus

Criteria for diagnosis of diabetes mellitus
Classic symptoms of diabetes such as polyuria, polydipsia, ketonuria, and rapid weight loss with random plasma glucose > 200 mg/dl
or
Fasting plasma glucose concentration > 126 mg/dl on more than one occasion
or
Glucose concentration at 2 h of > 200 mg/dl during an oral glucose tolerance test
Criteria for diagnosis of gestational diabetes mellitus
Two or more of the following plasma glucose concentrations after fasting and a 100 g oral glucose tolerance test:
Fasting serum glucose concentration > 95 mg/dl (5.3 mmol/liter)
1 h serum glucose concentration > 180 mg/dl (10 mmol/liter)
2 h serum glucose concentration > 155 mg/dl (8.6 mmol/liter)
3 h serum glucose concentration > 140 mg/dl (7.8 mmol/liter)

people in the United States, one-third of whom are undiagnosed. Prevalence is higher among Hispanics, Native Americans, African Americans, and Asian Indians, reaching as high as 50% among adult Pima Indians living in the United States. Development of type 2 diabetes is strongly influenced by genetic factors and environmental factors including obesity and decreased physical activity. Family history of diabetes increases the risk for development of this disease.

Type 2 diabetes mellitus is characterized by hyperglycemia, insulin resistance, and relative impairment in insulin secretion. Type 2 diabetes is often accompanied by other conditions, including hypertension, high serum triglyceride concentrations, and low serum high-density lipoprotein (HDL) cholesterol concentrations, that, like type 2 diabetes, can increase cardiovascular risk. This constellation of clinical conditions is referred to as "metabolic syndrome" and has insulin resistance as the main common pathogenetic factor. Although the mechanisms leading to insulin resistance are still a matter of investigation, evidence that this abnormality is the consequence of an interaction between genetic and environmental factors is accumulating. Obesity, particularly truncal obesity, and lack of physical activity have been shown to promote insulin resistance and, through this mechanism, are probably the most powerful risk factors for type 2 diabetes. However, the degree of fat accumulation and lack of physical activity necessary to induce insulin resistance seem to be modulated by genetic factors. This is evident from studies in families and in ethnic groups, such as the Asian Indians, who develop severe insulin resistance even with mild accumulation of total body fat. Once insulin resistance develops, the development of diabetes is determined by the degree of beta-cell compensation for the defective biological activity of insulin. If adequate hyperinsulinemia is maintained, the insulin-resistant individual may not develop hyperglycemia and the clinical picture of the metabolic syndrome will manifest without diabetes. On the other hand, the presence of a genetic predisposition to beta-cell decompensation seems to play a role in determining the onset of hyperglycemia and the complete clinical onset of type 2 diabetes. Again, acquired factors, i.e., obesity and insulin resistance, interact with genetic predisposition to determine beta-cell decompensation, a necessary step in the pathophysiology of type 2 diabetes. Both insulin resistance and beta-cell decompensation are needed for the development of this disease. The relative contribution of these two mechanisms to the pathogenesis of type 2 diabetes may vary in different individuals. The results will be increased hepatic glucose production and decreased insulin-mediated glucose utilization in the skeletal muscle. This leads to progressively worsening hyperglycemia. The constellation of metabolic abnormalities that accompany hyperglycemia in type 2 diabetes, i.e., dyslipidemia, hypercoagulable state, and hypertension, are mainly related to insulin resistance and precede the onset of hyperglycemia. This explains the common rapid progression of atherosclerotic disease in these patients. Microvascular complications, on the other hand, are mainly determined by hyperglycemia with mechanisms similar to those in type 1 diabetic patients.

MANAGEMENT OF DIABETES

Diabetes is a chronic disease and the principles of therapy are twofold, maintaining euglycemia and preventing or delaying complications of diabetes. Diet, weight reduction, and exercise can all be used to improve glycemic control. Stress management training might also be useful, although its effect is modest. In type 1 diabetes, insulin is the mainstay of therapy and is essential for survival. However, in type 2 diabetes, various other modalities of treatment may be used as either monotherapy or combination therapy.

Nonpharmacological Therapy

This involves diet, exercise, and weight reduction/maintenance. Both type 1 and type 2 patients benefit from this and many patients with type 2 may be managed with lifestyle changes alone. The diet for a diabetic individual is to be planned depending on age, level of

physical activity, obesity, other complications such as hyperlipidemia or hypertension, and cultural acceptability. The general principle of dietary therapy in type 2 diabetic patients is a low-calorie, low-fat, and complex carbohydrate diet. The controversy in the field of diabetic diet is due to potential problems with each of the dietary constituents: too much carbohydrate might worsen hyperglycemia, too much fat might increase the already high risk of atherosclerosis, and too much protein might promote the development of diabetic nephropathy. The traditional recommendation is that 55 to 60% of total calories should be derived from carbohydrate and most of the dietary carbohydrate should be in the form of unrefined, high-fiber foods (up to 40 g/day) with only modest amounts of sucrose and other refined sugar. Insoluble fiber, such as that found in whole wheat bread and brown rice, has a major impact on gastrointestinal transit time and fecal bulk. There is, however, very little alteration in the rate of blood glucose increase after a meal. In comparison, soluble fiber, such as that contained in vegetables, fruit, and especially legumes, slows the postprandial rise in blood glucose, often leading to a reduction in insulin requirements. Twelve to 20% of total calories should be derived from proteins (approximately 0.8 g/kg/day in adults). Higher levels are required in growing children and pregnant or lactating women and lower levels may be beneficial in patients with diabetic nephropathy. Less than 30% of total calories should be derived from fat, most of which should be mono- or polyunsaturated. Saturated fats and cholesterol intake should be less than 10% of total calories and less than 300 mg/day, respectively. Some data have questioned these standard dietary recommendations in patients with type 2 diabetes. In particular, a diet slightly lower in carbohydrate and higher in monounsaturated fat may result in a better metabolic profile. Therefore, the ADA has also recommended a diet high in monounsaturated fat for type 2 diabetic patients as an alternative to a high-complex-carbohydrate diet.

Some form of regular exercise is likely to be beneficial in most patients with diabetes, even those with advanced, long-standing disease. However, for those over age 35 years who have had diabetes for more than 10 years, a complete physical examination and exercise stress test should be performed before an exercise program is begun. The exercise should be performed regularly (at least three times per week) and preferably at the same time in relation to meals and insulin injections in patients treated with insulin. The duration and intensity of exercise should be increased gradually as tolerated by the patient. The type of exercise may have to be modified depending on preexisting complications, such as hypertension or neuropathy.

Lifestyle modifications (diet and exercise) have recently been shown to prevent the onset of type 2 diabetes in subjects with impaired glucose tolerance. Lifestyle modification also has a significant preventive effect on cardiovascular mortality. Thus, a diet and exercise program should be actively recommended and reinforced in all diabetic management plans.

Pharmacological Therapy

Various classes of oral agents are available for the management of hyperglycemia in type 2 diabetic patients. These include sulfonylureas and meglitinides, which are insulin secretagogues, biguanides and thiazolidinediones, which are insulin sensitizers, α-glucosidase inhibitors, which act primarily in the gut, and insulin therapy. Long-term studies on the natural progression of type 2 diabetes show a gradual worsening of beta-cell function, eventually requiring insulin therapy in a majority of patients. However, depending on the degree of insulin resistance, many patients with type 2 diabetes may not achieve glycemic control with insulin alone. Thus, combination therapy either with insulin secretagogues and insulin sensitizers or with insulin and insulin sensitizers is recommended. One major side effect with all pharmacological therapy, except monotherapy with metformin, is hypoglycemia. The incidence of hypoglycemia was higher in major clinical trials with intensive therapy to achieve good glycemic control. Another side effect with all agents except metformin is weight gain, though it may be variable with different agents (more with thiazolidinedione than with other agents). Metformin is recommended as monotherapy or as combination therapy with sulfonylurea and thiazolidinedione as well as insulin. One major side effect of metformin is diarrhea, which may be severe enough to require discontinuation of therapy. Another infrequent but serious side effect is lactic acidosis. To avoid lactic acidosis, metformin is contraindicated in patients with renal failure, liver failure, severe congestive heart failure, and significant lung disease. Thiazolidinediones have liver abnormalities as one major adverse effect. It can involve mild elevation of transaminases to fulminant liver failure. Periodic routine monitoring is necessary when patients are first started on these agents and prompt discontinuation of therapy if serum transaminases increase to more than three times baseline is warranted to prevent severe hepatotoxicity.

No pharmacological agent except insulin is recommended in the treatment of type 1 diabetes. Usually a

combination of short-acting and long-acting insulin is given by multiple injections to mimic normal physiologic insulin secretion. The mode of delivery can be either multiple subcutaneous injections or continuous subcutaneous insulin infusion by a programmable pump. Patients generally monitor their capillary blood glucose and adjust the dose of insulin to achieve optimal glycemic control. The choice of insulin and mode of delivery depend on the degree of hyperglycemia, the patient's willingness to monitor blood glucose closely, and the competency and trainability of the patient.

COMPLICATIONS

Diabetes is a chronic disease with significant late complications of the kidneys, eyes, and heart developing over many years or decades after onset of hyperglycemia. The rate of onset and development of these complications is not only dependent upon glycemic control but also on other genetic and environmental factors. One important complication is diabetic nephropathy, which can be recognized clinically as persistent proteinuria, which subsequently progresses to end-stage renal failure. Though evidence points to genetic susceptibility as a determinant, uncontrolled diabetes (hyperglycemia) appears to be a necessary factor for the development of nephropathy. Since genetic markers to identify individuals at risk are not yet available, tight glycemic control and early intervention with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers in all patients with diabetes are a useful strategy in preventing and/or delaying the onset of nephropathy. Another serious late complication is retinopathy, a significant cause of blindness. Both type 1 and type 2 diabetes patients develop background retinopathy within the first 5 to 15 years of diabetes. These patients are then susceptible to develop proliferative retinopathy with risk of vision loss. The actual incidence of proliferative retinopathy is related to glycemic control. A large clinical trial demonstrated a substantial benefit of tight glycemic control in the primary prevention of diabetic retinopathy: at 9 years, the incidence of new retinopathy was 12% with intensive therapy versus 54% with conventional therapy. Another trial demonstrated a similar benefit of tight glycemic control in the prevention of retinopathy in type 2 diabetes. Furthermore, routine screening for retinopathy to detect early changes to prevent vision loss is also a very effective strategy. The benefit of intensive therapy to achieve tight glycemic control was also noted in diabetic neuropathy patients.

The most notable complication and cause of mortality in patients with type 2 diabetes is coronary heart disease. There are conflicting data on the importance of glycemic control on the development of macrovascular disease in patients with type 2 diabetes. In one large study on type 2 diabetes, it was noted that cardiovascular disease was associated with traditional cardiovascular risk factors (including hypertension, smoking, age, and serum total/HDL cholesterol ratio) and with the duration of diabetes and not associated with the degree of glycemic control. However, a subanalysis suggested that reducing the HbA1c value by 1% was associated with an 18% reduction in myocardial infarction and a 15% reduction in stroke. Therefore, vigorous cardiac risk reduction in patients with type 2 diabetes with optimal lipid and blood pressure control, lifestyle modification, cessation of smoking, treatment with aspirin and angiotensin-converting enzyme inhibitor or angiotensin receptor blocker agent is essential for prevention of coronary heart disease.

GASTROINTESTINAL COMPLICATIONS OF DIABETES

Diabetes mellitus can affect many organs in the gastrointestinal tract. Dysphagia, nausea, vomiting, diarrhea, constipation, and fecal incontinence are common complaints among diabetic patients, although some of these symptoms can be due to the side effects of pharmacological agents taken for treatment of diabetes. Differentiating causes of these symptoms can be difficult and should not be attributed to diabetes without proper evaluation for other possible causes.

Although the pathogenetic mechanisms causing diabetic gastrointestinal symptoms remains poorly understood, the most common explanation is that autonomic visceral neuropathy causes most of the symptoms. Patients with gastrointestinal (GI) complications very often have additional manifestations of autonomic neuropathy such as orthostatic hypotension, urinary bladder dysfunction, and impotence. Other mechanisms, such as hyperglycemia and electrolyte imbalance affecting nerve function, altered production of various gut hormones affecting motility, and diabetic microangiopathy, have also been suggested.

Esophagus

Esophageal motor dysfunction in diabetics has been extensively studied by techniques such as barium study, nuclear methods, and manometry. However, there is not a close correlation between results of these studies and

clinical symptoms. The most typical symptoms are heartburn, dysphagia, and chest pain. Diabetics with dysphagia should be completely evaluated to rule out other conditions, such as gastroesophageal reflux disease, benign or malignant stricture, or esophagitis. Patients with chest pain should be assessed for coronary artery disease.

Stomach

The most common gastric disorder of diabetes is gastroparesis, which is manifested by postprandial fullness, epigastric pain, nausea, vomiting, and anorexia. A complete evaluation to exclude gastric outlet obstruction, peptic ulcer disease, and side effects of pharmacological agents must be performed in all diabetic patients with complaints of gastroparesis. Barium studies in patients with diabetic gastroparesis usually show an elongated stomach with sluggish, ineffective, or absent peristalsis. Because of impaired gastric emptying, these patients are prone to the formation of bezoars. Due to fluctuation in absorption from the small intestine, glucose control becomes erratic in patients with diabetic gastroparesis and frequent small meals should be recommended to improve glycemic control. Pharmacological prokinetic agents are used for treatment. If a patient fails prokinetic therapy (e.g., with metoclopramide) and anti-emetic therapy, other options are percutaneous endoscopic gastrostomy and jejunostomy that allows that allows gastric decompression and adequate nutritional support. Gastric pacing is another option that has been shown to improve gastric emptying in some patients.

Small Intestine

The incidence of diarrhea in diabetic patients is ~20%. Usually the diarrhea is chronic and intermittent, alternating with either normal bowel movement or constipation. Despite chronicity of the symptoms, weight loss is uncommon. Etiology of diarrhea is multifactorial, including autonomic neuropathy, bacterial overgrowth, and pancreatic insufficiency. Evaluation of the diabetic patient with diarrhea involves ruling out other causes including celiac disease (see below) and infection. Stool output should be quantified and a 72 h fecal fat measurement should be performed to assess for exocrine pancreatic insufficiency and sprue. A large number of diabetic patients fall in the category of idiopathic diarrhea and may benefit from a trial of conventional anti-diarrheal agents, clonidine, or psyllium.

Celiac Disease

The incidence of celiac disease is reported to be greater in diabetics than in the general population. The histocompatible antigens HLA-DR3 and HLA-DQB1*0201 have been linked to both celiac disease and diabetes, suggesting a genetic predisposition to both conditions. The clinical manifestation of celiac disease is similar to idiopathic diabetic diarrhea; however, it may present before onset of diabetes and is usually is accompanied by steatorrhea. A biopsy of the small bowel showing flattened villi and increased cellularity in the lamina propria establishes the diagnosis. Serum immunoglobulin A (IgA) anti-endomysial and IgA anti-gliadin antibodies have 80 to 100% sensitivity and specificity for celiac disease and can be used for diagnosis. A gluten-free diet improves both the symptoms and histology. With successful therapy, titers of these antibodies decrease or even disappear and thus can be used for monitoring patients with celiac disease.

Large Intestine

The most common GI complaint in diabetics is constipation (20 to 60%). The pathogenesis of constipation is poorly understood. Neurogenic dysfunction is considered to be an important factor in diabetic constipation. The evaluation of constipation should be based on age, severity of symptoms, and family history, thus ruling out other causes including colon cancer in high-risk candidates. Dietary fiber, stool softeners, and occasionally laxatives are used for the treatment of constipation in diabetics.

Fecal incontinence is another symptom that usually is associated with diarrhea and autonomic neuropathy. Therapy of fecal incontinent is difficult; however, most patients show improvement with control of diarrhea. If it fails, biofeedback and sphincter control improvement techniques can be used but usually are not very successful.

Gallbladder Disease

Diabetic patients have twice the incidence of gallstones compared to the general population. However, obesity and dyslipidemia are confounding factors and when corrected for these factors, diabetics do not seem to have a greater incidence of cholelithiasis than the general population. Several older studies had reported that when gallstones become symptomatic, morbidity and mortality is higher in diabetic patients than in the general population due to infectious complications. However, it is not clear whether diabetics with

asymptomatic gallstones are at a greater risk of becoming symptomatic than the general population. At present, diabetic patients with cholecystitis or biliary colic should be advised to undergo cholecystectomy as soon as possible. Asymptomatic gallstones in diabetics should be followed rather than treated by prophylactic cholecystectomy.

Liver Disease

The incidence of liver dysfunction in diabetic patients is high. It may range from a mild elevation of serum transaminases to (rarely) liver failure. Viral hepatitis is associated with diabetes, especially chronic hepatitis C. Oral hypoglycemic agents such as sulfonylurea and thiazolidinediones may cause abnormality of liver functions in diabetics. Thiazolidinediones may cause liver failure. Routine monitoring of serum transaminase levels is recommended for patients taking a thiazolidinedione. Stopping the agent usually leads to clinical and biological resolution.

One condition that is seen frequently in diabetic patients is hepatic steatosis. Fat accumulation in the liver occurs in up to 50% of patients with diabetes. Obesity is associated with hepatic steatosis as well. Intake of excessive dietary fat and carbohydrate leads to high levels of fatty acids that are stored in hepatocytes. Accumulation of fatty acids may provide a source of oxidative stress and lead from steatosis to steatohepatitis to cirrhosis. Only a small percentage of patients progress from steatosis to steatohepatitis and eventually to cirrhosis. This whole spectrum of conditions is now referred to as nonalchoholic fatty liver disease. Diagnosis of nonalchoholic fatty liver disease requires exclusion of alcohol abuse, absence of other causes such as viral infections, autoimmune diseases, drugs, and toxins. Liver biopsy is the best test for confirming the diagnosis; however, it may not be required in many straightforward cases. Management of nonalcoholic fatty liver disease is gradual weight loss and glycemic and lipid control. Patients should be advised to keep away from hepatotoxic agents such as alcohol.

Diabetic Gastroparesis

LAWRENCE R. SCHILLER
Baylor University Medical Center and University of Texas Southwestern Medical Center, Dallas

gastroparesis Chronic condition characterized by delayed gastric emptying, resulting in gastric retention of ingested material; may be idiopathic or due to drugs or an underlying condition, such as diabetes mellitus.
prokinetic drug Agent that accelerates transit through one or more segments of the gastrointestinal tract.

Diabetes mellitus is sometimes complicated by dysfunction of the stomach, characterized by slow gastric emptying that produces gastric retention and chronic nausea and vomiting. This condition was first reported in detail at the Mayo Clinic in 1945 by R. W. Rundles, who attributed the condition to neuropathy. The term "gastroparesis diabeticorum" was coined in 1958 by P. Kassander and the condition has been called diabetic gastroparesis since that time. Several hypotheses to account for this problem have been elaborated and therapies to manage the condition have been developed.

CLINICAL PRESENTATION

The initial description of diabetic gastroparesis emphasized the association of nausea and vomiting with long-standing, poorly controlled diabetes complicated by diabetic neuropathy, preponderantly in young men. It is clear now that patients with diabetes may have delayed gastric emptying and thus delayed glucose absorption without nausea or vomiting, and that a substantial number of women also are affected. Symptoms, if present, are chronic and variable, with exacerbations and remissions. Gastroparesis may be recognized unexpectedly during the investigation of dyspepsia by the radiographic or endoscopic finding of gastric retention of food.

PATHOPHYSIOLOGY

Little progress was made in understanding diabetic gastroparesis until the 1970s, when physicians gained a deeper appreciation of gastric physiology and accurate radioisotope gastric emptying studies became available. The most marked abnormality in patients with gastroparesis is impaired emptying of solids; liquid emptying is relatively well preserved. There is evidence of vagal dysfunction that may contribute to these findings in many patients with diabetic gastroparesis, thus confirming Rundles' original idea of the pathogenesis of gastroparesis. Loss of the vagally mediated interdigestive migrating motor complex appears to be critical. Recent studies have emphasized the key role that hyperglycemia plays in triggering symptoms and additional problems of gastric accommodation and pyloric function in patients with diabetes.

DIAGNOSIS

Diagnosis is based on recognition of clinical symptoms, including nausea and vomiting typically hours after meals, dyspepsia, early satiety, bloating, or weight loss in a diabetic patient with poor control of blood sugar. Most patients have a long history of diabetes (>10 years), but this is not always the case. Findings of diabetic peripheral and autonomic neuropathy, such as numbness or pain in the feet, abnormal sweating, Marcus–Gunn pupils, diarrhea or constipation, and fecal incontinence, typically are present. An abnormal radioisotope gastric emptying study showing slow emptying of solids over 4 hours can confirm the diagnosis.

MANAGEMENT

Treatment consists of efforts to control hyperglycemia, because maintenance of blood sugar levels <200 mg% is associated with reduced symptoms. "Prokinetic" drugs, such as metoclopramide, may reduce symptoms, but do not always speed gastric emptying. Erythromycin given intravenously before meals is the most effective available agent for speeding gastric emptying in diabetics with gastroparesis. This drug is a motilin-receptor agonist and induces increased propulsive activity in the stomach and upper intestine. Oral erythromycin has less consistent efficacy. Nonantibiotic macrolide motilin-receptor agonists are under development. Patients who are not responsive to drugs can be outfitted with

a gastrostomy tube for gastric drainage and a jejunostomy tube for feeding. Innovative treatments for diabetic gastroparesis include injection of botulinum toxin into the prepyloric antrum, gastric electrical stimulation, and pancreatic or islet cell transplantation. Initial reports suggest that botulinum toxin injection and gastric electrical stimulation may reduce symptoms, but gastric emptying may not be improved. Reversal of diabetes with successful pancreatic or islet cell transplantation can cure this condition.

apoptosis A mechanism of cell death that is controlled by specific metabolic cell death pathways and that results in fragmentation and condensation of the cell nucleus, without significant inflammation in the surrounding tissue.

autonomic Pertaining to the internal systems in the body (cardiovascular, pulmonary, gastrointestinal) that receive innervation that is not under voluntary control.

diabetic neuropathy Short-term and long-term nerve dysfunction in diabetes characterized by generalized slowing of conduction and increased threshold for excitation in peripheral and autonomic nerves.

gastrointestinal motility The process of contraction of the gastrointestinal wall that results in movement of food and secretions along the length of the gastrointestinal tract.

gastroparesis Delayed emptying of the stomach following a meal, sometimes associated with accumulation of nondigestible fibers and debris in the stomach.

neurodegenerative disease Slowly progressive disease in the central or peripheral nervous system resulting from neuronal damage and/or neuronal death.

Diabetic neuropathy encompasses a variety of nervous system impairments that occur in the setting of diabetes. Neuropathy can develop early in both human and animal models of this disease. The sensory nervous system is most often affected in both type I and type II diabetes and much of the research into the mechanisms underlying diabetic neuropathy has focused on sensory impairment. There is evidence that similar physiologic problems may underlie autonomic neuropathy. Several metabolic pathways have been implicated in the pathogenesis of diabetic neuropathy, some of which likely interact via common signal molecules. Hyperglycemia is a central and critical component of the pathogenesis of sensory and autonomic neuropathy. The intensity and extent of the functional and anatomical abnormalities of diabetic neuropathy parallel the degree and duration of hyperglycemia. Intensive treatment with insulin in the Diabetes Control and Complications Trial decreased clinical neuropathy by 60%, whereas trials of other agents, such as aldose reductase, were far less effective.

INTRODUCTION

Insulin treatment has a beneficial effect on both sensory and autonomic neuropathy. The most common manifestations of autonomic neuropathy are hemodynamic effects, such as impaired control of blood pressure and heart rate, and gastrointestinal symptoms. Autonomic

apoptosis A mechanism of cell death that is controlled by specific metabolic cell death pathways and that results in fragmentation and condensation of the cell nucleus, without significant inflammation in the surrounding tissue.

autonomic Pertaining to the internal systems in the body (cardiovascular, pulmonary, gastrointestinal) that receive innervation that is not under voluntary control.

diabetic neuropathy Short-term and long-term nerve dysfunction in diabetes characterized by generalized slowing of conduction and increased threshold for excitation in peripheral and autonomic nerves.

gastrointestinal motility The process of contraction of the gastrointestinal wall that results in movement of food and secretions along the length of the gastrointestinal tract.

gastroparesis Delayed emptying of the stomach following a meal, sometimes associated with accumulation of nondigestible fibers and debris in the stomach.

neurodegenerative disease Slowly progressive disease in the central or peripheral nervous system resulting from neuronal damage and/or neuronal death.

Diabetic neuropathy encompasses a variety of nervous system impairments that occur in the setting of diabetes. Neuropathy can develop early in both human and animal models of this disease. The sensory nervous system is most often affected in both type I and type II diabetes and much of the research into the mechanisms underlying diabetic neuropathy has focused on sensory impairment. There is evidence that similar physiologic problems may underlie autonomic neuropathy. Several metabolic pathways have been implicated in the pathogenesis of diabetic neuropathy, some of which likely interact via common signal molecules. Hyperglycemia is a central and critical component of the pathogenesis of sensory and autonomic neuropathy. The intensity and extent of the functional and anatomical abnormalities of diabetic neuropathy parallel the degree and duration of hyperglycemia. Intensive treatment with insulin in the Diabetes Control and Complications Trial decreased clinical neuropathy by 60%, whereas trials of other agents, such as aldose reductase, were far less effective.

INTRODUCTION

Insulin treatment has a beneficial effect on both sensory and autonomic neuropathy. The most common manifestations of autonomic neuropathy are hemodynamic effects, such as impaired control of blood pressure and heart rate, and gastrointestinal symptoms. Autonomic

neuropathy is a significant underlying cause of gastroparesis and colonic dysmotility in diabetic patients. Gastroparesis in diabetes has been demonstrated to be due to a combination of reversible changes related to hyperglycemia and metabolic products of glucose and to irreversible neuronal damage and loss. Noninvasive studies of gastric electromyographic function in normal human subjects indicate that acute hyperglycemia can precipitate significant dysmotility in the stomach, accompanied by subjective feelings of nausea and distension. There is a synergy between hyperglycemia and gastrointestinal function as gastroparesis can, in turn, worsen glycemic control. This is particularly problematic in insulin-dependent individuals, as the time course of their insulin administration may be poorly correlated with delivery of nutrients to the small intestine. For these reasons, aggressive control of glucose is beneficial in treating diabetic gastroparesis. Colonic dysmotility is also common in diabetes. Both constipation and diarrhea can occur and are often refractory to pro-kinetic agents, due to the combination of neuronal loss and myopathic changes in the gastrointestinal muscle. In addition to glycemic control, a bowel regimen including stimulant laxatives and enemas may be required for refractory constipation. Diabetic diarrhea is often socially debilitating, but can be controlled with the judicious use of anti-diarrheal medications. Diabetes also impairs pancreatic function. In addition to the primary effects of diabetes on pancreatic beta-cell survival, pancreatic exocrine secretion appears to be diminished in patients with documented autonomic neuropathy involving the parasympathetic system.

DIABETIC NEUROPATHY IS A NEURODEGENERATIVE PROCESS

Studies of neuron survival, function, and gene expression suggest that diabetes more closely mirrors degenerative neuronal disease, rather than an acute injury model, such as axotomy. Slow nerve conduction in sensory and motor neurons is observed within 2–4 months following the onset of diabetes in the streptozotocin-induced and BioBred/Wistar spontaneous rat models of diabetes. At this early stage, sensory neurons do not demonstrate detectable alterations in their size, number, or expression of mRNA for a variety of signal molecules involved in neuro-transmission and survival [CGRP (α and β), substance P, vasoactive intestinal peptide, galanin, somatostatin, heat shock protein 27, c-jun, SNAP 25, p75, TrkA, TrkB, TrkC]. This observation is in sharp contrast to the rapid up-regulation of similar signal pathways in sensory and motor neurons subjected to axotomy or other injuries. One issue that needs to be addressed in future studies is the effect of age on the progression and severity of neuropathy. Most of the data obtained from animal models of diabetes (whether chemical or spontaneous) have utilized youthful animals. Retrograde labeling of extrinsic and intrinsic innervation of the gastrointestinal tract in the Fisher 344 rat demonstrates significant neuronal loss, which increases in severity from proximal to distal gut and progresses linearly with increasing age. There appears to be a trophic effect of vagal afferent innervation, although the mechanism by which this occurs remains to be determined.

METABOLIC DERANGEMENTS

Significant alterations in metabolic pathways occur in both sensory and autonomic diabetic neuropathies. Abnormalities that occur early in the course of diabetes include increased production of sorbital by aldose reductase, increased formation of glycosylation end products, decreased production of myoinositol, and impaired regulation of cellular calcium. Increased calcium influx through voltage-activated membrane calcium channels in diabetic neurons results in excessive cytosolic calcium responses to a variety of stimuli. Diabetic neurons release more calcium from cytosolic pools and demonstrate impaired ability to re-sequester calcium, compared to nondiabetic controls. Similar abnormalities have been observed in neurons from normal animals subjected to hyperglycemia, suggesting that impaired calcium regulation is an early and potentially reversible metabolic derangement in diabetes. A modest improvement in peripheral nerve conduction has been demonstrated in human studies utilizing L-type calcium channel antagonists; however, the effect is likely limited by the fact that L-type currents account for only 20–30% of the total calcium current in sensory neurons. Blockade of the predominant N-type channel by ω-conotoxin is impractical, due to toxicity. Activation of protein kinase C (PKC) isoforms, particularly PKC α and PKC βII, has been implicated in the pathogenesis of diabetic sensory and autonomic neuropathy and retinopathy. Trials of PKC inhibitors, such as WAY151003 and cremophor EL, have demonstrated improved nerve conduction velocity and endoneurial blood flow in animal models.

With increasing duration of diabetes, additional structural and metabolic effects are observed in both human and animal models of diabetic neuropathy. Loss of specific neuronal populations does occur, although the effect is relatively modest. As outlined earlier, there may be a synergistic effect of aging on

neuronal survival. Significant anatomic changes in the synaptic structures and distortion of the nodes of Ranvier have been implicated in the progression of slowing of nerve conduction observed in long-term diabetes. Expression of a variety of neuropeptides and neuronal growth factors is decreased. Exogenous delivery of growth factors such as insulin-like growth factor I, neurotrophin-3, and nerve growth factor (NGF) has been shown to improve nerve conduction and neuronal survival in animal models. Despite the promise of these studies, a recent randomized controlled trial of recombinant human NGF was not effective in restoring nerve function in patients with diabetes. The lack of efficacy may have been due to the mechanism of delivery of NGF, changes in the formulation between trials, or a requirement for additional factors. Cross-talk or synergistic actions by multiple growth and survival factors have been observed in models of neuronal survival, leading to the suggestion that simultaneous delivery of several factors may be more effective. In addition to improving nerve conduction by indirect actions on cell swelling and calcium regulation, insulin may act as a trophic factor in diabetes. Studies in which insulin was injected unilaterally near an affected nerve resulted in unilateral improvement in nerve conduction and small fiber sprouting.

NEURONAL DEATH

Many authors agree that some neuronal loss occurs during a prolonged period of diabetes; however, the mechanism remains controversial. Apoptotic cell death has been described in hyperglycemic *in vitro* culture models; however, this phenomenon may reflect effects of extreme hyperglycemia. Apoptosis has also been described in cultured neuronal cells exposed to diabetic serum. Although the noxious factor or factors involved in promoting cell death in this model have not been definitely identified, IgG class immunoglobulins have been implicated based on the results of staining and adsorption studies. *In vivo* apoptosis rates are considerably lower than those observed in culture models; however, careful counting of a large number of sensory neurons in several murine diabetic models indicates a small ($\sim$1.5%) but significant increase in apoptosis rates, when compared to nondiabetic controls ($<$0.3%). The neuronal loss in diabetes appears to occur slowly over a period of years. Thus, a small increase in the number of apoptotic neurons present at any one time could translate over time into a significant neuronal loss. These mechanisms have been demonstrated to occur in models of autonomic neuropathy, suggesting that neuronal loss may also contribute to impaired gastric and colonic function in diabetes.

TREATMENT

In addition to the use of conventional analgesics, painful sensory neuropathy is increasingly treated with tricyclic anti-depressant drugs and topical capsaicin. In a comparison study, amitriptyline was more effective at relieving pain than desipramine, but was also more likely to cause significant anti-cholinergic side effects. Topical capsaicin causes a prolonged depletion of Substance P from sensory nerves and is a useful adjunct to other analgesics. Acupuncture and trans-cutaneous electrical stimulation of cutaneous nerves have also been used with some effect in mild to moderate neuropathy. These interventions are useful in the treatment of sensory neuropathy, but have been less helpful in modulating the severity of autonomic neuropathy.

Increasing knowledge of the metabolic derangements occurring in diabetic neuropathy has led to trials of other agents. Control of hyperglycemia remains the only intervention to date that retards clinical progression of both sensory and autonomic neuropathies in human diabetes. Despite early promise in animal studies, the use of aldose reductase inhibitors such as sorbinil and tolrestat results in minimal improvement in sensory and autonomic nerve conduction velocity and symptoms. Pro-kinetic medications such as metoclopramide, domperidone, and cisapride, which treat gastrointestinal dysmotility, have all been demonstrated to improve diabetic gastroparesis, but have a minimal effect on colonic motility. The latter may reflect the pathophysiologic finding of more severe neuronal injury and impairment in the distal gut. Unfortunately, the availability of these agents is limited. Domperidone is not available in the United States and cisapride has been withdrawn due to problems with cardiac arrhythmias. Erythromycin acts on motilin receptors to initiate coordinated motility in the stomach and upper small bowel. Administered four times daily, it is an effective and inexpensive treatment for gastroparesis. Because they act on myenteric neurons, the utility of pro-kinetic drugs is ultimately limited by the function of the residual innervation present in the gut. Finally, metabolic derangements appear to precede structural changes in diabetic neuropathy. Therefore, it is likely that future trials designed to prevent or retard the progression of diabetic neuropathy will be directed toward patients presenting earlier in the course of the disease, in an effort to intervene prior to the development of irreversible structural damage.

Diaphragmatic Hernia

WILLIAM HARFORD
Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

Bochdalek hernia Diaphragmatic defect in the postero-lateral chest at the lumbocostal junctions.
mixed diaphragmatic hernia Combination of sliding and paraesophageal hernia.
Morgagni hernia Diaphragmatic defect in the anterior chest at the sternocostal junctions.
paraesophageal hernia Defect in which part or all of the stomach protrudes through the esophageal hiatus alongside the esophagus.
posttraumatic diaphragmatic hernia Rent in the diaphragm due to trauma.
sliding hiatal hernia Defect in which the gastroesophageal junction and some portion of the stomach are displaced above the diaphragm, but the axis of the stomach axis remains unchanged.

A diaphragmatic hernia is an abnormal protrusion of an organ or structure into an opening in the diaphragm. In some cases, the protrusion can spontaneously resolve and is termed reversible. In other cases, the protrusion cannot spontaneously resolve and is termed incarcerated. The organ in a diaphragmatic hernia is termed strangulated when the vascular supply becomes compromised, causing ischemia or necrosis.

PATHOGENESIS

The frequency of sliding hiatal hernias increases with age and may be due to age-related deterioration of the phrenoesophageal membrane, which anchors the gastroesophageal junction to the diaphragm. As the membrane becomes lax, the normal positive intra-abdominal pressure and normal upward traction of the esophagus upon the stomach during swallowing may cause protrusion of the stomach above the diaphragm.

In addition to the stomach, the omentum, colon, or spleen may also enter a paraesophageal hernia. The stomach often twists on its axis, causing gastric volvulus. The gastroesophageal junction remains in a normal position at the level of the diaphragm. Paraesophageal hernias may be due to a congenital defect in the diaphragmatic hiatus anterior to the esophagus.

The diaphragm is derived from the septum transversum (separating the peritoneal and pericardial spaces), the mesentery of the esophagus, the pleuroperitoneal membranes, and the muscle of the chest wall. Congenital diaphragmatic hernias, such as Morgagni and Bochdalek hernias, occur where fusion of these components fails (see Fig. 1).

Posttraumatic diaphragmatic hernias are caused by blunt trauma (such as motor vehicle collisions) in approximately 80% of cases and by penetrating trauma (such as stab wounds or gunshots) in the remainder. Blunt trauma may cause large rents, whereas penetrating injuries often cause only small lacerations. Herniation of abdominal contents into the chest is thus more common after blunt trauma than after penetrating trauma. Approximately 70% of diaphragmatic injuries from blunt trauma occur on the left side. The right hemidiaphragm is somewhat protected by the liver. A small diaphragmatic defect may not lead to immediate herniation, but with time, normal negative intrathoracic pressure may cause gradual enlargement of the defect and protrusion of abdominal contents. A variety of viscera may be found in posttraumatic hernias, including stomach, omentum, colon, small bowel, spleen, and even kidney.

INCIDENCE AND PREVALENCE

Hiatal hernias are common among adults undergoing upper gastrointestinal barium X rays. Sliding hiatal hernias make up approximately 90 to 95% of diaphragmatic hernias found by X ray, whereas almost all of the rest are paraesophageal or mixed. Most sliding hiatal hernias thus discovered are small and of no clinical significance. Patients with symptomatic paraesophageal or mixed hernias are most often middle-aged to elderly.

Clinically significant congenital hernias are rare, occurring in approximately 0.1 to 0.5 per 1000 births. Bochdalek hernias most often present in newborns. Only a few first present in adulthood. Approximately 80% of Bochdalek hernias occur on the left. Morgagni hernias are thought to be congenital, but usually present in adults. They make up approximately 2–3% of surgically treated diaphragmatic hernias. In contrast to Bochdalek hernias, Morgagni hernias occur on the right side in 80 to 90% of cases. Diaphragmatic injury occurs in approximately 5% of patients who suffer multiple traumatic injuries, but the exact incidence of posttraumatic diaphragmatic hernia is unknown.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most patients with small sliding hiatal hernias have no symptoms. However, sliding hiatal hernias, particularly large hernias, contribute to the pathogenesis of gastroesophageal reflux. In addition to symptoms related to gastroesophageal reflux, large sliding hiatal hernias may cause dysphagia or discomfort in the chest or upper abdomen. Cameron ulcers or erosions may develop in sliding hiatal hernias. These mucosal lesions usually occur on the lesser curve of the stomach at the level of the diaphragm, suggesting that mechanical factors may play a role in their pathogenesis, although ischemia and peptic injury may also contribute. Up to 5% of patients with large hernias undergoing endoscopy may be found to have Cameron ulcers. Acute or chronic upper gastrointestinal bleeding may occur with Cameron ulcers.

Hiatal hernias may be seen as a soft-tissue density posterior to the heart on chest X ray, but are usually diagnosed on upper gastrointestinal barium X-ray studies.

In contrast to patients with small sliding hiatal hernias, patients with paraesophageal and mixed hiatal hernias are rarely completely asymptomatic. Approximately half of such patients have symptoms of gastroesophageal reflux. Dysphagia, chest pain, vague postprandial discomfort, shortness of breath, and chronic gastrointestinal blood loss are also reported. Paraesophageal hernias may be complicated by gastric volvulus.

On chest X ray, paraesophageal or mixed hiatal hernias may be seen as an abnormal soft-tissue density (often with a gas bubble) in the posterior chest. The best diagnostic study is upper gastrointestinal barium X ray. On upper endoscopy, paraesophageal hernias are usually obvious, but the paraesophageal component of a large mixed hernia may be missed, and the anatomy may be confusing, particularly if the hernia is associated with gastric volvulus.

Congenital diaphragmatic hernias are associated with a wide variety of clinical presentations, from death in the neonatal period to an asymptomatic incidental finding in adults. Bochdalek hernia may cause a syndrome of severe respiratory distress in newborns. Pulmonary hypoplasia occurs on the side of the hernia, but some degree of hypoplasia may also occur in the contralateral lung. Pulmonary hypertension is common. Serious chromosomal anomalies (most often trisomy 13, 18, and 21) are found in 30 to 40% of newborns with Bochdalek hernias. Respiratory failure and other congenital anomalies are the major causes of mortality in such infants. In older children and adults, a Bochdalek hernia may present with symptoms due to herniation of the stomach, omentum, colon, or spleen. Gastric volvulus may occur, and approximately half of adult patients present with acute incarceration. Patients may also be asymptomatic or have chronic nonspecific intermittent symptoms, including chest discomfort, shortness of breath, dysphagia, nausea, vomiting, or constipation.

The differential diagnosis of Bochdalek hernia includes mediastinal or pulmonary cyst or tumor as well as pleural effusion or empyema. Prenatal diagnosis may be made at sonography by visualizing stomach or loops of bowel in the chest. In older children and adults, the diagnosis may be suspected when a soft tissue mass in the posterior mediastinum is discovered on chest X ray. The diagnosis is usually confirmed by barium upper gastrointestinal X ray or by computerized tomography with oral contrast.

In contrast to Bochdalek hernias, Morgagni hernias are most likely to present in adult life. They may contain omentum, stomach, colon, or liver. As with Bochdalek hernias, patients may also be asymptomatic or have chronic nonspecific intermittent symptoms. They may also present with acute gastric, omental, or intestinal incarceration with obstruction and/or ischemia.

The differential diagnosis of Morgagni hernias is similar to that of Bochdalek hernias and the diagnosis of Morgagni hernias is often made in the same manner.

In contrast to Bochdalek hernias, Morgagni hernias are found in the anterior mediastinum, usually on the right. It is important to confirm the contents of the hernia with barium X rays or computerized tomography with oral contrast.

Rupture of the diaphragm is often masked by other serious injuries after serious trauma. It may go undetected even at exploratory laparotomy. Posttraumatic diaphragmatic hernias usually cause respiratory and/or abdominal symptoms. Such symptoms occurring several days to weeks after injury should suggest the possibility of a posttraumatic hernia. Positive-pressure ventilatory support after trauma may prevent herniation through a diaphragmatic tear, but upon attempted ventilator weaning, herniation may then occur. Symptoms may also present long after injury, up to 10 years or more later, obscuring the relationship between the acute illness and remote trauma.

Diaphragmatic injury should be considered in any case of serious trauma involving the area between the fourth intercostal space and the umbilicus. The chest X ray aids the diagnosis in only half of the cases. Rapid helical computerized tomography with sagittal reconstruction is very useful in diagnosis.

TREATMENT

Small sliding hiatal hernias do not require treatment. Surgery should be considered in cases of symptomatic giant sliding hiatal hernias, paraesophageal hernias, and mixed diaphragmatic hernias. Even among patients with asymptomatic paraesophageal hernias, approximately 30% will develop acute complications if left untreated, so many surgeons recommend repair when such hernias are discovered.

Treatment of all diaphragmatic hernias includes repair of the diaphragmatic defect either by suture approximation or by insertion of mesh. When the stomach has herniated, it should be fixed in the abdomen. Since there is a high prevalence of gastroesophageal reflux and esophageal motility disorders among patients with paraesophageal hernia, a fundoplication is usually included in the repair. Sliding hiatal or paraesophageal hernias may be associated with a shortened esophagus, making it difficult to fix the gastroesophageal junction below the diaphragm. In such cases an extra length of neo-esophagus from the proximal stomach is created by the surgeon (Colles-Nissen procedure). Both open and laparoscopic techniques are used for diaphragmatic hernia repair. Laparoscopic repair is associated with less blood loss, fewer overall complications, and shorter hospital stay than open repair. Return to normal activities is faster. Potential surgical complications include esophageal and gastric perforation, pneumothorax, and liver laceration. Long-term results are probably equal with either approach. Long-term complications may include dysphagia or the gas-bloat syndrome. Gastroesophageal reflux may occur if the fundoplication breaks down or migrates into the chest. Recurrence rates are approximately 10%.

Cameron ulcers or erosions are usually treated with anti-secretory medication, just as other gastric ulcers. However, in approximately one-third of patients these lesions may persist or recur despite medication, in which cases surgical repair of the associated hernia may be needed.

Infants with Bochdalek hernias usually require ventilatory support, but barotrauma may occur with standard ventilators. The advent of new techniques for ventilatory support such as high-frequency oscillation and extracorporeal membrane oxygenation has improved the prognosis of these infants, allowing stabilization before diaphragmatic repair. Most infants survive repair of the diaphragmatic hernia, but many have long-term neurological and musculoskeletal problems. Up to 50% develop gastroesophageal reflux.

A variety of techniques have been used for repair of congenital hernias, including open chest and/or abdominal approaches, as well as thoracoscopic and/or laparoscopic techniques. Acute diaphragmatic ruptures may be approached from the abdomen or through the chest. Since chronic posttraumatic diaphragmatic hernias may be associated with extensive adhesions and lack of a peritoneal hernia sac, they are best repaired through the chest or by a combined thoracoscopic/abdominal approach.

Diarrhea

MIHIR PATEL AND JOSEPH H. SELLIN
University of Texas Medical School, Houston

acute diarrhea Abnormal stool production that lasts for less than a month.
chronic diarrhea Abnormal stool production that lasts for more than a month.
inflammatory diarrhea Abnormal stool production associated with the presence of white cells or blood.
osmotic diarrhea Abnormal stool production associated with an osmotic gap of more than 100 mOsm/kg.
secretory diarrhea Abnormal stool production associated with an osmotic gap of less than 50 mOsm/kg.
steatorrhea Presence of more than 7 g of fecal fat excretion on a diet containing 100 g fat/day over a period of 48–72 hours. Steatorrhea can be broadly divided into three categories: intraluminal maldigestion, mucosal malabsorption, and postmucosal malabsorption related to obstruction of the lymphatics. Maldigestion is defective hydrolysis of nutrients and malabsorption is defective mucosal absorption.
stool osmotic gap The difference between luminal osmolality (equal to body fluid osmolality, approximately 290mOsm/kg) and luminal content osmolality, calculated by electrolyte measurements.

Diarrhea, derived from the Greek "to flow through," is a common health problem. More than 450,000 hospital admissions each year in the United States (1% of adult hospitalizations) are due to diarrheal illnesses. Based on a commonly used definition of chronic diarrhea (liquid stools for more than 1 month), a reasonable approximation is that chronic diarrhea affects approximately 5% of the population throughout the world.

INTRODUCTION

Diarrhea is a symptom, not a disease. It represents the end product of multiple gastrointestinal dysfunctions. The definition of diarrhea has traditionally been based on the volume, frequency, and/or consistency of stools. Patients often consider increased fluidity of stool as diarrhea. However, because it is difficult to measure stool consistency, most investigators have used stool frequency or stool weight to better define this condition. In Western countries, three or more bowel movements per day are considered to be abnormal. For the United States population, fecal weight of more than 200 g/day is also considered to be consistent with diarrhea. However, diarrhea should not be defined using only one criterion. Some individuals may have increased fecal weight but have normal stool consistency and no complaint of diarrhea. For example, Asian individuals consuming a high-fiber diet may well have a stool weight greater than 200 g and still be considered "normal." Other individuals have normal fecal weight, yet complain of diarrhea because their stools are loose and watery. Thus, a good working definition is three or more loose or watery stools per day or a definite decrease in consistency and increase in frequency of stools based on an individual baseline.

CLASSIFICATIONS

A classification scheme provides a framework for understanding the pathophysiology and treatment of diarrhea:

- Acute vs. chronic
- Large volume vs. small volume
- Motility vs. epithelial function
- Secretory vs. osmotic
- Watery vs. fatty vs. inflammatory

These classifications are not mutually exclusive. A diarrhea may be acute, inflammatory, and secretory in nature, or alternatively, chronic, osmotic, and small volume. Clinical context provides a focus for sifting through multiple potential etiologies. By considering these classifications simultaneously, the clinician can narrow the range of diagnostic possibilities.

PATHOPHYSIOLOGY AND DIAGNOSIS

Diarrhea, a complex clinical scenario, frequently represents a protective response to a variety of intestinal insults and assaults. It can also be a manifestation of an underlying systemic disease process. Normally 8 to 10 liters of fluid per day enters the small intestine. Of this load, approximately 2 liters is derived from the diet and the remainder comes from the secretions of the salivary glands, stomach, pancreas, liver, and the intestine. The small intestine normally absorbs all but 1.5 liters of this

 Copyright 2004, Elsevier (USA). All rights reserved.

fluid, which eventually enters colon. The colon can absorb approximately 90–95% of the remaining fluid, leaving 100 to 150 ml/day in the stool. The small intestinal fluid absorption is generally linked to nutrient absorption, whereas the colon primarily transports electrolytes to conserve water and regulate stool consistency. Despite a reserve capacity for absorption, an imbalance between secretion and absorption can readily lead to diarrhea.

Acute vs. Chronic Diarrhea

Acute Diarrhea

Diarrheal illness lasting for less than 4 weeks can be defined as an acute diarrhea. It represents the second most common cause of death worldwide and is the leading cause of childhood death. Etiological factors can vary. The most helpful clue is the clinical setting. Infectious causes are more common in developing countries. Contaminated water systems, extreme poverty, rapid urbanization, crowded substandard housing with inadequate sewage disposal, and poor education are responsible for the frequent occurrence of diarrhea in developing countries. In the United States, most acute diarrheas last only a few days and resolve without obtaining a specific diagnosis. They are usually labeled "viral gastroenteritis." Foreign travel was once thought to be a prerequisite for "exotic" infectious diarrheal illness. However, amebiasis, giardiasis, and other infectious agents may underlie diarrhea in individuals who have never visited any foreign countries. Acute diarrhea can also be seen in specific settings that lead to consideration of discrete diagnoses. Acute diarrhea occurring in hospitalized patients, for example, may be due to tube feedings, medications, ischemia, or antibiotic treatment (*Clostridium difficile* diarrhea).

Patients with acute onset of diarrhea should be questioned for passage of blood or mucus in the stool, duration and frequency of diarrhea, and symptoms of dehydration. Diarrheal illness lasting for more than 48 hours with fever and signs of dehydration or peritonitis needs urgent medical attention. Older and immunocompromised patients need close observation.

The diagnostic approach in acute diarrhea includes fecal leukocytes, occult blood, and stool cultures. Endoscopy is not commonly needed in the initial diagnosis of acute diarrhea. It may, however, be helpful in distinguishing inflammatory bowel disease from infectious diarrhea, in diagnosing *C. difficile* colitis, and in patients in whom ischemic colitis is suspected.

Management of patients with acute diarrhea depends on the causative agent. Signs and symptoms of dehydration should be treated immediately. Most of the cases of infectious diarrhea are self-limited. Empiric antibiotic therapy has not been shown to alter the course of illness. Patients should be carefully questioned about risk factors for *C. difficile*, such as recent hospitalization or antibiotic use. Antimotility agents should be used cautiously in acute infectious diarrhea. Specific antimicrobial therapy is recommended if an organism is isolated (see Fig. 1).

Chronic Diarrhea

Chronic diarrhea needs careful evaluation; it may have a complex pathogenesis and can be a frustrating problem, not only for patients but also for the physicians treating them. Many patients cannot maintain a good quality of life, and in some cases, chronic diarrhea jeopardizes their livelihood. Patients may feel socially isolated and view their lives as nothing more than being tethered to the toilet.

Initial evaluation should be focused on separating functional from organic causes. A detailed and thorough medical history and clinical assessment is extremely helpful. Careful questioning about prescription and over-the-counter medications may give useful hints. A patient's usual intake of fruits and of beverages containing high concentrations of sugar or caffeine should be estimated. Functional causes are more likely in the absence of significant weight loss (<5 kg), longer duration of symptoms (>1 year), and in the absence of nocturnal diarrhea. Once a functional etiology is ruled out, attempts should be made to determine specific etiological factors. This is where the classification framework becomes paramount in steering through diagnostic and therapeutic options. This classification allows the physician to isolate key characteristics of the patient's history. It is extremely important to recognize fecal incontinence. Many patients do not report this symptom voluntarily, but complain of diarrhea instead. If incontinence is a frequent problem, then diagnostic and therapeutic efforts should be directed toward incontinence rather than diarrhea (see Fig. 2).

Large-Volume vs. Small-Volume Diarrhea

The rectosigmoid area acts a storage reservoir. Clinically, intact "reservoirs" are critically important factors in diarrhea. When that storage capacity is compromised by inflammatory or motility disorders, frequent small-volume bowel movements occur. Painful defecation associated with urgency and small volume is highly suggestive of left colon or rectal involvement. Fewer and larger bowel movements are usually associated with right colon or small intestine disease processes.

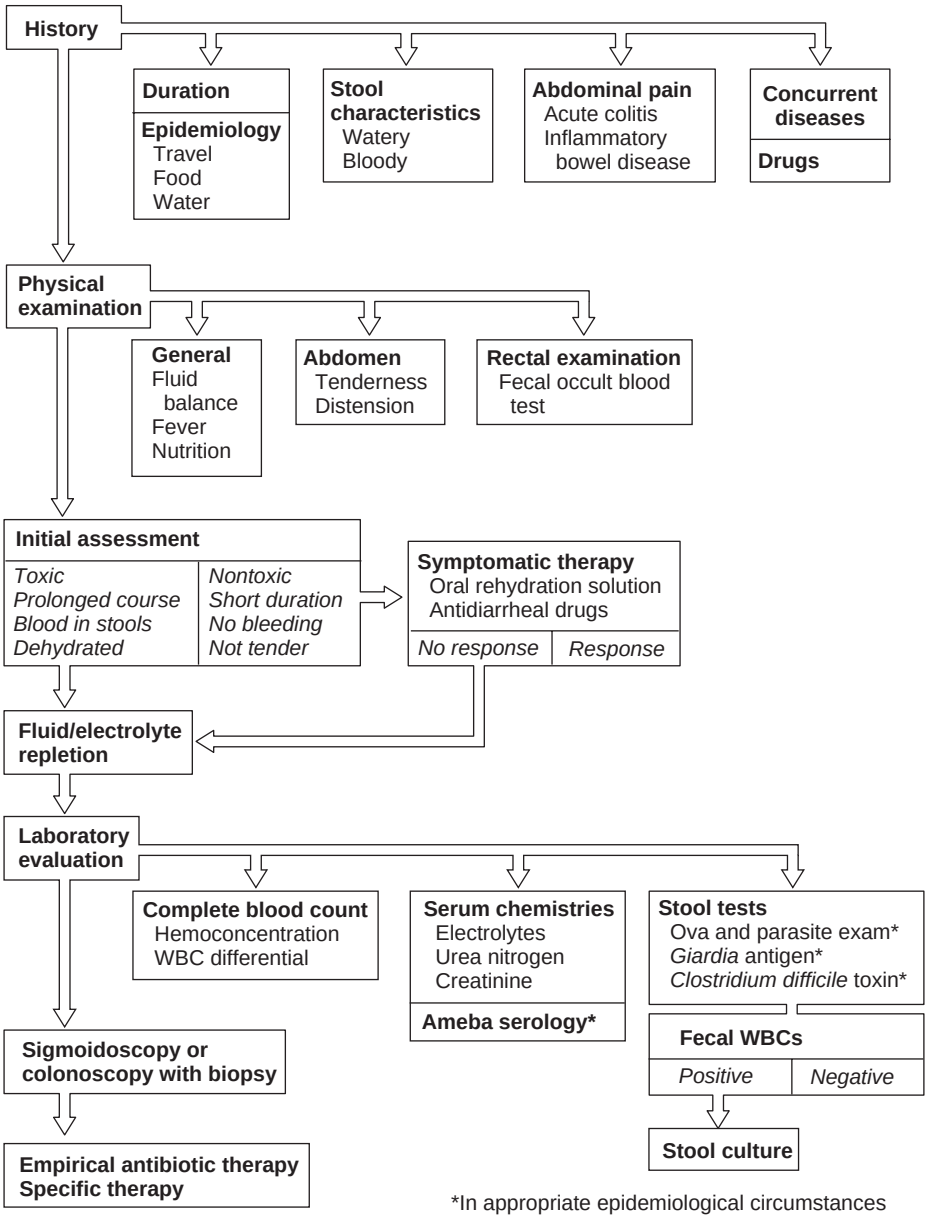

FIGURE 1 Flowchart for the evaluation of patients with acute diarrhea. Reproduced from Sellin (2002), with permission.

Motility vs. Epithelial Function

Most patients suffering from diarrhea, especially those in the Western world, would assume their symptoms are due to disordered motility, with luminal contents moving too quickly through the length of the gastrointestinal (GI) tract. However, slow transit, such as seen in scleroderma, can also lead to the diarrheal state, in part due to associated bacterial overgrowth causing epithelial disruption and altered electrolyte transport. Dysregulation of the enteric nervous system (due to surgical vagotomy, sympathectomy, or neuropathy secondary to systemic diseases) and the effects of certain mediators like vasoactive intestinal peptide (VIP) and nitric oxide may affect smooth muscle function in the gut. Dysregulation may also alter the dynamics of intestinal fluid absorption and epithelial functions. Surprisingly, there is little basic research directed to motility disorders in diarrhea. Instead, considerable emphasis has been placed on how the epithelial cells

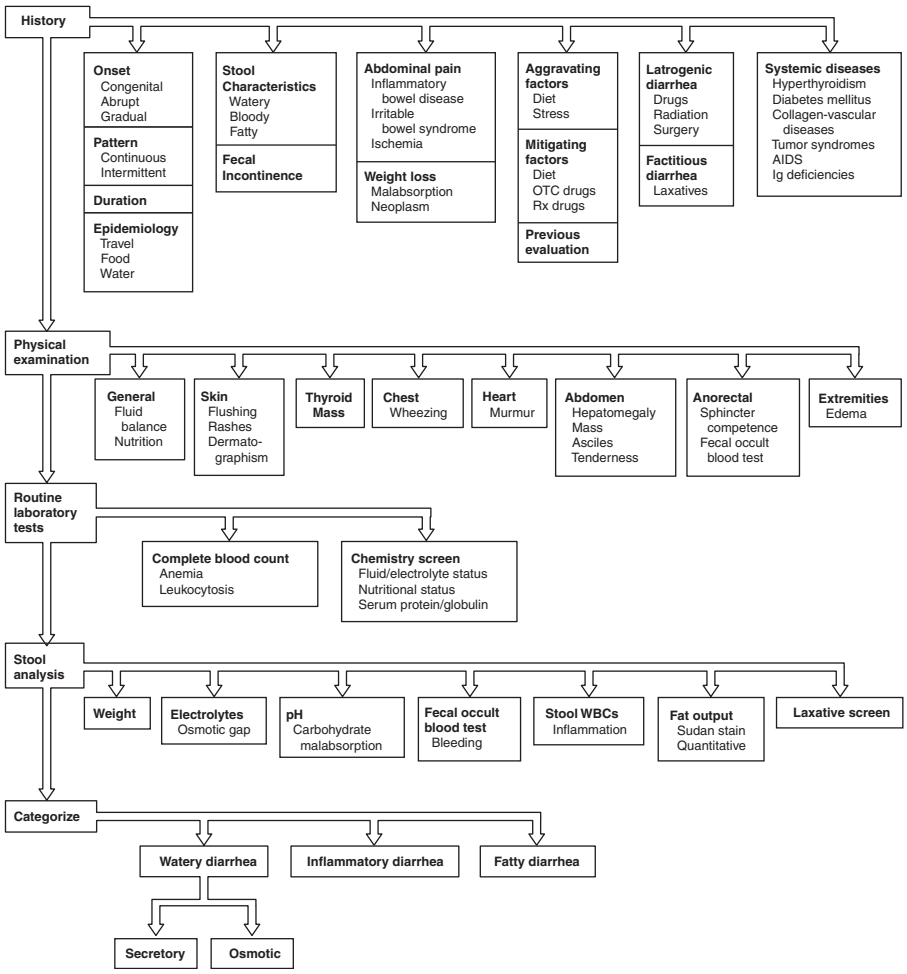

FIGURE 2 Flowchart for the initial evaluation of patients with chronic diarrhea. Reproduced from Sellin (2002), with permission.

lining the gut transport ions and nutrients and how they may be disrupted during diarrheal states. This focus on the epithelial functions has led to the differentiation of osmotic vs. secretory diarrhea.

Secretory vs. Osmotic Diarrhea

Water movement in the gut generally follows passively the movement of electrolytes and nutrients. The epithelial cells of the gastrointestinal tract have an elaborate system of pumps, carriers, and channels that provides orderly movement of ions and solutes through the cell (transcellular) and around the cell (paracellular). Sodium absorptive pathways provide the major driving forces for fluid absorption, whereas chloride movement into the gut drives secretion. In osmotic diarrhea, poorly absorbed solutes remaining in the gut lumen pull fluid from the submucosal space around the cells (paracellular). In secretory diarrhea, the transport machinery of the epithelial cells is taken over and either absorption is inhibited and/or secretion is stimulated.

Common examples of osmotic diarrhea are lactose malabsorption or diarrhea due to ingestion of magnesium-containing laxatives or unabsorbable solutes such as polyethylene glycol (PEG), used in colonic lavages and preparations for colonoscopies. Patients with lactose intolerance are lactase deficient. Lactose is usually metabolized to glucose and galactose, which are absorbable. In the setting of lactose intolerance, the unabsorbable lactose is not metabolized, leading to a failure to reabsorb fluid. Similarly, with magnesium or PEG, excess fluid entry into intestinal lumen leads to osmotic diarrhea. Other examples of osmotic diarrhea are mentioned in Table I.

The essential characteristic of osmotic diarrhea is that it disappears or improves with withdrawal of offending substances. Electrolyte absorption is unaffected by osmotically active substances and stool water has

TABLE I Major Causes of Diarrhea

Watery diarrhea			
Secretory	**Osmotic**	**Steatorrhea**	**Inflammatory diarrhea**
Osmotic laxative abuse	Nonosmotic laxative abuse	Malabsorption—mucosal diseases	Inflammatory bowel disease
	Congenital chloridorrhea	Short bowel syndrome	Infections
Magnesium-containing antacids	Bile acid malabsorption	Postresection diarrhea	Ischemic colitis
Carbohydrate malabsorption	Inflammatory bowel disease	Bacterial overgrowth	Radiation colitis
Short bowel syndrome	Collagenous colitis	Mesenteric ischemia	Neoplasia
	Vasculitis	Maldigestion	Microscopic colitis
	Postvagotomy diarrhea	Pancreatic insufficiency	Hypersensitivity
	Diabetic diarrhea	Emulsification problems	
	Hyperthyroidism	Problems with micelle formation	
	Addison's disease	Pancreas—cibal asynchrony	
	Bacterial toxins		
	Drugs		
	Neoplasia		
	Neuroendocrine tumors		

relatively low concentration of sodium and potassium. This is the basis for the calculation of the "fecal osmotic gap," which is the difference between luminal osmolality (equal to body fluid osmolality, approximately 290 mOsm/kg) and the measured luminal content osmolality:

$$\text{Stool osmolality} = 2(\text{Na} + \text{K})$$

$$\text{Fecal osmotic gap} = 290 - 2(\text{Na} + \text{K}).$$

A large osmotic gap (>50 mOsm/kg) is suggestive of the presence of osmotic diarrhea. When the osmotic gap is small, electrolytes account for most of the luminal osmolality and a secretory diarrhea is said to be present (see Fig. 3).

A number of conditions can lead to secretory diarrhea. These include many small intestine mucosal diseases and infections. Diseases affecting the colon alone (such as ulcerative colitis or microscopic colitis) may also produce secretory diarrhea. Bacterial and viral infections account for the vast majority of secretory diarrheas. Infections with microorganisms may produce enterotoxins that interact with the receptors modulating intestinal epithelial transport, leading to anion secretion through chloride channels. Enterotoxins may also block specific absorptive pathways, i.e., Na^+/H^+ exchange, thus inhibiting fluid absorption (see Fig. 4). Although other secretory conditions such as endocrine tumors and conditions such as congenital chloridorrhea and congenital sodium diarrhea are often considered in the listing of possible diagnoses, they are extremely uncommon.

Watery vs. Fatty vs. Inflammatory Diarrhea

Characteristics of the stool may help in differentiating diarrheas resulting from variety of causes. Watery diarrhea without blood, pus, or fat implies the presence of an osmotically active substance or unabsorbed/secreted electrolytes causing retention of excess of water in the lumen. Examples of watery diarrhea are bile acid malabsorption, carbohydrate malabsorption, and functional watery diarrhea due to irritable bowel syndrome.

Fatty diarrhea suggests the presence of conditions reducing fat absorption or digestion in the small intestine. Fatty diarrhea can be broadly divided into three categories: intraluminal maldigestion, mucosal

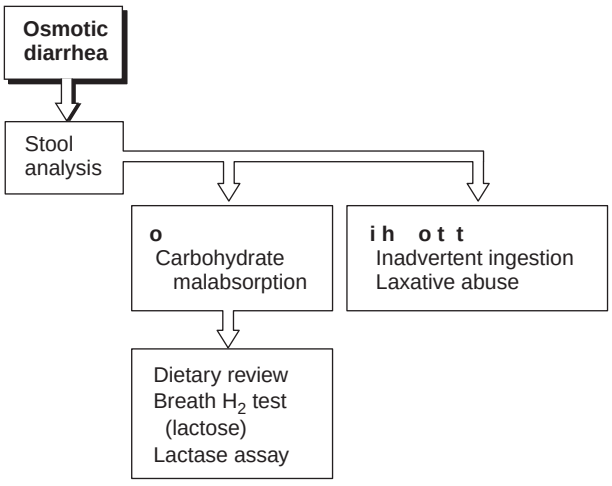

FIGURE 3 Flowchart for the evaluation of chronic osmotic diarrhea. Reproduced from Sellin (2002), with permission.

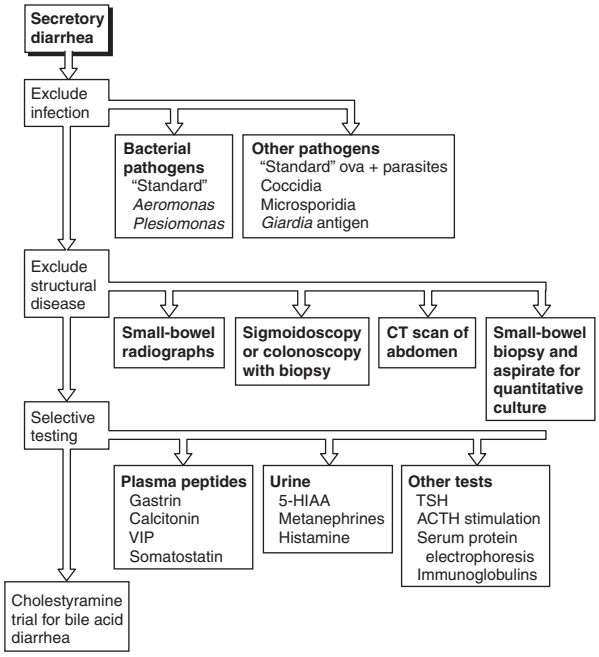

FIGURE 4 Flowchart for the evaluation of chronic secretory diarrhea. CT, Computed tomography; VIP, vasoactive intestinal peptide; 5-HIAA, 5-hydroxyindole acetic acid; TSH, thyroid-stimulating hormone; ACTH, adrenocorticotropic hormone. Reproduced from Sellin (2002), with permission.

malabsorption, and postmucosal malabsorption related to obstruction of lymphatics. Malabsorption can be global (carbohydrate, protein, and fat) or nutrient specific (vitamin B_{12}, lactose, or trehalose). It is important to identify differences between malabsorption and maldigestion. Malabsorption refers to impaired absorption of nutrients. It can result from congenital or acquired diseases affecting the intestinal epithelial surface. Examples are celiac disease, Whipple disease, abetalipoproteinemias, and lymphoma. Maldigestion refers to impaired hydrolysis and digestion of nutrients within the lumen. Examples of maldigestion include pancreatic insufficiency, hepatobiliary diseases with decreased micelle formation, or postsurgical complications leading to decreased emulsification and/or pancreas–cibal asynchrony (cibal, meaning "food intake," from the Latin, *cibus*).

Patients with chronic diarrhea with the presence of white cells or blood in the stool are classified as having inflammatory diarrhea. Basic pathologic characteristics are mucosal disruption and inflammation. Inflammatory bowel disease, radiation enteritis, enterocolitis, ischemia, and neoplasia are examples of inflammatory diarrhea. Common causes of infections causing inflammatory diarrhea are *C. difficile*, *Shigella*, cytomegalovirus, amebiasis, and tuberculosis. In these conditions, specific peptide mediators released by either bacteria or immune cells can alter epithelial function.

Most clinically significant diarrheas are complex and have several underlying pathophysiologic mechanisms rather than just one. An example of this complexity is cholera. Cholera is often cited as the paradigm of a secretory diarrhea. Cholera toxin, via the second messenger cyclic AMP, activates target apical chloride channels in epithelial cells, causing secretion. However, this same toxin also stimulates neural and endocrine cells that reinforce direct secretion by enterocytes. Studies have shown that cholera toxin also causes changes in intestinal motility and affects tight junctions, altering the permeability of intestinal mucosa. Thus, there may be added complexity in even the most straightforward example of secretory diarrhea. It is important to understand the multiple mechanisms that mediate a diarrheal illness. A single modulator may have multiple effects at the cellular and paracellular pathways and also at the muscular level. A full appreciation of the pathophysiology of diarrhea requires consideration of paracrine, immune, neural and endocrine modulators, a regulatory system that can be abbreviated by the acronym "PINES." Efforts to modulate this system with drugs may produce new classes of antidiarrheal agents in the future (see Fig. 5).

DIAGNOSTIC APPROACH AND MANAGEMENT

The initial evaluation of patients with diarrhea should include a detailed history and physical examination. The presence and absence of systemic diseases and

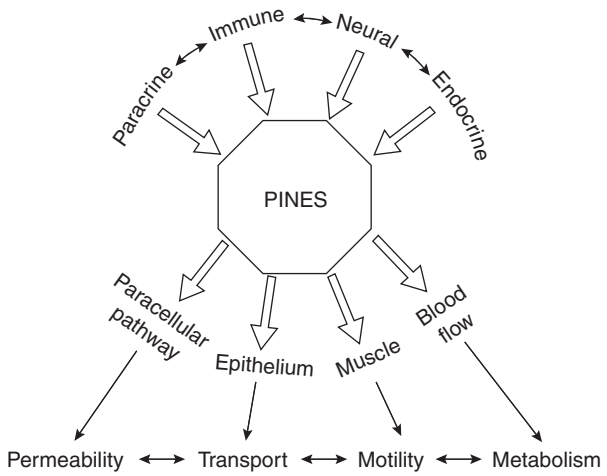

FIGURE 5 Paracrine/immune/neural/endocrine (PINES) regulatory system in the gut. Reproduced from Sellin (2002), with permission.

nutritional status should be carefully studied. Diagnostic evaluation of patients with chronic diarrhea should be directed at the most likely possibilities (Table I). Focused evaluation will help classifying diarrhea as being watery (osmotic vs. secretory), fatty, or inflammatory. Initial stool evaluation for the presence of occult blood (guaiac testing), white blood cells (Wright's stain or fecal lactoferrin assay), and fat (Sudan stain) can be helpful. Sudan staining of spot samples has a sensitivity of 78% and a specificity of 70% for detection of steatorrhea. Quantitative collection of stool over 48–72 hours provides a better idea of stool output and fat excretion but is not always essential. Fecal fat excretion of less than 7g/day on a 100-g/day fat diet is usually considered normal. Other than stool examination, routine laboratory tests (complete blood count and differential, liver function tests, prothrombin time, electrolytes, and thyroid-stimulating hormone) and sprue serology should be obtained.

As mentioned previously, analysis of stool electrolytes allows the physician to categorize diarrhea as osmotic or secretory. Although diagnosing an osmotic diarrhea produces a short list of suspects, finding a secretory diarrhea leaves many possibilities. Measurement of stool pH (less than 6) can be helpful in diagnosing conditions such as carbohydrate malabsorption. In patients with suspected laxative abuse, stool can be analyzed for laxatives by chemical or chromographic methods.

Structural diseases of the small intestine can be excluded by using noninvasive tests (small bowel radiography, breath tests) or, if needed, invasive tests such as small bowel biopsy. Some tests can be applied during initial screening and some can later separate out specific etiologies. One of the examples of a noninvasive test is the D-xylose test, which can differentiate malabsorption due to small intestinal mucosal disease from maldigestion due to pancreatic insufficiency by utilizing its natural physical properties. D-Xylose is a pentose monosaccharide that can be absorbed both by passive paracellular and transcellular pathways, reflecting the function of the proximal small intestine. Thus, this test is a measure of the permeability of the proximal small intestine. Absorption of D-xylose is normal in pancreatic insufficiency because pancreatic enzymes are not required for xylose absorption. Other noninvasive tests used for carbohydrate malabsorption rely on the fermentation of undigested carbohydrates by the intestinal bacteria, leading to increased hydrogen production.

Although jejunal cultures from the small bowel aspirate are considered a gold standard for diagnosing bacterial overgrowth, noninvasive breath tests (particularly the ^{14}C-labeled D-xylose test) are still recommended. In this test, D-xylose is catabolized by intestinal microflora. This action will lead to release of radioactive $^{14}CO_2$ that, after absorption, can be detected in breath samples.

Several invasive and noninvasive tests are available to evaluate pancreatic function and/or pancreatic structure as an indication of pancreatic insufficiency. Tests used to measure pancreatic function can be divided into two categories: direct and indirect. Direct tests are considered the gold standard. In the secretin stimulation test, pancreatic secretions are collected after stimulation by secretin, cholecystokinin, or the combination of both. Indirect tests measure pancreatic secretion after indirect stimulation, such as with a defined test meal. Both direct and indirect tests require duodenal intubation to collect pancreatic secretion samples and can thus be classified as "tube tests." Tubeless indirect tests include fecal fat assays, fecal chymotrypsin assays, fecal elastase measurements, and the pancreolauryl test. The choice of which pancreatic function test to use depends on the clinical question and availability of the test. It is important to understand that malabsorption does not occur until functional capacity is reduced to 5–10% of the normal. Thus, most of the tests may not show abnormal results unless moderate to severe pancreatic insufficiency is present.

Radiologic investigations such as computed tomography or endoscopic retrograde pancreatography may show changes in the duct and parenchyma at a later stage. A newer modality is endoscopic ultrasound, the role of which is still investigational but which has shown promising results in evaluating structural changes related to chronic pancreatitis. Most disorders that produce chronic diarrhea and gross histological changes in the colon can be diagnosed with sigmoidoscopic examination and biopsies, but some lesions exclusive to the right colon (e.g., infections in AIDS) may be missed without a complete colon examination. Testing for secretogogue-induced diarrhea should be selective. Rarely, measurement of plasma peptide concentration is required, based on the degree of suspicion and findings of radiological tests.

Specific treatment can be considered when a diagnosis is strongly suspected in the presence of supporting evidence. Examples include a patient with diarrhea due to limited resection of terminal ileum (<100 cm) in whom bile acid malabsorption is a likely cause and thus a trial of a bile acid-binding agent may be helpful. A patient with bacterial overgrowth may benefit from antibiotic therapy. A patient with suspected lactose intolerance may improve with avoidance of lactose-containing products.

Nonspecific symptomatic treatment may be considered in a patient whose diagnostic workup is pending or when the complexity of a problem is such that a definitive treatment is unavailable. A variety of medications are available. Different antidiarrheal agents may have different mechanisms of action but it is also important to understand specific side effects while using them. Loperamide oxide, bismuth subsalicylate, anticholinergics, and bulk-forming agents are relatively safe. Opiates have a potential for addiction. Bismuth subsalicylate in large doses, particularly in the presence of renal dysfunction, may precipitate salicylate toxicity. It also produces black stool that can easily be confused with melena. Anticholinergics should be used carefully in pediatric and elderly populations. The most common side effect of bulk-forming agents is bloating and flatulence.

Of all the therapeutic modalities available to treat diarrheal disease, none has been more important than the discovery and development of the oral rehydration solution (ORS), one of the major advances in public health in the twentieth century. ORS development is a paradigm of translational research, in which basic observations on the mechanisms of toxin-induced diarrhea were utilized to design an improved therapy. The oral rehydration solutions take advantage of our understanding of the pathophysiology of secretory diarrheal diseases such as cholera. In cholera, there is increased chloride secretion and inhibition of some, but not all, sodium absorptive pathways. While electroneutral sodium absorption is blocked, absorption of Na coupled with nutrients is unaffected. Therefore, supplying glucose and other small nutrient molecules via an ORS into the gut lumen can stimulate sodium absorption. The initial goal of the ORS is to offset the high morbidity and mortality associated with dehydration in geographic areas where intravenous fluids are unavailable or too expensive. The main constituents of ORSs are water, salt, and sugar. The ratio of the solutes was initially fixed, but over the past decade many modifications have been made. Currently, these modifications have allowed ORS use as a maintenance therapy for chronic diarrhea such as high output ostomy diarrhea and diarrhea due to short bowel syndrome. In the United States, ORS is underused. It is a misconception that simply drinking fruit juices and isotonic fluids such as Gatorade can prevent dehydration. A significant number of hospital admissions for dehydration might be avoided by wider utilization of ORS, as is done in developing countries.

The goal of the physician in evaluating patients with diarrhea is to make a definitive diagnosis as quickly and inexpensively as possible. The approach may be different in adult patients and in children. The majority of the patients can be diagnosed and treated with the help of careful history and physical examination, coupled with certain focused laboratory examinations. A better understanding of the pathophysiology of diarrhea and ongoing efforts to improve its diagnosis and management will undoubtedly reduce the economic burden and human cost throughout the world.

waterborne infection Infection acquired via contaminated water.

"Diarrhea" derives from the Greek words δια ρεω, meaning "flow through." Diarrhea occurs when the volume of the colonic fluid is greater than the absorptive capacity of this segment, as a result of impaired absorption and/or increased secretion. In infectious diarrheas, the abnormal function is brought about by microorganisms that colonize the intestinal mucosa and subvert normal gut physiology either directly or via enterotoxins.

INTRODUCTION

Diarrheal diseases are a major cause of morbidity and mortality around the world, especially in developing countries where children suffer the greatest brunt of infectious diarrhea, malnutrition, and death. Annually, approximately 5 million children and infants die worldwide due to diarrheal diseases. In North America, the rate per year is still 0.9 diarrheal episodes per child, and in special circumstances (daycare centers, institutions), the incidence is as high as 5 episodes per year. Fourteen hospital admissions per 1000 children younger than 12 months, per year, result from acute diarrhea. Among the adult population, most patients developing acute diarrhea are managed as outpatients or will not seek medical attention. However, 0.5 million hospital admissions per year, or 1.5% of all adult hospital admissions annually, are due to diarrhea. In developing countries, inadequate water supply, inefficient or nonexistent sewage removal systems, chronic malnutrition, and lack of access to oral rehydration are responsible for the high incidence of infectious diarrheal diseases. In the industrialized world, acute diarrhea is still one of the most frequent diagnoses in general practice and children, elderly, and immunocompromised patients are the most vulnerable individuals and account for the majority of these cases.

Regardless of the etiology, diarrhea is defined clinically as the occurrence of three or more episodes of loose stool or any loose stool with blood during a 24 h time period. Symptoms lasting less than 14 days represent acute diarrhea, whereas persistent diarrhea lasts more than 14 days but less than 4 weeks, and chronic diarrhea is defined by a duration of symptoms greater than 4 weeks.

Infectious diarrheas are miserable illnesses of overwhelming impact on the general survival of entire populations. Throughout history, thousands-strong armies have been defeated by raging diarrheal diseases: from the Greeks and Macedons under Alexander (Tucidides), to the Romans in the campaigns against the Gauls (Julius Caesar), to the Hundred Years War in 13th century Europe, to Napoleon, the Civil War in America, World War II, and the Vietnam War. Scores of previously healthy men suffered and died from the scourge of diarrhea and dysentery in all of these conflicts.

EPIDEMIOLOGY

Twenty years ago, 800 million to 1 billion episodes of infectious diarrhea and nearly 5 million deaths occurred per year worldwide, primarily in developing countries. Ten years later, survival had improved, but the incidence was virtually unchanged despite greater knowledge of the pathophysiology of diarrhea and greater intervention by the World Health Organization (WHO). Approximately 100 million episodes of acute diarrhea occur in the United States yearly, with an incidence of 1.2 to 1.5 diarrheal episodes per person-year. Medical costs/analyses show that 8.0 million Americans sought physician care for diarrhea yearly and 250,000 required hospitalization. Hospitalization and medical costs approached $560 million, whereas lost productivity totaled $200 million. Approximately another 8 million people sought physician care but were not hospitalized. These patients incurred $690 million in medical costs and $2 billion in loss of work hours. An estimated 90 million cases occurred in people who

 Copyright 2004, Elsevier (USA). All rights reserved.

did not seek physician care, costing nearly $20 billion in lost productivity. Approximately 90% of all these cases were presumably of infectious origin. Thus, the total cost estimate for diarrheal diseases exceeds $23 billion annually in the United States alone.

Although the elderly have an increased risk for death from diarrhea, death from diarrhea is rare among young children in industrialized countries. In fact, of all pediatric admissions for diarrhea, 0.05% resulted in death, compared with 3% in patients older than age 80. Increased age was the most important risk factor for death with an odds ratio of 52.6 (95% confidence interval, 37.0 to 76.9) for age 70 or older versus children >5 years. The national mortality figures for the 9-year period 1979–1988 in the United States show 51% of diarrheal deaths occurring in individuals older than age 74.

Acute infectious diarrhea is transmitted mostly through the fecal–oral route and by ingestion of contaminated water and food. Infection via the fecal–oral route occurs by direct contact with index cases, especially under conditions of crowding, such as daycare centers or nursing homes. Waterborne and food-borne outbreaks are another important source of disease transmission and result from general and/or individual failures in proper standards for the safe handling of foods. In most developing nations, acute diarrhea is endemic due to poor sanitation. Furthermore, epidemics of significant proportions often result from natural disasters in areas where water and food supplies are already chronically jeopardized. In some areas of the world, such as Asia, Africa, and Latin America, certain infectious diarrheas (e.g., cholera) have become ongoing pandemics lasting several decades, notwithstanding WHO efforts at eradication.

In most parts of the world, a definite seasonality is recognized in the incidence of acute diarrhea. In industrialized nations, the highest incidence of hospital admissions for diarrhea occurs in August and September and in the winter months. In developing nations with warmer climates and endemic conditions, variations in incidence occur from year to year in relation to precipitation indices and crop failures.

PATHOPHYSIOLOGY

Infectious diarrheas may be classified according to various criteria: duration, underlying mechanism, clinical presentation, etiology, and history. Table I summarizes the various criteria for classifying diarrheas in general and infectious diarrheas in particular.

In this section, infectious diarrheas are described according to the duration of the main gastrointestinal symptom.

Acute Infectious Diarrhea

Acute diarrheas last, by definition, less than 4 days and the majority are due to infectious agents. Most of these infections are self-limited and generally do not require medical intervention, unless severe dehydration and toxicity develop. However, immunocompromised patients, the elderly, and the very young may develop complications from enteric pathogens that warrant prompt and decisive medical intervention. A list of the major organisms involved in the etiology of acute infectious diarrheas is presented in Table II. Not listed is a type of acute enteritis, waterborne and of presumed infectious origin, that has been responsible for several outbreaks of traveler's diarrhea, known as Brainerd diarrhea. The etiologic agent of this disease still escapes definition.

Many of the acute infectious diarrheas observed worldwide are diagnosed in the course of local or epidemic outbreaks. Three major situations may be encountered: (1) waterborne infections; (2) Food-borne diarrhea; and (3) traveler's diarrhea. Whereas food-borne diarrhea is often associated with residual microbial toxins, waterborne and traveler's diarrheas are more often caused by active infection via the fecal–oral route. Table III summarizes the most common causes in these epidemiological situations.

A successful enteric pathogen possesses well-developed abilities to colonize, grow, and compete for nutrients in a crowded environment and to interact effectively with the host's enterocytes, inducing changes in the balance between absorption and secretion of water and electrolytes. In most gut infections, a pathogen enters via the oral route and colonizes an area of the

TABLE I Classification of Infectious Diarrheas According to Various Criteria

Duration	Mechanism	Clinical findings	Etiology	Patient's History
Acute	Secretory	Inflammatory	Bacteria	Age
Persistent	Nonsecretory	Noninflammatory	Viruses	Travel
Chronic			Unicellular parasites	Immunocompetence
			Worms	Food-/waterborne
				Postinfectious

intestine. Exceptions to this paradigm are the ingestion of preformed toxins. Pathogens produce diarrhea by three basic mechanisms: (1) enterotoxins that induce active intestinal secretion (*Vibrio cholerae*, *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium botulinum*, rotavirus); (2) cytotoxic mediators (most bacteria, parasites); and (3) invasins promoting endocytosis, with subsequent tissue invasion and mucosal injury [*Shigella, Salmonella*, enteroinvasive *Escherichia coli* (EIEC)]. In addition to direct effects by microorganisms and their products, enteropathogens induce intestinal damage indirectly via the mucosal inflammatory response, which involves secretion of various powerful mediators of secretion and apoptosis. A summary of the current knowledge about the pathogenesis of the most common acute infectious diarrheal syndromes is shown in Fig. 1.

TABLE III Agents Associated with Outbreaks of Acute Infectious Diarrheas

Waterborne	Foodborne	Traveler's
Vibrio cholera	*Campylobacter*	*Escherichia coli*
Campylobacter	*Salmonella*	*Campylobacter*
Salmonella	*E. coli*	*Salmonella*
Shigella	*Shigella*	*Shigella*
E. coli	*Staphylococcus aureus*	*Aeromonas/ Plesiomonas*
Giardia	*Clostridia*	*Giardia*
Entamoeba hystolytica	*Vibrio parahaemolyticus*	*Cryptosporidium*
Cryptosporidium	Caliciviruses	*Cyclospora*
Cyclospora	Norwalk virus	*Isospora*
Microsporidia	*Giardia*	*Rotavirus*
Enteroviruses	*Cryptosporidia*	

On the basis of these three mechanisms, acute infections present as watery, noninflammatory diarrheal syndromes or inflammatory diarrheal syndromes. The majority of watery, noninflammatory diarrhea cases are self-limited diseases characterized by low-grade fever, nausea, vomiting, large-volume diarrhea, and the absence of blood and leukocytes in the stools. This presentation is typically reported in patients infected with enterotoxigenic *Escherichia coli*, *V. cholerae*, clostridial and staphylococcal food poisoning, rotavirus, Norwalk virus agent, *Giardia lamblia*, and *Cryptosporidium*. On the other hand, the inflammatory diarrheal syndrome is characterized by frequent, small-volume stools that may contain blood and leukocytes, tenesmus, fever, and severe abdominal pain. The most common microorganisms causing this syndrome include *Salmonella*, *Shigella*, *Campylobacter*, enterohemorrhagic *E. coli*, EIEC, *Clostridium difficile*, *Entamoeba histolytica*, and *Yersinia*. Table IV describes the basic biologic, pathophysiologic, and clinical characteristics pertinent to the most common enteric pathogens.

Persistent Infectious Diarrhea

Persistent diarrhea is emerging as a major world health problem. Children are more likely to develop persistent diarrhea and suffer malnutrition, wasting, and immunocompromise as a consequence. Persistent diarrhea is defined by loose–soft stools occurring at increased frequency and lasting for more than

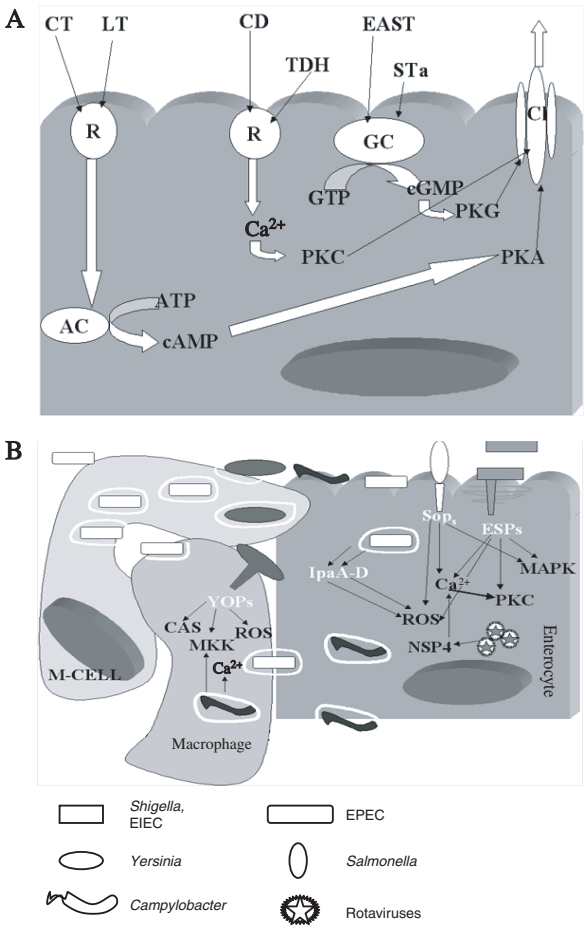

FIGURE 1 Infectious diarrhea: mechanisms of action of major enteric bacteria and viruses. Enteric pathogens can induce intestinal injury with consequent diarrhea in three ways: (1) by producing enterotoxins that interact with receptors located on the gut epithelial cells and evoke anion secretion, such as *V. cholera*, EPEC, EAEC, STEC, *C. difficile*, and *S. aureus* (A); (2) by invading the gut epithelium and M cells, thus altering the cell cytoskeleton and activating intracellular pathways through virulence factors. Organisms that lead to diarrhea through these mechanisms include EIEC, *Shigella*, EPEC, *Salmonella*, and rotaviruses (B); (3) by invading mucosal macrophages and inducing inflammatory responses leading to intestinal epithelial damage and anion secretion. *Campylobacter* and *Yersinia* use this mechanism (B).

2 weeks after the end of an acute episode of gastroenteritis. Persistent infectious diarrhea may result from multiple repeated infections, or persistent infection by the original organism, or as the so-called postgastroenteritis syndrome. Overall, the incidence of persistent infectious diarrhea is equally distributed in industrialized countries, including the United States, and developing nations. Table V lists the most common infectious agents associated with persistent diarrhea.

Postinfectious persistent diarrhea is a poorly defined syndrome that occurs as a sequela of an acute episode with definite infectious etiology. Patients may develop mild to severe degrees of malabsorption, from lactose intolerance to inability to absorb proteins, fat, and sugars, as well as permanent blunting of villi as assessed by histopathology. The condition is characterized by watery, malodorous stools and progressive wasting.

Chronic Infectious Diarrhea

Chronic infectious diarrhea occurs mostly in immunocompromised patients. After an acute infectious episode, patients sometimes develop chronic symptoms that are independent of the etiologic agents of acute diarrhea (irritable bowel syndrome with diarrhea, or, occasionally, ulcerative colitis). Table VI lists the most common agents isolated from cases of chronic infectious diarrhea.

By definition, chronic diarrhea lasts more than 4 weeks and patients developing this syndrome quite often are hospitalized and have undergone antibiotic therapy for other reasons. Elderly, human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), transplant, and cancer patients are easy targets for reinfections or reactivation of only partially subdued infectious organisms. In addition to the causes listed above, bacterial overgrowth can occur in areas of bowel stasis or impaired bowel motility. Postsurgery patients, diabetics, posttrauma patients, and intensive care patients are more likely targets of chronic infectious diarrheas from bacterial overgrowth.

SPECIAL HOSTS

The Elderly

Infectious diarrhea causes high morbidity and mortality among the aging population worldwide. Multiorgan complications from an acute episode of infectious diarrhea are also more frequent among the elderly. Life expectancy in the United States has risen from an average of 45 years in the 20th century to 75 years at present. By the year 2025, 22% of the U.S. population will be older than age 65. Gastrointestinal physiology and gut colonization change constantly with aging and contribute in a significant way to increasing the susceptibility of elderly people to enteric infections. Furthermore, the gastric acid barrier in the elderly is impaired. The most frequently isolated organisms and most deadly in elderly patients with diarrhea are *C. difficile*, *Salmonella*, and toxigenic *E. coli*. These three agents top the list of

TABLE IV Acute Infectious Diarrhea: Biology, Pathophysiology, and Clinical Findings by Etiologic Agent

Organism	Microbiology	Pathophysiology	Epidemiology	Clinical findings
Bacteria				
Salmonella: S. enteritidis; S. typhimurium; S. typhi	Invasive, gram-negative rod; 2000 serotypes	Nontoxigenic; fimbriae, SPI-1 gene-encoded effectors (inv, spa, sic, sip, TTSS, etc.), plasmid-encoded effectors (sop A-E2, hsp)	Salmonellosis in USA: 1.4 million cases/year; >500 death/year; Typhoid fever in USA: 400 cases/year; worldwide: 16 million cases with 600,000 death/year	Salmonellosis: fever, abdominal cramps, diarrhea; typhoid fever: fever, headache, malaise, vomiting; uncommon diarrhea
Shigella	Invasive, gram-negative rod; 4 species	Toxigenic; pili, flagella, TTSS, Mxi-Spa, IpaA-C, IpgD effectors	USA: 450,000 cases/year (*S. sonnei*), worldwide: *S. flexneri* and *S. dysenteriae*; fatality rate 5–15%	Fever, abdominal pain, malaise, watery or bloody diarrhea
Escherichia coli	Gram-negative rod			
EIEC	Invasive	Pili, TTSS, IpaC, Esps, adhesin		Watery or bloody diarrhea
EPEC	Noninvasive or limited invasion; typical and atypical strains	TTSS, Bfp, intimin, EspF	USA: unknown Worldwide: unknown	Watery diarrhea, nausea, vomiting
EAEC	Adherent, limited invasion	Fimbriae, TTSS, EAST, cytotoxin		Watery diarrhea
ETEC	Noninvasive, adherent	TTSS, Cfs, LT, ST	USA: 80,000 cases/year	Watery diarrhea
EHEC	Noninvasive, adherent	Toxigenic; Intimin, Stx 1 and 2	USA: 70,000 cases/year; 61 deaths	Bloody diarrhea
Yersinia enterocolitica	Gram-negative rod	TTSS, Ysc, Yop effectors	USA: 1 case/100,000/year (culture-confirmed)	Fever, abdominal pain, bloody diarrhea
Vibrio:	Non invasive, gram-negative sickle-shaped			
V. cholera		CtxA, ctxB, zot, ace, tcpA effectors, toxR, tcpP	USA: 0–5 cases/year; pandemic in Asia, Africa, Latin America	Profuse watery diarrhea, vomiting
V. parahaemolyticus/ V. vulnificus		TxA/B	USA: 3000/95 cases/year; 7/35 deaths/year	Watery diarrhea, abdominal cramps
Campylobacter jejuni	Invasive, gram-negative	Type IV secretion	USA: 2.4 million cases/year; 124 deaths/year	Fever, abdominal cramps, diarrhea (often bloody)
Staphylococcus aureus	Noninvasive, gram-positive cocci	Staph enterotoxin	USA: true incidence unknown	Nausea, vomiting, watery diarrhea
Bacillus cereus	Rod-shaped, spore-forming	Stable emetic toxin, heat- and acid-labile enterotoxin	USA: 2% food-borne outbreaks/year;	Emetic syndrome and diarrheal syndrome
Listeria monocytogenes	Invasive, gram-positive	LLO, ActA	USA: 2500 cases/year; 500 deaths/year	Fever, abdominal pain, watery diarrhea
Clostridium perfringens	Noninvasive, gram-positive, spore-forming	CpA, cpE	USA: 2% of all acute infectious diarrheas	Nausea, vomiting, diarrhea

Clostridium difficile	Noninvasive, gram-positive, spore-forming	NeuroTx A, cytoTxB	USA: 25% of all antibiotic-associated diarrheas	Watery diarrhea, fever, anorexia, abdominal pain
Aeromonas/Plesiomonas	Gram-negative rod	Cytotoxic enzymes	USA: rare	Watery or bloody diarrhea, abdominal cramps
Viruses				
Rotavirus	*Reoviridae*, dsRNA	NSP4 enterotoxin	USA: 3 million cases/year; worldwide: l million deaths/year	Vomiting, watery diarrhea
Norwalk virus	*Caliciviridae*, ssRNA	Unknown	30% of all cases of diarrheas in children >1 year	Nausea, vomiting, diarrhea
Calicivirus	*Caliciviridae*, ssRNA	Unknown	1.5% of all cases of viral gastroenteritis	Nausea, diarrhea
Adenovirus	*Adenoviridae*, dsDNA, type 40 and 41	Unknown	<1% of all cases of viral gastroenteritis	Fever, vomiting, diarrhea
Astrovirus	*Astroviridae*, ssRNA	Unknown	1.5% of all cases of viral gastroenteritis	Watery diarrhea
Coronavirus	*Coronaviridae*, ssRNA	Unknown	<1% of all cases of viral gastroenteritis	Vomiting, diarrhea
Herpes simplex virus	*Alphaherpesvirinae*, dsDNA	Unknown		Fever, tenesmus, watery or bloody diarrhea
Cytomegalovirus	*Betaherpesvirinae*, dsDNA	Unknown	Rare in immunocompetent; 16% in solid organ transplants; 5% in HIV/AIDS	Fever, malaise, abdominal tenderness, diarrhea
Parasites, unicellular				
Giardia lamblia	Diplomonadida, cysts and throphozoites, 5 chromosomes (5K genes)	VSP (analogy with sarafotoxins)	USA: 2.5 million cases/year; endemic in developing countries	Diarrhea, flatulence, abdominal cramps, malabsorption
Entamoeba histolytica	Entamoebidae, cysts and throphozoites, 14 chromosomes	Cysteine proteinases	USA: infrequent; worldwide: 400 million infections/year, 100,000 deaths/year	Asymptomatic, mild gastroenteritis, or bloody dysentery
Cryptosporidium parvum	Alveolata, oocysts and throphozoites, ongoing genome sequencing	Peptidases	USA: 2% of the general population; worldwide: unknown	Asymptomatic or watery diarrhea
Cyclospora cayetanensis	Alveolata, oocysts and sporozoites, ongoing genome sequencing	Unknown	USA: unknown, outbreak related to contaminated berries; worldwide: unknown, endemic in Guatemala and Peru	Fever, watery diarrhea, fatigue
Microsporidia	Microsporidia, spores and schizontes	Unknown	Unknown	Asymptomatic or watery diarrhea
Isospora belli	Alveolata, oocysts and throphozoites	Unknown	Unknown	Asymptomatic or watery diarrhea
Blastocystis hominis	Stramenopiles	Unknown	Unknown	Asymptomatic or watery diarrhea
Balantidium coli	Alveolata, cysts and throphozoites	Unknown	USA: rare	Asymptomatic to bloody diarrhea

TABLE IV Acute Infectious Diarrhea: Biology, Pathophysiology, and Clinical Findings by Etiologic Agent (*continued*)

Organism	Microbiology	Pathophysiology	Epidemiology	Clinical findings
Dientamoeba fragilis	Parabasalidea, throphozoites, no cysts	Peptidases	USA: infrequent	Nausea, malaise, mucous diarrhea, abdominal pain
Worms				
Strongyloides stercoralis	Helminths, nematodes, filariform larvae, can complete life cycle in humans	Organism effectors and host responses	USA: 4% prevalence in Appalachian States; worldwide: 100 million cases/year, 60% prevalence in tropical countries	Mild to severe diarrhea, malaise, fatigue, malnutrition
Anchilostoma duodenalis, Necator, americanus	Helminths, nematodes, filariform larvae and eggs	Organism effectors and host responses	USA: uncommon; worldwide: in tropical countries prevalence is increasing due to climate changes	Mild to severe diarrhea, abdominal pain, weight loss
Hymenolepsis nana, H. diminuta	Cestodes, cysticercoids and adult worms in humans (fleas and beetles intermediate hosts)	Organism effectors and host responses	USA: rare; worldwide: Latin America	Abdominal cramps, mucous diarrhea upon rupturing of villus by cysticercoids
Heterophyes heterophyes	Trematodes, metacercariae and eggs (fish and snails intermediate hosts)	Organism effectors and host responses	USA: rare; worldwide: endemic in Egypt, Middle East, and Far East	Asymptomatic to severe mucous diarrhea, intestinal wall granulomas

Note. SPI, *Salmonella* pathogenicity island; TTSS, type 3 secretory system; Tx, toxin; Cfs, cytotoxic factors; EAST, enteroaggregative heat-stable toxin; LT, heat-labile toxin; ST, heat-stable toxin.

TABLE V Agents Associated with Persistent Infectious Diarrhea

Bacteria	Parasites
Salmonella	*Cryptosporidium parvum*
Shigella	*Cyclospora cayetanensis*
Escherichia coli[a]	*Giardia lamblia*
Yersinia	*Entamoeba hystolytica*
Campylobacter	*Balantidium coli*
Clostridium	*Dientamoeba fragilis*

[a] EIEC, enteroinvasive *E. coli*; EAEC, enteroadherent *E. coli*; ETEC, enterotoxigenic *E. coli*; EPEC, enteropathogenic *E. coli*.

outbreaks in long-term and short-term care facilities and *Salmonella* by itself accounts for more than 50% of cases and more than 80% of deaths in food-borne outbreaks in nursing homes.

HIV/AIDS

More than 50% of HIV/AIDS patients in the United States experience infectious diarrhea and this estimate may approach 100% in developing countries where the HIV epidemic is currently raging unchecked. These patients are more likely to develop persistent or chronic diarrhea after an acute episode because of their impaired immunity, with a significant increase in morbidity and mortality. Table VII lists the most common causes of infectious diarrhea in AIDS patients.

The American Gastroenterological Association (AGA) has published a set of general guidelines for the management of chronic diarrhea in AIDS patients. At least three sets of stool samples should be secured for common enteric bacteria and parasites, including microsporidia, cryptosporidia, and *C. difficile*. Febrile patients with diarrhea should have blood cultures for common enteric bacteria. Patients with CD4 lymphocyte counts of <100 cells/mm are at high risk for disseminated mycobacterial infection.

TABLE VI Agents Associated with Chronic Infectious Diarrhea

Bacteria	Parasites
Campylobacter	*Amoeba*
Mycobacterium tuberculosis	*Cryptosporidium*
Aeromonas	*Giardia lamblia*
Plesiomonas	*Isospora*
Salmonella	*Cyclospora*
Clostridium difficile	*Strongyloides*
	Trichuris
	Schistosoma

CLINICAL AND LABORATORY FINDINGS

The most important finding in patients presenting with acute diarrhea is the degree of volume depletion, i.e., dehydration. Postural changes in blood pressure are a reliable sign of dehydration. Fever, abdominal tenderness, increased bowel sounds, or blood on rectal examination should alert the physician to acute infectious diarrhea.

Microscopic examination of a stool sample or rectal swab is a traditional and helpful tool in the rapid, bedside investigation of diarrheal illness. The specimen is placed on a glass slide and mixed thoroughly with two drops of methylene blue. The presence of ova, cysts, and/or leukocytes may point directly to a diagnosis. The AGA guidelines on managing acute diarrhea indicates empiric antimicrobial therapy in the case of positive fecal leukocytes in a febrile patients.

Endoscopy has limited utility in the investigation of acute infectious diarrhea and is not cost-effective. It may have a place, however, in cases of persistent or chronic diarrhea.

PREVENTION

Preventative measures against infectious diarrhea must include improvements in sanitation (water supply, sewer systems, housing), education of the general population and, where applicable, vaccination campaigns. Unfortunately, no effective vaccines are available for the organisms that cause infectious diarrheas, with the exception of typhoid fever.

TREATMENT

Most acute diarrheal illnesses are self-limited and no specific therapy is required. Water and electrolyte loss can be prevented or treated with oral fluid–electrolyte solutions. Intravenous saline–glucose solutions are recommended in cases of moderate to severe dehydration. Glucose in the intestinal lumen facilitates the absorption of sodium and the cotransport mechanism for these solutes appears to be unhampered by infection with microorganisms or by their toxins.

Antimotility therapy should be reserved for severe cases and chronic diarrheas and avoided in infants and children. Antibiotic or antiviral treatment should be considered in moderate to severe cases in which a microbiological diagnosis is obtained or strongly

TABLE VII Agents Associated with Diarrhea in AIDS Patients

Bacteria
Shigella
Salmonella
Escherichia coli
Campylobacter
Yersinia enterocolitica
Clostridium difficile
Clostridium perfringens

Diarrhea, Pediatric

JEFFREY A. RUDOLPH* AND PAUL A. RUFO†
*Children's Hospital Medical Center, Cincinnati and †Children's Hospital Boston

acute diarrhea A diarrheal illness of less than 14 days duration. Acute diarrheal disease in children is most often the result of self-limited viral infections. Management includes prompt assessment and repletion of hydration status. Evaluation for an etiologic process is generally not warranted unless there is an associated finding such as blood in the stool or systemic symptoms.

chronic diarrhea A diarrheal illness of greater than 14 days duration. Chronic diarrhea in children can be due to either infectious or noninfectious processes. Evaluation for a specific etiology is indicated. Management of comorbid conditions such as poor growth or malnutrition is essential.

colitis Any inflammatory process affecting the colon. Colitis usually presents clinically as bloody diarrhea, abdominal cramping, and tenesmus.

congenital diarrhea A group of diarrheal illnesses that are present from birth. Congenital diarrhea can be the result of either a specific genetic defect in a secretory or absorptive pathway or abnormal intestinal development.

gastroenteritis A diarrheal process that affects the upper gastrointestinal tract and presents most typically as an acute watery diarrhea. Gastroenteritis usually denotes an acute diarrhea that is infectious and self-limiting.

hemolytic uremic syndrome A sequela of *Escherichia coli* O157:H7 colitis. This toxin-mediated microangiopathy results in a triad of hemolytic anemia, thrombocytopenia, and renal failure. The occurrence of the syndrome is generally limited to children under 10 years of age.

inflammatory diarrhea A diarrheal illness in which the predominant pathologic finding is an invasion of the intestinal epithelium by immunocytes. This type of diarrhea can be the result of either a normal immune response to an abnormal environment, as in infection, or an abnormal immune response to a normal environment, as in inflammatory bowel disease.

IPEX syndrome (immunodysregulation, polyendocrinopathy, and enteropathy: X-linked) An inherited X-linked syndrome that results from a mutation in the FOXP3 gene in humans. It is characterized by autoimmune enteropathy and multiple endocrinological abnormalities including diabetes mellitus, hypothyroidism, and hemolytic anemia.

osmotic diarrhea A diarrheal illness that is driven by osmotic forces that promote a net flux of water out of the interstitium and into the intestinal lumen. A stool sodium level of mEq/liter and an osmotic gap of greater than 100 mosm/liter suggest an osmotic diarrhea.

secretory diarrhea A diarrheal illness that is driven by the active secretion of salt and water by intestinal epithelial cells. A stool sodium level of >70 mEq/liter, an osmotic gap of less than 100 mosm/liter, and a failure of the diarrhea to respond to a controlled fast suggest a secretory diarrhea.

Diarrheal diseases continue to contribute significant morbidity and mortality to pediatric populations in developed and developing countries around the world. The prevalence of diarrheal illness across cultures is inversely proportional to the availability of public sanitation, clean water supply, and adequate medical care. As such, it is not surprising that the incidence of diarrheal disease is much higher in developing societies and can approach 10 episodes per child per year in children under 5 years of age. In these areas, aggregate mortality can reach 3 to 5 million deaths per year. In the United States and other developed nations, both the incidence (1–2 episodes per year) and mortality (approximately 400–500 deaths annually) are considerably decreased. Nonetheless, the burdens placed on Western health care systems by pediatric diarrheal disease are considerable and approximately 20% of all pediatric ambulatory visits and 10% of all inpatient hospital admissions in children under 3 years of age are for the evaluation and treatment of these disorders and their complications.

The frequency and consistency of stool can vary considerably from individual to individual, as well as in the same individual over time. There has therefore remained a lack of a consensus as to how diarrheal illness should be defined. Investigators have employed a number of qualitative and quantitative dimensions of stool output to address this issue in the past. For the most part, children pass between one and three stools, or approximately 5–10 ml of stool per kilogram of body weight, per day. As such, investigators have begun to use these benchmarks as the upper limits of normal in their identification of subjects in studies addressing acute or chronic diarrheal disease.

REGULATION OF INTESTINAL FLUID SECRETION AND ABSORPTION

The mucosa lining the gastrointestinal tract must reconcile daily a seemingly contradictory array of physiologic tasks. These conflicting responsibilities include the maintenance of a tight barrier against potentially virulent bacterial and viral pathogens in the intestinal lumen, while at the same time presenting a selectively permeable interface through which to carry out immune surveillance and nutrient absorption. In this context, intestinal fluid secretion can serve both defensive (flushing away pathogens and toxins) and homeostatic (maintenance of mucosal hydration necessary to facilitate enzymatic digestion) purposes.

Stool output in humans is a composite of ingested, secreted, and absorbed fluid intermixed with residual dietary matter and cellular debris. Adults typically ingest approximately 2 liters of fluid per day and produce an additional 9 liters in the form of salivary, gastric, small intestinal, and pancreato-biliary secretions, to complete the process of digestion. The small intestine and colon have evolved highly efficient intercellular and transcellular pathways for the reabsorption of the vast majority (approximately 99%) of this intestinal fluid, and the average adult will pass only approximately 200 g of stool per day. This balance between fluid secretion and absorption is therefore quite tight. Any microbiologic, dietary, pharmacologic, or hormonal input that affects cell membrane transporters and/or the intercellular tight junctions responsible for fluid absorption can tip this net fluid balance in favor of secretion (or reduced absorption) and thereby trigger the increased stool output observed in patients with diarrheal illnesses.

The cellular basis for salt and water secretion in the intestine, as well as in other hydrated mucosal surfaces in the body, depends upon a vectorial transport of Cl^- ions by specialized epithelial cells. Intestinal crypt epithelial cells use basolateral membrane Na^+/K^+-ATPase pumps as well as the Na^+- and K^+-coupled cotransporter NKCC1 to accumulate Cl^- ions above their electrochemical gradient (Fig. 1). The subsequent opening of Cl^- channels located in the apical membrane of enterocytes permits sequestered Cl^- ions to move down their electrochemical gradient and into the intestinal lumen. The parallel activation of plasma membrane K^+ channels conducts K^+ outside, thereby sustaining the inside-negative cell membrane potential that is necessary to initiate and maintain a Cl^- secretory response.

Fluid secretion in the intestine is tightly regulated by endocrine as well as neuroenteric mechanisms that utilize either cyclic nucleotides [3′,5′-monophosphate (cAMP) or cyclic GMP (cGMP)] or Ca^{2+} as second messengers. Cyclic nucleotide-dependent agonists initiate Cl^- secretion through the parallel activation of the apical membrane Cl^- channel CFTR (the cystic fibrosis transmembrane receptor) as well as the basolateral membrane K^+ channel KCNQ1/KCNE3. In contrast, agonists utilizing Ca^{2+} as a second messenger activate the apical membrane Cl^- conductance CaCC in concert with the basolateral membrane K^+ channel IK1 (KCNN4). The net movement of Cl^- ions into the intestinal lumen imparts a transiently negative charge to this extracellular compartment and positively charged Na^+ ions move via paracellular pathways in response. The osmotic force generated by transported Cl^- and Na^+ ions pulls water molecules along to effect net fluid secretion. The activity of CFTR is regulated primarily by cAMP- and cGMP-dependent protein kinases. In contrast, Ca^{2+}-dependent Cl^- secretion in the intestine conducted by CLCA appears to be limited by the generation of the intracellular down-regulatory intermediates inositol-3, 4,5,6-tetrakisphosphate, and phosphorylated extracellular signal-regulated kinase.

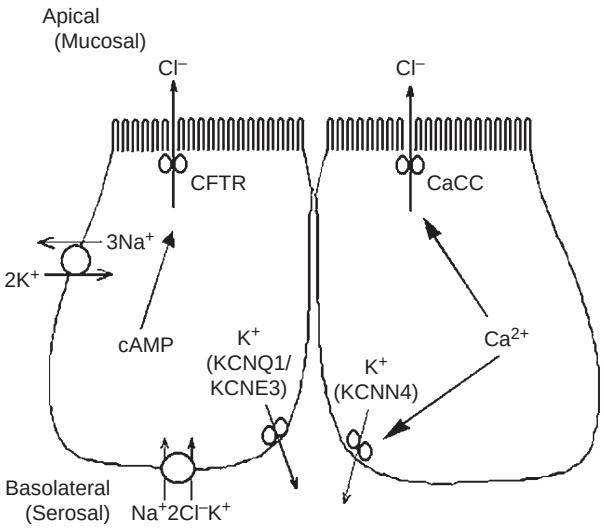

FIGURE 1 Intestinal crypt epithelial cells use basolateral membrane Na^+/K^+-ATPase pumps as well as the Na^+- and K^+-coupled cotransporter NKCC1 to accumulate Cl^- ions above their electrochemical gradient. The subsequent opening of Cl^- channels located in the apical membrane of enterocytes permits sequestered Cl^- ions to move down their electrochemical gradient and into the intestinal lumen. The parallel activation of plasma membrane K^+ channels conduct K^+ outside, thereby sustaining the inside-negative cell membrane potential that is necessary to initiate and maintain a Cl^- secretory response.

Whereas Cl^- secretion drives intestinal fluid secretion, fluid absorption is mediated primarily by the vectorial transport of Na^+ ions out of the intestinal lumen and into the interstitium. Na^+ transport can be

electrogenic (as in the case of apical Na^+ channels), Na^+-coupled, or electroneutral. The accumulation of absorbed Na^+ ions in the tissue interstitium favors the subsequent movement of Cl^- ions and water molecules out of the intestinal lumen via transcellular and paracellular pathways, thereby effecting salt and water uptake. Na^+ channels have been identified in the apical membrane of gut epithelium. By acting in a coupled fashion with basolateral membrane Na^+/K^+-ATPase pumps, these channels permit lumenal Na^+ ions to move down their electrochemical gradient and into the cell. The favorable Na^+ gradient established by Na^+/K^+ pumps has also been exploited by the small intestine to promote nutrient absorption. SGLT1 is the Na^+-coupled glucose transporter expressed along the apical membrane of enterocytes. Similarly, Na^+ uptake in the small intestine is effected through Na^+-coupled amino acid transporters that are present along the enterocyte brush border. Finally, the Na^+/H^+ exchanger NHE-3, expressed in the apical membrane of enterocytes, appears to mediate electroneutral Na^+ transport in the intestine.

The tasks of intestinal fluid secretion and absorption are separated spatially along the length of the crypt–villus axis through a segregation of relevant plasma membrane channels and transporters. Cells newly differentiated at the crypt base display a primarily secretory phenotype and express high levels of CFTR. As these cells mature and migrate up the axis to take up more villous positions, they express increasing numbers of absorptive proteins including NHE-3 and Na^+-coupled glucose and amino acid transporters. Stool output is therefore the net product of intestinal fluid secretion originating in crypt cells (which occupy approximately one-third of the crypt–villus axis) and fluid absorption from villus cells (which take up the remaining two-thirds of the crypt–villus axis). Any disorder damaging surface villi, and thereby decreasing the villus/crypt ratio, will selectively decrease mucosal absorptive potential and cause increased stool output. This explains the increased stool output observed in patients with celiac disease, postviral syndromes, and giardiasis.

APPROACH TO THE CHILD WITH DIARRHEA

Diarrhea can be classified on the basis of several descriptive factors (acute versus chronic, inflammatory versus noninflammatory, infectious versus noninfectious, secretory versus osmotic) that aid in the diagnostic approach. These include the duration of the illness, the existence of a secretory or osmotically driven mechanism, the presence or absence of a pathogen, and the degree of mucosal inflammation. Although the pathogenesis of diarrheal disease can be explained by a discrete process in some patients, increased stool output is more often the result of a combination of factors. As such, patients with inflammatory diarrhea can present with a secretory component due to the local release of endogenous secretagogues. Clinical diagnosis rests on an understanding of the close interplay between environmental and host factors in these patients.

Central to the diagnosis of a diarrheal illness is the clinical context in which it presents. Characteristics of the individual, such as age, are often the first clue in determining an etiology. This is most apparent in the case of congenital diarrheas, which present exclusively within the first few days of life. Components of the child's overall health, such as atopy or immunodeficiency, can also suggest a particular etiology. Environmental factors, including diet, must also be taken into consideration in the diagnostic approach to the pediatric patient with diarrhea. In the setting of infectious diarrhea, an exposure history such as an ill contact at home or in daycare, a recent travel history, or contact with a pet or animal, can sometimes provide useful epidemiologic information when attempting to understand how a pathogen may have been acquired.

The character of the stool itself is often helpful when arriving at a specific diagnosis. Stool that is both watery and voluminous in nature suggests an abnormality in the absorptive or secretory function of the small intestine. In contrast, crampy abdominal pain, tenesmus, and the presence of frank blood in the stool suggest colitis or large bowel disease.

Several aspects of diarrheal disease in children merit special consideration. Children, and most especially infants, are more susceptible to dehydration than their adult counterparts. This is due both to their greater overall body surface area relative to their weight and to a dependence on caregivers, who may be less likely to offer fluids to or feed a child who is vomiting or appears ill. Poor growth and malnutrition can also become a factor in children when diarrhea is chronic in nature. During infancy and early childhood, a large proportion of caloric intake is devoted to growth. Diarrheal disease, resulting in inadequate intake or poor nutrient absorption during this critical developmental period, can alter weight gain and, in severe cases, result in stunted linear growth.

The scope of the remaining article will discuss the causes, evaluation, and treatment of diarrheal disease in infants and children. By convention, the discussion will be segregated into infectious causes and noninfectious causes with a special reference to age of onset where appropriate.

INFECTIOUS DIARRHEA IN CHILDREN

Infectious diarrhea is usually of acute onset in a previously healthy child. Fortunately, most causes of infectious diarrhea are self-limited and require only symptomatic care. However, if left untreated, acute diarrheal illness can progress to chronic diarrhea in some patients. Fever is a common associated symptom of infectious diarrhea and vomiting is not unusual, especially if the infection occurs in the upper gastrointestinal tract (i.e., gastroenteritis). In general, infectious diarrheas are secretory or mixed secretory/osmotic in character. Toxin production, pathogen adherence, or frank tissue invasion all can contribute to increased Cl^- secretion by affected epithelial cells. When pathogenic invasion of the epithelium occurs, there is usually an inflammatory component to the diarrhea as well. Pathogens that cause diarrhea can be viral, bacterial, or parasitic.

Viruses are the most common cause of acute infectious gastroenteritis in children (Table I, part A). There are several reasons for the preponderance of cases of viral diarrheas. The naive immune system of an infant has not been exposed to many of the viral pathogens present in the environment. In addition, daycare provides group settings that facilitate the transmission of enteric and respiratory viral diseases.

TABLE I Etiology of Pediatric Diarrhea

Infectious diarrhea	Noninfectious diarrhea
A. Viral pathogens	**D. Inflammatory**
Rotavirus	Inflammatory bowel disease
Adenovirus	Celiac disease
Norwalk agent	Allergic enteropathy
Calicivirus	Autoimmune enteropathy
Astrovirus	Graft-versus-host disease
Coronavirus	**E. Noninflammatory**
B. Bacterial pathogens	**Congenital diarrheas**
Campylobacter spp.	Congenital chloride diarrhea
Salmonella spp.	Congenital sodium diarrhea
Shigella spp.	Microvillus inclusion disease
Escherichia coli	Tufting enteropathy
Enterotoxigenic	Carbohydrate transporter defects
Enteropathogenic	Dissacharidase deficiency
Enterohemorrhagic (shigatoxin producing)	Amino acid transporter defects
Enteroadherent	Pancreatic insufficiency
Enteroinvasive	Bile acid transport defects
Yersinia spp.	Abetalipoproteinemia
Vibrio spp.	**Acquired diarrheas**
Aeromonas spp.	Toddler's diarrhea
Plesiomonas spp.	Short bowel syndrome
Clostridium difficile	Small bowel overgrowth
C. Parasitic pathogens	Antibiotic-associated diarrhea
Giardia lamblia	Münchausen's syndrome
Cryptosporidia	Secondary lactase deficiency
Cyclosporidia	
Entamoeba histolytica	
Nematodes	
Cestodes (tapeworms)	
Trematodes	

Rotavirus is the most common viral pathogen. All children exposed to rotavirus, regardless of whether or not they manifest symptomatic diarrhea, will develop circulating antibodies to this pathogen. The decreasing incidence of rotavirus in adults is thought to be due to the protective effect of these antibodies. Rotaviruses are small, wheel-shaped viruses approximately 70 nm in diameter. Of the four major groups (A, B, C, and D), type A viruses are the most important in children. The virus invades the epithelium and promotes an inflammatory response that ultimately contributes to the destruction of the villous surface. However, the frequency and severity of stool output in these patients does not correlate closely with the degree of intestinal damage observed endoscopically or histologically. This has led to the speculation that there are other pathogenic mechanisms that contribute to the malabsorption and net fluid losses observed in these patients. Although villous destruction can be severe in rotaviral disease, recovery is rapid in most patients and symptoms typically resolve in 2 to 7 days.

Caliciviruses, including the Norwalk and Norwalk-type agents, are the second leading cause of pediatric viral diarrheas. This group of viruses presents in a similar fashion to rotavirus, with the exception that the diarrhea is usually milder. Astroviruses are similar to calciviruses and are a common cause of diarrheal illness. Adenovirus (serotypes 40 and 41) is a well-established cause of viral diarrhea and has a slightly longer incubation period and a longer course than rotaviral disease. More recently, Torovirus has been implicated as a potential cause of diarrhea in children. However, more definitive epidemiologic data concerning this pathogen are currently lacking.

Bacterial infections can also cause diarrheal disease in infants and children (Table I, part B). As in the case of viral diarrhea, the onset of bacterial illness is usually acute and presents with fever and sometimes vomiting. Because the most common forms of bacterial diarrhea are invasive, bloody diarrhea is often reported in these patients. Specific types of bacterial illness have been reported to occur more commonly in specific age groups. *Campylobacter jejuni*, for instance, has a bimodal distribution of onset with the first peak occurring in children from 1 to 5 years old and a second peak in adolescents. Nontyphoid *Salmonella enteritidis* can cause a bacteremia in infants and in

immunocompromised hosts. *Shigella* species can be found in the toddler age group, but is not a commonly isolated pathogen in the United States. *Clostridium difficile*, an important cause of antibiotic-associated diarrhea in adults, is not usually a pathogen in infants. *C. difficile* toxin can be found in up to 10% of healthy newborns and is even more prevalent in neonatal intensive care units. The reason for the inability of this organism to cause diarrhea in infants remains unclear. Based on animal studies, it is thought that the receptor for this toxin is developmentally regulated and absent in early infancy. *Vibrio cholerae* causes a prototypical bacterial secretory diarrhea. It produces a toxin composed of two subunits. The B, or binding, subunit displays a pentameric form that binds selectively to the ganglioside GM_1. The A, or active, subunit is internalized by intestinal epithelia, alters signal transduction, and leads to increased production of cAMP and Cl^- secretion. Other forms of toxin-producing organisms include enterotoxigenic *Escherichia coli*, the pathogen responsible for traveler's diarrhea, and organisms responsible for acute food poisoning such as *Staphylococcus aureus* and *Bacillus cereus*. *E. coli* O157:H7 is an important pathogen in children. This enteropathic *E. coli* adheres to the intestinal lumen and produces a toxin that is absorbed and causes the hemolytic–uremic syndrome.

Parasitic disease causing diarrhea is far less common in industrialized countries (Table I, part C). One notable exception is *Giardia lamblia*, which is especially prevalent in the daycare setting. *Giardia* can present as an acute diarrheal illness or as a more chronic process. The mechanism by which this organism causes diarrhea is not fully understood. There is no gross alteration in intestinal architecture or evidence of a significant immunologic response. There are multiple other parasites that can cause diarrheal disease in children. However, these occur much less commonly and will not be discussed further.

NONINFECTIOUS DIARRHEA IN CHILDREN

Occasionally, a child will present with a diarrheal illness that is not self-limiting. Fever may or may not be present and other co-morbidities, such as growth failure and malnutrition may be prominent. Stool cultures are negative. The etiology of diarrheal disease in these patients can be broadly classified as being inflammatory or noninflammatory in nature, based on clinical history, physical examination, and biochemical workup. Similar to patients with infectious diarrhea, the increased stool output observed in these patients is typically the result of a combination of pathogenic mechanisms.

Inflammatory Diarrhea

The intestine displays a tremendous capacity to generate an immune response based on the presence of numerous effector immunocytes that lie within the intestinal mucosa and submucosa. More recent data have demonstrated that intestinal epithelial cells themselves also possess the ability to process lumenal antigens and present them to the underlying immune cells. The intestinal epithelium is in constant contact with the external environment. It is subsequently in a constant state of low-grade inflammation (often referred to as "physiologic inflammation") that is the result of the epithelium playing its role in the surveillance of and response to the broad array of dietary, microbiologic, and toxigenic stimuli present within the intestinal lumen. When the degree of mucosal inflammation is severe enough to affect the absorptive and secretory function of the intestine, diarrhea ensues.

A number of immune defects or imbalances can affect the intestine (Table I, part D). Inflammatory bowel disease is example of an inflammatory diarrhea that is likely the result of a genetically driven dysregulated immune response to the lumenal environment. It is also likely that genetic predisposition may leave some individuals vulnerable to an exaggerated immune response to dietary antigens that are usually not perceived to be a threat to intestinal function. This may explain the incidence of allergic enteropathies in some children. In patients with celiac disease, or gluten-sensitive enteropathy, there is an immune-mediated response to a protein present in wheat and related grain products. Although these patients can show marked diarrhea, they more commonly present with a failure to thrive precipitated by the introduction of wheat-containing solid foods between 6 and 9 months of age.

Autoimmune disease can target the intestinal epithelium itself and antibodies directed against enterocytes contribute to the severe inflammation and tissue destruction observed histologically in these patients. The IPEX syndrome is an X-linked autoimmune enteropathy that is associated with polyendocrinopathy and results in high morbidity and mortality. The gene defect is thought to lie within the FOXP3 gene and it has been shown to encode the protein scurfin, a regulator of T-cell function in mice. The important role played by lymphocytes in maintaining intestinal barrier function can be appreciated in the context of bone-marrow transplant recipients. Diarrhea is a major feature of graft-versus-host disease, a clinical condition in which

donor lymphocytes recognize host intestinal epithelial cells as being foreign. Activated immunocytes subsequently initiate a destructive process that is manifest histologically as increased epithelial cell apoptosis and clinically as a secretory or inflammatory diarrhea.

Noninflammatory Diarrheas

Children can also suffer from diarrhea that is neither infectious nor inflammatory in nature. These diarrheal illnesses can be broadly categorized into congenital or acquired forms (Table I, part E). Congenital diarrheas are most often the result of abnormal gene expression, resulting in a clinical presentation within the first week of life. Congenital chloride diarrhea is caused by a mutation in the Down-Regulated in Adenoma (DRA) gene, thought to be a colonic chloride transporter. This disease presents uniformly *in utero* with polyhydramnios. Severe diarrhea and abdominal distension appear shortly after birth and profound electrolyte disturbances can occur in these patients if not resuscitated promptly. In contrast, the cause of congenital sodium diarrhea is not known but is thought to be due to a functional uncoupling of sodium and hydrogen exchange in the intestine. No mutations have been described in the known Na^+/H^+ exchangers in the intestine to date. The clinical presentation of congenital sodium diarrhea is similar to congenital chloride diarrhea with the exception that stool chloride levels in these patients are typically lower and the stool pH tends to be more alkaline. In addition to defects in ion transporters, there have been a number of diseases that have been described with altered transport of glucose, galactose, and amino acids. Gastrointestinal symptoms vary from defect to defect. Amino acid transport defects often have extraintestinal manifestations whose consequences far outweigh changes in bowel patterns.

Congenital diarrheas can also be caused by genetic defects that result in the malabsorption of the products of digestion such as carbohydrates and fat. Congenital disaccharidase deficiencies are rare and result in an osmotically driven diarrhea. Much more common are the transient and secondary deficiencies in mucosal disaccharidase levels that result from small intestinal injury or inflammation. Fat malabsorption can also present with diarrhea of variable severity. Congenital fat malabsorption can be the result of pancreatic insufficiency, seen in patients with cystic fibrosis, or due to specific genetic defects such as abetalipoproteinemia. Fat malabsorption is characterized by varying degrees of greasy and malodorous stools. Finally, congenital disorders of the intestinal architecture can lead to diarrhea. Microvillus inclusion disease is a rare autosomal recessive disease that is characterized by severe watery diarrhea at birth. Diagnosis is based on a histologic demonstration of marked or complete villous atrophy and electron microscopic evidence of intracellular microvillus inclusions and absent or rare microvilli.

There are multiple acquired forms of pediatric diarrhea that can be characterized as being noninfectious and noninflammatory in nature. Often, these diarrheas result from a predisposing insult that diminishes the ability of the intestinal mucosa to absorb nutrients, thereby contributing to an osmotic diarrhea. The most common example of this is toddler's diarrhea or chronic nonspecific diarrhea of childhood. There is no underlying inflammatory or biochemical abnormality that drives the increased stool output seen in these young children. In many cases, these patients will respond to a reduced dietary intake of fruit juices. Because many of these juices contain large amounts of sorbitol, an indigestible carbohydrate, they can induce an osmotic diarrhea. As such, the diarrhea will resolve in most patients within a few days after removal of the offending juice. Other examples of acquired and primarily noninflammatory diarrheas that fall into this category include antibiotic-associated diarrhea, short bowel syndrome, and small bowel bacterial overgrowth. Additionally, Münchausen's syndrome-by-proxy must always be considered in children with diarrhea and no predisposing factors.

LABORATORY EVALUATION OF DIARRHEA

Laboratory evaluation of the pediatric patient with diarrhea varies with the suspected cause and is dictated by the clinical picture. Any suspicions about potential inflammation or bacterial infection should be addressed immediately. Evaluation of acute diarrhea is usually limited to cases in which a given patient is presenting with systemic symptoms or co-morbidities. Chronic diarrhea must always be evaluated, especially in the context of poor growth or malnutrition. An evaluation that proceeds in a logical and stepwise manner generally results in the most expedient and cost-effective diagnosis.

The first step in the evaluation process is to determine whether or not the presenting patient's symptoms are most consistent with an inflammatory or noninflammatory process. This can be done by an examination of the stool for gross or occult blood or the presence of fecal leukocytes. Previous studies have also demonstrated the sensitivity and specificity of biochemical assays for fecal lactoferrin, a constituent of neutrophil granules. Patients with infectious or inflammatory diarrhea will

typically present with rectal bleeding or overt (positive fecal leukocyte smear) or biochemical evidence (lactoferrin) of fecal white blood cells. In contrast, these studies should be negative in patients with noninflammatory (viral, osmotic, or secretory) diarrheal disease. Nonetheless, although these markers may increase the yield of sending stool cultures, they do not exclude intestinal inflammation and any final decision about pursuing an infectious workup must be made on clinical grounds.

If there is clinical or biochemical evidence of an inflammatory process, then routine stool cultures remain the gold standard in the search for a bacterial cause of diarrhea. Most hospital-based laboratories have a standard panel of cultures associated with common pathogens including *Campylobacter*, *Shigella*, *Salmonella*, and *Yersinia enterocolitica*. Many hospitals also routinely screen for *E. coli* O157:H7. The identification of some pathogens relies on the detection of a particular toxin that is produced by the bacteria and released into the stool. *C. difficile* is perhaps the best recognized pathogen in this class.

The diagnosis of parasitic disease is most often made by a close microscopic evaluation of the stool for ova and parasites. The identification of *Giardia* and Cryptosporidia has been further facilitated by the development of enzyme-linked immunosorbent assay (ELISA)-based stool tests. It is imperative to know a specific laboratory's capabilities and limitations prior to interpreting the results of any stool, toxin, or parasitic studies.

Most "noninflammatory" diarrheal disease is viral in nature. However, routine evaluation of stool for viral pathogens is not often useful because of the self-limiting nature of the disease process in the vast majority of patients, the specialized nature of obtaining viral cultures, and the expense of detecting specific viral pathogens. One notable exception is the rotavirus stool antigen test. This commercially available ELISA-based test provides relatively rapid results that can assist both in patient care and in making decisions about the need for isolation of hospitalized patients. Other viral stool tests include polymerase chain reaction-based screening for viral DNA in the case of adenovirus. However, these more costly and specialized tests are typically reserved for the evaluation of immunocompromised patients, in whom targeted supportive or antiviral therapy is much more critical.

Characterization of the stool can be helpful for determining the nature of noninflammatory diarrheal illness. Stool evaluation for fat, pH, and reducing substances is important in determining whether or not there is an underlying malabsorptive process. The presence of "neutral" fat in the stool suggests some deficiency in the production or delivery of pancreatic (lipase) or hepatic (bile acid) secretions into the intestinal lumen. An increase in "split" fat in the stool indicates a primary inability of enterocytes to perform fat absorption. Reducing substances are the result of undigested carbohydrates making their way into the large intestine. The presence of these fecal sugars can be readily assessed with commercially available colorimetric strips or test solutions. It must be remembered that sucrose is a nonreducing sugar. As such, stool must first be pretreated with an acid solution to make this nonreducing sugar detectable. Undigested carbohydrates, as well as dietary fiber, are consumed by bacteria in the large bowel and generate short-chain fatty acids. Carbohydrate malabsorption can therefore also be assessed by a fall in stool pH.

Stool electrolytes can help to determine whether or not a diarrheal process is secretory in nature. In general, a stool Na^+ concentration of greater than 70 mEq/liter is indicative of a secretory process. The stool osmotic gap, calculated by

$$([Na^+] + [K^+]) \times 2 - \text{stool osmolarity}$$

$$[Na^+] = \text{concentration of Na}$$

$$[K^+] = \text{concentration of K}$$

is useful in distinguishing between osmotic and secretory diarrheal disease. An osmotic gap greater than 100 mosm/liter suggests an underlying osmotic process. Similarly, whereas osmotic diarrhea will typically respond to a dietary fast, secretory diarrheal diseases are driven by processes that are independent of exogenous (dietary or pharmaceutical) factors.

The ability to study the large and small intestine of patients using videoscopic endoscopy has greatly advanced the ability to diagnose and treat diarrheal disease in pediatric and adult patients. Clinicians are now able to assess the gross appearance of the lining of the small and large intestine, obtain biopsy samples for histologic examination, measure directly mucosal disaccharidase levels, collect pancreatic and biliary secretions, and sample fluid from the small intestine for quantitative culture.

Blood tests can often prove to be useful adjuncts to stool studies. Peripheral eosinophilia may point to an underlying allergic disease. Decreased serum albumin levels can suggest malnutrition or a protein-losing enteropathy. Specialized serum tests such as the detection of antibodies directed against tissue transglutaminase are highly predictive of celiac disease. However, for most patients, blood work plays a

supportive role in the workup of diarrheal disease. Results from serologic studies most often suggest an etiology that will need to be confirmed by more definite stool or endoscopic studies.

TREATMENT OF DIARRHEAL DISEASE

The treatment of pediatric diarrheal disease can be divided into symptomatic and curative therapies. First and foremost in the treatment of any child with diarrhea is a prompt assessment of hydration status. For most cases of mild to moderate diarrhea, oral rehydration solutions are the first line of therapy. When oral intake is limited secondary to an altered mental status or when severe dehydration or shock is present, intravenous replacement of fluid and electrolytes can be lifesaving. Once the patient is adequately hydrated, the diet may be readily advanced. The provision of adequate calories is critical to maintain an anabolic state that will provide the metabolic fuel necessary to promote epithelial restitution. The advantages of enteral supplementation should not be overlooked as lumenal contents have been shown to be trophic to the intestinal epithelium. A transient lactose intolerance may occur in either acute or chronic diarrhea. This can be addressed using soy, rice-based, or lactose-free milk products. High-fructose and sorbitol-containing drinks are palatable, but should be avoided due to the increased osmotic load they place on an already compromised epithelial lining. Other supportive measures that have been used include antisecretory agents, anti-motility agents, and resin binders. These agents decrease overall stool output by slowing intestinal transit. Although clinically beneficial in most cases, clinicians must be wary of the possibility that these agents can contribute to third-spacing of body fluid in distended and pharmacologically atonic intestinal loops.

Specific therapies that are designed to treat the underlying cause of diarrhea can be employed. This includes antibiotic use in certain forms of infectious diarrheas. In general, however, antibiotics should be avoided in patients with diarrheal disease unless there are systemic consequences of the diarrhea, such as that observed with *Salmonella* infections in infants and the elderly. Inappropriate antibiotic use can lead to resistant organisms or prolong the carrier state. Notable exceptions include infectious diarrheas that may become chronic if left untreated, such as diarrhea caused by *C. difficile* and *G. lamblia*.

Other specific therapies for diarrheal disease in pediatric patients include the following: immunosuppression in the immunologically mediated diarrheas such as inflammatory bowel disease or autoimmune enteropathy; specific replacement of electrolytes in the case of the congenital chloride and sodium diarrheas; or enzyme replacement therapy in patients with pancreatic insufficiency or lactose intolerance. Removal of an offending agent, such as gluten-containing foods in celiac disease, lactose in lactase deficiency, or specific dietary antigens in congenital or acquired protein intolerances, can be critical in certain diarrheal illnesses.

SUMMARY

The intestine is a site of competing physiologic processes including salt and water secretion, nutrient absorption, and immune surveillance. Stool output is subsequently the net product of opposing secretory and absorptive capacities that are separated geographically along the length of the intestine as well as along the length of the crypt–villus axis. Any disruption of these tightly regulated homeostatic processes can lead to altered stool formation and the development of pathologic diarrhea. In most cases, these illnesses are self-limited in nature and respond favorably to supportive measures. Nonetheless, pediatric diarrheal diseases remain a significant cause of morbidity and mortality worldwide.

The diagnostic approach to diarrheal disease in children differs substantially from that pursued in other age groups. Consideration must be given to congenital or developmental etiologies not seen in adult populations. Moreover, because children are still growing, the impact of chronic diarrheal processes on linear growth and physical development must also be addressed. Evaluation of diarrheal disease in pediatric patients should proceed in a stepwise fashion that begins with an in-depth clinical history and includes a limited number of microbiologic and biochemical tests. Physicians with a firm grasp of the epidemiology and pathogenesis of diarrheal illness in children will be better positioned to pursue a rational approach to the diagnosis and management of their pediatric patients with these common and potentially debilitating illnesses.

Diet and Environment, Role in Colon Cancer

MARÍA ELENA MARTÍNEZ AND ELIZABETH T. JACOBS
University of Arizona, Tucson

colorectal adenocarcinoma A malignant neoplasm of the colon or rectum.
colorectal adenoma A benign neoplasm of the colon or rectum with malignant potential.
colorectal polyp A growth protruding from the mucosal surface into the bowel lumen.
dietary fiber The components of plant material that are resistant to digestive secretions produced by humans.

Significant progress has been made over the past decade in identifying factors that modify the risk of colorectal cancer. Large international variation in colorectal cancer incidence and mortality rates, and the prominent increases in the incidence of colorectal cancer in groups that migrated from low to high incidence areas, provided important evidence that lifestyle factors influencethe development of this malignancy. These observations formed the basis for various hypotheses of lifestyle factors in the etiology of colorectal neoplasia. The focus of this article is on the role of diet in relation to colorectal cancer.

FAT AND RED MEAT

Rates of colon cancer are strongly correlated with national per capita disappearance of animal fat and meat, with correlation coefficients ranging between 0.8 and 0.9. A sharp increase in colon cancer incidence rates in Japan in the decades following World War II coincided with a 2.5-fold increase in fat intake. Intake of animal or saturated fat or red meat has been shown to be associated with colon cancer risk; however, some studies do not support these associations. Data from earlier epidemiologic studies provided some evidence for a positive association between dietary fat and increased risk of several cancers, including the colorectum. However, an overall review of studies

recently published indicates that there is no strong evidence for the association of colon cancer with high fat consumption per se and that the association may partly be explained by animal fat or red meat consumption. In addition, whether this association is independent of total energy intake is unclear. Results of combined data from 13 case-control studies of colon cancer showed a positive association between energy intake and no association for various fat components in the diet independent of energy intake.

Results of some prospective studies of colon cancer have shown positive associations with fat or red meat consumption but the data are less compelling for total fat than for red meat. Other cohort studies have shown statistically significant or suggestive positive associations for intake of processed meats and risk of colon cancer. Although published reports support a possible or probable increased risk of colon cancer in relation to red meat, an expert workshop convened in Australia did not support this association.

FIBER, FRUIT, AND VEGETABLES

High consumption of fruit and vegetables has been shown to be associated with a decreased risk of colorectal neoplasia, particularly for vegetable consumption. Foods high in fiber have also been shown to be inversely associated with colon cancer risk in most, but not all studies. Conversely, results of large prospective studies have shown weak or nonexistent inverse associations for fiber intake and risk of colon cancer. As with case-control studies, when sources of fiber were examined separately, a reduced risk appears to be stronger for vegetable sources than for other fiber components. However, in a large prospective study examining the role of fiber on risk of colorectal neoplasia in female nurses, no association was observed between colorectal cancer and fiber intake. Additionally, when data from the Nurses' Health Study and the Health Professionals Follow-up Study cohorts were combined for a follow-up of over 1,700,000 person-years to yield 937 cases of colon and 244 of rectal cancer, no protective effect was observed for fruit and vegetable intake and colorectal cancer.

Given the scientific and public health interest related to fiber and fruit and vegetable consumption and colorectal cancer risk, two separate, large U. S. trials were conducted to test these associations. The interventions included a diet high in fiber, high in fruit and vegetables, and low in fat versus a usual diet and a high (13.5 g/day) versus low (2.0 g/day) wheat bran fiber intervention. No statistically significant difference in adenoma recurrence rate was shown for either intervention.

MICRONUTRIENTS

Calcium

The role of calcium in colorectal neoplasia has been investigated in a variety of study settings including animal studies, international correlational studies, case-control and cohort studies, and intervention studies of adenoma recurrence. It is hypothesized that calcium might reduce colon cancer risk by binding secondary bile acids and ionized fatty acids to form insoluble soaps in the lumen of the colon; this in turn reduces the proliferative stimulus of these compounds on colon mucosa.

Results of analytic epidemiological studies that have examined calcium as a risk factor for colorectal cancer have been inconsistent. Data from large cohort studies show weak, nonsignificant inverse associations with no evidence of a dose–response relationship. Results from the Nurses' Health Study, in which data from three dietary questionnaires were collected prospectively over 6 years, did not support a major inverse association between calcium intake and risk of colorectal cancer over a 6-year period. The modest effect of calcium intake on risk of colorectal neoplasia observed in epidemiologic studies is consistent with findings from a recent adenoma recurrence intervention trial. In this trial, calcium supplementation (1200 mg of elemental calcium versus placebo) among 913 participants who underwent adenoma removal was associated with a statistically significant reduction in the risk of adenoma recurrence.

Folic Acid

In addition to animal data, an increasing epidemiologic body of evidence shows a potential role for folate in reducing the risk for colorectal cancer. An additional study using plasma folate also supports this finding. However, data from a large case-control study (1993 cases and 2410 controls) showed no important inverse association between dietary folate and colon cancer risk. Perhaps the strongest evidence is derived from the Nurses' Health Study cohort, where increased consumption of supplemental folic acid, after a period of 15 or more years, was associated with a 75% reduction in risk of colon cancer. In addition, studies of colorectal adenomas support a protective effect of folic acid in colorectal neoplasia.

Further evidence of a role for folate is that inherited variation in the activity of methylenetetrahydrofolate reductase (MTHFR), a critical enzyme in the production of the form of folate that supplies the methyl group for methionine synthesis, influences the risk of colon cancer. In this proposed pathway, key nutrient and nonnutrient components are involved and different endogenous forms of folate, 5-methyltetrahydrofolate and 5,10-methylenetetrahydrofolate, are essential for DNA methylation and DNA synthesis, respectively. DNA hypomethylation is among the earliest events observed in colon carcinogenesis; however, it is unclear whether this process directly influences the carcinogenic process. Additional micronutrients involved in the DNA methylation process include vitamins B6 and B12. Furthermore, since alcohol is known to influence folate metabolism and methyl group availability, its interaction with the key micronutrients must be considered in this process.

Other Micronutrients

Several additional micronutrients have been implicated in relation to colorectal neoplasia; however, the evidence for their specific role is unclear. Among the proposed micronutrients, those with antioxidant potential are thought to be important in protection against the development of colorectal cancer. These include β-carotene, selenium, and vitamins C and E and have been shown to be inversely associated with colon cancer risk, perhaps through their effects on cell proliferation. Among participants in the American Cancer Society's Cancer Prevention Study II cohort, regular use of vitamin C or E supplements was not associated with colorectal cancer mortality.

Selenium, an essential trace mineral found in cereal grains and seafood, has been shown to be inversely related to colorectal cancer. Correlational data show higher cancer mortality rates in low-selenium areas compared to those of high-selenium regions. Perhaps the most provocative finding to date derives from secondary analyses of the Nutritional Prevention of Skin Cancer study, where a greater than 50% reduction in colorectal cancer incidence was shown with a selenium intervention of 200 μg/day compared with placebo. When these results were updated to include an additional 3 years of participant follow-up, a similar magnitude of reduction was observed, with a Hazard Ratio of 0.46 (95% CI = 0.21−1.02; $P = 0.057$). Since the results were based on secondary end-point data among a population in selenium-deficient areas of the United States, additional large trials will be needed.

To test the antioxidant hypothesis on colorectal cancer etiology, a randomized controlled trial with adenoma recurrence was conducted. Participants were randomized to one of four arms: 25 mg of β-carotene; 1 g of vitamin C and 400 mg of vitamin E; 25 mg of β-carotene, 1 g of vitamin C, and 400 mg vitamin E; or placebo. Recurrence rates after 4 years of follow-up between the placebo group and the intervention groups were similar, suggesting a lack of effect of chemopreventive properties by these antioxidant nutrients. In addition, results of a secondary analysis of the Alpha-Tocopherol, Beta-Carotene Prevention (ATBC) Study showed no significant protective effect of β-carotene, α-tocopherol, or both nutrients combined, on colorectal cancer.

PHYSICAL ACTIVITY

Although not a dietary factor per se, a sedentary lifestyle is linked to obesity and overall caloric imbalance. Results of prospective and retrospective studies support an inverse association between physical activity and risk of colon cancer, but not rectal cancer. The results are consistent across studies, in men and women, and whether assessing occupational or leisure-time activity. In a study that assessed the joint effect of physical activity and body mass index (BMI), the highest risk of colon cancer was shown among those both physically inactive and with high BMI levels.

GENE−NUTRIENT INTERACTIONS

Major advances in characterization of new genomes have provided tremendous excitement in the scientific community and the area of cancer prevention is no exception. Low-penetrance susceptibility genes occur commonly and lead to sporadic disease; these susceptibility genes aggregate with disease and may interact with environmental factors or other genes to increase the risk of cancer. Genetic polymorphisms, defined as changes in the nucleotide sequence (mutations) that are present in at least 1% of the population, have been explored in the recent literature in relation to cancer etiology, including colorectal cancer. Examples from recent reports include markers of folate status and mutations in the *MTHFR* gene, well-cooked meat (a source of heterocyclic amines), and polymorphisms in the cytochrome P450 genes as well as the *N*-acetyltransferase genes 1 and 2, and cruciferous vegetable consumption (source of dietary isothiocyanates) and polymorphisms in the glutathione-*S*-transferase family of genes. This

complex area of research continues to evolve; however, proposed complex interactions can be adequately addressed only in the setting of large epidemiological studies with sufficient statistical power to generate meaningful results.

DIETARY AND LIFESTYLE GUIDELINES

Dietary Guidelines from the American Cancer Society are based on the mass of the published data (Table I). Of these guidelines, the most consistent support for any one variable from the scientific literature is found for physical activity and lower risk of colon cancer. Although these guidelines target cancer prevention, they have a great deal in common with guidelines aimed at the prevention of other chronic diseases. Recommendations from a large, international panel of experts were similar to those of the American Cancer Society.

SUMMARY AND FUTURE CHALLENGES

The past decade has been filled with a plethora of literature related to the primary prevention of colorectal cancer. Although the precise mechanisms have not been clarified, several lifestyle factors are likely to have a major impact on colorectal cancer development. Physical inactivity and, to a lesser extent, excess body weight are consistent risk factors for colon cancer. Although not addressed in this article, exposure to tobacco products early in life is associated with a higher risk of developing colorectal neoplasia. Diet and nutritional factors are also clearly important. Excess alcohol consumption, probably in combination with a diet low in some micronutrients such as folate and methionine, appears to increase risk. Diets high in red meat may also increase risk. The role of fiber, although recently challenged, continues to be supported, given the overall general findings from numerous studies. Furthermore, additional support on the role of folic acid awaits the results of ongoing intervention trials of adenoma recurrence.

TABLE I American Cancer Society Guidelines on Diet, Nutrition, and Cancer Prevention

Choose most of the foods you eat from plant sources:
Eat five or more servings of fruit and vegetables each day
Eat other foods from plant sources, such as breads, cereals, grain products, rice, pasta, or beans several times each day
Limit your intake of high-fat foods, particularly from animal sources
Choose foods low in fat
Limit consumption of meats, especially high-fat meats
Be physically active: Achieve and maintain a healthy weight
Be at least moderately active for 30 min or more on most days of the week
Stay within your healthy weight range
Limit consumption of alcoholic beverages, if you drink at all

Dietary Fiber

DAVID N. MOSKOVITZ AND YOUNG-IN KIM
University of Toronto and St. Michael's Hospital

adenoma A benign epithelial tumor in which the cells form recognizable glandular structures.

colorectal adenocarcinoma A malignant new growth confined to the colon or rectum, made up of epithelial cells tending to infiltrate the surrounding tissue and giving rise to metastases.

constipation A bowel movement every 3 to 4 days or less with the presence of straining, hard stools, feelings of incomplete evacuation, or two or fewer bowel movements per week.

dietary fiber The components of plant material that are resistant to digestive secretions produced by humans.

diverticulitis Inflammation of a diverticulum that may undergo perforation with abscess formation.

diverticulosis Gastrointestinal disease characterized by the presence of diverticula (pouches or sacs created by the herniation of the lining mucous membrane through a defect in the muscular coat of a tubular organ).

inflammatory bowel disease Consists of ulcerative colitis and Crohn's disease, both of which are chronic, relapsing disorders of unknown etiology affecting primarily the gastrointestinal tract.

irritable bowel syndrome A functional bowel disorder in which abdominal pain is associated with defecation or a change in bowel habit, with features of disordered defecation and distension.

resistant starch That portion of ingested starch that escapes digestion in the small intestine.

short-chain fatty acids Organic acids produced by anaerobic fermentation of undigested carbohydrates within the colonic lumen.

Dietary fiber consists of the components of plant material that are resistant to digestive secretions produced by humans. There is no internationally accepted definition or method for determining the dietary fiber content of foods. The roles that dietary fiber plays in a number of gastrointestinal diseases are examined in this article.

DIETARY FIBER

The U. S. Expert Panel on Dietary Fiber defined dietary fiber as the endogenous components of plant materials in the diet that are resistant to digestion by enzymes produced by humans. The components consist of nonstarch polysaccharides and lignin as well as other associated substances (Table I). The polysaccharide constituents of fiber are composed of cellulose, β-glucans, hemicelluloses, pectin, gums and mucilages, and seaweed extract. These components themselves are made up of primarily glucose, galactose, and mannose chains as well as secondary xylose, fucose, and galactiose chains. Depending on its solubility in water and buffer solution, dietary fiber can be further analytically classified as soluble (some hemicelluloses, pectins, gums, and mucilages) or insoluble (most hemicelluloses, celluloses, and lignins). When the effect of dietary fiber on the colon is being considered,

TABLE I Classification of Dietary Fiber

Classification
Nonstarch polysaccharides
Celluloses
Noncelluloses: hemicelluloses, pectins, gums, mucilages
Nonpolysaccharides: lignins
Classification based on solubility
Soluble: pectins, gums, mucilages, hemicelluloses
Insoluble: celluloses, lignins, hemicelluloses
Minor components
Phylates, cutins, saponins, lectins, protein, waxes, silicon
Related components
Resistant starch and protein
Lignans

the classification of fiber as fermentable (i.e., metabolized by colonic bacteria) or nonfermentable is also useful. Some starch escapes small bowel digestion and reaches the colon; this starch is referred to as "resistant starch." There are three categories of resistant starch: physically enclosed starch, ungelatinized crystallite granules, and retrograded amylose. Resistant starch escapes digestion in the small bowel, but enters the colon, where it can be fermented by bacteria. As a result, resistant starch is similar to dietary fiber. Resistant starch represents 2 to 5% of the average starch ingested in the Western diet.

Analytical methods that estimate the dietary fiber content of foods exist. These assays likely underestimate the actual dietary fiber content in foods. The methods are based on the assumption that all starch is digested in the small bowel and that other complex carbohydrates are completely undegraded; dietary fiber is therefore considered to include all plant polysaccharides except starch and nonpolysaccharides. Currently available assays that account for resistant starch estimate the amount of polysaccharides that reach the colon to be in the range of 15 to 25 g/day. Even with the inclusion of resistant starch in the assessment of dietary fiber intake, currently available assays account for less than one-third of total dietary fiber that reaches the colon. Therefore, the assays that are currently available to estimate nonstarch polysaccharides and resistant starch do not accurately measure dietary intake and underestimate the amount of dietary fiber that reaches the colon.

Dietary fiber is found mainly in legumes, vegetables, whole grain cereals, nuts, and fruits. In the Third National Health and Nutrition Examination Survey (NHANES III, 1988 to 1994), mean dietary fiber intake in the U. S. adult population (>19 years old) is 17 g/day for males and 13 g/day for females. The median intakes of dietary fiber for adults were 12−14 g, indicating that a large portion of adults do not meet the currently recommended amounts for good health.

Short-chain fatty acids (SCFA) are organic acids produced by anaerobic fermentation of undigested carbohydrates within the colon. Acetate, propionate, and butyrate account for 90−95% of SCFA in the colon, with isobutyrate, valerate, iosovalerate, and caproate constituting the rest. Once inside the colonocyte, SCFA are an important energy source for the cell. Butyrate is the preferred SCFA to meet colonic energy requirements. The SCFA could account for up to 80% of the energy requirements of the colon and for 5−10% of total body energy requirements. Butyrate is the preferred SCFA to meet colonic energy requirements and is the best energy source for the colon.

Different types of dietary fiber exert their physiological effects in various parts of the digestive tract. The effect of dietary fiber on the small intestine is to slow transit and regulate digestion. Fiber also influences viscosity, water-binding capacity, and cation exchange in the small intestine. Most of the action of dietary fiber takes place in the colon. Approximately 40−95% of fiber is fermented by intestinal flora, mainly anaerobic bacteria. The fermentation products have physiological effects. Fermentable products provide substrates for bacterial growth, which contributes to fecal bulk. Acids produced by bacteria acidify the colon, modify lipid metabolism, and affect mucosal growth. Large-fiber products provide a physical resistance against water absorption, resulting in decreased fecal density, which prevents impaction and constipation. The interest in dietary fiber is due to its role in various diseases. In 1975, Trowel and Burkitt proposed that a low-fiber diet was associated with a number of diseases including colon cancer, diabetes, gallstones, obesity, and diverticular disease. Based on the evidence of the effect of fiber on health, it is recommended that the daily intake of carbohydrate should consist of 55−60% of the daily energy intake from a variety of sources with an increase in the form of complex carbohydrates. Any change in dietary intake of fiber should be gradual.

COLORECTAL CANCER

Introduction

It is estimated that 1,284,900 new cancers will be diagnosed in 2002 and that 550,000 Americans will die of cancer this year. There were 148,300 estimated

new cases of colorectal cancer (CRC) (72,600 male; 75,700 female) in 2002. It is estimated that 56,600 people will die from CRC in 2002. CRC is the third most common cancer and the second most common cause of cancer death after lung cancer in the United States. CRC results from an interaction between environmental and genetic factors. Dietary and lifestyle factors are among the most important environmental factors implicated. It has been estimated that 35% (10 to 70%) of all cancers are attributable to diet and that 50 to 75% of CRC in the United States may be preventable through dietary modifications. Dietary factors implicated in colorectal carcinogenesis include consumption of red meat, animal and saturated fat, refined carbohydrates, and alcohol, as well as total caloric (energy) intake. The intake of dietary fiber, vegetables, fruits, antioxidant vitamins, calcium, and folate is negatively associated with the development of CRC. Epidemiological studies suggest that the risk of developing CRC is related to overall diet and lifestyle patterns. However, because of inherent limitations associated with study design, a cause-and-effect relationship between dietary or other lifestyle factors and CRC is difficult to establish. Epidemiological, animal, and interventional studies examining this relationship often produced conflicting results. Observations that suggest that overall diet and lifestyle, rather than individual factors, play the more important role underscore the importance of as yet undetermined interactions among dietary components and lifestyle factors in the development of CRC.

Dietary fiber is one of several factors whose role in colorectal carcinogenesis has been extensively studied. The relationship between fiber intake and CRC risk, however, has not been clearly established.

Evidence

The inverse relationship between dietary fiber intake and the risk of CRC has been investigated by four types of human epidemiological studies: correlation (or ecological) studies, case-control studies, prospective studies, and interventional trials.

Correlation Studies

Correlation studies examine the relationship between the per capita consumption of a dietary factor and the prevalence, incidence, or mortality of CRC in the population. Of 28 published international, within-country correlation studies of CRC and fiber, vegetables, grains, fruits, and cereals, 23 (82%) showed either a strong or a moderate protective effect of dietary fiber on the development of CRC. Four studies found no evidence for a protective effect of fiber. One study showed that a significant excess risk of CRC was associated with high intake of fiber-rich foods. Limitations exist when interpreting data generated from correlation studies. Studies are based on intake of crude fiber, which greatly underestimates total dietary fiber levels; correlation studies fail to correct for unmeasured confounding factors that may be responsible for the observed association and they do not control for other dietary variables.

Case-Control Studies

Case-control studies compare prior consumption of a dietary factor in subjects with CRC and matched control subjects without CRC. Limitation in retrospective studies is the accuracy with which intake of dietary factors or supplementation can be established: individuals may misreport their habitual past diets. Furthermore, control individuals often have another disease that may be related to diet. Another problem associated with case-control studies is selection bias because of the absence of patients who do not survive long enough to be enrolled in the study. Three analyses have critically evaluated the bulk of case-control studies that address the role of dietary fiber in CRC. In a meta-analysis by Trock *et al*., 15 (65%) of 23 studies demonstrated either a strong or moderate protective effect of dietary fiber and vegetables. Only 2 studies (9%) lacked support for a protective effect of fiber. With fiber-rich diets, a 43% reduction in CRC risk was observed [odds ratio (OR), 0.57; 95% confidence interval (CI), 0.50−0.64] when the highest and lowest quartiles of intake were compared. Howe *et al*. performed a combined analysis of data from 13 case-control studies. The individual data records for 5287 case subjects and 10,470 control subjects were pooled for a common analysis. The risk of CRC was shown to decrease incrementally as dietary fiber intake increased. Consumption of more than 31 g of fiber per day was associated with a 47% reduction in the risk of CRC compared with diets incorporating less than 10 g of fiber per day (95% CI, 0.47−0.61). When all of the studies were combined and adjusted for total energy intake, age, and sex, individuals who consumed 27 g fiber per day had a 50% reduction in the risk of developing CRC compared with those who consumed less than 11 g fiber per day [relative risk (RR), 0.51; 95% CI, 0.44−0.59]. Friedenreich *et al*. examined the study design features and data collection methods from the 13 case-control studies to determine whether they influenced the results obtained from a pooled analysis. Their results show that subjects consuming >27 g fiber per day had a 50% reduction

in the risk of developing CRC compared with those taking <11 g fiber per day (OR, 0.49; 95% CI, 0.37−0.65).

Several case-control studies have investigated the relationship between dietary fiber or fiber-rich foods and the risk of colonic adenomas, well-established precursors of adenocarcinoma. Data suggest that there exists an inverse relationship between fiber intake and the development of colonic adenomas. The magnitude of the reduction in the risk ranged from 10 to 60%. Some studies show a dose-dependent inverse association between colorectal adenoma risk and dietary intake of fiber but other studies suggest that the protective effect associated with dietary fiber is evident in women or for large (>1 cm) adenomas.

In summary, most of the published case-control studies show either a strong or a moderate protective effect of dietary fiber, consistent with the fiber hypothesis. Studies conducted in meta-analysis format provide strong support for the protective effect of dietary fiber on colorectal carcinogenesis. The strongest argument for the fiber hypothesis that can be made from case-control studies is the protective effect of dietary fiber among studies conducted in populations with different patterns of diet and CRC. The combined analysis and meta-analyses of case-control studies suggest, on average, a 50% reduction in the risk of developing CRC in individuals with the highest dietary fiber intake compared with those with the lowest fiber intake. Most case-control studies show a significant inverse dose-dependent relationship between dietary fiber intake and the risk of CRC and colorectal adenomas. Several shortcomings associated with case-control studies limit the interpretation of the results. Limitations associated with analytical methods of determining fiber content in diet, the effect of other potential anti-carcinogens present in fiber-rich foods, and questionnaires that have not been validated are all factors affecting study results.

Prospective Studies

Prospective studies assess the diets of a large group of healthy individuals and include follow-up over time. Prospective studies can control and correct confounding factors more adequately than correlation and case-control studies. They provide the opportunity to obtain repeated assessments of diet at regular intervals. Earlier prospective studies investigated the relationship between dietary fiber intake and CRC mortality. One study from Japan investigated the relationship between diet and other lifestyle variables and major causes of deaths in 265 subjects, ages ≥ 40 years, followed up for 13 years. This study observed that CRC mortality rate decreased as rice and wheat consumption increased with an RR of 0.6 in those with the highest intake ($>720\,cm^3$ of rice and wheat per day) compared with those with the lowest intake ($<180\,cm^3$/day). A Dutch study with a follow-up of 13 years involving 871 middle-aged men showed a threefold reduction in cancer mortality in men in the highest quintile of dietary fiber intake compared with men in the lowest quintile. Another study involving 25,493 white California Seventh Day Adventists followed up for 21 years showed no protective effect of cereal or green salad intake on CRC mortality. Data from Cancer Prevention Study II, an ongoing prospective mortality study, support the protective role of dietary fiber in colorectal carcinogenesis. Multivariate analyses showed that the risk of fatal colon cancer decreased with more frequent consumption of vegetables and high-fiber grains (P trend $= 0.031$ in men and 0.0012 in women).

More recently, several well-designed prospective studies have examined the relationship between dietary fiber intake and the risk of CRC and adenomas; the findings, however, are not consistent. In the Nurses' Health Study, 121,700 female registered nurses between 34 and 59 years of age in the United States completed a mailed questionnaire on known and suspected risk factors for cancer. Every 2 years thereafter, follow-up questionnaires were sent to identify new cases of cancer. A subgroup of these women show that energy-adjusted intakes of crude and total dietary fiber were both inversely associated with the risk of colon cancer. These results were not statistically significant. Only fiber from fruit was associated with any appreciable reduction in risk. This trial, extended for 16 years of follow-up, identified 787 new cases of CRC among the 88,757 eligible women. Total dietary fiber intake was not significantly associated with the incidence of CRC. The relative risk for the quintile group with the highest (median 24.9 g/day) compared with the lowest (median 9.8 g/day) total dietary fiber intake was 0.95 (95% CI, 0.73 to 1.25) and no dose-dependent inverse association was observed (P trend $= 0.59$).

The Health Professional Follow-up Study is a prospective study of heart disease and cancer among 51,529 U. S. male health professionals between the ages of 40 and 75 years. Among 47,949 men who were free of diagnosed cancer in 1986, 205 new cases of colon cancer were diagnosed and confirmed between 1986 and 1992. Age, family history of CRC, obesity, physical activity, cigarette use, alcohol consumption, and other confounding factors were adjusted for analysis. No clear association between total dietary fiber intake and risk

of colon cancer was observed. In this study, however, dietary fiber was inversely associated with risk of adenoma (P trend <0.0001); RR for men in the highest (>28.3 g/day) vs the lowest (<16.6 g/day) quintile was 0.36 (95% CI, 0.22−0.60).

The Iowa Women's Health Study included 98,030 postmenopausal women ages 55 to 69 years. A statistically nonsignificant inverse association was observed between dietary fiber intake and the risk of colon cancer.

In summary, published large prospective studies have produced equivocal findings. Data from earlier prospective studies examining the relationship between dietary fiber intake and CRC mortality proved to be inconsistent. Recent large prospective studies show a significant inverse relationship with a 30% reduction of CRC mortality in subjects consuming the highest amount of dietary fiber compared with those consuming the lowest amount. Published prospective studies of the relationship between dietary fiber intake and the risk of CRC or adenomas have demonstrated a protective effect of dietary fiber against distal colon and rectal adenomas in men. The quality of recent studies is impressive. Recent prospective studies involved a large number of patients and controlled for confounding factors. Limitations exist in that some studies failed to take into account changing dietary fiber patterns. In such cases, it is impossible to delineate the period of exposure to dietary fiber and the risk of developing CRC. The imprecise estimation of dietary fiber limits study results. Moreover, fiber values assigned to individual foods have errors. Finally, the applicability of the results from highly selected subpopulations to the general population is questionable.

Intervention Trials

Randomized intervention studies in humans should provide definitive support for the purported cause-and-effect relationship between a dietary factor and CRC. Intervention studies are often difficult to carry out because of the slowly progressive nature of neoplastic transformation and the large number of subjects necessary to achieve an adequate statistical power. In many studies, intermediate biomarkers of CRC rather than occurrence or recurrence have been used as endpoints. Biomarkers include adenoma, proliferation markers, mitotic index, DNA aneuploidy aberrant crypts, mucins, and alterations of several molecular biological markers. Intermediate biomarkers have limitations and most have not been validated in clinical studies. Several randomized or single-arm intervention studies using a high-fiber diet as a component of chemopreventive strategies against the development of CRC have been conducted. Subjects with familial adenomatous polyposis who had undergone total colectomy and ileorectal anastomosis at least 1 year before entry into the trial were randomized to receive a low-fiber supplement (2.2 g/day) plus placebo (control group), a low-fiber supplement (2.2 g/day) plus ascorbic acid (4 g/day) and α-tocopherol (400 mg/day), or a high-fiber supplement (22.5 g/day) plus ascorbic acid (4 g/day) and α-tocopherol (400 mg/day). Those who had consumed 11 g of supplemental fiber in addition to their usual dietary fiber intake had a significant reduction in polyp occurrence in the rectal stump and polyp number decreased incrementally as the amount of ingested, prescribed fiber increased. One study from the Arizona Cancer Center was a single-arm study that investigated the effect of supplemental wheat bran fiber on a proliferation marker ([^{3}H]thymidine labeling index) in patients who had undergone resection for colon or rectal cancer. In this study, 13.5 g of supplemental wheat bran per day significantly reduced colorectal epithelial proliferation. The same investigators completed a double-blind, randomized study to determine the effects of wheat bran (2.0 or 13.5 g/day) and calcium carbonate (250 or 1500 mg/day) supplementation on [^{3}H]thymidine labeling index in rectal mucosal biopsies and fecal bile acid concentrations at 3 and 9 months. The results of this study showed that neither wheat bran fiber nor calcium treatment significantly decreased the labeling index. In the Australian Polyp Prevention Project, a diet high in fiber and low in fat was shown to prevent recurrence of large adenomas (>10 mm). The Toronto Polyp Prevention Study reported on 201 subjects with adenomatous colorectal polyps. Patients were randomized after polypectomy to receive counseling on a diet low in fat (<50 g/day or 20% of energy) and high in fiber (50 g/day) or to follow a normal Western diet. After 2 years of follow-up with colonoscopy, an intention to treat analysis showed no significant difference between groups with regard to the recurrence of adenomatous polyps. It was, however, shown that women who ate the low-fat, high-fiber diet showed a nonsignificant 50% reduction in polyp recurrence (RR 0.5; 95% CI 0.2−1.9) associated with a reduced concentration of fecal bile acids.

Three recent intervention studies did not support the use of dietary fiber in reducing CRC risk. In the Polyp Prevention Trial, 2079 subjects with resected colonic adenomas were randomized to a diet low in fat (20% fat calories), high in fiber (18 g/1000 kcal daily), and enriched with vegetable and fruits (5−8 servings daily) or to a control group given a standard brochure in healthy eating. The end-point was the development of recurrent colorectal adenomas. The

results show that a diet low in fat and high in fiber, fruits, and vegetables does not affect the rate of recurrence of colorectal adenomas. In the Arizona Colon Cancer Prevention Trial, Alberts *et al*. randomly assigned 1303 subjects to either a diet high in wheat bran fiber (13.5 g/day) or a diet low in fiber (2 g/day); the primary end-point was the presence or absence of new adenomas at the time of follow-up colonoscopy. The relative risk of recurrence of adenoma in the high-fiber group compared with the low-fiber group was 0.99 (95% confidence interval 0.71−1.36; $P = 0.93$). The investigators concluded that a dietary supplement of wheat bran fiber does not protect against recurrence of colorectal adenomas. Bonithon-Kopp *et al*. for the European Cancer Prevention Organization Intervention Study showed that fiber supplemented as ispaghula husk may have adverse effects on colorectal adenoma recurrence especially in patients with high calcium intake. In their study, 665 patients with a history of colorectal adenomas were randomly assigned to one of three treatment groups (calcium gluconolactate and carbonate, fiber, or placebo). The primary end-point was adenoma recurrence.

In summary, nine intervention studies in humans have been completed and published (Table II). One study was uncontrolled and eight were randomized and placebo controlled. Six studies used adenoma recurrence or regression as the end-point of the trial and the other three used less well-established intermediate biomarkers of CRC. Four studies showed a moderate protective effect of dietary fiber supplements. The other five studies showed no effect on labeling index or adenoma recurrence. Weaknesses of earlier studies are short follow-up, small numbers of subjects, poor compliance with dietary interventions, high drop-out rates, and use of less well-established intermediate biomarkers. Results of these intervention studies should therefore be interpreted with caution. This is emphasized by the recent results of three intervention studies detailed earlier showing either a null effect or an increased risk associated with fiber intervention. Other limitations are associated with intervention trials in humans. Blind or double-blind trials are difficult to perform with foods or dietary macronutrients that are recognizable. Often, in nonblind studies of foods, subjects in the control group may adopt the dietary behavior of the treatment group if they think the treatment diet is beneficial. Moreover, the time between a change in the level of a dietary factor and any expected change in the incidence of cancer is uncertain. Finally, patients at higher risk for the development of CRC tend to be underrepresented in trials as studies often enroll motivated health-conscious people. Studies in which intervention shows no effect do not indicate that the agents are irrelevant or harmful in the context of whole diets or among normal healthy populations. Conversely, trials in which intervention shows beneficial effects are good evidence that the agents used are protective.

Biological Mechanisms

Burkitt's initial hypothesis was that dietary fiber increases stool bulk. This had the effect of diluting potential carcinogens and decreasing transit time. As a result, there would be less contact time between potential carcinogens in the lumen and the gut mucosa (Table III).

Dietary fiber can bind carcinogens as well as bile acid. Fecal bile acids have been shown to be cytotoxic to or act as mitogens on colonic epithelial cells in animal and *in vitro* studies. The mechanism by which dietary fiber may modulate carcinogenesis involves cytokinetics of the colonic mucosa. Conversion of primary to secondary bile acids by bacterial enzymes may be prevented if the dietary fibers to which the bile acids or bile salts are bound are undegraded in the colon. Bound bile acids or bile salts pass out of the alimentary tract in the feces.

Epidemiological studies have shown that human populations with lower fecal pH have lower rates of colon cancer. Direct experimental acidification of the colon contents in animal models has not always led to a reduction in tumorigenesis. Dietary fiber decreases fecal pH, resulting in reduced solubility of free bile acids. Furthermore, the activity of the colonic bacterial enzyme 7-dehydroxylase, which converts primary bile acids to secondary bile acids, is inhibited at a pH of <6 to 6.5. Acidification of colonic contents increases the availability of calcium for binding to free bile and fatty acids, thereby inhibiting their effects on the colonic mucosa.

Another potential mechanism of dietary fiber relates to alterations in colonic microflora. Dietary fibers modulate colonic bacterial enzyme activity; however, the relationship between colonic bacterial enzyme activity and development of human CRC has not been elucidated. Bacteria are the major water-holding component of feces. Dietary fibers degraded in the colon have been shown to increase fecal bulk by a stimulation of bacterial growth. Increased fecal bulk and reduced transit time resulting from increased bacterial growth reduce interactions of carcinogens with the colonic mucosa. Dietary fiber decreases the numbers of anaerobes, resulting in a decrease in secondary bile acids.

McKeown-Eyssen and Giovannucci have put forward a unifying hypothesis explaining how diet and

TABLE II Summary of Intervention Studies Using High Fiber

Study	Location (year)	Case diagnosis	Sample size	Type of study	Intervention	Duration	Primary end-point	Outcome
De Cosse *et al.*	USA (1989)	FAP, total colectomy, ileorectal anastomosis	58	RCT	Low-fiber supplement (2.2 g/day) + Vitamin C (4 g/day) + Vitamin E (400 mg/day) vs High-fiber supplement (22.5 g/day) + Vitamin C (4 g/day) + Vitamin E (400 mg/day) vs Placebo	4 years	Adenoma regression occurrence	High fiber protective only if >11 g/day Vitamins C and E: 22% decrease compared to baseline trend toward protection
Alberts *et al.*	USA (1990)	Previous CRC	17	Single-arm uncontrolled	Fiber supplement (wheat bran, 13.5 g/day)	8 weeks	Proliferation labeling index [^{3}H]thymidine	
Alberts *et al.*	USA (1997)	Previous colorectal adenomas	100	RCT	2 × 2 Factorial Fiber (wheat bran): high (13.5 g/day), low (2.0 g/day); Calcium: high (1500 mg/day), low (250 mg/day)	9 months	Proliferation labeling index [^{3}H]thymidine—no effect; total fecal bile acids 52% decrease with high fiber; fecal deoxycholic bile acids—36% decrease with high fiber	Proliferation labeling index [^{3}H]thymidine—no effect; total fecal bile acids 52% decrease with high fiber; fecal deoxycholic bile acids—36% decrease with high fiber
Toronto Polyp Prevention Group	Canada (1994)	Previous colorectal adenoma	201	RCT	Dietary counseling to achieve 20% fat calories and 50 g fiber/day vs Placebo	2 years	Adenoma recurrence	No effect
Australian Polyp Prevention Project	Australia (1995)	Previous colorectal adenomas	424	RCT	2 × 2 × 2 Factorial: <25% fat calories; 25 g wheat bran/day; β-Carotene (20 mg/day)	4 years	Adenoma recurrence	Low-fat, high-fiber decreased recurrence of >10 mm adenomas
Arizona Cancer Center Polyp Prevention Study	USA (2001)	Previous colorectal adenomas	1400	RCT	High-fiber supplement (13.5 g wheat bran/day)	3 years	Adenoma recurrence	No effect
Polyp Prevention Trial	USA (2001)	Previous colorectal adenomas	2079	RCT	20% fat calories/day; 18 g fiber/1000 kcal/day; 5–9 servings of vegetables and fruits/day vs Typical North American diet	4 years	Adenoma recurrence	No effect
European Cancer Prevention Organization Study	Europe (2001)	Previous colorectal adenomas	656	RCT	3.8 g ispaghula husk/day vs 2 g/day calcium vs Placebo	3 years	Adenoma recurrence	Increased incidence of colonic adenomas

Note. FAP, familial adenomatous polyposis; RCT, randomized controlled trial.

TABLE III Mechanisms of Action of Dietary Fiber

Increased stool bulk
Dilution of potential carcinogens
Decrease in transit time
Binding to potential carcinogens
Binding to bile acids
Decrease in fecal bile acid concentrations
Prevention of conversion of primary to secondary bile acids
Lower fecal pH
Reduced solubility of free bile acids
Inhibition of 7 α-dehydroxylase
Inhibition of bacterial degradation of normal fecal constituents to potential carcinogens
Altered colonic microflora
Changes in bacterial species
Stimulation of bacterial growth
Inhibition of microbial enzymes
Prevention of insulin resistance and hyperinsulinemia
Fermentation of fecal flora to SCFA
Induction of apoptosis
Inhibition of proliferation
Modulation of gene expression

lifestyle factors modulate colorectal carcinogenesis. Epidemiological studies have shown that insulin-like growth factor-I (IGF-I) is positively associated with the risk of CRC. Experimental studies have shown that IGF-I has mitogenic and anti-apoptotic actions on CRC cells. The hypothesis suggests that dietary and lifestyle factors associated with CRC risk cause insulin resistance and hyperinsulinemia. It is hyperinsulinemia that may in turn stimulate the growth of colorectal tumors. Insulin is an important growth factor for colonic mucosal cells and colon cancer tissue has both insulin and IGF-I receptors. Insulin receptors can be bound by IGF-I and a binding protein from IGF-I inhibits the growth of colon cancer cells *in vitro*. IGF-I is regulated by six binding proteins (IGFBP-1 to IGFBP-6). Insulin inhibits the production of IGFBP-1. Chronically elevated fasting insulin levels may lead to a decrease in circulating IGFBP-1 concentrations and an increase in IGF-I bioavailability. This increase in bioavailability over time may increase the risk of CRC. Interestingly, subjects with acromegaly, characterized by chronic growth hormone and IGF-I hypersecretion, have an increased risk of developing CRC. It has been postulated that the stimulation of IGF-I receptors by IGF-I or IGF-II in subjects with acromegaly promotes colorectal carcinogenesis. Two recently published large prospective studies indicate a modest increase in CRC risk in subjects with type 2 diabetes compared with nondiabetic control subjects. As soluble fiber affects glycemia and insulinemia, the insulin hypothesis could be a mechanism by which dietary fiber can modulate colorectal carcinogenesis.

Mechanisms relating to SCFA will be addressed in the next section.

Short-Chain Fatty Acids/Resistant Starch

SCFA produced by fermentation of dietary fiber and resistant starch by colonic bacteria play a role in colorectal carcinogenesis. Butyrate inhibits growth in colonic tumor cell lines and induces differentiation and apoptosis. Butyrate also has been shown to alter the binding of regulatory transacting proteins to specific DNA sequences that control the expression of the gene. Butyrate has been shown to inhibit histone deacetylase, resulting in hyperacetylation of histones and increased accessibility of DNA to factors controlling gene expression. Hyperacelylation of histones disrupts ionic interactions with the adjacent DNA backbone, creating less densely packed chromatin, allowing transcription factors to activate specific genes. It has been postulated that the link between histone hyperacetylation-induced transcriptional regulation and growth inhibition may lie in the effects on specific cell cycle regulators. Butyrate increases apoptosis in various cell lines. Butyrate induces apoptosis through a histone hyperacetylation-mediated pathway that results in the conversion of capase-3 from its proenzyme form to the catalytically active protease. Another theory postulates that SCFA significantly inhibit colon cancer cell invasion by inhibiting urokinase plasminogen activator secretion and stimulating tissue inhibitor matrix metalloproteinase, which protects the basement membrane against degradation.

A report by Vernia *et al*. indicated that fecal acetate was lower in cancer patients than in those with polyps or in controls. Weaver *et al*. showed that there were no consistent differences in SCFA between patients with various gastrointestinal diseases.

SCFA are an important energy source for the colonocytes. Fermentation of dietary fiber and resistant starch by colonic bacteria generates SCFA. Butyrate and other SCFA have been shown to have anti-carcinogenic properties. Further studies are needed to delineate the effects of SCFA on colorectal carcinogenesis.

Resistant starch, defined as that portion of ingested starch that escapes digestion in the small intestine, has been shown to increase stool bulk, decrease fecal pH, alter the colonic microflora, decrease secondary bile acid concentrations and cytotoxicity of fecal water, decrease colonic mucosal proliferation, increase

colonic fermentation, and contribute to the synthesis of SFCA, especially butyrate. Data from studies are inconclusive. A published international correlation study supports the protective role of resistant starch in the development of CRC. In this study, there was a strong inverse association between starch consumption and CRC (correlation coefficient, $r = 0.70$; $P < 0.001$). In three different studies using chemical rodent models of CRC, resistant starch was observed to be protective, have no effect, or enhance tumorigenesis. Resistant starch was shown to significantly increase small bowel tumors in a study using a knockout murine model of the adenomatous polyposis coli gene (Apc1638N).

Fructooligosaccharides

Interest in fructooligosaccharides (FOS) as a health-promoting agent is on the rise. FOS constitute a group of linear fructose oligomers with a degree of polymerization ranging from one to five oligosaccharides. FOS occur in a number of plants such as chicory, onions, asparagus, and wheat. FOS escape digestion in the human upper intestinal tract and reach the colon, where they are completely fermented mostly to lactate, short-chain fatty acids, and gas. As a consequence of their fermentation, their caloric value is 2 kcal/g. Interest regarding the health benefits of FOS has increased as the role of prebiotics and probiotics on gut health continues to evolve. Prebiotics are nondigestible food ingredients that affect the host by selectively stimulating the growth or activity, or both, of one or a limited number of bacteria in the colon. FOS are the only products that meet all criteria allowing classification as prebiotics. An important property of FOS is the stimulation of bifidobacterial growth coupled with the suppression of the growth of potentially harmful pathogens. FOS are associated with a decrease in fecal pH, an increase in fecal organic acids, a decrease in the production of nitrogenous end products in urine and stool, and a decrease in fecal bacterial enzymatic activity. Several studies to date have examined the role of FOS in health and disease. Delzenne *et al*. in 1995 showed that FOS enhanced the bioavailability of calcium, magnesium, and iron in rats. Cherbut *et al*. conducted a study investigating the effect of FOS on colitis in rats. They found that FOS reduced intestinal inflammatory activity by decreasing lactic acid bacteria counts in the intestine. These results have promoted investigations into the effect of FOS on human diseases of chronic inflammation. Olesen *et al*. have recently demonstrated that in patients with irritable bowel syndrome, long-term use of FOS does not affect symptoms or disease outcome. Studies examining the effects of FOS on colon cancer, inflammatory bowel disease, and the absorption of specific nutrients are currently under way. The importance of FOS on disease outcomes therefore remains to be proven.

Summary

The strongest evidence that supports the fiber hypothesis is witnessed in the protective effect of dietary fiber among correlation and case-control studies. However, large prospective studies conducted in specific populations in the United States do not support the protective effect of dietary fiber on the development of CRC. Moreover, human interventional studies have failed to confirm a positive role for fiber in the reduction of CRC. Currently available evidence from epidemiological, animal, and intervention studies does not unequivocally support the protective role of fiber against the development of CRC. However, when the whole body of evidence from these studies is analyzed critically, the overall conclusion supports an inverse association between dietary fiber intake and CRC risk.

Whereas most studies have adjusted for potential confounding factors, it is difficult to delineate the effect associated with dietary fiber from other potential anticarcinogens. It is possible that undetermined interactions among anti-carcinogens present in fiber-rich foods and fiber are responsible for the observed protective effect of dietary fiber on the development of CRC. Three combined analyses or meta-analyses of case-control studies suggest a 50% reduction in the risk of developing CRC in subjects with the highest dietary fiber intake compared with those with the lowest intake. Although it is difficult to estimate accurately the magnitude of CRC risk reduction attributable solely to dietary fiber or fiber-rich foods, there appears to be a significant degree of reduction.

Animal studies suggest that insoluble and less fermentable fibers and wheat bran are the most effective in reducing CRC rates. Recent analysis in human studies suggests that only total dietary fiber, fruit fiber, and soluble fiber are significantly associated with decreased risk of colonic adenomas. Although the role of resistant starch in colorectal carcinogenesis has recently received much attention, convincing epidemiological evidence is lacking except for one international correlation study that showed a strong inverse association between starch and resistant starch consumption and CRC risk.

CRC mortality rates may be reduced through dietary means by an estimated 50–75%. CRC risk reduction associated specifically with dietary fiber intake has been estimated at 50% when subjects with the highest dietary intake are compared to those with the lowest dietary intake. The maximum daily dose of dietary fiber associated with a significant degree of CC risk reduction has yet to be established. Two combined studies of case control subjects suggest a 50% reduction in CRC risk in individuals consuming 27 g/day compared with those consuming less than 11 g/day of fiber. Prospective studies suggest that intakes between 28 and 33 g/day of dietary fiber are necessary to show a significant reduction in CRC risk. Any fiber intervention with the goal of reducing mortality due to CRC should be initiated at least 10–20 years before the peak age incidence of CRC. This is based on the principle that dietary fiber has its full impact on preventing CRC decades after initiation of a modified fiber-rich diet. Clearly, individuals at high risk for developing CRC, such as those with familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer, will achieve the greatest benefit from dietary fiber. However, extrapolating data from these patients suggests that the general population will benefit from dietary modification.

It is difficult to advise patients regarding the role of fiber and CRC. It is reasonable to recommend total fiber intake of at least 20 to 30 g/day. Dietary fiber should be from all sources, including five to seven servings of vegetables and fruits daily and generous portions of whole grain cereals as recommended by the World Health Organization and the National Cancer Institute. The guidelines can be used in conjunction with the dietary fiber recommendations (Table IV).

TABLE IV Dietary Recommendations

Daily carbohydrate intake: 55–60% of daily energy intake
Total fiber intake: 20–30 g/day
Eat each of the five food groups daily (meat, dairy products, grains, fruits, and vegetables)
Reduce total fat intake to less than 25 to 30% of total calories and saturated fat to less than 10% of total calories
Eat 5 or more servings of fresh vegetables and fruits daily (raw better than cooked; include deep yellow vegetables and dark green cruciferous vegetables)
Eat red meat infrequently (substitute chicken or fish without skin)
Eat more fiber-rich foods such as whole-grain cereals, fruits, and vegetables (daily total of 20 to 30 g fiber)
Avoid obesity
Eat salt-cured, smoked, and nitrite-cure foods in moderation
Keep alcohol consumption moderate
Participate in daily physical activity
Do not smoke

DIVERTICULAR DISEASE

Introduction

Diverticular disease encompasses two disease entities: diverticulosis and diverticulitis. Disease incidence increases from less than 5% at age 40, to 30% by age 60, to 65% by age 85. Although a male preponderance was noted in early series, more recent studies have suggested either an equal distribution or a female preponderance. Geographic variations exist in both the prevalence and pattern of diverticulosis. In some Westernized nations, prevalence rates of 5 to 45% exist with a tendency toward left-sided disease. In Africa and Asia, where the prevalence is less than 0.2%, diverticulosis is predominantly right-sided. Diverticulosis or diverticular disease of the colon is due to outpouchings of colonic mucosa through points of weakness in the colonic wall where the blood vessels penetrate the muscularis propria. Diverticulitis represents micro- or macroscopic perforation of a diverticulum. These diverticula are prone to infection or "diverticulitis," presumably because they trap feces with bacteria. Among all patients with diverticulosis, 70% remain asymptomatic, 15 to 25% develop diverticulitis, and 5 to 15% develop some form of diverticular bleeding. Diverticula and vascular ectasias cause the majority of lower gastrointestinal bleeding. Severe hemorrhage occurs in 3–5% of all patients with diverticulosis. The bleeding is arterial and caused by medial thinning of the vasa recta as it courses over a diverticulum. Patients with acute diverticulitis present with increasing left lower quadrant pain and fever, often with constipation and lower abdominal obstructive symptoms such as bloating and distension. The diagnosis of acute diverticulitis is made on the basis of the history and the physical examination. Physical examination reveals localized tenderness in the left lower quadrant and, with severe infection and an abscess, there may be peritoneal signs in the left lower quadrant. In some cases, a palpable mass can be identified over the sigmoid colon (the most common site of diverticulitis). Computer tomographic (CT) scanning has become the optimal method of investigation in patients suspected of having acute diverticulitis. After resolution of an episode of acute diverticulitis, the colon requires full evaluation by colonoscopy, barium enema, or both, to establish the extent of disease.

From a clinical perspective, the diagnosis of diverticular disease is controversial. Confusion exists

regarding the differences between diverticulitis and diverticulosis with irritable bowel disease. The distinction between the two entities is important not only from a clinical perspective but also from a research perspective. Classification of patients into the proper disease entity is critical in achieving good research outcomes. The confusion between diverticulitis and diverticulosis with irritable bowel syndrome (IBS) symptoms lies in the clinical presentation of symptoms. The classic features of diverticulitis include pain, fever, bowel obstruction, absence of blood in stool, and bloating. These symptoms clearly overlap with the symptoms of diverticulosis overlapping those of IBS. The distinction between the two entities therefore lies in clinical acumen as well as investigations. Patients with diverticulitis can present with an elevated white count, plain X rays suggestive of an obstruction, or a CT scan showing a perforation or an abscess. These findings are typically absent in diverticulosis with IBS. Future studies therefore need to include both clinical and laboratory investigations when classifying the various diverticular diseases.

Etiology

It has been proposed that low dietary fiber predisposes to the development of diverticular disease. In one study, Burkitt and Painter demonstrated that individuals in the United Kingdom eating a Western diet low in fiber had colonic transit times of 80 h and a mean stool weight of 110 g/day. In comparison, Ugandans eating very-high-fiber diets had transit times of 34 h and greater stool weights, >450 g/day. Longer transit times and smaller stool volumes were considered to contribute to the development of diverticular disease increases in intralumenal pressures. Such changes can lead to diverticular herniation.

The ultimate etiology of diverticular disease is unknown. Leading theories suggest that altered colonic motility plays a major role in the development of diverticulum. Higher resting, postprandial, and neostigmine-stimulated pressures in diverticular patients suggest that a delay in transport with augmentation of water reabsorption could cause excessively high pressures, forcing mucosa to herniate. Observations that diverticular disease is less common in vegetarians than nonvegetarians is compatible with a role for dietary fiber, since vegetables and fruits are important sources of fiber. A recent report evaluating a cohort of over 47,000 men provided strong evidence for the role of dietary fiber. Total dietary fiber intake was noted to be inversely associated with the risk of symptomatic diverticular disease after adjustment for age, energy-adjusted total fat intake, and physical activity. Results from the Health Professionals Follow-up Study suggest an etiologic role of fiber in diverticular disease. The study followed 51,529 male health professional over a 6-year period. A significant inverse association was found between insoluble dietary fiber and the risk of developing symptomatic diverticular disease. The greatest benefit was seen in those consuming an average of 32 g/day of total fiber.

Other dietary factors that might contribute to the pathogenesis of diverticular disease have been examined. There is no substantially increased risk associated with smoking, caffeine, or alcohol. Other studies suggest an association between obesity in men under 40 years of age and acute diverticulitis. This finding is consistent with observations that the risk of symptomatic diverticular disease is increased (relative risk 2.35 to 3.32, 95% CI) by a diet characterized by a high intake of total fat or red meat and a low intake of dietary fiber.

Treatment

The mainstay of treatment for preventing diverticulosis is a diet high in fruit and vegetable fiber. This suggestion is based on observations that low-fiber diets are associated with colonic diverticulosis. Recommendations are also based on results from the aforementioned Health Professionals Follow-up Study.

The management of uncomplicated diverticulosis involves a diet high in fruit and vegetable fiber. The majority of patients with diverticular disease will remain asymptomatic. There are no data to support any therapeutic recommendations in this group of patients. Multiple uncontrolled studies demonstrating the effect of fiber in patients with diverticulosis exist; however, the lack of a placebo group complicates the results. The first randomized controlled trial of a high-fiber diet in patients with symptomatic diverticular disease was conducted in 1977 by Brodribb. Results were reported on 18 patients at 1 and 3 months, with results indicating a statistically significant decrease in bowel symptoms in those in the treatment arm. Conversely, a study by Ornstein *et al*. failed to show a difference in symptoms between patients taking bran versus placebo after 4 months. Other well-conducted studies have reported conflicting results regarding the use of fiber. Despite conflicting data, it appears safe to recommend a diet high in fiber for patients with uncomplicated diverticular disease.

Complicated diverticulosis includes diverticulitis and hemorrhage. Patients with mild diverticulitis are often treated as outpatients with broad-spectrum

oral antibiotics. Patients may expect symptoms of increasing pain, fever, or inability to tolerate oral foods. Such patients are treated with a clear liquid diet. Patients with more severe diverticulitis admitted to hospital should be placed on bowel rest with clear liquids or nothing by mouth. Intravenous fluid therapy is required. Intravenous antibiotics should be initiated to target colonic anaerobes and gram-negative rods. Improvement is expected within 2–4 days, at which point the diet can be advanced. Fifteen to 30% of patients hospitalized with acute diverticulitis will require surgery. The likelihood of recurrence and the role of elective surgical resection are important to prevent further attacks as the risk of recurrence after an acute attack ranges from 7 to 62%. Recurrent attacks are less likely to respond to medical and diet therapy and often require emergent surgery.

CROHN'S DISEASE

Introduction

Inflammatory bowel disease refers to two disorders, ulcerative colitis and Crohn's disease, both chronic, relapsing disorders of unknown etiology.

Crohn's disease is a chronic inflammatory disorder that occurs throughout the world, with a prevalence of 10 to 100 cases per 10^5 people. Although the disorder can begin at any age, its onset most often occurs between 15 and 30 years of age. There appears to be a familial aggregation of patients with Crohn's disease such that 20–30% of patients with Crohn's disease have a family history of inflammatory bowel disease. Epidemiological studies suggests that the disorder occurs most frequently among people of European origin. Crohn's disease is three to eight times more common among Jews than among non-Jews and is more common among whites than nonwhites.

The typical clinical manifestations for most patients with Crohn's disease include diarrhea, abdominal pain, weight loss, and fever (Table V). The transmural nature of the inflammatory process leads to fibrotic strictures that can lead to episodes of small bowel or colonic obstruction. Transmural inflammation is also associated with the development of sinus tracts that can lead to serosal penetration and bowel wall perforation. Penetration of the bowel wall often presents not as an acute abdomen but as an indolent process related to the production of fistulas. Weight loss and fever are the primary systemic symptoms in Crohn's disease.

Patients with Crohn's disease can be divided into those with small bowel disease alone (30%), those with both small and large bowel involvement (50%), and those with disease involving only the colon (20%). The hallmark of Crohn's disease is inflammation, which may or may not be accompanied by noncaseating granulomas, extending through all layers of the gut wall. Microscopic examination reveals (1) hyperplasia of perilymphatic histiocytes, (2) diffuse granulomatous infiltration, (3) discrete noncaseating granulomas in the submucosa and lamina propria, (4) edema and lymphatic dilation of all layers of the gut, and (5) monocytic infiltration within lymph nodules and Peyer's patches on the serosal surface of the bowel.

The impact of dietary fiber in Crohn's disease focuses on (1) the role of fiber in the etiology of disease and (2) the role of fiber in the management of disease. The role of management will be discussed in the next section.

Several studies have investigated the role of dietary fiber in Crohn's disease. One study in 1979 by Thornton *et al.* interviewed 30 patients newly diagnosed with Crohn's disease. Patients were asked about their habitual pre-illness diet. When compared to healthy controls matched for age, sex, social class, and marital status, it was found that the Crohn's disease patients ate more refined sugar and slightly less fiber, raw fruit, and vegetables. It was postulated that a diet high in refined sugar and low in raw fruit and vegetables may predispose to Crohn's disease. In a review by Riemann *et al.* in 1984, it was shown that patients with Crohn's disease have a significantly increased consumption of refined carbohydrates compared to controls. Persson *et al.* conducted a population-based case control study of inflammatory bowel disease and dietary habits in Stockholm, Sweden. The relative risk for Crohn's disease was increased in

subjects who had a high intake of sucrose and decreased for subjects who had a high intake of fiber. The difficulty with the studies investigating the role of dietary fiber's causal effect in Crohn's disease is the retrospective nature of the studies, the inability to control for confounding factors, and the small sample sizes. Therefore, one cannot draw a conclusion about any causative role for fiber in Crohn's disease.

Treatment

In patients with narrowing of the lumen, the rationale for restricting dietary fiber is apparent. Fiber intake can be reduced by avoiding coarse whole grain breads and cereals, nuts, and most fruits and vegetables. Fruit and vegetables may not pass through strictures and may cause a bolus obstruction behind a stricture. Patients with symptoms suggestive of mild or partial bowel obstruction should avoid the intake of raw fruits and vegetables. Studies have investigated the role of dietary fiber in managing Crohn's disease. One study by Koga *et al.* evaluated the effectiveness of a low-residue diet in maintaining remission in people with Crohn's disease. The results suggest that drinking a low-residue drink for longer than 1 year following induction of remission was useful for the maintenance of disease remission. Kasper *et al.*, in 1979, measured the mean daily intake of dietary fiber, sugar, starch, fat, protein, and total energy in patients with Crohn's disease and controls matched for age, sex, and socioeconomic background. In the patients with Crohn's disease, the mean dietary fiber intake was greater than in controls. Crohn's disease patients also exhibited greater sugar and starch consumption with greater total energy intake. Heaton *et al.*, in 1979, treated 32 patients with Crohn's disease with a fiber-rich, unrefined carbohydrate diet in addition to conventional management. The results of the trial show fewer hospital admissions in the diet-treated patients than in those receiving only conventional management. In 1985, Jones *et al.* investigated 20 patients with Crohn's disease in which remission was maintained by either an unrefined carbohydrate fiber-rich diet or a strict exclusion diet. Their results show greater remission rates in patients on exclusion diets than in those on the carbohydrate fiber-rich diet. In a study by Levenstein *et al.* in 1985, there was no difference in hospitalization, need for surgery, new complications, nutritional status, or postoperative recurrence between patients on a low-residue diet and those following a normal Italian diet. In a recent study by Stange *et al.* in 1990, patients with Crohn's disease received either an exclusion diet or a diet low in refined carbohydrates and rich in fiber. A total of 26 patients were observed for 1 year. There was no difference between diets with respect to Crohn's disease activity index.

ULCERATIVE COLITIS

Introduction

Ulcerative colitis is an inflammatory disease of unknown etiology affecting the colonic mucosa from the rectum to the cecum. The diagnosis of ulcerative colitis rests on discovery of a combination of clinical and pathological criteria, investigation of the extent and distribution of lesions, and exclusion of other forms of inflammatory colitis caused by infectious agents (*Entamoeba histolytica, Clostridium difficile, Campylobacter jejuni, Escherichia coli*, and *Shigella dysenteriae*). The inflammatory state in ulcerative colitis is confined to the mucosa. Polymorphonuclear cells accumulate in the crypt abscesses and frank necrosis of the surrounding crypt epithelium occurs. Several crypt abscesses may coalesce to produce ulceration visible on the mucosal surface. Following mucosal destruction, highly vascular granulation tissue develops in denuded areas, resulting in friability and bleeding. Diarrhea and rectal bleeding, two of the most prominent symptoms of ulcerative colitis, are related both to the extensive mucosal damage that renders the colon less capable of absorbing electrolytes and water and to the highly friable vascular granulation tissue.

Treatment

A low-residue diet is recommended during acute phases of colitis because insoluble particles irritate the bowel and make diarrhea worse. Recently, however, the rarity of ulcerative colitis in developing countries together with the ability of dietary fiber to affect colonic function and its bacterial content have suggested that a low intake of fiber might be a factor in causing ulcerative colitis. A high-fiber diet can be prescribed for patients during quiescent phases of the disease. In one open-label, parallel group, multicenter randomized trial, the effect of *Plantago ovata* seeds compared with mesalamine in maintaining remission in ulcerative colitis was investigated. The primary end-point was maintenance of remission for 12 months. Results show that treatment failure occurred in 40% of the *P. ovata* seed group, 35% of the mesalamine group, and 30% of the *P. ovata* plus mesalamine group. *P. ovata* seeds might be as effective as mesalamine in maintaining remission in ulcerative colitis. Hallert *et al.* investigated the efficiency of ispaghula husk in relieving gastrointestinal symptoms in patients with ulcerative colitis in remission compared with placebo. Results show that

ispaghula can be helpful in the management of symptoms secondary to ulcerative colitis. It has been shown that germinated barley foodstuff results in significant clinical and endoscopic improvement in patients with ulcerative colitis.

SCFA have been proposed as a topical treatment for active distal ulcerative colitis. Colonic biopsy specimens from patients with ulcerative colitis reveal impaired utilization of butyrate as measured by carbon dioxide production. The rationale behind using SCFA in ulcerative colitis is that supraphysiologic lumenal SCFA concentrations may be able to overcome the partial metabolic defect of the colonic mucosa to oxidize SCFA. Moreover, SCFA stimulate colonic cell proliferation, provide a more effective barrier between mucosa and the intralumenal contents, dilate the resistance arteries of the colon, and increase blood flow and mucosal oxygen uptake. Four uncontrolled studies investigating the effect of SCFA on distal active ulcerative colitis have been published. In all four trials, 50–78% of the patients had clinical improvement, some with complete remission, during the study periods ranging from 4 to 6 weeks. Disease activity indices and endoscopic appearance all improved. The trials to date are limited by the small number of subjects, varying combinations and concentrations of SCFA, and differences in study design and patient populations. In a study by Breuer *et al*. in 1997, 103 patients with distal ulcerative colitis were entered into a 6-week, double-blind, placebo-controlled trial of rectal SCFA twice daily. Of the 91 patients completing the trial, more patients in the SCFA-treated group than in the placebo-treated group improved (33% vs 20%, $P = 0.14$, NS). In summary, SCFA irrigation can effectively treat refractory distal ulcerative colitis that has failed to respond to standard topical, systemic, or combination therapies. As a first-line treatment of mild to moderate distal ulcerative colitis, SCFA are associated with a modest clinical response rate. SCFA are as effective as topical corticosteroid and 5-aminosalicylic acid in inducing clinical, endoscopic, and histologic improvement in mild to moderate distal ulcerative colitis. SCFA are free of significant side effects and are well tolerated. Unresolved issues regarding SCFA include their role in maintaining remission of distal ulcerative colitis once active disease is brought under control.

DIVERSION COLITIS

Diversion colitis is an inflammatory process that occurs in segments of the colon after surgical diversion of the fecal stream. Several studies have documented that endoscopic abnormalities and histologic changes occur in the distal colonic segment of most patients after intestinal diversion. Pathologic examination shows lymphoglandular complexes expanding the submucosa with increased lymphocytes and plasma cells. Cryptitis with abscesses, patchy neutrophil infiltration in the lamina propria, and superficial erosions overlying lymphoid follicles are common findings. The disease is characterized by bleeding from inflamed colonic mucosa, tenesmus, mucus discharge, and abdominal pain. The majority of patients remain asymptomatic. Diversion colitis is likely caused by a deficiency of SCFA, which serve as lumenal nutrients for colonocytes as earlier studies showed beneficial effects of SCFA on diversion colitis. The definitive treatment of diversion colitis is restoration of intestinal continuity. However, randomized controlled studies did not confirm a beneficial role of SCFA in the treatment of diversion colitis. These studies were hampered by small sample size and short duration of treatment. In those patients with preexisting inflammatory bowel disease, SCFA combined with anti-inflammatory drugs may be effective.

IRRITABLE BOWEL SYNDROME

Introduction

IBS is defined as "a functional bowel disorder in which abdominal pain is associated with defecation or a change in bowel habit, with features of disordered defecation and distention." Criteria for IBS have been formalized in the Rome and Manning Criteria (Table VI). The incidence of IBS is 1% per year with a prevalence of 2.9–20%. The prevalence of IBS is lower in the elderly and higher in female patients. Patients are classified into subgroups based on predominant symptom. Subgroups include constipation-predominant IBS, diarrhea-predominant IBS, and IBS with alternating bowel movements.

IBS is considered a biopsychosocial disorder resulting from a combination of psychosocial factors, altered motility and transit, and increased sensitivity of the intestine or colon. One hypothesis suggests that IBS results from altered peripheral functioning of visceral afferents and the central processing of afferent information that are important in the altered somatovisceral sensation and motor dysfunction. As infectious diarrhea precedes the onset of IBS symptoms in 7–30% of patients, it has therefore been postulated that persistent neuroimmune interactions after infectious gastroenteritis result in continuing sensorimotor dysfunction. Food allergens may play a role in IBS as symptoms often improve with dietary exclusion. Stress and

TABLE VI Criteria for the Diagnosis of Irritable Bowel Syndrome

Manning Criteria	Rome II Criteria
Pain relieved by defecation More frequent stools at the onset of pain Looser stools at the onset pain Visible abdominal distension Passage of mucus Sensation of incomplete evacuation	At least 12 weeks or more, which need not be consecutive, in the previous 12 months of abdominal pain or discomfort with 2 of 3 features: relief with defecation, onset associated with a change in the frequency of stool, onset associated with a change in (appearance of) stool

emotions affect gastrointestinal function and cause symptoms in patients with IBS.

Treatment

There are currently no evidence-based guidelines on how patients with IBS should be treated. The dietary treatment of patients with IBS has centered around bran supplementation, manipulating the dietary fiber content of the diet, and the identification of food intolerance. Dietary intervention needs to be individualized with respect to the patient's symptoms. An in-depth assessment of a patient's dietary intake is essential prior to any therapeutic dietetic intervention. Of eight studies evaluating the role of diet in IBS, five identified food intolerance as a major contributor to symptoms. Unfortunately, because of impracticalities in trial design, there are no randomized control trials. In summary, seven studies mentioned dairy products, six mentioned coffee, and five mentioned wheat. Others cite eggs, corn, potatoes, onions, fruits, and vegetables. In the majority of the studies, the patients with diarrhea responded favorably to an exclusion diet compared to other subtypes of IBS. The recommendation that elimination diets control the symptoms of IBS is based on poorly designed and incomplete trials.

The mainstay of dietary therapy for IBS has centered around the manipulation of dietary fiber. Rees *et al*. conducted a critical review of clinical trials examining the effect of dietary fiber on symptoms in patients with IBS. It was shown that six of eight investigations detected no significant difference in most of the symptoms of IBS when fiber was compared to placebo. In the eight trials, the amount of supplement varied, the form in which the fiber was administered differed, and the type of fiber supplement was different. The literature does not support any beneficial effects of increasing insoluble nonstarch polysaccharides in IBS patients. Bran is reported to be no better than placebo in relief of overall IBS symptoms and may be worse than a normal diet for symptoms of IBS caused by intralumenal distension. However, subgroup analysis suggests that increasing insoluble wheat products in the diet may be of some benefit in patients with predominantly symptoms of constipation. There appears to be significant improvement in constipation if sufficient quantities of fiber (20–30 g/day) are consumed. It is therefore common practice to start with a low dose, increasing gradually and abandoning high levels of supplementation (>30 g/day) if patients experience worsening of symptoms. It is therefore generally recognized that fiber may have a role in treating constipation with a minimal role in the relief of abdominal pain and diarrhea.

The use of dietary fiber in patients with constipation-predominant IBS was prompted by the success of fiber in controlling general symptoms of constipation. Constipation is defined as a bowel movement every 3 to 4 days or less. An international panel of experts developed a consensus definition of constipation. Components of the definition include the presence of straining, hard stools, feelings of incomplete evacuation, or two or fewer bowel movements per week. The prevalence of constipation has been estimated to be 2% of the U.S. population.

An initial approach to the management of constipation consists of a gradual increase in fiber intake. To date, only one meta-analysis investigating therapeutic trials has been conducted. Tramonte *et al*. evaluated 25 treatments in 36 randomized trials. Although there was inadequate evidence to conclude that fiber was superior to laxatives, there was agreement that both fiber and laxatives improve bowel movement frequency in adults with chronic constipation. It is well known that there is a dose response between fiber intake and fecal output.

Studies have shown that patients with IBS develop symptoms after being exposed to a sorbitol diet. Trials cannot confirm a true malabsorption of carbohydrates in patients with IBS and therefore the role of

carbohydrate and sorbitol is not routinely considered in the management of IBS. Although the number of subjects reporting lactose intolerance is higher (60% compared to 27%) than in the general population, the actual percentage of lactose intolerance in patients with IBS is the same as in healthy subjects. The inconclusive findings and association of lactose intolerance and IBS can be explained by poorly designed studies. Moreover, lactose intolerance has been associated with gastrointestinal symptoms; however, whether this is due to lactase deficiency or increased sensitivity is not known.

In summary, the goal of dietary manipulation in patients with IBS is to help patients control their symptoms. Abnormal eating practices need to be assessed in relation to the patient's symptoms. Exclusion diets should be tried only when patients complain of multiple food intolerance and single food avoidance has not helped control symptoms. Patients consuming large quantities of sorbitol should be discouraged, especially if their symptoms are predominantly pain and diarrhea. In those patients in whom dairy products are associated with symptoms, a trial milk-free or lactose-free diet should attempted. If a patient's predominant symptom is constipation, an assessment of fluid intake should be undertaken. Regular meal patterns should be encouraged. An assessment of the type and quantity of nonstarch polysaccharides consumed should be made. The addition of bran and insoluble fibers should be discouraged, with more emphasis placed on increasing the proportion of foods containing a higher concentration of soluble nonstarch polysaccharides.

Dietary Reference Intakes (DRIs): Concepts and Implementation

JOHANNA DWYER
Tufts University and Tufts–New England Medical Center Hospital

adequate intake The nutrient intake amount that is set when experts believe that the data on the requirement are still preliminary.

estimated average requirement The amount of a nutrient that meets the requirement for a specific criterion of adequacy of half of the healthy individuals of a specific age, sex, and life stage.

estimated energy requirement The requirement for energy for individuals of normal weight with body mass indices of between 18.5 and 25 for adults.

Recommended Dietary Allowance The average daily dietary intake level that meets the nutrient requirements of nearly all (97–98%) healthy persons of a specific sex, age, life stage, or physiological condition (such as pregnancy or lactation).

tolerable upper intake level The highest level of chronic, usual daily nutrient intake that is likely to pose no risk of adverse health effects to almost everyone in the population.

total energy expenditure A set of equations that estimate the energy expenditure needed to maintain current body weight and activity levels.

This article describes the dietary reference intakes, which are reference standards for nutrient requirements that were recently completed by Health Canada and by the Food and Nutrition Board, Institute of Medicine, National Academy of Sciences in the United States. The rationale for developing a series of dietary reference intakes for nutrients is that by the early 1990s, it had become apparent that much new work on nutrient needs, the balance and interactions between nutrients, and the relationship of diet and development of chronic degenerative diseases had become available and needed to be incorporated into the thinking about dietary standards. New techniques for evaluating the biological functions of nutrients were also available and more precise estimates of energy output were at hand. Also, there was a need to evaluate whether requirements needed to be stated for many nonnutrients in food with biological activities of health significance. The development of the dietary reference intakes permitted expert groups of biomedical scientists to update data on the validity and reliability of existing dietary standards, to present a new paradigm for assessing dietary adequacy and excess using new statistical techniques, and to plan adequate, balanced intakes that were moderate in their dietary contributions. A new paradigm was needed because the existing nutrient standards could not appropriately address the uses to which they were applied. After over a decade of deliberations, by 2003 the new dietary reference intakes were nearly completed for all known nutrients and methods for applying them for assessing and planning intakes of individuals and groups are now available. This article focuses on their application to individuals for clinical purposes in the United States and Canada.

DIETARY REFERENCE INTAKE VALUES

Dietary reference intakes (DRIs) are quantitative recommendations for nutrient intakes used as reference values or standards for planning and evaluating the diets of healthy people. The DRIs include the estimated average requirement (EAR) for vitamins, minerals, and macronutrients, including protein, essential fatty acids, carbohydrate, and fiber when possible, and three other reference values, the Recommended Dietary Allowances (RDAs), the adequate intake (AI), and the tolerable upper intake level (UL). For energy, the total energy expenditure (TEE) and estimated energy requirement (EER) are presented. For energy-yielding nutrients, an acceptable macronutrient distribution range (AMDR) is also presented.

The process for establishing estimated average requirements and other dietary reference intakes used in the United States and Canada is described in detail in monographs on groups of nutrients published by the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes of the Food and Nutrition Board, Institute of Medicine, National Academy of Sciences. They replace both the 1989 Recommended Dietary Allowances that had been used previously in the United States and previous reference data used in Canada.

ESTIMATED AVERAGE REQUIREMENT

The EAR is the amount of a nutrient that meets the requirement for a specific criterion of adequacy of half of the healthy individuals of a specific age, sex, and life stage. Table I presents the EAR for nutrients. In setting the EAR, the evidence for each possible functional criterion that might be chosen is considered and the reason for selecting the criterion that is finally chosen is justified. The amount of the nutrient necessary to meet the appropriate criterion of adequacy varies from one individual to the next. Requirements are usually distributed normally or can be transformed to achieve a normal distribution. The EAR is not useful for estimating nutrient adequacy in individuals because it is a mean requirement for a group and since the variation around the mean is considerable, the range of error is considerable. For example, at the EAR, 50% of the individuals in a group are below their requirement and 50% are above it. Thus, a person whose usual intake is at the EAR has a 50% risk of an inadequate intake during the reporting period. An individual with an intake between the EAR and the RDA would have a risk of inadequacy between 50 and 2−3%. An individual whose usual intake is below the EAR would have a risk of inadequacy between 50 and 100%. The precise amount of a nutrient that will be adequate for any given individual is therefore unknown. It can be stated only in terms of probabilities and thus the EAR has little use in clinical practice.

RECOMMENDED DIETARY ALLOWANCES

The RDA is the average daily dietary intake level that suffices to meet the nutrient requirements of nearly all (97−98%) healthy persons of a specific sex, age, life stage, or physiological condition (such as pregnancy or lactation). It is the nutrient intake goal for planning the diets of individuals. Tables II and III present the RDA for vitamins and minerals, respectively.

To ensure that the needs of any given individual are met, a measure of variability around the EAR, usually the standard deviation, is assumed. Then, the RDA, the amount of the nutrient that covers virtually everyone in the population [defined statistically as 2 standard deviations (SD) above the EAR], is calculated assuming a normal distribution of nutrient requirements. Thus, the RDA is the EAR + 2 SD. If the SD is not available, using a coefficient of variation (CV) of 10%, the RDA is set at 1.2 times the EAR. If the CV is assumed to be 15%, then the RDA is set at 1.3 times the EAR.

As intakes fall further and further below the RDA, the risk, but not the certainty, of inadequacy increases. The RDA is a good target for individuals to aim for in planning their diets. The RDA is not appropriate for assessing the diets of individuals or for assessing or planning the diets of groups. The RDA should not be applied as a standard for the evaluation of group (population) nutrient intakes because it is overly generous; by definition, the RDA exceeds actual requirements of all but approximately 2−3% of the population. Thus, many individuals whose intakes are below the RDA may still be getting enough of the nutrient in question to be above their requirement levels.

ADEQUATE INTAKE

For some nutrients, it is not possible to calculate an EAR and set a RDA because data on the nutrient requirement (EAR) for the function of health significance that has been chosen is not available. However, there may be enough information to make quantitative recommendations about healthful nutrient intake levels. An AI is set when experts believe that data on the requirement using the criterion that has been chosen to determine the requirement are still preliminary. This signifies that more research is needed before an EAR and a RDA for that particular criterion or function can be determined. The AI is an appropriate goal or target for the nutrient intake of individuals. The AI is *not* a requirement and it should not be interpreted as such. Rather, it is an average or median intake in a group of healthy people, all of whom are assumed to be meeting their nutrient requirements. Thus, falling below the AI does not necessarily signify deficiency. Tables II and III also contain the AI for nutrients that have them.

The AI is a value based on observed or experimentally determined approximations of nutrient intakes by groups of healthy people that is used when an EAR and a RDA cannot be determined. For infants, the AI is always based on the mean intakes of groups of healthy infants. For adults, in some instances the AI is set as the mean of diets in some reference group. For other nutrients, the criteria are less precisely determined, but they are always chosen to be generous enough for good health.

TOLERABLE UPPER INTAKE LEVELS OF NUTRIENTS

Requirements for nutrients consist not only of values that ensure adequacy, but should also recognize that avoiding intakes far in excess of the RDA is important

Note. This table presents estimated average requirements (EARs), which serve two purposes: to assess the adequacy of population intakes and to calculate Recommended Dietary Allowances for individuals for those nutrients. EARs have not been established for vitamin D, vitamin K, pantothenic acid, biotin, choline, calcium, chromium, fluoride, manganese, or other nutrients not yet evaluated via the DRI process.

[a] As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

[b] As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[c] As niacin equivalents. 1 mg of niacin = 60 mg of tryptophan.

[d] As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

Note. This table presents Recommended Dietary Allowances (RDAs) in **boldface type** and adequate intakes (AIs) in lightface type. Both RDAs and AIs may be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover needs of all individuals in the group, but due to lack of data or uncertainty in the data the percentage of individuals covered by this intake cannot be specified with confidence.

[a] As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. To calculate RAEs from REs of provitamin A carotenoids in foods, divide the REs by 2. For preformed vitamin A in foods or supplements and for provitamin A carotenoids in supplements, 1 RE = 1 RAE.

[b] calciferol. 1 μg calciferol = 40 international units of vitamin D.

[c] In the absence of adequate exposure to sunlight.

[d] As α-tocopherol. includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[e] As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; for infants ages 0–6 months, preformed niacin (not NE) is meant.

[f] As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g] Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h] Because 10 to 30% of older people may malabsorb food-bound B12, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B12 or a supplement containing B12.

[i] In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j] It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period— the critical time for formation of the neural tube.

TABLE III Dietary Reference Intakes: Recommended Intakes for Individuals, Elements

Life-stage group	Calcium (mg/day)	Chromium (μg/day)	Copper (μg/day)	Fluoride (mg/day)	Iodine (μg/day)	Iron (mg/day)	Magnesium (mg/day)	Manganese (mg/day)	Molybdenum (μg/day)	Phosphorus (mg/day)	Selenium (μg/day)	Zinc (mg/day)

Note. This table presents Recommended Dietary Allowances (RDAs) in **boldface type** and adequate intakes (AIs) in lightface type. Both RDAs and AIs may be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover needs of all individuals in the group, but due to lack of data or uncertainty in the data the percentage of individuals covered by this intake cannot be specified with confidence.

since such intakes can disturb body functions and cause acute, progressive, or permanent disability. Therefore, caution is warranted in consuming large amounts of nutrients. Tables IV and V present the UL for vitamins and minerals, respectively. The UL of a nutrient is the highest level of chronic, usual daily nutrient intake that is likely to pose no risk of adverse health effects to almost everyone in the population. Below the UL, individuals should be able to biologically tolerate this amount of the nutrient. The UL is set for the adverse effect that is believed to be most likely to harm health and for which sufficient data are available. The UL is set by determining the level at which no observed adverse effects are noted or the lowest level of intake associated with observed adverse effects. An uncertainty factor is then applied to ensure that even very sensitive persons would not experience adverse effects at the UL dose chosen. For many nutrients, data on the adverse effects of large amounts of nutrients are unavailable or they are so limited that a UL cannot be determined. However, the lack of a UL does *not* mean that the risk of adverse effects is nonexistent from high intakes, but only that data are not yet available and the verdict on risk is unknown. The UL is *not* intended to be a recommended level of intake.

TABLE IV Dietary Reference Intakes: Tolerable Upper Intake Levels (ULs)[a] of Vitamins

Life-stage group	Vitamin A (μg/day)[b]	Vitamin C (mg/day)	Vitamin D (μg/day)	Vitamin E (mg/day)[c,d]	Vitamin K	Thiamine	Riboflavin	Niacin (mg/day)[d]	Vitamin B6 (mg/day)	Folate (μg/day)[d]	Vitamin B12	Pantothenic acid	Biotin	Choline (g/day)	Carotenoids[e]

[a] UL indicates the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to lack of suitable data, ULs could not be established for vitamin K, thiamine riboflavin, vitamin B12, pantothenic acid, biotin, or carotenoids. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

[b] As preformed vitamin A only.

[c] As α-tocopherol; applies to any form of supplemental α-tocopherol.

[d] The ULs for vitamin E, niacin, and folate apply to synthetic forms obtained from supplements, fortified foods, or a combination of the two.

[e] β-Carotene supplements are advised only to serve as a provitamin A source for individuals at risk of vitamin A deficiency.

[f] ND, not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

TABLE V Dietary Reference Intakes: Tolerable Upper Intake Levels (ULs)[a] of Elements

[a] UL indicates the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to lack of suitable data, ULs could not be established for arsenic, chromium, and silicon. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

[b] Although the UL for arsenic, was not determined, there is no justification for adding arsenic to food or supplements.

[c] The ULs for magnesium represent intake from a pharmacological agent only and do not include intake from food and water.

[d] Although silicon has not been shown to cause adverse effects in humans, there is no justification for adding silicon to supplements.

[e] Although vanadium in food has not been shown to cause adverse effects in humans, there is no justification for adding vanadium to food and vanadium supplements should be used with caution. The UL is based on adverse effects in laboratory animals and these data could be used to set a UL for adults but not children and adolescents.

[f] ND, not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

There is no established benefit for healthy individuals in consuming nutrient levels above the RDA or AI. The amounts of individual foods that most people eat rarely reach levels that are likely to exceed the UL. Nutrient supplements that provide more concentrated amounts of nutrients per dose have a somewhat greater potential risk of excess.

TOTAL ENERGY EXPENDITURE AND ESTIMATED ENERGY REQUIREMENT

There is no RDA or AI for energy because although there are no adverse effects from consuming slightly more minerals, protein, or energy than is necessary to meet one's requirement, small amounts of energy excess cause weight gain. That is, a RDA for energy that exceeded the energy requirements of 97 to 98% of all individuals in the population would cause weight gain. Therefore, energy needs are stated as minimal average requirements. The EER is the requirement for energy for individuals of normal weight with a body mass index of between 18.5 and 25 for adults. This reflects the energy expenditure associated with an individual's sex, age, height, weight, and physical activity level. The TEE is a set of equations that estimate the energy expenditure needed to maintain current body

TABLE VI Dietary Reference Intakes: Recommended Intakes for Individuals, Macronutrients

Note. This table presents Recommended Dietary Allowances (RDAs) in **boldface type** and adequate intakes (AIs) in lightface type. Both RDAs and AIs may be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover the needs of all individuals in the group, but due to lack of data or uncertainty in the data the percentage of individuals covered by this intake cannot be specified with confidence.

[a] Based on 0.8 g protein/kg body weight for reference body weight.

TABLE VII Acceptable Macronutrient Distribution Ranges

Macronutrient	Range (as percentage of total energy)		
	Children, 1–3 years	Children, 4–18 years	Adults
Fat	30–40%	25–35%	20–35%
n–6 Polyunsaturated fats (linoleic acid)	5–10%	5–10%	5–10%
n–3 Polyunsaturated fats[a] (α-linolenic acid)	0.6–1.2%	0.6–1.2%	0.6–1.2%
Carbohydrate	45–65%	45–65%	45–65%
Protein	5–20%	10–30%	10–35%

Source. Reprinted, with permission, from the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine (2002). "*Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids*". National Academies Press, Washington, DC. [a]Approximately 10% of the total can come from longer-chain *n*-3 fatty acids.

weight and activity levels. Those who are obese may need to lose weight by taking in less energy and expending more energy than specified by these values in order to achieve optimal health.

ACCEPTABLE MACRONUTRIENT DISTRIBUTION RANGE

The acceptable macronutrient distribution ranges for individuals are presented for macronutrients as a proportion of total energy intakes. These values are estimated to minimize the potential for chronic disease over the long term, to permit essential nutrients to be consumed at adequate levels, and to be associated with adequate energy intakes and physical activity to maintain energy balance.The AMDRs for adults are as follows: 20–34% of calories should come from fat (of which 5–10% of calories should come from *n*-6 polyunsaturated fatty acids and 0.6 to 1.2% of calories should come from *n*–3 polyunsaturated fatty acids), 45–65% of calories should come from carbohydrates, and 10–35% of calories should come from protein. Although AMDRs for protein and carbohydrate do not vary with age, for children the AMDRs for total fat are 30–40% for ages 1–3 years and 25–35% for ages 4–18 years. In order to know with confidence that an individual's intake falls within the AMDR, the procedure is similar to that used to determine that usual intakes exceed the AI or remain below the UL. Necessary data include the individual's average intake of the macronutrient of interest as a percentage of his energy intake over a sufficient number of days, the day-to-day standard deviation of percentage energy intake within persons of that sex and life-stage group, and the range or boundaries of the AMDR. To determine the degree of confidence that intake is above the lower end of the AMDR, the equation for the AI is used. To determine the degree of confidence that intake is below the upper end of the AMDR, the equation for the UL is used. Table VI presents DRIs for macronutrients. Table VII presents AMDRs for fat, carbohydrate, and protein and Table VIII presents additional advice on intakes.

CONCLUSION

Each of the DRIs has specific uses in dietary assessment, for making nutritional recommendations and for dietary planning for individuals. The appropriate use of the

TABLE VIII Additional Macronutrient Recommendations

Dietary cholesterol	As low as possible while consuming a nutritionally adequate diet
Trans-Fatty acids	As low as possible while consuming a nutritionally adequate diet
Saturated fatty acids	As low as possible while consuming a nutritionally adequate diet
Added sugars	Limit to no more than 25% of total energy

Digestion, Overview

JAMES J. FARRELL
University of California, Los Angeles

digestion A process in which ingested nutrients are broken down into smaller components to facilitate their absorption by the small intestine.
endopeptidase An enzyme that cleaves peptide bonds within a dietary protein that are adjacent to certain specific amino acids.
exopeptidase An enzyme that removes a single amino acid from the carboxyl-terminal of a dietary peptide or protein.

The different parts of the gastrointestinal tract act in an integrated and coordinated manner under the control of neural and humoral regulatory mechanisms to ensure that nutrients are absorbed with remarkable efficiency: less than 5% of ingested carbohydrate, fat, and protein is excreted in the stool of adults following their normal diet. Absorptive mechanisms adapt to the nature and amount of various nutrients presented to the intestinal tract. These changes occur during early development, throughout life, and at times of specific need (e.g., during pregnancy).

INTRODUCTION

The cerebral (or cephalic) phase of digestion, whether triggered by the sight, smell, or thought of food, initiates the digestive process with the salivary and gastric secretory responses mediated via the autonomic nervous system. Good mastication and mixing with saliva initiate digestion of starch by salivary amylase and of fat by gastric lipase in the stomach. Protein digestion begins in the stomach with secretion of gastric pepsinogens and their rapid conversion to pepsins by gastric acid. Gastric emptying is carefully controlled so that food enters the duodenum at a controlled rate, thus allowing efficient mixing with pancreaticobiliary secretions. This ensures that the nutrient is presented optimally to the pancreatic enzymes, which function best at neutral pH. The major digestive processes occur in the duodenum.

The gallbladder is stimulated to contract and the pancreas to secrete simultaneously in response to the presence of nutrients in the duodenal lumen. The simultaneous release of bile salts, pancreatic enzymes, and bicarbonate provides optimal conditions for further nutrient digestion. The activation of pancreatic proteolytic enzymes by enteropeptidase released from the duodenal mucosa encourages proteolysis within the duodenal lumen rather than the pancreatic duct.

Once intestinal chyme leaves the ileum and enters the colon, most nutrients have been digested and absorbed and colonic function largely resolves itself into dehydration of lumenal contents through the absorption of salt and water. Dietary fiber may be digested by colonic bacteria, with release of short-chain fatty acids, which do not usually have much nutritional significance.

DIGESTION AND ABSORPTION OF FAT

Approximately 40% of adult energy requirements are supplied by lipids, of which triglycerides form the majority. The majority of fatty acids present in dietary triglyceride are oleate and palmitate. In animal triglyceride, most fatty acids are long-chain saturated fatty acids. Polyunsaturated fatty acids, such as linoleic and linolenic acid, are derived from phospholipid of vegetable origin. Cholesterol and phospholipids constitute the remaining types of lipid.

The problem of fat insolubility in water dominates the mechanisms that have been developed to digest and absorb lipid, which occurs mostly in the upper two-thirds of the jejunum. Liberation of fatty acids from the glycerol backbone of triglycerides (lipolysis) is achieved by lipases. This process occurs initially in the stomach and then in the small intestine. First, a stable emulsion of fat droplets of such a size that they present a large surface area to the digestive enzyme is required. This stable emulsion is then presented to pancreatic lipase. The presence of co-lipase, secreted by the pancreas with lipase (molar ratio 1 : 1), is critical in approximating lipase to triglyceride. The products of lipolysis are distributed between the aqueous, oil, and intermediate phases in a number of forms prepared for transfer across the lumen to the mucosal brush border membrane. The shuttling of these products is dependent, in part, on the formation of micelles with bile salts. Although the uptake of lipid digestion products by

 Copyright 2004, Elsevier (USA). All rights reserved.

enterocytes has been accepted as a passive process, it is possible that some lipids may be taken up by enterocytes via carrier-mediated processes that are energy dependent. The brush border membrane–fatty acid-binding protein, which is likely to be concerned with the transfer of fatty acids into the cell, could provide one explanation for facilitated diffusion and the observed saturability of fat absorption.

Once within the cell, fatty acids bind to specific fatty acid-binding proteins, which are found predominantly in the jejunum and more in villous cells than in crypt cells. They may assist transfer across the cytoplasm to the endoplasmic reticulum for triglyceride resynthesis. In the endoplasmic reticulum, triglyceride is resynthesized by two processes. In the first process, monoglyceride is reesterified with absorbed fatty acid after it has been activated to form acyl coenzyme A (the monoglyceride pathway). This route, involving monoglyceride esterification, accounts for the majority of the triglyceride synthesized during the absorptive phase. During fasting, triglyceride (and phospholipid) is synthesized via the second route, which involves acylation of α-glycerophosphate with the formation of phosphatidic acid and, thence, triglyceride or phospholipid.

Once synthesized, triglyceride, cholesterol and its esters, and phospholipids are packaged for export in the form of chylomicrons and very-low-density lipoproteins (VLDLs). During fasting, VLDLs are the major triglyceride-rich lipoproteins that emerge from the epithelium; after feeding, chylomicrons predominate. Once the chylomicrons have formed in the smooth endoplasmic reticulum, they are transferred to the Golgi apparatus. Golgi-derived chylomicron vesicles are then incorporated into the basolateral membrane and secreted by exocytosis into the lymphatic circulation. During absorption, lacteals distend, and endothelial cells, which overlap one another in the fasting state, move apart and open gaps through which chylomicrons can readily pass.

DIGESTION AND ABSORPTION OF CARBOHYDRATE

Carbohydrate provides 45% of total energy requirements. Approximately half of the digestible carbohydrate is starch derived from cereals and plants, in which it is the major storage form. Starch (as either amylose or amylopectin) is made up of long chains of glucose molecules. Other major sources of dietary carbohydrate include sugar derived from milk (lactose), sugars contained within the cells of fruit and vegetables (fructose, glucose, sucrose), or sugar purified from cane or beet sources (sucrose). Processed foods form a major source of dietary sugars, particularly fructose."Nonstarch polysaccharides" form the majority of the"unavailable" carbohydrate. This includes cellulose and hemicelluloses, both of which are resistant to digestion in the small bowel because their β-1-4 bond, unlike the α bond in starch, is resistant to amylases. They are, however, broken down to some extent by colonic bacteria to yield short-chain fatty acids, which are avidly absorbed by colonic mucosa.

Salivary amylase depends for its effect on its proximity to the ingested starches and the time spent within the mouth. Pancreatic amylase is the major enzyme of starch digestion and, as with salivary amylase, produces short oligosaccharides: maltotriose, maltose, and α-limit dextrins; glucose monomer is not produced. Most of this hydrolysis occurs within the lumen, but because amylase also attaches itself to the brush border membrane of enterocytes, some digestion may occur at this site.

The terminal products of lumenal starch digestion just mentioned, together with the major disaccharides in the diet (sucrose and lactose), cannot be absorbed intact and are hydrolyzed by specific brush border membrane hydrolases that are maximally expressed in the villi of duodenum and jejunum (Table I). Lactase hydrolyzes lactose to produce one molecule of glucose and one of galactose. Sucrase–isomaltase hydrolyzes sucrose to yield one molecule of glucose and one of fructose. In addition, two other carbohydrases participate in terminal hydrolysis of starch products. Maltase acts on 1-4-linked oligosaccharides containing as many as nine glucose residues, liberating glucose monomers. α-Limit dextrinase is responsible for rapid hydrolysis of penta- and hexa-α-limit dextrins.

The three major diet-derived monosaccharides, glucose, galactose, and fructose, are absorbed by saturable carrier-mediated transport systems located in the

TABLE I Brush Border Membrane Carbohydrases

Enzyme	Substrate	Products
Lactase	Lactose	Glucose Galactose
Maltase	α-1-4 linked oligosaccharides up to 9 residues	Glucose
Sucrase–isomaltase (sucrase–α-dextrinase)		
Sucrase	Sucrose	Glucose Fructose
Isomaltase	α-limit dextrin α 1-6 link	Glucose

brush border membrane of enterocytes. The active transport of glucose and galactose is achieved by the same transport protein that acts as a sodium cotransporter. Sodium enters the cell across the apical membrane moving down its concentration gradient, bringing with it glucose or galactose in a one-to-one molar ratio. Fructose absorption occurs by facilitated diffusion; that is, transport occurs not against a concentration gradient but with a carrier protein to achieve transport rates greater than one would expect from simple diffusion.

Most hexoses are exported from the epithelial cell by way of the basolateral membrane using a facilitated diffusion (not requiring energy) via a specific carrier. Two genes that are expressed in the small intestine, GLUT2, the basolateral membrane-associated glucose transporter, and GLUT5, an apical membrane fructose transporter, encode these facilitative sugar transport proteins. Once the hexoses have entered the interstitial space, they pass onward by diffusion into the portal circulation.

Not all potentially digestible carbohydrate is absorbed in the small intestine. As much as 20% of dietary starch may escape into the colon, particularly that derived from cereals and potatoes. Most of this is metabolized by colonic bacteria and the short-chain fatty acids thus derived are readily absorbed. Hydrogen and methane are also generated and they contribute to flatus.

DIGESTION AND ABSORPTION OF PROTEIN

Dietary proteins are the major source of amino acids and provide approximately 10 to 15% of energy intake. Digestion of proteins begins in the stomach with the action of pepsins, which are released from their precursor pepsinogens by autoactivation in an acid pH. Pepsins remain active at the acid pH of gastric contents to produce a mixture of peptides with a small portion of amino acids.

Each of the pancreatic proteases is secreted as a proenzyme and thus must be activated within the lumen by enterokinase (enteropeptidase), which is liberated from the brush border membrane (Table II). It acts to convert trypsinogen to trypsin, which in turn activates the other proteases and continues to split more trypsin from trypsinogen. Trypsin, chymotrypsin, and elastase (endopeptidases) have specificity for peptide bonds adjacent to certain specific amino acids. They split peptide bonds in the protein molecule, whereas exopeptidases remove a single amino acid from the carboxyl-terminal end of the peptide. The final products of intralumenal digestion are thus produced by cooperative activity of endo- and exopeptidases and consist of a number of neutral and basic amino acids together with peptides of two to six amino acids in length.

In contrast to the absorption of carbohydrate, which is largely restricted to uptake of hexose monomers across the brush border membrane, amino acids can be absorbed either as monomers or as di- or tripeptides. However, the fact that the vast majority of the end products of protein digestion that reach the portal circulation are amino acids speaks strongly in favor of the presence of peptidases in the epithelium.

Evidence suggests that small peptides utilize a separate transporter system from those utilized by single amino acids. Di- and tripeptides are taken up by a single type of transporter and there is some stereospecificity because the length of the amino acid side chains on the di- or tripeptides is important; the longer the side chain, the more preferred the substrate for the absorption site. The L-isomers of the amino acids in dipeptides are much preferred to the D-isomers, whereas the presence of acidic and basic amino acid residues in dipeptides

TABLE II Pancreatic Proteolytic Enzymes

Enzyme	Action	Products
Trypsin	Endopeptidase; cleaves internal bonds at lysine or arginine residues; cleaves other pancreatic proenzymes	Oligopeptides
Chymotrypsin	Endopeptidase; cleaves bonds at aromatic or neutral amino acid residues	Oligopeptides
Elastase	Endopeptidase; cleaves bonds at aliphatic amino acid residues	Oligopeptides
Carboxypeptidase A	Exopeptidase; cleaves aromatic amino acids from carboxy-terminal end of protein and peptides	Aromatic amino acids and peptides
Carboxypeptidase B	Exopeptidase; cleaves arginine or lysine from carboxy-terminal end of proteins and peptides	Arginine, lysine, and peptides

reduces affinity for the transport system, compared with neutral amino acid residues. Affinity is also greater for dipeptides than for tripeptides, at least in the example of peptides containing glycine. The transporter for peptides is not dependent on sodium, but cotransport with protons may occur instead.

Although there appears to be only one type of dipeptide transporter in the brush border membrane for the 400 different possible dipeptides, there is a multiplicity of transport mechanisms for the 20 amino acids. These are sited on villous enterocytes and involve carrier-mediated active transport or facilitated diffusion processes; a small proportion may be absorbed by simple diffusion. Separate sodium-dependent, active transport processes for basic and acidic amino acids have also been demonstrated and there is some evidence to suggest that facilitated diffusion of these types of amino acids also occurs, although this is likely to be a minor pathway.

The intestinal basolateral membrane possesses a set of amino acid transport systems that are different from those in the brush border membrane. The amino acid transport systems in the basolateral membrane function to export amino acids from the enterocytes into the portal circulation during feeding. They also participate in the import of amino acids from the circulation into the enterocyte for cellular metabolism when amino acids are not available from the intestinal lumen, such as between meals. The intestinal basolateral membrane also possesses a peptide transporter system that is probably identical to that in the brush border membrane. This transport system facilitates the exit of hydrolysis-resistant small peptides from the enterocyte into the portal circulation.

VITAMINS

Water-Soluble Vitamins

With the loss of the capacity for hepatic synthesis, a specific absorptive mechanism for vitamin C has developed in humans. Folic acid consists of the complex pterin molecule conjugated to *para*-aminobenzoic acid and glutamic acid. Although much dietary folate is in the form of polyglutamates comprising at least six glutamic acid residues, much is present as formyl- and methylhydrofolate. Absorption of dietary polyglutamates depends on hydrolysis at the brush border membrane followed by transport into the cytoplasm. Uptake is achieved by a specific carrier-mediated, sodium-dependent, pH-sensitive process that is active at acid pH. Specific sodium-dependent active transport processes have also been demonstrated for thiamine, riboflavin, pantothenic acid, and biotin.

Vitamin B12 (cobalamin) exists largely as hydroxycobalamin, methylcobalamin, and adenosylcobalamin and these are found almost entirely in animal sources. Three types of binding proteins are involved in the absorption of cobalamin: one in saliva, one in gastric juice, and one in the circulation. The vitamin is released by gastric acid and pepsin from the various dietary proteins with which it is associated. The first specific binding protein secreted in saliva, the R protein, takes up the free cobalamin and binds it with strong affinity. In the duodenum, where the R protein is hydrolyzed by pancreatic enzymes, that intrinsic factor is able to bind the cobalamin that has been released. This complex resists pancreatic proteolysis, passes down the intestine to the terminal ileum, and there binds to specific receptors on ileal enterocytes. After binding to the receptor, the intrinsic factor–cobalamin complex probably enters the cell intact by translocation. Free cobalamin leaves the base of the cell, where it is immediately bound to an ileal pool of transcobalamin II, which transports it into the portal circulation.

Fat-Soluble Vitamins

Vitamin A (retinol) is absorbed in the small bowel. Transport across the apical membrane appears to occur by passive diffusion. Vitamin A leaves the mucosa largely in chylomicrons as retinyl palmitate. Most of a person's requirement for vitamin D is supplied by endogenous synthesis in the skin during exposure to sunlight and dietary intake becomes critical only when such exposure is inadequate. Like vitamin A, vitamin D absorption occurs by simple passive diffusion in the small intestine. Bile salts are unnecessary, but lumenal pH influences absorption. Absorption is reduced at neutral pH and increased in acid. Most absorbed vitamin D passes into the lymphatics unchanged. Vitamin E is absorbed passively across the intestinal mucosa. The ester form, in which many vitamin preparations are presented, is hydrolyzed prior to absorption, but the ester can be absorbed intact. Vitamin E is transported into the lymphatics largely unchanged.

Vitamin K is found in two forms. K_1, the major dietary form, is found in green vegetables, but beef liver is another good source. K_2 is produced by colonic bacteria, and although some may be absorbed from the colon this alone is an inadequate source if K_1 absorption is impaired. Absorption of K_1 from the small intestine is dependent on lumenal bile salts and uptake is achieved by a carrier-mediated process, whereas K_2 absorption is entirely passive.

MINERALS AND TRACE ELEMENTS

Various divalent ions are essential nutrients; some are absorbed in milligram amounts and are major constituents of the body, whereas others are necessary only in trace amounts. Iron, calcium, magnesium, phosphorus, and sulfur are in the former category and specialized absorptive mechanisms are involved in their assimilation. Zinc, copper, iodine, and selenium are considered trace elements and their absorption is not as well understood.

Absorption of calcium across the intestinal mucosa is achieved by two parallel processes: an active, transcellular transport process and a passive, paracellular diffusive process. Under normal dietary conditions, the duodenum is the major site for active transport, whereas passive, paracellular transfer occurs throughout the small intestine. Despite this localization of the active transport site, quantitatively more calcium may be absorbed in the jejunum and ileum than in the duodenum because of the relative amounts of time the lumenal contents spend in these regions of the intestine. The human jejunum absorbs calcium faster than the ileum and absorption rates in both are increased by treatment with vitamin D. The rate-limiting step in the absorption process is the intracellular calbindin concentration, which is regulated by a metabolite of vitamin D, 1,25-dihydroxyvitamin D_3, produced in the kidneys from 25-hydroxyvitamin D_3 converted by the liver from absorbed vitamin D.

In contrast to calcium, magnesium absorption in the basal state is greater in the human ileum than in the jejunum. Jejunal magnesium absorption is increased by vitamin D, whereas ileal absorption is not. Ileal transport involves both a paracellular, diffusive pathway and a transcellular, carrier-mediated, saturable process. There is some competition from calcium for the diffusive pathway but not for the saturable, presumably carrier-mediated process.

Most iron absorption occurs in the proximal small intestine and the ferrous (Fe^{2+}) form is absorbed better than the ferric (Fe^{3+}) form. The latter is insoluble at pH values above 3 and gastric acid and some sugars and amino acids render it more available for absorption. The presence of some anions, such as oxalate, phosphate, and phytate, precipitate iron out of solution and reduce its absorption. The iron in hemoglobin and myoglobin is well absorbed, and although these apparently compete with inorganic iron for absorption, the organic molecules are absorbed intact by a separate process. An iron transport protein, called divalent metal ion transporter 1 (DMT-1, also called DCT-1 or Nramp2), that is responsible for dietary iron absorption in the villus cells of the small intestine has been identified. The stimuli for increased iron absorption include iron deficiency, hypoxia, increased erythropoiesis, and pregnancy, but the circulating signal to the intestine is unknown.

ADAPTATION TO CHANGES IN NEED OR LOAD

One of the most fascinating aspects of intestinal function is the phenomenon of adaptation. Two specific forms of intestinal adaptation have been identified in the intestine: (1) mucosal hypertrophy leading to a global increase in absorption of all nutrients and (2) an increase in specific transport mechanisms induced in response to specific dietary needs or availability.

Resection of more than 50% of the human intestine results in increased fecal nitrogen losses, which slowly return toward normal, thus indicating that mucosal adaptation has occurred. This is due largely to hypertrophy of intestinal mucosa, which is manifested in increases in the number of villous enterocytes and in villous height without an obvious increase in the absorption rate per individual cell. Absorption increases for all nutrients and absorptive capacity may be enhanced up to fivefold in response to intestinal resection.

The digestive capacity of pancreatic juice can be altered by changes in nutritional intake. A high-protein diet enhances proteolytic enzyme production, a high-carbohydrate diet enhances amylase secretion, and a high-fat diet stimulates lipase secretion. Furthermore, adaptive responses to changes in dietary intake influence mucosal digestive and absorptive processes. Activity of the disaccharidase enzymes sucrase and maltase increases in response to high carbohydrate intake over several days but not to manipulation of protein intake. Absorptive function also adapts to dietary manipulation. Transport activity for carbohydrates, fats, and lipids rises in response to increased dietary loads. In another example, absorptive mechanisms for a number of vitamins and trace elements are switched on by low dietary loads and switched off by a large load. Here, absorption is enhanced in nutrient deficiency but inhibited with nutrient excess, when potentially toxic effects may result.

Disinhibitory Motor Disorder

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

achalasia Pathologic failure of relaxation of gastrointestinal sphincters and nonsphincteric smooth muscles.

interstitial cells of Cajal Pacemaker cells that generate electrical slow waves in the gastrointestinal tract.

megacolon Dilatation of the colon.

paraneoplastic syndrome Autoimmune pathology in tissues of patients with certain forms of cancer.

pseudo-obstruction Failure of propulsive motility that cannot be explained by mechanical blockage in the gastrointestinal tract.

syncytium Group of cells that behave as a unit due to some form of coupling between cells (electrical coupling in smooth muscles).

Trypanosoma cruzi Blood-borne protozoan parasite responsible for Chagas' disease.

Postnatal loss of, or congenital absence of, the enteric nervous system has pathologic effects on intestinal motility. In disinhibitory motor disorder, the pathophysiologic basis is loss or malfunction of enteric inhibitory motor neurons, to the musculature causing the spasticity and achalasia associated with a number of symptoms and diseases.

INTRODUCTION

In the enteric nervous system, a subpopulation of the motor neurons consists of inhibitory motor neurons to the musculature. Neurotransmitters released from inhibitory motor neurons suppress contractile activity in the musculature. Inhibitory motor neurons are among the missing neurons when the enteric nervous system is either destroyed by disease processes or fails to develop *in utero*. The primary pathologic effect in disinhibitory motor disorder is chronic intestinal pseudo-obstruction that is associated with hyperactive contractile activity of the circular coat of the intestinal musculature.

Disinhibitory Motor Disorder

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

achalasia Pathologic failure of relaxation of gastrointestinal sphincters and nonsphincteric smooth muscles.

interstitial cells of Cajal Pacemaker cells that generate electrical slow waves in the gastrointestinal tract.

megacolon Dilatation of the colon.

paraneoplastic syndrome Autoimmune pathology in tissues of patients with certain forms of cancer.

pseudo-obstruction Failure of propulsive motility that cannot be explained by mechanical blockage in the gastrointestinal tract.

syncytium Group of cells that behave as a unit due to some form of coupling between cells (electrical coupling in smooth muscles).

Trypanosoma cruzi Blood-borne protozoan parasite responsible for Chagas' disease.

Postnatal loss of, or congenital absence of, the enteric nervous system has pathologic effects on intestinal motility. In disinhibitory motor disorder, the pathophysiologic basis is loss or malfunction of enteric inhibitory motor neurons, to the musculature causing the spasticity and achalasia associated with a number of symptoms and diseases.

INTRODUCTION

In the enteric nervous system, a subpopulation of the motor neurons consists of inhibitory motor neurons to the musculature. Neurotransmitters released from inhibitory motor neurons suppress contractile activity in the musculature. Inhibitory motor neurons are among the missing neurons when the enteric nervous system is either destroyed by disease processes or fails to develop *in utero*. The primary pathologic effect in disinhibitory motor disorder is chronic intestinal pseudo-obstruction that is associated with hyperactive contractile activity of the circular coat of the intestinal musculature.

Copyright 2004, Elsevier (USA). All rights reserved.

ENTERIC INHIBITORY MOTOR NEURONS

The physiologic importance of enteric inhibitory motor neurons emerges from requirements for compatibility of neural control with the physiology of the digestive musculature. The intestinal musculature behaves like a self-excitable electrical syncytium. Action potentials triggered anywhere in the muscle will spread from muscle fiber to muscle fiber in three dimensions throughout the syncytium, which could potentially be the entire length of the small or large intestine. The action potentials, as they spread, trigger contraction of the muscle. A nonneural pacemaker system of electrical slow waves (i.e., basic electrical rhythm) accounts for the self-excitable characteristic of the electrical syncytium; this is accomplished by specialized pacemaker cells, the interstitial cells of Cajal. In the integrated system, the electrical slow waves are an extrinsic factor to which the intestinal circular muscle responds with action potentials, which in turn trigger contractions.

The cellular neurophysiology of enteric inhibitory motor neurons explains why the intestinal circular muscle generally fails to respond with action potentials and contractions during each and every slow-wave cycle. Ongoing activity of the inhibitory motor neurons also explains why action potentials and contractions do not spread from muscle fiber to muscle fiber and cause an entire length of intestine to contract after they are initiated at any site in the syncytium. Inhibitory motor neurons to intestinal circular muscle discharge continuously. Continuous discharge of action potentials in subpopulations of intestinal inhibitory motor neurons results in continuous inhibition of the autogenous activity of the circular muscle. Studies done in segments of intestine *in vitro* show that when neuronal discharge of inhibitory motor neurons is prevalent, muscle action potentials and associated contractile activity are absent or occur only at reduced levels with each electrical slow-wave cycle. When the inhibitory neuronal discharge is blocked experimentally, every cycle of the electrical slow wave triggers intense discharge of action potentials and large-amplitude contractions. Vasoactive intestinal polypeptide and nitric oxide are two of the inhibitory neurotransmitters released at the neuromuscular junctions. Continuous release of these transmitters can be detected experimentally in intestinal preparations.

PATHOPHYSIOLOGIC BASIS

The physiology of neuromuscular relations in the intestine predicts that spasticity and achalasia will accompany any condition wherein inhibitory motor neurons are destroyed. Without inhibitory control, the self-excitable syncytium of nonsphincteric regions will contract continuously and behave as an obstruction. This happens because the muscle is freed to respond to the pacemaker with contractions that propagate without any amplitude, distance, or directional control. Contractions spreading in the uncontrolled syncytium collide randomly, resulting in fibrillation-like behavior in the affected intestinal segment.

Loss or malfunction of inhibitory motor neurons is the pathophysiologic basis of disinhibitory motor disease. It underlies several forms of chronic intestinal pseudo-obstruction and failure of relaxation of tension in sphincters of the digestive tract. Enteric neurodegeneration in its earlier stages may be manifest as symptoms that can be confused with the irritable bowel syndrome.

Neuropathic forms of intestinal pseudo-obstruction arise from degenerative changes in the enteric nervous system. Failure of propulsive motility in the affected length of intestine reflects loss of the neural microcircuits that program and control the repertoire of motility patterns required for the necessary functions of that region. Intestinal pseudo-obstruction occurs in part because contractile behavior of the circular muscle is hyperactive but disorganized in the denervated regions. Hypercontractile activity is a diagnostic sign of the neuropathic form of chronic intestinal pseudo-obstruction in humans. The hyperactive and disorganized contractile behavior reflects the absence of inhibitory nervous control of the muscles that are self-excitable (autogenic) when released from the braking action imposed by inhibitory motor neurons.

Degenerative noninflammatory and inflammatory enteric neuropathies are two forms of disinhibitory motor disease that culminate in pseudo-obstruction. Noninflammatory neuropathies can be either familial or sporadic. The mode of inheritance may be autosomal recessive or dominant.

Degenerative inflammatory enteric neuropathies are characterized by a dense inflammatory infiltrate confined to enteric ganglia. Paraneoplastic syndrome, Chagas' disease, and idiopathic degenerative disease are recognizable forms of pseudo-obstruction related to inflammatory neuropathies. Paraneoplastic syndrome is a form of pseudo-obstruction in which commonalty of antigens between small-cell carcinoma of the lungs and enteric neurons leads to immune attack, resulting in loss of neurons. The majority of patients with symptoms of pseudo-obstruction in combination with small-cell lung carcinoma have immunoglobulin G autoantibodies that react with enteric neurons. Immunostaining with sera from paraneoplastic patients shows a characteristic pattern of staining in enteric neurons. The detection of

antienteric neuronal antibodies in the patient's serum is a means to a specific diagnosis.

The association of enteric neuronal loss with symptoms of pseudo-obstruction in Chagas' disease also reflects autoimmune attack on the neurons, mimicking the situation in the paraneoplastic syndrome. *Trypanosoma cruzi*, the blood-borne parasite that causes Chagas' disease, has antigenic epitopes similar to antigens expressed on the surfaces of enteric neurons. This activates the immune system to assault the gut neurons coincident with the attack on the parasite.

Idiopathic inflammatory degenerative neuropathy occurs unrelated to neoplasms, infectious conditions, or other known diseases. Small groups of patients have been identified with early complaints of symptoms similar to the irritable bowel syndrome; in these patients, the symptoms progressively worsened and were later diagnosed as idiopathic degenerative inflammatory neuropathy based on full-thickness biopsies taken during exploratory laparotomy that revealed chronic intestinal pseudo-obstruction. Each patient had inflammatory infiltrates localized to the enteric nervous system. Analysis of sera from these cases shows circulating antibodies against enteric neurons.

Recognition of the complex functions of the enteric nervous system leads to the conclusion that early neuropathic changes are expected to be manifest as functional symptoms that worsen with progressive neuronal loss. In diagnostic motility studies (e.g., manometry), degenerative loss of enteric neurons is reflected by hypermotility and spasticity because inhibitory motor neurons are included in the missing neuronal population.

Diverticulosis

BRUCE HENNESSY AND SHERYL PFEIL
Ohio State University

diverticula of the colon Herniations of the mucosa and submucosa though or between fibers of the major muscle layer (muscularis propria) of the colon.
diverticulosis Presence of multiple diverticula of the intestine, common in middle age; the lesions are acquired pulsion diverticula.
diverticulum Pouch or sac opening from a tubular or saccular organ, such as the gut or bladder.

Colonic diverticular disease is extremely common, particularly in the middle-aged and older populations. A colonic diverticulum is a herniation through the muscularis, generally at the site of a nutrient artery. Colonic diverticuli are rarely found in patients under the age of 30 years, and occur with increasing prevalence as a population ages. More than two-thirds of the United States population will have diverticulosis of varying degrees by age 80 years. There is no reported difference in prevalence between men and women.

EPIDEMIOLOGY

The ethnic and geographic variation in colonic diverticulosis is marked. Left-sided diverticulosis is classically associated with a Western diet, and to a lesser degree European ancestry. Although left-sided diverticulosis is still common in East Asians and Indians, right-sided diverticulosis is far more common in these patients than it is in the Western population. The prevalence of diverticulosis has steadily increased over the past 80 years. The Western diet, specifically the lack of high intake of dietary fiber, has been blamed for this change. Another theory regarding the modern increase in diverticulosis is the lower physical activity level of people in industrialized countries. Higher levels of physical activity seem to reduce the risk of diverticular disease.

PATHOPHYSIOLOGY

The formation of acquired colonic diverticulosis is thought to be secondary to increased intraluminal pressure. The lumen of the sigmoid colon narrows when the circular muscle layer enlarges, causing shortened taeniae. Pressure increases as luminal narrowing occurs, according to the law of Laplace. The luminal pressure is exaggerated by the chambering effect of colonic motility, whereby chambers are created by colonic segmentation. Diverticuli are most likely to develop at weak places in the bowel wall. The insertion of the vasa recta is thought to be such a weak point.

UNCOMPLICATED DIVERTICULOSIS

Colonic diverticuli are often diagnosed incidentally. They are often observed during screening flexible sigmoidoscopy and colonoscopy. They also may be apparent on plain abdominal films, computed tomography (CT) scans, or barium enemas. The importance of diagnosing asymptomatic diverticulosis is questionable. The mere presence of diverticulosis does not require specific therapy other than recommending a high-fiber diet. A high-fiber diet appears to be associated with a lower risk for developing diverticulosis. Treatment and prevention call for the same lifestyle changes. Although there is no evidence that dietary change will reverse diverticulosis, a high-fiber diet may decrease the risk of developing diverticular complications. Other dietary changes are controversial. The age-old advice to avoid nuts and seeds is based on their theoretical risk of becoming lodged in a diverticulum and inciting diverticulitis. This theory is unproved, and there is considerable debate with regard to the necessity of these dietary recommendations.

DIVERTICULITIS

Diverticulitis and diverticular bleeding are the most common complications of diverticulosis. Diverticulitis occurs from the erosion of the diverticular wall by focal necrosis and inflammation, resulting in perforation. Perforation occurs on two different levels, micro- or macroperforation. A microperforation is walled off by the adjacent mesentery and pericolic fat. The microperforation may resolve or it may form a focal

 Copyright 2004, Elsevier (USA). All rights reserved.

abscess, or lead to obstruction or fistula formation to an adjacent organ. Macroperforation causes free air entry and peritonitis.

Diverticulitis typically presents with left lower quadrant pain. The pain is often present for several days prior to presentation. Diverticulitis is sometimes accompanied by nausea and vomiting or constipation. Less commonly, a patient may experience diarrhea or narrow stools. Physical exam findings provide a limited but important cornerstone in the diagnosis of diverticulitis. The most common finding on examination is left lower quadrant tenderness. An uncommon but more impressive finding is that of a palpable left lower quadrant mass. Physical examination findings of general tenderness and peritonitis may reflect perforated diverticulitis. Exam findings, although important, will rarely provide enough information to make a diagnosis of diverticulitis.

Laboratory studies may be equally nonspecific. The patient will generally have a leukocytosis, indicating an infective or inflammatory process. Diverticulitis that occurs in close proximity to the bladder or that develops a colovesical fistula may cause pyuria on urinalysis and can be mistaken for a urinary tract infection. Other laboratory tests, including liver enzymes, amylase, and lipase, are generally normal. Chemistries are also commonly normal unless the patient presents with sepsis and acidosis.

The history and physical findings may prompt further evaluation with imaging studies. Generally, an acute abdominal series is obtained first. Plain abdominal films are useful to exclude macroperforation with free air perforation and colonic obstruction. Prior to giving the patient oral contrast, both obstruction and free air must be ruled out. Computed tomography is the generally accepted "gold standard" for diagnosing diverticulitis. Common CT findings of diverticulitis include bowel wall thickening, colonic diverticulosis, soft tissue density within the pericolic fat, and an abscess or phlegmon. Computed tomography has a very high sensitivity and specificity for detecting diverticulitis, which makes CT imaging a powerful tool in the diagnosis of diverticulitis. It may also provide additional information to exclude other causes of abdominal inflammation. Barium enema is generally not warranted in suspected diverticulitis secondary to the potential for barium to escape through a perforation into the peritoneal space. If performed in the face of suspected diverticulitis, the enema should consist of water-soluble contrast only. There is also no role for colonoscopy in acute diverticulitis. Colonoscopy is contraindicated because of the risk of perforation. Colonoscopy should be performed following resolution of the acute episode. Colonoscopy is performed after diverticulitis subsides to evaluate for tumors, polyps, and strictures, and to evaluate the extent of diverticular disease.

Treatment of acute diverticulitis depends on the severity of the process. A patient with mild to moderate diverticulitis can be treated as an outpatient with oral antibiotics and bowel rest. More severe disease requires inpatient therapy. Antibiotic regimens for diverticulitis must cover gut flora, including both gram-negative and anaerobic organisms. Uncomplicated diverticulitis is treated with oral antibiotics such as ciprofloxacin and metronidazole for 7–10 days. Patients should also be placed on a clear liquid diet. Patients with more complicated disease require intravenous antibiotics, bowel rest, and intravenous fluids. Diverticulitis may be complicated by abscess formation, obstruction, fistula formation, or peritonitis. Percutaneous drainage of an abscess can be performed by interventional radiologic technique. Abscess drainage and concurrent antibiotic treatment are sufficient treatment in a subgroup of patients, especially patients not considered surgical candidates. Percutaneous drainage may also allow time for bowel preparation and resolution of inflammation, thereby allowing resection and primary anastomosis with a one-step surgical procedure. Most patients with fistulas and/or obstruction do require surgery, but not emergently. Peritonitis is a more severe complication that requires immediate surgical intervention. Emergent surgery in this setting often involves a two-step procedure consisting of a resection of the diseased colon and colostomy. This is followed by colostomy takedown and reanastomosis at a later date.

Patients suffering recurrent diverticulitis may also be referred for elective surgery. Surgery involves removing the diseased portion of the colon as well as removing the sigmoid colon. The sigmoid colon is removed to eliminate the "high-pressure" area of the colon, in order to prevent further diverticulum formation and recurrent episodes of diverticulitis.

DIVERTICULAR BLEEDING

Diverticular bleeding is a significant source for lower gastrointestinal bleeding and an important cause of morbidity and mortality in those patients over age 60 years of age. Less than one-fifth of patients with diverticulosis will have at least one episode of hematochezia. Of these patients, only a few will present with massive hemorrhage and hypovolemia. Recurrent inspissation of fecal matter within the diverticulum causes a weakening of the arterial wall, following

which rupture and bleeding may occur. Bleeding is often painless and patients do not often have symptoms other than bleeding. Diverticulitis does not typically present with bleeding. Treatment consists of two important steps, resuscitation/stabilization of the patient and localization of the bleeding. Colonoscopy is the test of choice to diagnose, localize, and in some cases to treat diverticular bleeding. Failure of colonoscopy to provide a diagnosis or localization may prompt further evaluation by radionuclide imaging or angiography. Proper localization of the bleeding source provides crucial information in the event that bleeding cannot be controlled and surgical intervention is required. Fortunately for patients, three-quarters of those with diverticular bleeding will stop bleeding spontaneously and require no further therapy.

Dumping Syndrome

GEORGE A. SAROSI, JR.
University of Texas Southwestern Medical Center, Dallas

antrectomy Partial removal of the distal stomach encompassing the gastric antrum.
chyme Mass of partially digested food and digestive juices.
pyloroplasty Surgical division of the pyloric muscle, destroying it as a sphincter, and reconstruction of the pyloric channel to facilitate gastric emptying.
vagotomy Surgical transaction of the vagus nerve to reduce gastric innervation.

Dumping syndrome is a spectrum of symptoms thought to be a consequence of rapid gastric emptying following vagotomy and/or bypass or destruction of the pylorus. The symptoms of dumping syndrome occur after the ingestion of food and are absent in the fasting state. Dumping syndrome typically includes both gastrointestinal and vasomotor symptoms, and can be quite variable in presentation. The incidence of dumping syndrome after gastric surgery is variable, and depends to some degree on the operation performed. However, about 10% of patients will have significant dumping symptoms after gastric surgery.

DIAGNOSIS

The diagnosis of dumping syndrome is made largely on clinical grounds and hinges on the presence of typical symptoms in a patient following gastric surgery. Dumping occurs in the postprandial period and is categorized into two forms, early and late. Early dumping occurs within 30–60 minutes of eating and typically presents with both gastrointestinal and vasomotor symptoms. Gastrointestinal symptoms include fullness, bloating, crampy abdominal pain, nausea, vomiting, and explosive diarrhea. The vasomotor symptoms include diaphoresis, weakness, dizziness, flushing palpitations, and an intense urge to lie down. Late dumping occurs 2–3 hours after eating and usually presents with only vasomotor symptoms. In patients with severe dumping symptoms, weight loss and food fear may also be present. Although there are no commonly accepted tests for dumping

Copyright 2004, Elsevier (USA). All rights reserved.

which rupture and bleeding may occur. Bleeding is often painless and patients do not often have symptoms other than bleeding. Diverticulitis does not typically present with bleeding. Treatment consists of two important steps, resuscitation/stabilization of the patient and localization of the bleeding. Colonoscopy is the test of choice to diagnose, localize, and in some cases to treat diverticular bleeding. Failure of colonoscopy to provide a diagnosis or localization may prompt further evaluation by radionuclide imaging or angiography. Proper localization of the bleeding source provides crucial information in the event that bleeding cannot be controlled and surgical intervention is required. Fortunately for patients, three-quarters of those with diverticular bleeding will stop bleeding spontaneously and require no further therapy.

Although there are no commonly accepted tests for dumping

Copyright 2004, Elsevier (USA). All rights reserved.

syndrome, radioisotope gastric emptying studies demonstrating rapid gastric emptying are often used to confirm the clinical suspicion. Several clinical scoring systems have also been used to support the diagnosis of dumping. Recently, investigators have suggested a simple provocative test to confirm the diagnosis of dumping. After ingestion of 50 g of oral glucose, a heart rate rise of greater than 10 beats per minute in the first hour has been found to be a sensitive predictor of early dumping. Late dumping is confirmed with this test by documenting typical vasomotor symptoms in the postchallenge period.

PATHOPHYSIOLOGY

Early and late dumping differ in their pathophysiology. In early dumping, the rapid delivery of hyperosmolar chyme into the small intestine as a consequence of rapid gastric emptying results in several maladaptive responses. The presence of hyperosmolar proximal small intestinal contents is thought to lead to fluid shifts into the intestinal lumen, which results in intestinal distension and precipitates the gastrointestinal symptoms of early dumping. In addition, an oral glucose challenge leads to both peripheral and splanchnic vasodilatation, with both peripheral and splanchnic blood pooling, which is thought to result in the vasomotor symptoms of early dumping. Release of a variety of gastrointestinal hormones is enhanced in patients with early dumping; these include enterglucogon, vasoactive intestinal peptide (VIP), peptide YY, pancreatic polypeptide, and neurotensin. In late dumping, the rapid delivery of glucose to the small bowel followed by rapid glucose absorption is thought to result in an exaggerated insulin release. This exaggerated insulin secretion combined with rapid gastric emptying results in a excess insulin state 2–3 hours after eating and hypoglycemia with subsequent vasomotor symptoms. The exact cause of the excess insulin is unclear, but the enteric hormone glucagon-like peptide-1 (GLP-1) may play an important role in late dumping.

TREATMENT

Most cases of dumping syndrome will improve with time. The initial mainstay of therapy for dumping syndrome is dietary modification. For most patients, instituting an "antidumping" diet will effectively control dumping symptoms. An antidumping diet consists of (1) frequent small meals, ideally six or more per day, (2) low amounts of simple sugars, moderate amounts of fat, and high amounts of complicated carbohydrates, protein, and fiber, and (3) dry meals, with mealtime liquid intake delayed at least 30 minutes after solid intake. For patients with pronounced vasomotor symptoms, lying down for 30 minutes postprandially may decrease the unpleasantness of the vasomotor symptoms. Dietary fiber supplementation has been shown to help with reactive hypoglycemia. Acarbose, a competitive inhibitor of carbohydrate absorption, has also been shown to help with late dumping, although with long-term use it can cause malabsorption. In patients with severe dumping, or in those whose symptoms fail to respond to dietary modification, the next step should be the use of octreotide, the long-acting somatostatin analogue. Octreotide acts to delay intestinal transit time, causes splanchnic vasoconstriction, and suppresses the release of a wide variety of enteral hormones, including insulin. In a systematic review of seven randomized controlled trials, octreotide, when administered prior to meals, has been shown to alleviate the gastrointestinal symptoms and vasomotor symptoms of early dumping and to prevent reactive hypoglycemia. An initial dose of 50 μg, administered 15–60 minutes prior to meals, should alleviate symptoms. The dose can be increased to 100 μg as needed. Side effects of octreotide therapy include malabsorption and steatorrhea, but the steatorrhea can be managed with pancreatic enzyme supplementation. Although there is a relative paucity of published long-term results of octreotide therapy, extrapolation from intermediate results suggests it is safe and effective.

For patients with debilitating dumping symptoms that are refractory to dietary modification and octreotide, remedial surgery should be considered. In general, a cautious approach when considering surgical therapy of dumping is appropriate, because most cases of dumping will improve with time and because no remedial operation has a 100% success rate. For patients whose initial operation was a pyloroplasty, surgical reconstruction of the pylorus is the preferred approach. In patients with an antrectomy and Billroth II reconstruction, conversion to either a Billroth I reconstruction or a Roux-en-Y reconstruction is the preferred approach. For patients with a Billroth I reconstruction as their initial operation, conversion to a Roux-en-Y reconstruction is the preferred approach. In patients for whom the Roux conversion fails to resolve dumping syndrome, the addition of a 10-cm antiperistaltic segment of jejunum downstream from the gastric outlet is a very effective antidumping procedure, but can result in significant incidence of gastric outlet obstruction. For this reason, an antiperistaltic jejunal interposition should probably not be used as a primary antidumping operation.

Duodenal Motility

WILLIAM L. HASLER
University of Michigan Medical Center, Ann Arbor

fed motor pattern The stereotypic contractile pattern that initiates soon after a caloric meal and that is responsible for mixing and propulsion of food residue for efficient digestion and absorption.

gastric emptying The process by which ingested material is passed in a controlled fashion into the duodenum, where it undergoes further mixing and propulsion.

interstitial cells of Cajal Specialized cells that are located at the interface of the longitudinal and circular muscle layers and that generate rhythmic electrical depolarizations (slow waves) that act as pacemakers for duodenal contractions.

migrating motor complex The stereotypic contractile pattern present during fasting that is responsible for the clearance of undigested debris and sloughed enterocytes during the interdigestive period.

myenteric plexus The nerve layer that resides between the longitudinal and the circular muscle layers and that regulates all local and programmed motor activities of the duodenum.

peristaltic reflex The basic local motor reflex that is responsible for caudal propulsion of intralumenal contents.

The duodenum accepts lumenal contents delivered from the stomach and processes them for absorption or distribution to other intestinal regions. Many duodenal contractile patterns are similar to those of the distal intestine, whereas some complexes are unique to the region. Duodenal motility is controlled by myogenic characteristics, extrinsic and intrinsic nerves, and circulating hormones. External influences from central nervous system activation or immune factors modulate duodenal contractile function as do intralumenal stimuli.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The duodenum spans the region from the pylorus to the ligament of Treitz. The duodenal wall has two regions of muscle tissue, the muscularis externa and the muscularis mucosa. The muscularis externa consists of an outer longitudinal layer and an inner circular layer and is the major effector of mixing and propulsion. The role of the muscularis mucosa is poorly understood. Duodenal smooth muscle cells are spindle-shaped and uninucleate with no specialized regions for neuronal interaction. They are electrically active with membrane potentials of −40 to −80 mV. Duodenal smooth muscle is supplied with a rich network of intrinsic nerve tissue with modulatory influences from extrinsic innervation.

Duodenal myoelectrical activity exhibits ubiquitous membrane potential fluctuations of 3–15 mV oscillating at a frequency of 11–12 cycles per minute (cpm). This duodenal slow wave is electrically isolated from that of the distal stomach by a thick fibrous septum at

Duodenal Motility

WILLIAM L. HASLER
University of Michigan Medical Center, Ann Arbor

fed motor pattern The stereotypic contractile pattern that initiates soon after a caloric meal and that is responsible for mixing and propulsion of food residue for efficient digestion and absorption.

gastric emptying The process by which ingested material is passed in a controlled fashion into the duodenum, where it undergoes further mixing and propulsion.

interstitial cells of Cajal Specialized cells that are located at the interface of the longitudinal and circular muscle layers and that generate rhythmic electrical depolarizations (slow waves) that act as pacemakers for duodenal contractions.

migrating motor complex The stereotypic contractile pattern present during fasting that is responsible for the clearance of undigested debris and sloughed enterocytes during the interdigestive period.

myenteric plexus The nerve layer that resides between the longitudinal and the circular muscle layers and that regulates all local and programmed motor activities of the duodenum.

peristaltic reflex The basic local motor reflex that is responsible for caudal propulsion of intralumenal contents.

The duodenum accepts lumenal contents delivered from the stomach and processes them for absorption or distribution to other intestinal regions. Many duodenal contractile patterns are similar to those of the distal intestine, whereas some complexes are unique to the region. Duodenal motility is controlled by myogenic characteristics, extrinsic and intrinsic nerves, and circulating hormones. External influences from central nervous system activation or immune factors modulate duodenal contractile function as do intralumenal stimuli.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The duodenum spans the region from the pylorus to the ligament of Treitz. The duodenal wall has two regions of muscle tissue, the muscularis externa and the muscularis mucosa. The muscularis externa consists of an outer longitudinal layer and an inner circular layer and is the major effector of mixing and propulsion. The role of the muscularis mucosa is poorly understood. Duodenal smooth muscle cells are spindle-shaped and uninucleate with no specialized regions for neuronal interaction. They are electrically active with membrane potentials of −40 to −80 mV. Duodenal smooth muscle is supplied with a rich network of intrinsic nerve tissue with modulatory influences from extrinsic innervation.

Duodenal myoelectrical activity exhibits ubiquitous membrane potential fluctuations of 3–15 mV oscillating at a frequency of 11–12 cycles per minute (cpm). This duodenal slow wave is electrically isolated from that of the distal stomach by a thick fibrous septum at

the pylorus. Few gastric slow waves (3 cpm) propagate into the duodenum because of this septum, but some spike potentials cross the pyloric region in patches and may form the basis for gastroduodenal coordination. The duodenal slow wave controls the direction and maximal frequency of phasic contractions, although its amplitude usually is insufficient to elicit contraction under basal conditions. Neurohumoral stimuli evoke motor activity by inducing spike potentials of brief duration (10–100 ms) but high amplitude (50 mV) in phase with the slow wave. The interstitial cells of Cajal (ICC) at the interface of the circular and longitudinal muscle layers are believed to be responsible for slow-wave generation. In cat intestine, rhythmic oscillations are generated only by tissue containing ICC. In animals with a genetic absence of ICC, slow-wave activity is undetectable. Cyclic fluctuations in intracellular calcium underlie this electrical rhythmicity. In humans, the dominant small intestinal slow-wave pacemaker is in the duodenum. This site entrains adjacent regions; however, some uncoupling occurs over the entire intestine, resulting in decreases in slow-wave frequency in the ileum (7–8 cpm). These properties are advantageous for the different roles of each region. Proximally, nutrients are propelled over a large mucosal surface area for rapid digestion and absorption while, distally, retarded propulsion permits absorption of slowly digested and absorbed substances such as fats and bile.

Duodenal smooth muscle is innervated by the vagus and splanchnic nerves that relay information to and from the extraintestinal ganglia, the spinal cord, and the central nervous system. The myenteric plexus provides the major intrinsic innervation. The number of intrinsic neurons greatly exceeds the number of extrinsic fibers. Thus, most motor activities are directed by intrinsic nerves, whereas extrinsic innervation provides a modulatory function. Low-threshold preganglionic vagal cholinergic neurons activate nicotinic receptors within enteric ganglia and excite motor activity. High-threshold preganglionic vagal neurons are inhibitory to motor activity via release of vasoactive intestinal polypeptide (VIP) and nitric oxide (NO). Preganglionic cholinergic sphlanchnic neurons project from the spinal cord to the prevertebral ganglia. Noradrenergic postganglionic neurons then project to the enteric ganglia and inhibit excitatory cholinergic transmission. Afferent fibers outnumber efferent fibers by 10-fold in the vagus and by 3-fold in the splanchnic nerves. The duodenum is richly supplied with sensory fibers that may respond to chemical, thermal, or mechanical stimulation. Mechanoreceptors in the outer muscle layers or myenteric plexus are activated by passive distension or during active contractions. Mesenteric and serosal receptors respond to tension or to forceful contraction and may mediate visceral pain perception. The density of myenteric neurons ranges from 3700 to 12,170 per square centimeter in the cat small intestine, approximating that of the spinal cord. Motor neurons typically project 1–2 mm longitudinally although some fibers extend for 30 mm. Excitatory fibers run cephalad and inhibitory fibers project caudally. Eighty to 90% of myenteric neurons contain either tachykinins (40–45%) or VIP (40–45%), with no overlap between the two groups. Tachykinin neurons containing Substance P, neurokinin A, and acetylcholine mediate most of the excitatory functions of intestinal smooth muscle. The inhibitory supply to the duodenum is provided by NO- and VIP-containing myenteric neurons. A number of other transmitters modulate the physiologic motor activity of the small intestine.

ORGANIZED MOTOR PATTERNS OF THE DUODENUM

The best characterized organized motor patterns in the duodenum are the interdigestive migrating motor complex and the fed motor pattern. Other contractile complexes are observed infrequently at irregular intervals, often during illness. In many instances, duodenal motor patterns resemble those of the jejunum and ileum; however, patterns specific to the duodenum may be observed.

Migrating Motor Complex

The migrating motor complex (MMC) serves the role of housekeeper of the small intestine by propelling undigested food residue and sloughed enterocytes. The MMC consists of four phases with a total duration of 84–112 min. Phase I is a period of motor quiescence lasting 40–60% of the cycle. Phase II, occupying 20–30% of the cycle, exhibits irregular phasic contractions. Phase III is a 5- to 10-min period of lumenally occlusive, rhythmic contractions occurring at the slow-wave frequency. Phase IV is a transitional period of irregular contractions between phase III and phase I. Seventy-one percent of phase III complexes originate in the stomach, 28% begin in the duodenum, and 1% originate in the proximal jejunum. Most MMCs terminate in the jejunum. MMC cycle duration is nearly twice as long if the previous phase III complex originated in the stomach versus the duodenum. Phase III contractions propagate over longer distances than those in phase II. The transit of inert substances is four times faster in phase III than in phase I and 50% of total flow occurs during phase III. On cineradiography, transit during phase

III is characterized by intermittent boluses of 4–5 cm in length separated by 1- to 2-cm ring contractions.

The MMC is influenced by extrinsic and intrinsic neural sources. Bilateral vagotomy, removal of the superior and inferior mesenteric ganglia, total sympathectomy, and complete extrinsic denervation do not prevent MMC cycling, although cycle duration and regularity may be altered. Isolated denervated intestinal segments exhibit spontaneous phase III activity, which propagates aborally, demonstrating that the complex is programmed into enteric nerves. Cholinergic and noncholinergic pathways participate in MMC contractions. In dogs, atropine, the ganglionic blocker hexamethonium, or the neural toxin tetrodotoxin eliminates MMC cycling. Adrenoceptor antagonists disrupt MMC cycling, whereas NO synthase inhibitors evoke premature MMC activity. Ablation of myenteric serotonergic neurons prolongs MMC periodicity and decreases propagation velocities, whereas 5-HT_3 antagonists inhibit phase III activity and prolong cycle length.

The major humoral regulator of MMC activity is motilin, which is released from specialized cells in the duodenal mucosa. Antral phase III complexes correlate temporally with plasma motilin elevations in healthy humans and premature antral phase III activity is inducible by motilin infusion. In dogs, gastroduodenal phase III is abolished for several hours after infusion of motilin antisera and is replaced by irregular phasic contractions. Resection of duodenal motilin-producing tissue alters fasting antroduodenal motility in dogs. Motilin stimulates antral phase III in part through cholinergic pathways, because atropine reduces its contractile effects. However, duodenal phase III activity is controlled by atropine-resistant noncholinergic mechanisms. The stimulus for motilin cycling is not known. Motilin fluctuations are blocked by atropine and hexamethonium, suggesting regulation by cholinergic pathways, and motilin release is evoked by vagal stimulation, bile release, cholinergic agonists, opioid agents, NO synthase inhibitors, and duodenal pH changes, but the roles of these factors in regulating motilin release are unclear. There are differences in the motilin dependence of phase III complexes in the duodenum compared to the distal intestine. Ectopic complexes in the jejunum or ileum often are not associated with motilin elevations. The effects of motilin antisera on jejunal and ileal phase III complexes are minimal and ectopic phase III complexes form in these regions after duodenal resection. Thus, "programming" of phase III in the distal intestine is a motilin-independent phenomenon that is entrained by the actions of motilin on the antrum and duodenum.

The duodenal MMC cycles in phase with biliary motor activity and secretory functions. Gastric acid and pepsin production and intestinal fluid secretion increase prior to duodenal phase III as does the release of bicarbonate, bile acids, bilirubin, pancreatic enzymes, and secretory immunoglobulin A. Duodenal phase III has been proposed to contribute to gallbladder refilling during the interdigestive period. Chronic pancreatitis disrupts the synchrony of MMC activity and pancreatic exocrine cycling, suggesting differential regulation of the two phenomena.

Fed Motor Pattern

After a meal, the duodenal MMC is replaced by a fed pattern of intermittent phasic contractions of varying amplitude that serve to mix and propel intestinal contents. Forty-four percent of fed contractions do not propagate. Of the contractions that do, 90% migrate <30 cm and 66% migrate <9 cm. In some studies, a transitional motor pattern is observed immediately after meal ingestion characterized by highly propagative contractile clusters that expose extended regions of mucosa to nutrients. The duration of the fed motor pattern is dependent on meal characteristics. In dogs, a mixed 450 kcal meal induces a fed pattern of >3 h. In humans, a 400 kcal meal with 9% fat disrupts MMC activity for 294 ± 21 min, whereas a meal with 50% fat prolongs the fed period to 410 ± 42 min.

Neural input is important for induction of the fed pattern. In humans, sham-feeding disrupts duodenal phase III, indicating a cephalic contribution. Bilateral vagotomy, splanchnicectomy, mesenteric ganglionectomy, and total extrinsic denervation do not prevent induction of the fed state, but bilateral vagotomy shortens its duration and increases the latency to the onset of contractions. If nutrients are perfused into an isolated, extrinsically innervated intestinal loop, the MMC is disrupted in the unconnected main portion of the intestine, demonstrating the importance of extrinsic supply. Intestinal transection and reanastomosis decreases the frequency and amplitude of fed contractions in dogs and decreases propagation, showing the modulatory effects of intrinsic nerves. Atropine and hexamethonium abolish fed motor activity and NO synthase inhibitors shorten its duration. The hormonal mediators of the fed motor pattern are less defined. Investigation has focused on CCK as CCK levels increase 5- to 10-fold after eating and CCK analogues increase intestinal motility. However, motilin cycling is suppressed by meals but is unaffected by CCK infusion. In rats, CCK receptor blockade prevents MMC disruption by eating. In dogs, CCK receptor an-

tagonists reduce but do not prevent the fed response or the interruption of MMC cycling after eating. Other transmitters inhibit the MMC and induce complexes similar to the fed pattern. Neurotensin has received attention based on its ability to convert the fasting to a fed pattern along the entire small intestine in rats and humans.

The mechanism for reversion to MMC cycling after completion of the fed pattern is uncertain. The first MMC after eating begins distal to the duodenum, indicating that factors that initiate normal complexes are not yet operational. The initial duodenal phase III occurs soon after completion of gastric emptying. In dogs, continuous intraduodenal nutrient perfusion induces a fed pattern for only a finite time, after which the fasting pattern returns.

Other Stereotypic Contractile Complexes

The duodenum participates in other infrequent contractile complexes that may serve distinct roles in health and disease. Giant migrating complexes (GMCs) are intense contractile waves that propagate aborally for long distances in the intestine. Most GMCs begin in the distal intestine rather than the duodenum and clear debris from the ileum. GMCs are increased in several diarrheal conditions. Discrete clustered contractions (DCCs) consist of 3–10 contractions preceded and followed by 1 min of motor quiescence and are seen in the proximal and distal intestine. A highly propagative pattern in the duodenum and proximal jejunum, called the rapidly migrating contraction, migrates for 200 cm at >30 cm/s. Retrograde peristaltic contractions (RPCs) develop in the mid small intestine after emetic agents are administered and migrate orally to the duodenum before vomiting occurs. RPCs migrate rapidly (8–10 cm/s) over distances >100 cm and serve to evacuate intestinal contents into the stomach so that they may be expelled during emesis.

Motor Patterns Specific for the Duodenum

In addition to participating in the organized motor activity of the entire small intestine, the duodenum exhibits motor patterns that are specific for the region. The duodenal cross-sectional area increases during phase II of the MMC to accommodate pancreaticobiliary secretions, indicating region-specific tonic changes. Retroperistaltic contractions in the duodenum propel lumenal contents orally. Retrograde duodenal motor activity during late phase III directed against antral phase III pressure waves may increase fasting duodenal pH and nocturnal antral pH, serving to protect both regions. Retroperistaltic activity is associated with duodenogastric reflux of bicarbonate and immunoglobulin A, which may reconstitute the antral mucosal barrier during fasting. Duodenogastric retropulsion of bile is minimized by phase III-associated closure of the sphincter of Oddi. During the fed period, 40–50% of pressure waves in the proximal duodenum are retrograde in nature, which may contribute to controlling gastric emptying. Correlative ultrasonographic studies show bursts of duodenogastric reflux prior to pyloric closure during gastric emptying, suggesting the presence of duodenal mixing and retropulsion. Other investigators have questioned the importance of retrograde duodenal activity. Using impedancometry, one group reported that only 4% of fasting and 8% of fed bolus fluid movements were retrograde. Another study observed that only 2 of 180 phase III pressure wave sequences were purely retrograde. Similarly, during duodenal lipid perfusion, most pressure waves propagate in an antegrade direction. Some have observed bidirectional contractions in the proximal duodenum during phase III, especially toward the end of the complex.

EXTRINSIC AND INTRINSIC MODULATION OF DUODENAL MOTOR ACTIVIITY

Motor patterns in the duodenum are modified by external neural and immunologic stimulation. Duodenal motility also is subject to modulation by reflex activations of other regions of the gastrointestinal tract.

Extrinsic Factors

Duodenal motility is influenced by input from the central nervous system. Sleep decreases MMC cycle length, reduces propagation velocity, and increases contractile amplitudes. Intestinal phase III is reduced by depression and stress. Stress also prolongs the intestinal fed motor pattern. Corticotropin-releasing factor (CRF) may be a physiologic mediator of stress effects on the gut. In mice, cold stress effects on intestinal transit are mimicked by intracerebroventricular CRF. MMC inhibition by CRF in dogs is associated with suppression of motilin cycling. The effects of CRF and stress are reversed by CRF antagonists. Other transmitters acting centrally also modify duodenal motility. Inhibition of NO synthase in the brain suppresses duodenal phase III in dogs via vagal pathways. Destruction of hypothalamic and locus ceruleus adrenergic pathways lengthens MMC periodicity. Central neural calcitonin, calcitonin gene-related peptide, neurotensin, and opioids evoke intestinal phase III activity, whereas neuropeptide Y delays intestinal transit.

Duodenal motor activity is modulated by immunologic stimulation. In rats antigen-sensitized by intraperitoneal egg albumin, subsequent oral albumin evokes diarrhea that is associated with MMC disruption and induction of high-amplitude clustered contractions. A role for mucosal mast cells is demonstrated by the abilities of mast cell stabilizers and degranulation inhibitors to blunt antigen-induced intestinal motor responses. Intestinal infections also disrupt gut motor function. In rats, *Yersinia enterocolitica* and *Escherichia coli* alter MMC cycling via free radical generation. Similarly, fasting myoelectric activity increases and spike potentials are generated with *Hymenolepsis diminuta* infection. Much information on the impact of the immune system on gut function has been provided by studies of the nematode *Trichinella spiralis*. In rats, *T. spiralis* disrupts intestinal motility and induces GMCs. Intestinal muscle from *T. spiralis*-infected rats exhibits increased smooth muscle responses to contractile agonists and blunted neurally mediated contractions with associated decreases in Substance P and VIP content. Both T-lymphocyte-dependent and -independent pathways are involved in these pathophysiologic responses.

Intrinsic Regulation

Duodenal motor activity is affected by stimuli within the gut. The peristaltic reflex is the most basic reflex response demonstrable in intestinal segments. Stimuli that evoke the peristaltic reflex include mucosal pinching, hypertonic saline infusion, and radial stretch. The peristaltic reflex consists of an excitatory response proximal to stimulation (ascending contraction) and a distal inhibition (descending relaxation). The ascending contraction is characterized by simultaneous circular muscle shortening and longitudinal muscle relaxation and descending relaxation involves simultaneous longitudinal contraction and circular relaxation. Ascending contractions are partly inhibited by atropine at low levels of stimulation, whereas tachykinin antagonists or antisera block contractions induced by intense radial stretching, indicating dual cholinergic and tachykinin mediation. VIP and NO likely mediate the descending relaxation as both are released during peristalsis. Serotonin is released with distension and lowers the threshold for eliciting the reflex. Mucosal stimulation initiates the reflex by activating 5-HT_4/5-HT_{1P} receptors on sensory neurons in human intestine. In marmoset intestine, 5-HT_4 receptors are activated by low serotonin concentrations and 5-HT_3 receptors are activated by higher concentrations.

Nonmechanical stimuli have modulatory influences on duodenal function as well. Intraduodenal lipid or bile perfusion decreases duodenal flow in association with increased lumenal diameter, isolated low-amplitude pressure waves, and reduced propagation distances. In contrast, hydrochloric acid and hyperosmolar solutions retard duodenal propagation by inducing tonic duodenal occlusions. Duodenal myotomy reduces the evoked duodenal contractions with enhancement of lumenal propulsion.

Stimulation of other gut segments also modulates duodenal motility. The inhibitory intestino-intestinal reflex is the inhibition of several hundred centimeters of intestine by abrupt stretching or dilation of a localized segment. In humans, the inhibitory effects of distension are more pronounced in the duodenum than in the ileum. Distension of the stomach abolishes fasting duodenal motor activity and delays intestinal transit via nonvagal NO-mediated neural pathways. In other studies, gastric fundus distension produces irregular phasic contractions mimicking the duodenal fed pattern, some of which are propagated from the antrum. Colonic nutrient perfusion inhibits duodenal fasting activity, whereas colonic distension delays MMC onset via nicotinic ganglionic receptors.

DUODENAL FEEDBACK REGULATION OF GASTRIC EMPTYING

The duodenum plays a crucial role in regulating gastric emptying. The absence of duodenal motor activity is associated with accelerated emptying, whereas continuous duodenal contractions delay liquid emptying. Enhanced liquid emptying also is noted after duodenal myotomy. Duodenal pH receptors mediate inhibition of emptying by duodenal acidification. Duodenal amino acid perfusion slows both solid and liquid emptying. Placement of a duodenal fistula to divert nutrients converts liquid emptying to rapid first-order kinetics instead of the normal curvilinear profile. Agents acting on intestinal osmoreceptors increase duodenal outflow resistance and delay emptying. Inhibition of gastric emptying by lipids requires component fatty acids, because perfusion of nonhydrolyzable fats does not inhibit gastric emptying. Osmoreceptors mediating hypertonic saline-evoked inhibition of emptying are located only in the duodenum, whereas acids and lipids have inhibitory effects on longer segments.

The mediators that regulate duodenal inhibition of gastric emptying are incompletely characterized. Intestinal capsaicin reduces the inhibition of emptying induced by hydrochloric acid, glucose, and lipid, indicating the importance of afferent pathways. Duodenal transection impairs the nutrient-evoked delay of gastric emptying, showing the participation of intrinsic

duodenal neurons. NO may facilitate gastric emptying by inhibiting obstructing pyloroduodenal motor activity. Physiologic CCK infusions inhibit liquid emptying, whereas CCK antagonists accelerate emptying of mixed meals, glucose, lipids, and radiopaque markers in most studies. The ability of the CCK antagonist devazepide to blunt the retardation of emptying evoked by peptones decreases as the caloric density increases, indicating CCK-independent factors with greater nutrient loads.

The inhibitory effects of duodenal stimulation on gastric emptying are mediated by specific enterogastric reflexes. Duodenal acid exposure induces gastric fundus relaxation via secretin-dependent and -independent pathways. Duodenal distension inhibits antral contractions, a reflex that is partly blocked by vagotomy or splanchnicectomy and abolished by both. In contrast, duodenal distension-evoked inhibition of antral activity is unaffected by duodenal transection. Intraduodenal lipids, proteins, or hydrochloric acid decreases spontaneous antral contractions, effects reduced but not abolished by vagotomy. Vagal application of capsaicin partly reverses the inhibitory effects of protein, glucose, and trypsin inhibitor on antral motor activity, showing mediation by afferent neurons. Duodenal lipids, amino acids, glucose, hypertonic saline, or hydrochloric acid elicits pyloric closure and decreases transpyloric flow. Proximal duodenal distension produces greater pyloric responses than more distal stimulation. Isolated pyloric contractions evoked by duodenal hydrochloric acid are antagonized by atropine and the ganglionic blocker hexamethonium but are not blocked by vagotomy. The ability of the topical anesthetic xylocaine to prevent acid-induced pyloric contraction is evidence of a role of mucosal receptors in this reflex. Intrinsic pathways are involved in pyloric responses as duodenal transection prevents induction of pyloric contractions by duodenal distension. The 5-HT_3 antagonist zacopride reduces pyloric motor responses to intraduodenal hydrochloric acid, indicating that serotonergic nerves play a role. CCK may mediate the pyloric response to intraduodenal lipids; however, other studies suggest that CCK plays a limited role in enteropyloric reflex activity under physiologic conditions. Mediation by opioid pathways is suggested by the ability of naloxone to block pyloric contractions induced by intraduodenal amino acids.

Duodenal Obstruction

GEORGE A. SAROSI, JR.
University of Texas Southwestern Medical Center, Dallas

annular pancreas Congenital condition in which the pancreas does not rotate normally during embryogenesis, resulting in an extrinsic compression of the second portion of the duodenum.

duodenal atresia Congenital condition in which the embryonic cells lining the duodenum fail to completely resorb, resulting in a blockage in the duodenum (stricture).

duodeno-jejunostomy A surgical procedure in which the proximal duodenum is attached side-to-side to the proximal jejunum in order to bypass an obstructing lesion in the mid- to distal duodenum.

web A thin membrane of tissue attached to the wall of the intestine and causing a variable degree of intestinal blockage.

The duodenum is the most proximal portion of the small bowel, extending from the pylorus to the ligament of Treitz. Although a relatively uncommon site of intestinal obstruction, specific issues in duodenal obstruction can make these disorders difficult to manage. Obstruction of the first portion of the duodenum is usually due to peptic ulcer disease and is best thought of as a gastric outlet obstruction. This article focuses on duodenal obstruction occurring beyond the ampulla of Vater in both neonates and adults.

CLINICAL PRESENTATION

Duodenal obstruction presents in a similar fashion to a proximal small bowel obstruction. Adult patients report bloating, epigastric discomfort, and nausea with bilious emesis. Patients report symptoms regardless of oral intake, but they are often worsened by oral intake. Despite symptoms of proximal obstruction, the patients often continue to have normal bowel movements and flatus although they may report acholic stools. In neonates and infants, the history usually reveals only reports of poor feeding, fussiness, and bilious emesis. Many of the causes of duodenal obstruction in infants are associated with other congenital abnormalities. On examination, the patients often have epigastric fullness and tenderness, but an otherwise nondistended abdomen. In some cases, a mass may be palpable in the epigastrium. Laboratory evaluation will be consistent with vomiting and dehydration. Metabolic alkalosis is less consistent than in gastric outlet obstruction because of the loss of pancreatic bicarbonate with postampullary obstruction. Plain abdominal radiographs will sometimes demonstrate a double-bubble sign with an air-distended stomach, a closed pylorus, and an air-distended duodenum. A listing of the etiologies of duodenal obstruction broken down by patient age is presented in Table I.

TABLE I Etiologies of Duodenal Obstruction in Neonates, Infants, and Adults

Neonates and infants	Adults
Malrotation ± midgut volvulus	Malignancy
	Periampullary cancer[a]
	Lymphoma
	Renal malignancies
	Ascending colon cancer
	Metastatic cancer
Duodenal web	Inflammatory diseases
	Chronic pancreatitis
	Pancreatic pseudocyst
	Acute pancreatitis
	Crohn's disease
	Retroperitoneal fibrosis
Duodenal atresia	Vascular anomalies
	Preduodenal portal vein
	SMA or SMV syndrome
	Abdominal aortic aneurysm
Annular pancreas	Congenital malformations
	Duodenal web
	Annular pancreas
	Malrotation
Proximal jejunal atresia	Intramural or retroperitoneal hematoma
Vascular anomalies	Foreign body
Preduodenal portal vein	Bouveret's syndrome (gallstone obstruction of the duodenum)
	Duodenal diverticulum

Note. SMA, superior mesenteric artery; SMV, superior mesenteric vein.

[a] Periampullary cancer includes cancer of the head of the pancreas, the distal bile duct (cholangiocarcinoma), the ampulla of Vater, and the second portion of the duodenum close to the ampulla of Vater.

DIAGNOSTIC EVALUATION

Neonates

Duodenal obstruction in neonates and infants should be considered a surgical emergency until the diagnosis of malrotation with potential midgut volvulus can be ruled out. In a neonate with a presentation of duodenal obstruction, an upper gastrointestinal (GI) contrast study needs to be obtained urgently to establish the presence of a GI rotational abnormality. If malrotation cannot be ruled out by contrast study, these neonates require surgery to rule out malrotation and treat the obstruction. In neonates with normal gastrointestinal rotation and in adults, the evaluation and management of duodenal obstruction can proceed at a less urgent pace as the likelihood of bowel infarction from a midgut volvulus is low. In a neonate, the initial therapeutic effort is directed toward correcting volume deficits and any electrolyte abnormalities and toward nasogastric decompression. At this time, identification and management of additional congenital anomalies should also occur. In a neonate, no additional diagnostic evaluation beyond an upper GI contrast study is of significant preoperative value and after adequate preoperative preparation the infant should undergo surgery for correction of the source of duodenal obstruction.

Adults

In an adult patient, the initial management should consist of nasogastric decompression and correction of existing volume and electrolyte abnormalities. Because the likelihood of malrotation and midgut volvulus is low, debate exists about the next appropriate diagnostic study beyond the initial plain abdominal radiographs. Although upper GI contrast study will establish the presence of duodenal obstruction and give information as to the exact location of the obstruction, it cannot provide much information about the etiology of the obstruction. In contrast, abdominal computed tomography (CT) scan with GI and intravenous contrast will localize the obstruction and also can provide staging information for malignancies, diagnose a variety of inflammatory processes, and provide information about vascular etiologies of duodenal obstruction. For these reasons, CT would seem to be the most appropriate initial imaging modality in the evaluation of duodenal obstruction. If water-soluble GI contrast agents are used, CT does not interfere with the ability to perform subsequent upper GI endoscopy. While a diagnostic evaluation is ongoing, a careful assessment of the patient's nutrition should be undertaken, as many patients with duodenal obstruction will have a prolonged preoperative period of poor oral intake and subsequent malnutrition.

MANAGEMENT

Neonates

The therapy for duodenal obstruction will depend on the etiology of the obstruction. In neonates, essentially all of the etiologies will require surgical intervention. In the case of malrotation, an urgent laparotomy with detorsion of the small bowel, lysis of the Ladd's bands, and appendectomy is the surgical therapy of choice. In the case of a duodenal web, duodenotomy and web excision, duodeno-duodenostomy, and duodeno-jejunostomy have been used with good results. In the case of duodenal atresia and annular pancreas, bothduodeno-duodenostomyandduodeno-jejunostomy have all been used, depending on the location of the atresia and the mobility of the duodenum. Surgical therapy of duodenal obstruction in neonates is in general associated with excellent outcomes.

Adults

Medical Therapy

Treatment options for duodenal obstruction for adults are somewhat wider than for neonates, in part based on the broader differential diagnosis. Whereas some causes of duodenal obstruction can be managed with medical therapy, the majority will require surgical intervention. In the case of patients with malignant duodenal obstruction, a third option, intralumenal stenting, should be considered.

In patients with inflammatory etiologies for duodenal obstruction such as Crohn's disease, pancreatitis, and pancreatic pseudocysts, medical management of the underlying disease will occasionally result in partial or complete resolution of the obstruction. In Crohn's disease and acute pancreatitis, a 1- to 2-week course of conservative therapy is usually warranted prior to operation, although there is a paucity of outcome data to support this contention. An initial course of conservative management of duodenal obstruction secondary to intramural or retroperitoneal hematoma is warranted as several series have shown the majority to resolve over a 2-week period of observation. Duodenal obstruction secondary to peripancreatic lymphoma will often resolve in patients with a good response to chemotherapy and for this reason a conservative approach is warranted in managing these duodenal obstructions.

Surgery and Stenting

For the majority of causes of duodenal obstruction, the primary therapy will be surgical. For benign processes of an inflammatory, vascular, or congenital nature, or for foreign body obstruction, surgical extraction of the foreign body or web or a bypass of the obstruction will provide an effective and durable treatment of the obstruction with low morbidity. Many patients with duodenal obstruction will be malnourished at presentation and a 1- to 2-week course of preoperative nutrition support is often valuable for patients. The preferred operation for most causes of benign duodenal obstruction is a duodeno-jejunostomy, bypassing the obstruction from a point on the duodenum proximal to the obstruction to the proximal jejunum. In cases where the obstruction is in close proximity to the ampulla of Vater, a gastrojejunostomy may be preferable to a duodeno-jejunostomy in order to avoid inadvertent injury to the ampulla and/or common bile duct. If a gastrojeunostomy is performed for benign disease, consideration must be given either to an acid-reducing procedure, such as a parietal cell vagotomy, or to lifetime therapy with a proton pump inhibitor, as gastrojejunostomies are known to predispose patients to marginal ulcers.

In cases of malignant duodenal obstruction, surgical therapy remains the mainstay of therapy, but in cases where treatment of the obstruction is for palliation rather than cure, endolumenal stenting is emerging as an attractive alternative to surgery. The majority of malignant obstructions of the duodenum will be secondary to periampullary malignancies, often pancreatic cancers. The first goal in treating malignant duodenal obstruction is determining whether the patient is a candidate for pancreaticoduodenectomy with curative intent. In patients without evidence of metastatic disease or of locally advanced disease, the optimal surgical approach to duodenal obstruction is an attempt at curative resection. In the majority of patients, however, where resection for cure is not an option, a number of options for palliation of duodenal obstruction exist.

The least invasive option is placement of an endolumenal stent across the obstruction via either flexible endoscopy or fluoroscopy. There is a growing experience in managing duodenal obstruction utilizing self-expanding metallic stents placed across the obstruction. Primary success rates for symptomatic improvement of 85–90% have been reported in small case series. Recurrent obstruction rates of 15–20% prior to death have been reported in stented patients, but in some of these cases, repeat stent placement was possible. The reported incidence of GI perforation secondary to stent placement appears to be low.

In cases where stent placement is not possible or fails, surgical bypass of the obstruction remains the therapeutic gold standard. For malignant duodenal obstruction, a gastrojejunostomy is the procedure of choice based on its technical ease and the fact that few patients with malignant obstruction will survive long enough to develop ulcer complications of this operation. Most surgeons will also place a gastrostomy tube at the time of a bypass to allow the 10–20% of patients with poor gastric emptying after the gastrojejunostomy to avoid a long-term nasogastric tube. Gastrojejunostomy and gastrostomy tube placement can be performed using either a laparoscopic or a conventional open surgical approach with acceptable morbidity and mortality rates.

Duodenal Ulcer

RUPERT WING-LOONG LEONG* AND FRANCIS KA-LEUNG CHAN†
*University of New South Wales, Australia and †Chinese University of Hong Kong

cyclooxygenase Enzyme that exists in two isoforms, cyclooxygenase-1 and cyclooxygenase-2. Cyclooxygenase-1 is constitutive and regulates normal function in many organs. Cyclooxygenase-2 is inducible and is expressed by inflammatory cells to mediate inflammatory responses. A variant of cyclooxygenase-1 has been found in the central nervous system.

erosion Histologically defined as a defect that does not penetrate the muscularis mucosae; endoscopically, a lesion with a diameter less than 3–5 mm and with no perceptible lesion depth.

gastric metaplasia Mucus-type gastric cell growth that replaces the normal villous surface of the duodenal mucosa.

Helicobacter pylori Spiral-shaped gram-negative bacilli that inhabit the gastric mucous layer.

mucosal-associated lymphoid tissue lymphoma Low-grade B cell lymphoma of the stomach, principally caused by infection by *Helicobacter pylori*.

nonsteroidal antiinflammatory drugs Compounds that nonselectively inhibit the cyclooxygenase enzyme and are potent antiinflammatory and antipyretic agents.

non-ulcer dyspepsia Syndrome of recurrent chronic epigastric pain with no ulceration found on gastroscopy.

trefoil factors Family of acid- and enzyme-resistant peptides secreted by the mucin-secreting cells in the gastrointestinal tract; protect the gastrointestinal mucosa and assist ulcer healing.

ulcer Defined histologically as a defect that penetrates the muscularis mucosa; the exact endoscopic definition remains controversial, with disagreement on the lesion size (usually 3–5 mm), but most agree perception of lesion depth is necessary.

urease Enzyme produced by *Helicobacter pylori*; converts urea into ammonia and assists in survival of the bacteria in the stomach. Utilized by various tests to detect the presence of the *H. pylori*.

urease breath test Method to test for *Helicobacter pylori*. A carbon isotope-labeled urea compound is swallowed; in the presence of *H. pylori* urease, the compound is metabolized into isotopic carbon dioxide (^{13}C or ^{14}C) that is detected in exhaled breath.

A duodenal ulcer refers to a break in the duodenal mucosal integrity. The histopathologic description encompasses an epithelial defect that extends down through the muscularis mucosae into the submucosa. The endoscopic definition usually requires the surface breach to be at least 5 mm in diameter and with perceivable depth, characteristics that distinguish ulcers from erosions. Because erosions are superficial, they heal without scarring and are unlikely to be complicated apart from slow blood loss. Duodenal ulcers are usually solitary, round, punched out lesions that occur most often in the proximal 2 cm of the duodenum on the anterior or posterior walls. This area corresponds to the area of highest acidity and is also the junction between the gastric antral and intestinal mucosa.

EPIDEMIOLOGY

The incidence of peptic ulceration has changed dramatically over the past century. Prior to the nineteenth century, duodenal ulceration was uncommon. Duodenal ulcer incidence then increased up until the late 1950s, after which time there was a progressive decline. The peak in the incidence of duodenal ulcer and ulcer mortality occurred 10 to 20 years after that of gastric ulcer. Since the 1980s, although there has been an increase in the use of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) that relates to increased risk of ulcers, there has been a plateau in the incidence of duodenal ulcer that correlates with the introduction of histamine-2 (H2) receptor antagonists. Peptic ulcers in the past two decades have been characterized by occurrence in an older population and incidence in a higher proportion of females. The recurrence of ulcers in the elderly in recent years may be the result of failure to recognize *Helicobacter pylori* involvement in the treatment of ulcers in the 1970s and 1980s.

The temporal trend of peptic ulcer incidence follows a birth-cohort effect. The population born between the 1870s and 1900s had the highest risk of developing peptic ulcers, and as that group died, the incidence of peptic ulcers declined. This birth-cohort effect supports an environmental etiology of ulcers as opposed to a genetic cause; the environmental factor exerted its effect at a young age, and this factor is now postulated to be *H. pylori*. The widespread acquisition of *H. pylori* occurred at the onset of the industrial revolution of the nineteenth century, which was characterized

 Copyright 2004, Elsevier (USA). All rights reserved.

by increases in urbanization, overcrowding, and poor hygiene. Subsequently, in the second half of the twentieth century, increasing sanitation standards may have resulted in the decline in the transmission rate of *H. pylori* and ultimately the declining incidence of ulcer disease. However, the within-country incidence of peptic ulcer varies despite the same rate of *H. pylori* infection, suggesting that additional factors contribute towards the pathogenesis of ulcers and the changing temporal trends. Other factors postulated to be relevant to the declining incidence of peptic ulcer include dietary changes, reduced cigarette smoking, improved treatment for peptic ulcers, and improved diagnosis that excludes cases of non-ulcer dyspepsia, which may have been previously misdiagnosed as ulcers.

Duodenal ulceration is geographically heterogeneous. In Asia, the incidence of peptic ulcers continued to climb in the latter half of the twentieth century, in contrast to the trend in the West. In China, the prevalence of duodenal ulcers in the north in patients undergoing gastroscopy is 23% compared to 9.7% in the south, and the prevalence of duodenal ulcer is twice that of gastric ulcer. Asians, compared to Caucasians, present with ulcers at a younger age and the male to female ratio is higher.

Duodenal ulcer is now more common than gastric ulcer in the West, and affects 6–15% of the population. Despite improved endoscopic and pharmacological management of ulcer hemorrhage, the mortality rate has remained at 7% because more elderly patients with comorbidities now suffer from ulcer complications. Therefore, peptic ulcer disease imposes a significant economic burden on the community and a significant risk of morbidity and mortality on the individual.

ETIOLOGY

Factors implicated to be important for the cause of duodenal ulcers have ranged from personality type, emotional stress, and genetic susceptibility. However, in recent decades, two causes stand out as the principal etiological factors of duodenal ulcers—*H. pylori* and NSAIDs.

Helicobacter pylori

Helicobacter pylori was first isolated in 1982 at Royal Perth Hospital by Robin Warren and Barry Marshall. The serendipitous growth of the spiral organism on culture plates that were left in the incubator is legendary and marked the beginnings of a landmark medical discovery. At the time, an infection as the cause of ulcer disease was contrary to the dogma that bacteria could not survive the acid milieu of the stomach. In the two decades following its discovery, the role of *H. pylori* in causing chronic gastritis was proved through Koch's postulates, and eradication of the bacteria was found to prevent ulcer recurrence. *Helicobacter pylori* has now been shown to cause 80% of duodenal ulcers.

Helicobacter pylori, a flagellated and microaerophilic gram-negative bacillus related to the genus *Campylobacter*, is 3 μm long and has a characteristic spiral shape. The bacteria inhabit the gastric antral mucus layer, often overlying inflamed gastric mucosa. Biochemically, *H. pylori* produces the enzyme urease, which allows it to survive in the hostile acidic environment of the stomach by converting urea into ammonia to neutralize acid and maintain a periplasmic pH of 6.2. This acid-neutralizing ability is limited, however, and the organism survives poorly in the corpus of the stomach due to the high concentration of acid-producing parietal cells, and preferentially colonizes the less acidic gastric antrum. Two complete genomes of *H. pylori* have been published so far.

Helicobacter pylori is the most common infection worldwide, affecting 80% of the population in developing countries, but only 20–30% of Western nations. The bacteria are transmitted from person to person and are acquired in childhood through oral–oral or fecal–oral transmission. The prevalence of infection increases with age due to the cohort effect. Risk factors for infection include domestic overcrowding, lower socioeconomic status, poor hygiene, and exposure to gastric contents of infected individuals.

Aspirin and NSAIDs

Aspirin, introduced in the early 1900s, proved to be one of the major therapeutic advances in the treatment of inflammatory conditions and in the prevention of atherosclerotic vascular diseases. However, endoscopic studies as early as the 1930s demonstrated a predisposition toward aspirin causing ulcerogenesis and bleeding in the gastrointestinal tract, with a point prevalence for ulcer of 20%. This is believed to be related to cyclooxygenase (COX), which exists in two main isoforms. COX-1 is the constitutive form that is found in the gastrointestinal mucosa and platelets; it has a housekeeping role in maintaining the supply of prostaglandin necessary for gastrointestinal mucosal integrity. COX-2, inducible in inflammatory states, is the form of the enzyme produced by leukocytes. COX-3, a COX-1 variant that is expressed in the brain, may be the enzyme that becomes inhibited in the central analgesic and antipyretic effects of NSAIDs and acetaminophen.

NSAIDs and *Helicobacter pylori* Interaction

The role of NSAIDs ingestion in patients who are infected *H. pylori* is a controversial issue. There is now good evidence from prospective randomized studies and a meta-analysis to suggest that NSAIDs and *H. pylori* have at least an independent additive effect on the risk of ulceration.

Other Risk Factors

Smoking

Smoking increases acid production and inhibits duodenal and pancreatic bicarbonate secretion. Smoking alone is often insufficient to induce duodenal ulceration but may have an additive or synergistic effect in the presence of other risk factors.

Personality

The role of stress in causing gastroduodenal ulceration is well demonstrated in animal models; ice water immersion and restriction in movement cause ulceration in mice. Stressful occupation and the "type A" personality have been traditionally linked to the development of ulcer possibly through hyperacidity and local ischemia.

Hypercalcemia

Hypercalcemia increases acid secretion in healthy volunteers. In addition, hypercalcemia increases gastrin secretion in patients with gastrinoma.

Constitutional

People who have increased parietal cell mass, which is probably genetically determined, are more prone to developing duodenal ulceration because of acid hypersecretion. Monozygotic twins show a higher concordance rate for peptic ulcers than do dizygotic twins. Blood group O, Lewis phenotype Le (a−b−), and the ABH nonsecretor trait have also been implicated as genetic risk factors.

Zollinger−Ellison Syndrome

Zollinger−Ellison syndrome (ZES) is a gastrin-secreting neuroendocrine tumor that can be solitary or multifocal. Autonomous gastrin secretion increases the basal acid output (BAO) of the parietal cells and leads to peptic ulceration. There may be other concurrent endocrinopathies as part of a multiple endocrine neoplasia (MEN) syndrome. Screening tests include serum calcium, which can identify the hyperparathyroidism component of the MEN syndromes, and fasting gastrin level >1000 pg/ml. Gastrin elevation following injection with secretin supports ZES. BAO is typically increased (>15 mEq/hour). Radiology, scintigraphy, and selective venous sampling can localize these tumors. Gastrinomas are potentially malignant and should be treated by surgical resection.

Systemic Mastocytosis

In systemic mastocytosis, there is a proliferation of functionally or cytologically abnormal mast cells that may autonomously secrete histamine, among other mediators, resulting in hyperacidity. Patients may develop abdominal pain and gastroduodenal ulceration.

Other Causes of Ulceration in the Duodenum

Infective Ulcers

Cytomegalovirus, herpes simplex, fungal, and tuberculous infections can cause ulceration, most commonly in immunosuppressed patients and in the elderly.

Crohn's Disease

Crohn's disease rarely affects the proximal duodenum. Features suggestive of Crohn's disease include atypical location of deep ulcers, nodularity, perforation, stricturing, fistulization, non-caseating granulomas, and ulcers that are resistant to acid suppression and responsive to treatment of Crohn's disease.

Stress Ulcers

Stress ulcers (Cushing's ulcers) and ulcers in burns patients (Curling's ulcers) are acute, multifocal, superficial (0.5−2 cm) ulcers and erosions that show more necrosis than inflammation on histology. They may be caused by shock and local ischemia induced by cytokine release.

Neoplasm

Malignancy of the small bowel is uncommon and may present as primary neuroendocrine tumors, lymphomas, or metastasis from melanomas; hematological cancers; or infiltration by pancreas or gallbladder cancers.

Idiopathic

Data from Western countries show that 20% of patients have ulcers that are not associated with NSAIDs or *H. pylori*. A proportion of these patients may have taken aspirin-containing compounds or NSAIDs without reporting their use, or there may have been a false negative *H. pylori* test. However, there is a growing trend for these "non-NSAID, non-*H. pylori* ulcers" to be found worldwide. Most of these patients are elderly with comorbidities and, in particular, chronic liver disease.

PATHOGENESIS

Only 10–15% of patients infected with *H. pylori* develop duodenal ulcers. Ulcerogenesis requires a combination of host and bacteria factors, as illustrated in Table I.

Antral-Predominant Gastritis

Duodenal ulceration almost never occurs concurrently with gastric cancer, despite both being related to *H. pylori*. It appears that location and extent of the *H. pylori* gastritis determine why different diseases develop. The degree of luminal acidity is of prime importance in determining the site of gastritis. Patients with high acidity tend to develop body-sparing nonatrophic antral gastritis. People with this pattern of gastritis do not develop hypochlorhydria and tend to have increased acid secretion. This pattern is more likely if *H. pylori* were acquired in later childhood. Often this pattern occurs concurrently with duodenitis with gastric metaplasia due to the effect of the increased duodenal acid load.

Gastric Secretion, Duodenitis, and Duodenal Ulcer

Several factors have been found to be important in the pathogenesis of duodenal ulcer.

Gastric Acid Hypersecretion

Patients with duodenal ulcers have on average a higher acid output (both basal and maximal gastric acid output) than do healthy individuals. Often their parietal cell mass is higher and does not decrease following cure of *H. pylori* infection, suggesting an inherent predisposing factor for the development of ulceration independent of *H. pylori* infection.

TABLE I Host and Bacterial Factors Important in the Pathogenesis of Duodenal Ulcers

Host factors	Bacterial factors
Gastric acid hypersecretion	Virulence factors, cytotoxins
Increased parietal cell mass	Mucolytic enzymes
Increased gastrin production	Urease production
Increased gastrin sensitivity	Cytokine induction
Reduced somatostatin production by D cells	
Reduced intraduodenal neutralizing effect	
Inhibition of duodenal bicarbonate release	
Loss of gastrin inhibition effect	
Neutralization of bile acids	

Gastrin

Patients who are infected with *H. pylori* have an exaggerated gastrin release in response to meals and this phenomenon reverses following eradication of the bacteria. Factors that ordinarily inhibit gastrin release, namely, antral acidification, antral distension, and duodenal fat administration, are impaired in the setting of *H. pylori* infection. Reduction of somatostatin production by the antral D cells due to antral gastritis contributes to the loss of gastrin inhibition.

Gastric Metaplasia and Duodenal Acid Load

Gastric metaplasia, which develops in response to an increased duodenal acid load, allows colonization of *H. pylori* to occur in the duodenum. Colonization of *H. pylori* in the metaplastic gastric tissue induces further metaplasia because of bacteria-activated inflammation, duodenitis, and ulceration. Increased duodenal acid load, through precipitation of bile salts, neutralizes the inhibitory effect of bile on the survival of *H. pylori*. *Helicobacter pylori* also produces a nitric oxide synthase inhibitor that impairs bicarbonate secretion in response to acidification of the duodenal bulb in duodenal ulcer patients. This normalizes following the cure of *H. pylori* infection.

Helicobacter pylori and Duodenitis

Infection of the duodenum results in chronic active duodenitis, and the inflamed mucosa renders the duodenum even more susceptible to damage by acid and pepsin. *Helicobacter pylori* produces virulence factors that induce an inflammatory response. Vacuolating cytotoxin A (vacA), an extracellular toxin found frequently in *H. pylori* strains from patients with duodenal ulcers, increases polymorph recruitment and migration. The cytotoxin-associated gene A (cagA) protein is produced by 60% of strains in the United States and by almost 100% of strains in Asia. The cagA-positive strains induce more cytokines, especially interleukin-8 (IL-8), and are significantly associated with increased chronic inflammatory activity. IL-8 promotes neutrophil recruitment and activation, leading to inflammatory injury to the epithelium. The cagA protein, which is injected into the host cell following attachment of the organism to the epithelium, interacts with a tyrosine phosphatase to mediate phosphorylation.

CLINICAL FEATURES

Symptoms and Signs

The textbook description of duodenal ulcer pain states that it is intermittent and seasonal in spring

and autumn. The pain typically is epigastric and burning in quality, occurring in the evening and early morning, waking the patient from sleep between midnight and 3 am, corresponding to times of high duodenal acid load. Eating food and antacids relieves the pain. However, many patients with duodenal ulcers are asymptomatic. Importantly, 10% of patients taking a NSAID presenting with complicated ulcers do not have antecedent abdominal pain, possibly due to the analgesic effect from the drug. Conversely, many patients who have ulcerlike pain turn out to have gastroduodenitis or non-ulcer dyspepsia and not a duodenal ulcer. Thus, the sensitivity and specificity of typical dyspepsia for the diagnosis of duodenal ulcer is low.

Vomiting is uncommon unless there is scarring and deformity of the pylorus or duodenum. Patients may present with complications such as peritonitis if the ulcer perforates or with hematemesis or melena caused by the ulcer eroding into a major blood vessel, usually a branch of the gastroduodenal artery. Anemia may result from chronic iron deficiency from blood loss.Examination of a patient with duodenal ulcer is often unrewarding. There may be nonspecific tenderness at the epigastrium. Peritonitis, especially with right-sided tenderness, predominantly suggests perforation with peritoneal contamination down the right paracolic gutter. Right-sided abdominal tenderness and peritonitis may be caused by a perforated peptic ulcer with peritoneal contamination along the right paracolic gutter.

Diagnosis

Endoscopy

Esophagogastroduodenoscopy (EGD) has revolutionized the diagnosis of upper gastrointestinal ulcers. EGD can diagnose ulcers as well as treat bleeding ulcers, using various combinations of through-the-scope therapeutic capabilities, such as injection, clipping, and thermocoagulation. For these reasons, EGD is considered to be the gold standard for the diagnosis of peptic ulcers, but should be avoided in perforated duodenal ulcers because gaseous distension by the endoscope can aggravate peritonitis or result in pneumoperitoneum.

Imaging

Plain erect chest X-ray helps to exclude perforated peptic ulcers. Double-contrast barium meals can also detect ulcers.

Tests for Helicobacter pylori

As one of the major causes of duodenal ulcers, *H. pylori* is readily diagnosed by either invasive means (with an endoscopy) or noninvasive means (without an endoscopy), as shown in Table II. Noninvasive tests are convenient, inexpensive, and sufficiently accurate to diagnose *H. pylori*. Invasive tests can be performed if an EGD is indicated for the patient.

Biopsy urease test At least three commercially available biopsy urease kits test for the presence of the *H. pylori* enzyme urease collected during endoscopic gastric biopsies. The presence of this enzyme changes the color of a pH-sensitive indicator within 24 hours (but often within 1 hour), providing an easy and fast way of diagnosis at the time of endoscopy. Luminal blood can produce a false negative urease test result and therefore histology is recommended for patients who present with recent upper gastrointestinal bleeding. The sensitivity of the biopsy urease test is 89–95% with a specificity of close to 100%.

Histology and culture Histology of antral biopsies is the gold standard for the diagnosis of *H. pylori* and with proper staining technique has a sensitivity of 90–100%. Culture of antral biopsies is usually reserved for research purposes or to identify antibiotic susceptibility after failed attempts at *H. pylori* eradication.

Urea breath test The urea breath test (UBT) detects for the presence of gastric urease. Following ingestion of carbon-labeled urea (^{13}C or ^{14}C), *H. pylori*-produced urease in the stomach metabolizes the urea into ammonia and carbon dioxide. The carbon isotope is then exhaled as a labeled carbon dioxide and can be directly measured. The sensitivity of the urea breath test is reduced by recent use of antibiotics, bismuth, and acid suppressive drugs, which impair the ability of *H. pylori* to metabolize urea. The sensitivity and specificity of UBT is approximately 90% and 96% respectively.

Serology Whole blood, serum, and finger-prick serology are inexpensive and convenient but do not prove current *H. pylori* infection. Serum immunoglobulin G (IgG) antibodies are almost universally present in patients who have *H. pylori* infection and decline slowly following eradication therapy. However, 15% of patients continue to have a positive antibody result 6 months following a cure, therefore the test should

TABLE II Investigations for *Helicobacter pylori*

Invasive (endoscopy–biospy based)	Noninvasive (endoscopy not required)
Biopsy urease test (e.g., CLO test)	Urea breath test
Histology	Serology
Culture	Urine antibody
	Fecal antigen

not be employed for confirmation of eradication in the short term.

Fecal antigen, urine and saliva antibody Urinary and salivary excretion of *H. pylori* antibody can diagnose exposure to *H. pylori* but may not differentiate between past and current infection. Fecal antigen assays detect antigen and therefore can be used to monitor for eradication of the organism.

MANAGEMENT

The management of duodenal ulcers involves healing of the ulcer, removal of the cause of the ulceration (such as ceasing smoking and NSAID use), and eradication of *H. pylori*. For high-risk patients who are on long-term NSAIDs, maintenance acid suppressive therapy may be indicated.

Acid Suppression

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) directly inhibit the H^+,K^+-ATPase pumps in the parietal cell and are more potent acid inhibitors than are H2 receptor antagonists (see Table III). Ulcer healing by PPIs occurs within 2 weeks in 70–80% of patients compared to 50–60% of those taking H2 receptor antagonists. The profound suppression of gastric acidity raises gastrin levels by two- to fourfold, but neuroendocrine tumors have not occurred in humans.

Histamine-2 Receptor Antagonists

H2 antagonists are particularly useful in the prevention of nocturnal acid production; a single nightly dose has been introduced for patients with nocturnal gastroesophageal reflux disease (GERD) and peptic ulcer healing.

TABLE III Acid Suppressive Therapy

Therapy	Dose (mg)[a]
Histamine-2 receptor antagonist	
Cimetidine	400
Ranitidine	150
Famotidine	20
Nizatidine	150
Proton pump inhibitor	
Omeprazole	20
Lansoprazole	30
Pantoprazole	40
Rabeprazole	20
Esomeprazole	40

[a] For histamine-2 receptor antagonists, the dose is twice/day or, alternatively, a double dose at night; for proton pump inhibitors, the dose is once/day.

TABLE IV High-Risk Ulcer Patients for Ulcer Recurrence and Ulcer Hemorrhage

Patient factors	Medication factors
Previous peptic ulcer or bleeding	High-dose, multiple NSAIDs
Elderly age	Concomitant corticosteroid usage
Comorbidities (e.g., heart or lung disease)	Concomitant anticoagulant usage

Long-Term Maintenance Therapy

Long-term maintenance therapy is advisable for high-risk patients and also for patients who have had ulcer complications while on NSAIDs or aspirin and who must remain on these medications (Table IV). Patients should be treated to eradicate *H. pylori* if it is present. The choice of maintenance therapy includes an H2 receptor antagonist, a PPI, or misoprostol (a prostaglandin E1 analogue). A high-dose H2 receptor antagonist such as famotidine (40 mg, twice daily) significantly reduces duodenal ulceration associated with NSAIDs. A PPI and misoprostol are also highly effective, but diarrhea with misoprostol limits its use, and 30% of patients cannot tolerate the drug at the required dose.

Eradication of *Helicobacter pylori*

Eradication of *H. pylori* substantially reduces the risk of ulcer recurrence and, for most patients, avoids the need for long-term maintenance therapy in preventing ulcer recurrence. The odds ratio of ulcer recurrence following eradication is 0.20 (95% CI, 0.13–0.31). At 6 months, ulcer treatment is successful in 1 out of 2.8 patients. Table V shows the ulcer recurrence rates according to successful or failed *H. pylori* eradication. Because the reinfection rate is low (0.6–2% per year), eradication therapy is both an effective and cost-effective means of treating ulcers.

Treatment

Eradication regimens (Table VI) that achieve a cure of >90% on a "per protocol" basis and >80% on "intention to treat" are recommended. First-line therapy consists of a PPI and two antibiotics—amoxicillin and clarithromycin or metronidazole given twice daily for 7 days. The original bismuth triple therapy, bismuth, metronidazole, and tetracycline (BMT) for 2 weeks, is less well tolerated and less convenient because it

TABLE V Meta-analyses on Duodenal Ulcer Relapse Rates Depending on *Helicobacter pylori* Status after Treatment

	Pooled ulcer recurrence rate	
Study	*H. pylori* eradicated	*H. pylori* not eradicated
Laine *et al.* (1998)	20	56
Hopkins *et al.* (1996)	6	67
Tytgat (1995)	3	58
Penston (1994)	7	67

involves a four-times-daily regimen. The combination of BMT with a PPI (so-called quadruple therapy) is an important option for patients who have had failed first-line therapy.

Confirmation of Eradication

No eradication regimen has a 100% cure rate. Patient compliance may not be satisfactory and antibiotic resistance is a growing concern. Therefore, confirmation of eradication is recommended for all patients who receive treatment, but is mandatory for those who present with ulcer complications. The urea breath test or stool antigen test are the preferred means of posteradication testing and should be preformed at least 4 weeks after treatment. Antisecretory drugs should be ceased at least 1 week prior to testing (Fig. 1).

Vaccination and Hygiene

Vaccination to control spread of *H. pylori* is under research and likely to be available in the future. Transmission of the organism because of poor hygiene and overcrowding is also a problem that needs to be addressed.

TABLE VI *Helicobacter pylori* Eradication Regimen[a]

Regimen[b]	Days of treatment	Eradication success rate (%)
PBMT	7	85

Treating Other Causes of Peptic Ulcers

Aspirin and NSAIDs

Drugs less ulcerogenic than aspirin and NSAIDs should be used if patients develop duodenal ulcers from taking these medications. Clopidogrel, an antiplatelet agent that targets the adenosine diphosphate receptor on platelets, can be substituted for aspirin. This agent is safe, well tolerated, and clinically has a superior efficacy in cardiovascular secondary prophylaxis compared to aspirin, and has lower gastrointestinal toxicity. Higher cost, however, limits its widespread use. A COX-2 inhibitor may be substituted for NSAIDs. COX-2 inhibitors generally have a better gastroduodenal safety profile than non-selective NSAIDs, especially in short-term treatment of less than 6 months. COX-2 inhibitors also do not have the antithromboxane effects of NSAIDs, and do not protect against cardiovascular diseases. The addition of aspirin to COX-2 inhibitors negates the beneficial effects of COX-2 inhibitors in the upper gastrointestinal tract.

Smoking

Smoking increases the risk of peptic ulcers and therefore patients should be advised to stop smoking.

Recurrent Duodenal Ulcers and Idiopathic Ulcers

Despite the successful eradication of *H. pylori*, ulceration may still recur in some people. The causes may include unreported or inadvertent use of NSAIDs or aspirin, failed *H. pylori* eradication, or a reinfection with *H. pylori*. One report from Hong Kong shows that 17% of endoscopically diagnosed duodenal ulcers are not associated with *H. pylori* or NSAIDs, and 64% of these patients have concomitant diseases. The pathogenesis of these ulcers is unknown. Managing these patients includes treating the underlying disease and long-term administration of acid suppressants.

CONCLUSIONS

The incidence of duodenal ulcers is expected to decline as the prevalence of *H. pylori* infection is reduced worldwide and the use of the less toxic COX-2 inhibitors is increased. The growing availability and use of acid suppressant drugs and, in particular, proton pump inhibitors will also reduce the incidence ulcer disease. However, with the aging population and the increasing numbers of patients requiring aspirin for cardiovascular prophylaxis, more elderly patients are at risk of ulcer disease and complications. They may remain

asymptomatic until the development of an ulcer complication. Due to their comorbidities, ulcer morbidity and mortality may remain substantial. There is also a worldwide trend of increasing incidence of non-*H. pylori*, non-NSAID ulcers, the pathogenic mechanism of which remains poorly understood. These ulcers tend to affect patients with concomitant diseases. Further study into this phenomenon is required.

Duodenitis

M. M. WALKER* AND N. J. TALLEY†

Imperial College School of Science, Technology and Medicine, London and †University of Sydney, Nepean Hospital

granuloma Focal nodular accumulation of histiocytes in tissue.

H2 blocker Compound that inhibits gastric acid secretion; also known as histamine-2 receptor antagonist.

Helicobacter pylori Bacterium that infects the stomach, induces gastritis, and increases the risk for peptic ulcers in the duodenum and stomach.

metaplasia Replacement of one type of epithelium with another type normally not present.

proton pump inhibitor Group of compounds of the substituted benzimidazole class; inhibit the H^+,K^+-ATPase of the parietal cell (proton pump), thus inhibiting gastric acid secretion.

Duodenitis is inflammation of the duodenal mucosa and may be defined by either characteristic endoscopy appearances (from erythema to erosions or ulceration) or by histopathology (reflecting a definitive increase in chronic inflammatory cells in the lamina propria with or without a neutrophil infiltrate).

PEPTIC DUODENITIS

Most gastroenterologists view duodenitis as part of the peptic diathesis due to gastric *Helicobacter pylori* infection or, more rarely, nonsteroidal antiinflammatory drugs (NSAIDs). Ischemia may be another etiologic factor. Idiopathic erosive duodenitis has been described. At endoscopy, duodenitis may be manifest as an erythematous or exudative, erosive, hemorrhagic, or nodular appearance, as described in the endoscopic arm of the Sydney classification of gastritis. Other endoscopic classifications include that of Joffe, in which the term "salami duodenum" is embodied, meaning erosions associated with or without petechial hemorrhages. Nodular duodenitis, characterized endoscopically by multiple erythematous nodules in the proximal duodenum, is a distinct entity. Although the association of duodenitis with dyspepsia remains unclear, erosive duodenitis probably causes symptoms. Erosive duodenitis signifies increased duodenal ulcer risk and should be treated as such with confirmation of *H. pylori* status and exclusion of NSAID use. Nonerosive duodenitis may also reflect ulcer risk but the link is controversial. Duodenitis may also be due to infection, particularly in immunosuppressed patients, as well as associated with inflammatory bowel disease (e.g., Crohn's disease), and rarely may be seen in celiac disease.

EPIDEMIOLOGY

In a large series of patients with dyspepsia at endoscopy, 9% had endoscopic duodenitis. By histology, duodenitis has been described in 32% of an asymptomatic population, but less than 10% of these patients had moderate to severe duodenal inflammation.

PATHOLOGY AND BIOPSY OF THE DUODENUM

The correlation between endoscopic duodenitis and histology is relatively good. Mild duodenitis is defined histologically by an increase in cellularity of the lamina propria. This can be difficult to assess because the duodenal mucosa has normally many mononuclear cells present—therefore, a definite increase in lymphocytes should be seen. The normal range of intraepithelial lymphocytes is 10−30/100 epithelial cells. If erosion of the surface epithelium is seen or neutrophils are present in the lamina propria or epithelium, this is regarded as active duodenitis. Gastric metaplasia (due to chronic acid insult) is restricted to the surface epithelium and should be confirmed by a periodic acid Schiff (PAS) stain to show the mucin pattern of the surface epithelial cells. Brunner gland hyperplasia may cause a nodular endoscopic appearance and is believed to be an adaptive response to acid. Hyperplastic polyps occur occasionally. Granulomas and excess macrophages may also be seen. Pathogens such as *Giardia lamblia* should be actively excluded, because these do not always provoke inflammation.

The duodenum should be biopsied by site according to clinical indication. The duodenum is divided into four parts, but the fourth part is rarely reached with the standard forward-viewing endoscope. Peptic

 Copyright 2004, Elsevier (USA). All rights reserved.

duodenitis and gastric metaplasia occur in the first and second parts, partial villous atrophy occurs in the second and third parts, and pathogens may infect any part. Antral mucosa may protrude into the duodenum in tongues, up to 10 mm distal to the pylorus. Duodenitis and gastric metaplasia can be patchy and at least two biopsies are recommended, one from the anterior wall and one from the roof. Partial villous atrophy is also patchy and it is preferable to take two biopsies from each of the second and third parts. Culture of biopsy or duodenal aspirates can aid identification of pathogens.

PATHOGENS

If there is immunosuppression, the common duodenal pathogens are microsporidia, cryptosporidia, mycobacteria, and cytomegalovirus. In mycobacterial infection, endoscopy may show a coarse granular mucosa or characteristic fine white nodules, which are particularly prominent in the duodenum. Infection with the protozoan *G. lamblia* also shows nonspecific endoscopic and pathological changes. Whipple's disease, due to *Tropheryma whippelii*, is a rare multisystem bacterial infection with characteristic duodenal pathology. Schistosomiasis can cause duodenal ulceration.

INFLAMMATORY BOWEL DISEASE

Crohn's disease can be present throughout the duodenum and has a high histological prevalence (up to 12%) in patients with this disease. This condition is strongly associated with active inflammation and, in the absence of *H. pylori* infection, elsewhere this finding should arouse suspicion of Crohn's disease. Ulcerative colitis is only rarely associated with duodenitis, although reports are increasing in frequency, particularly in children.

TREATMENT

Treatment of duodenitis involves establishing the underlying cause and instituting appropriate therapy. In peptic duodenitis, this involves eradication of *H. pylori* or cessation of NSAIDs. If NSAIDs are unavoidable, appropriate antiulcer cotherapy with a proton pump inhibitor (PPI) or H2-blocker (H2B) must be instituted. Idiopathic erosive duodenitis associated with dyspepsia usually responds to acid suppression with a PPI or H2B. Pathogens, once identified by biopsy or culture, can be suitably treated.

Duodenum, Anatomy

ROBERT ANDERS
University of Chicago Hospitals

duodenum The first 25 cm of the small intestine.
mucosa An epithelial-lined surface with supporting tissues that forms the digestive and absorptive surface of the small intestine.

The duodenum forms the first part of the small intestine. Medieval anatomists measured the duodenum at 12 finger lengths and named it for the Latin word for twelve (*duodecim*). Starting at the gastric outlet and ending at the duodejejunal junction, the duodenum is C-shaped and has been arbitrarily divided into the superior, descending, horizontal, and ascending segments. The superior segment travels posteriorly at the level of the first lumbar vertebra. The remaining segments are located in the retroperitoneal space. The descending segment contains the ampulla of Vater, a sphincter-guarded orifice through which the biliary and pancreatic ducts drain. An additional minor duodenal papilla allows for drainage of the accessory pancreatic duct but is variably present. The horizontal segment, at the level of the third lumbar vertebra, crosses the body's midline. The duodenum ends as it emerges from behind the peritoneum where a fibrous band, the suspensory ligament of the duodenum (ligament of Treitz), marks the beginning of the jejunum.

IMPORTANT GROSS ANATOMY RELATIONS

The blood supply to the duodenum is from both the celiac artery via the superior pancreaticoduodenal branches of the common hepatic artery and the gastroduodenal artery and the superior mesenteric artery via the inferior pancreaticoduodenal artery. The gastroduodenal artery is closely applied to the posterior wall of the duodenum and perforation from deep ulceration can lead to life-threatening hemorrhage. The head of the pancreas is tucked in the curve of the C-shaped duodenum. Space-occupying lesions of the pancreas can deform the duodenum or affect the function of the major duodenal papilla. Since the duodenum is the only small intestinal segment located in the retroperitoneum, the duodenum is firmly attached to the body wall in the duodenal fossa. This feature allows for identification of the freely mobile jejunum during endoscopic procedures.

MICROSCOPIC ANATOMY

The wall of the duodenum is composed of several distinct layers. The innermost three layers constitute the mucosa. First, there is a layer of stratified ciliated columnar epithelial cells facing the lumen; second, there is the lamina propria, which contains mucus-secreting Brunner's glands, connective tissue, lymphoid tissue, vascular tissue, and neural tissue; and third, there is a layer of smooth muscle called the muscularis mucosa. The submucosa is an interface between the mucosa and the muscularis propria layers. The submucosa is of variable thickness and forms a distribution network of vascular and lymphatic channels as well as nerve fibers and ganglion cells forming the Meissner's plexus. The next layer is the muscularis propria, which is composed of an inner circular smooth muscle layer and an outer longitudinal smooth muscle layer, separated by the neural plexus of Auerbach. The outermost layer is the serosa, which contains connective, adipose, and vascular tissue with a single mesothelial covering.

IMPORTANT MICROSCOPIC CONSIDERATIONS

The epithelial cell functions to control the digestion and absorption of intestinal nutrients. The functional surface area of the duodenum (and the rest of the small intestine) is critical to intestinal function. The mucosal surface area is increased by dense circumferential mucosal folds referred to as plicae circularis. A further expansion of the surface is seen in the formation of villous projections and crypts or invaginations between villi. The brush border is a special ciliated epithelial interface with microvilli present at the apex of the columnar epithelial cells that project into the gastrointestinal lumen. Goblet, endocrine, and paneth cells are specialized neighboring epithelial cells that are also found in the surface epithelium. Nonepithelial cells, such as lymphocytes, eosinophils, mast cells, and macrophages, are scattered throughout the lamina propria and are also present in follicular aggregates. These cells play a role in the immune-mediated defense of the intestine.

achalasia An esophageal motor disorder characterized by failure of the lower esophageal sphincter to relax and loss of esophageal peristalsis.

fundoplication Surgical procedure for the treatment of gastroesophageal reflux disease that involves strengthening the lower esophageal sphincter by wrapping the fundus around it.

Zenker's diverticulum A pharyngeal out-pouching above the upper esophageal sphincter as the result of weakness in the posterior pharyngeal wall.

Dysphagia, from the Greek meaning "difficulty swallowing," is a symptom describing the sensation of food being held up from passage into the digestive tract after it is swallowed. Although any number of abnormalities involving the swallowing mechanism can result in dysphagia, it is most commonly associated with esophageal disorders. An accurate incidence of dysphagia is difficult to determine; however, population-based estimates have suggested a prevalence of 7% in the general population and up to 50% of elderly institutionalized patients.

PATHOPHYSIOLOGY

Swallowing involves a complex network of coordinated neuromuscular activities that serve to transport food and fluid from the oral cavity to the stomach, while at the same time protecting the airway. A defect in any part of the swallowing mechanism can lead to symptoms of dysphagia. A volitional component of the deglutitive process transfers the bolus to the pharynx and an automatic component transports this bolus into the esophagus and stomach. The deglutitive process has been broken down into various phases: the preparatory oral phase, pharyngeal phase, and esophageal phase. The oral phase involves the preparation of the food into a bolus that can be transported into the esophagus and involves the oral musculature as well as the salivary glands for digestion and lubrication. Once the bolus is ready, it is transferred by the tongue to the posterior pharynx. A series of reflexive responses then occurs, resulting in a conformational change of the pharynx from a respiratory to a digestive pathway. The proximal esophagus transports the bolus down to the stomach in an orderly fashion by peristalsis aided by gravity. The duration of the oropharyngeal phase is usually a couple of seconds and the esophageal phase is less than 10 s. Dysphagia results when there is a failure of the oropharyngeal or esophageal neuromusculature to propel a food bolus into the stomach in a normal pattern or when there is an obstruction to normal passage due to narrowing of the esophagus.

CLASSIFICATION

Dysphagia has traditionally been categorized into two groups on the basis of the location of the problem,

either oropharyngeal or esophageal. Oropharyngeal dysphagia, as the name suggests, results from disorders of the oropharyngeal phase of swallowing and is commonly associated with neuromuscular disorders. A list of the common causes of oropharyngeal dysphagia is presented in Table I. Esophageal dysphagia is typically a result of mechanical obstruction or motor dysfunction of the esophagus, although both causes are not mutually exclusive. The degree of esophageal narrowing required before symptoms develop is variable but most patients will not experience dysphagia at an esophageal diameter above 20 mm. A list of the causes of esophageal dysphagia is given in Table II. Globus sensation is a common complaint, though not true dysphagia. Although the patient describes a sensation of a lump in the throat or neck, there is no clear structural or mechanical etiology, and it is usually unrelated to swallowing. In fact, globus is often most noticeable when the patient is not eating and may in fact improve when they eat.

TABLE II Causes of Esophageal Dysphagia

Mechanical (narrowing of the esophageal lumen)
Intrinsic mucosal stricture
Peptic (gastroesophageal reflux-related)
Caustic injury
Pill injury
Esophageal ring
Esophageal web
Malignancy
Extrinsic compression

Vascular compression—Aortic arch or aberrant other vascular structures such as right brachial cephalic artery (dysphagia lusoria)
Motor (abnormality in esophageal smooth muscle function)
Achalasia
Esophageal spasm
Hypertensive LES
Scleroderma

EVALUATION

History and Physical Examination

An accurate history is vital in the diagnosis of the etiology of dysphagia and can facilitate further work-up. Asking the patient to describe what happens when they eat or asking them to describe a swallow can be very helpful in distinguishing oropharyngeal from esophageal dysphagia. Certain historical features that suggest an oropharyngeal cause of dysphagia include poor bolus transfer, cough during swallow, and nasal regurgitation. On the other hand, patients with esophageal dysphagia typically describe food "sticking" or getting "hung up" in the chest when they swallow. Unfortunately, the patient's localization of where the food sticks does not help differentiate between a proximal or a distal esophageal problem, although if the patient describes a more distal esophageal location, there is a greater correlation. Clinical points to elucidate from the history are whether the dysphagia is related to solids or liquids or both. Dysphagia to solids occurs prior to liquids in most causes of mechanical esophageal obstruction. On the other hand, motor disorders typically affect both liquids and solids. Progressive dysphagia is more suggestive of a progressive narrowing of the esophagus, often related to malignancy (rapid progression) or gastroesophageal reflux disease (slow progression), whereas intermittent dysphagia is most often related to esophageal rings. Odynophagia refers to pain with swallowing, typically in the chest, and is most commonly associated with pill-induced esophagitis. In immunosuppressed patients, it is typically seen with infectious esophagitis.

In addition to a description of the nature of the dysphagia itself, a thorough history will assist in determining the etiology of the dysphagia. Gastroesophageal reflux may lead to dysphagia by two mechanisms. First, chronic reflux can lead to esophageal strictures that can cause dysphagia. Second, peptic esophagitis can result in esophageal dysmotility that may lead to dysphagia. Conditions such as scleroderma are associated with esophageal motor disorders that can cause dysphagia.

Physical examination in most patients with dysphagia is normal. Occasionally, watching the patient swallow will demonstrate a neuromuscular abnormality. Listening to the side of the neck during swallow may reveal a "sloshing," which is related to the presence

of food or fluid in a Zenker's diverticulum. A brief neurologic examination may reveal an underlying neurologic cause of dysphagia.

Laboratory and Radiologic Evaluation

Laboratory studies are normal in most patients with dysphagia. Anemia may be seen from bleeding as a result of a number of esophageal mucosal abnormalities. Iron deficiency anemia of any cause may result in dysphagia as a result of a web in the proximal esophagus, a condition referred to as Plummer-Vinson syndrome. Thyroid testing is routinely performed, since subtle abnormalities in thyroid functions may result in muscular weakness leading to dysphagia.

Barium fluoroscopic studies play an important role in the evaluation of patients with dysphagia. Symptoms suggestive of an oropharyngeal cause of dysphagia are best evaluated by an oropharyngoesophagram. This test involves the administration of oral contrast medium while cineradiography of the oropharyngeal and esophageal portions of the swallow mechanism is performed, often in conjunction with a speech pathologist.

The barium esophagram has traditionally been performed to evaluate any esophageal motor or mechanical abnormality. If the patient complains of dysphagia to solids, a challenge with a barium-coated solid, such as a marshmallow, will help determine the site of obstruction if the patient's symptoms are reproduced. Generally, subtle mechanical obstruction and most motor disorders are better detected with a barium esophagram than endoscopy. Certain motor disorders, such as achalasia and scleroderma, have classic radiographic patterns that can be diagnostic.

Endoscopy and Esophageal Manometry

Endoscopy in patients with dysphagia is helpful in two respects: it allows direct visualization of the esophageal mucosa and the opportunity to perform esophageal dilation, with either balloons or bougies to help relieve symptoms of dysphagia. In patients with symptoms suggestive of a motor cause of their dysphagia, esophageal manometry can help determine the nature of the disorder. Manometry involves placement of a fine flexible tube through the nose into the esophagus to measure contractile pressures of the esophageal body and lower esophageal sphincter. Disorders such as achalasia and esophageal spasm can be detected with this technique. Manometry of the upper esophageal sphincter can also be performed; however, this is largely a clinical research tool at this time.

MANAGEMENT

Although diagnosing the cause for dysphagia is not typically difficult, treating it can be challenging. Particularly frustrating is oropharyngeal dysphagia, which can be very debilitating with an increased risk for aspiration and sometimes necessitating a feeding tube. Cerebrovascular accidents are the most common cause of oropharyngeal dysphagia and fortunately many patients recover their swallowing function with time. Certain oropharyngeal exercises can strengthen weak muscles and improve symptoms of dysphagia.

Esophageal dysphagia treatment is tailored to its cause. Gastroesophageal reflux-related dysphagia can be treated with dilation followed by acid suppressive medication or surgical fundoplication. Benign structural disorders, such as rings, webs, and strictures, are typically treated with endoscopic dilation with balloon or bougienage, although many patients require repeated dilations over time. Occasionally, patients are able to self-dilate their esophagus with bougies that they pass themselves as needed. Medical therapy for motor disorders is typically limited to smooth-muscle-relaxing agents, such as nitrates and calcium channel blockers. Although they can be effective, the durability of the effect is often short. A recent development has been the use of botulinum toxin in patients with achalasia. Injection of this agent at the time of endoscopy is helpful in the treatment of this disorder; however, the duration of benefit is limited. Finally, surgical resection of the esophagus is therapy for malignancy, if cure is considered to be possible by performing this procedure. Endoscopically placed esophageal stents have been used for palliation of dysphagia secondary to malignancy; however, newer types of stents are being developed for use in benign conditions.

SUMMARY

Dysphagia is a symptom associated with a myriad of disorders involving the esophagus and oropharynx. A detailed history can often determine the etiology of the symptom, which can be further evaluated with barium radiography and endoscopy. Although therapies for oropharyngeal dysphagia are limited, esophageal dysphagia can be treated effectively, largely by endoscopic means. In the future, newer methods of treatment will help patients with this symptom resume as normal deglutition as possible.

arthrochalasia Joint instability or tendency to dislocate.
collagen Strong, elastic, fibrous protein; the foundation of all connective tissues in the body.
dermatosparaxis Skin fragility.
kyphoscoliosis Backward and lateral curvature of the spine.

Ehlers–Danlos syndrome refers to a heterogeneous group of heritable collagen disorders characterized by joint hypermobility and increase in skin elasticity and tissue fragility. Originally described in 1892, the disorder was expanded to include 10 subtypes, but these groupings were simplified in 1997 to include six types. The most current classification scheme recognizes these six types.

ETIOLOGY AND PATHOGENESIS

A variety of mutations have been described in Ehlers–Danlos syndrome (EDS) (see Table I), and most involve defects in posttranslational modification of collagen. Mutations in the type V collagen genes account for up to 50% of cases of classic EDS. The most well-characterized genetic defect is found in the vascular type of EDS, which results from mutations in the gene for type III procollagen (*COL3A1*). The collagen is thus structurally abnormal and affords diminished support of cutaneous, skeletal, vascular, and other structures.

TABLE I Classification Scheme for Ehlers–Danlos Syndrome

Type	Description
Classic (former EDS I and II)	Autosomal dominant, accounts for 80% of all cases and characterized mainly by skin and joint involvement
Hypermobile (former EDS III)	Autosomal dominant, with predominantly joint involvement
Vascular (former EDS IV)	Variable inheritance, with common vascular and bowel complications
Arthrochalasia and dermatosparaxis (former EDS VIIA, B, and C)	Autosomal dominant (arthrochalasia) and autosomal recessive (dermatosparaxis), with short stature and round faces
Kyphoscoliosis or Ocular-Scoliotic (former EDS VI)	Autosomal recessive with kyphoscoliosis, marfanoid habitus, and ocular involvement
Other	Poorly differentiated EDS types; includes X-linked EDS

CLINICAL FEATURES

Cutaneous

In EDS, there is an increase in skin laxity and fragility. Traction on the ears or elbows will reveal this increase in elasticity. The skin may have a velvety feel. Bruising and varicose veins are common.

Musculoskeletal

Joint hypermobility with characteristic hyperextensibilty of the joints is a classic finding in EDS. Joint dislocation and kyphoscoliosis are particularly prominent in some subtypes of EDS. Facial dysmorphism and variations in stature are common in certain subtypes of EDS.

Gastrointestinal

Breakdown of gums and loss of teeth is common in EDS. Hiatal hernias are a common structural defect. Complications of peptic ulcer disease are more frequent, including perforation and bleeding. Erosion of duodenal ulcers posteriorly into the aorta can be catastrophic. Perforation of the small and especially the large intestine are among the most commonly reported gastrointestinal complications of EDS, especially in patients with the vascular type of EDS, because type III collagen is the major supportive constituent of the bowel wall.

DIAGNOSIS

The diagnosis of EDS is based on clinical history, family history, physical examination, and analysis of genetic defects (when available).

THERAPY AND PROGNOSIS

Therapy is largely supportive and involves joint protection, avoidance of trauma, and care in treating wounds. Pregnancy is contraindicated in the vascular type of EDS because of the risk of uterine rupture.

noninvasive techniques of electrogastrography are used to record electrogastrograms (EGGs). The frequencies in the EGG signal reflect the pacesetter potential activity of the stomach, the electrical events that control the frequency and propagation of gastric peristaltic contractions. The normal human gastric pacesetter potential activity and the normal EGG signal are approximately 3 cycles per minute (cpm). Gastric dysrhythmias are abnormal gastric myoelectrical activities termed tachygastria, bradygastria, and mixed dysrhythmias. Gastric dysrhythmias are found in a variety of conditions in which nausea and upper gastrointestinal symptoms are prominent. Gastric dysrhythmias are commonly present in patients with gastroparesis, a severe neuromuscular abnormality of the stomach. In patients with unexplained nausea and dyspepsia symptoms, EGG tests diagnose eugastria or gastric dysrhythmias and appropriate treatment can be planned. Electrogastrographic techniques are also used in clinical research studies where the effects of various therapies on symptoms and gastric electrical rhythms are assessed.

MYOELECTRICAL ACTIVITY OF THE STOMACH

Pacesetter Potentials

The stomach is a complex neuromuscular organ (Fig. 1). Contractions and relaxations of the gastric fundus, corpus, and antrum are neuromuscular events under myoelectrical, neurological, and hormonal control. Gastric peristaltic contractions are controlled by the pacesetter potential activity of the stomach. Gastric pacesetter potentials are also termed gastric slow waves. Gastric pacesetter potentials originate in a pacemaker region on the greater curvature of the stomach, between the fundus and the corpus (Fig. 1). These electrical depolarization and repolarization waves travel circumferentially and migrate distally at a rate of approximately 3 cpm in humans (Fig. 2). The gastric pacesetter potentials control the frequency and propagation of velocity of gastric peristaltic contractions. The fundus of the stomach does not have intrinsic pacesetter potential activity.

Rhythmicity of the gastric pacesetter potential activity originates in the interstitial cells of Cajal. These cells form networks within and between the muscular layers of the stomach wall. The interstitial cells of Cajal that lie near the circular muscle layer of the stomach wall control the frequency of depolarization of the circular muscle (Fig. 1). The interstitial cells of Cajal are also in close proximity to the enteric neurons of the intrinsic nervous

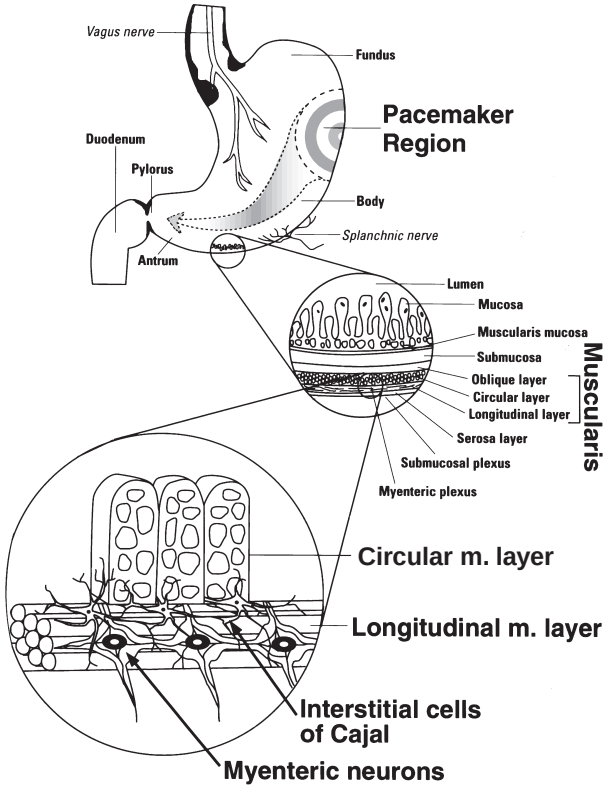

FIGURE 1 Diagram of major anatomical regions of the stomach (top), muscle layers of the gastric wall (middle circle), and detail of the relationships among longitudinal muscle, circular muscle, interstitial cells of Cajal, and myenteric neurons (bottom circle). See text for details.

system of the gut. Enteric nervous system and parasympathetic nervous system inputs to the stomach are transmitted to the pacemaker cells and thus to the circular muscle cells through these relationships.

Action Potentials and Plateau Potentials

Circular muscle contractions of the stomach wall occur during action potential or plateau potential activity. Action potential activity and plateau potential activities are linked to the pacesetter potentials that bring the circular smooth muscle membrane to the threshold of depolarization and contraction. Thus, a normal gastric peristaltic wave is composed of electrical components—the pacesetter potential linked with the action potential or plateau potential activity (Fig. 3). Consequently, increased electrical activity occurs at the pacesetter potential frequency of 3 cpm during recurrent peristaltic contractions.

These gastric neuromuscular events generate changes in electrical activity that are recorded from

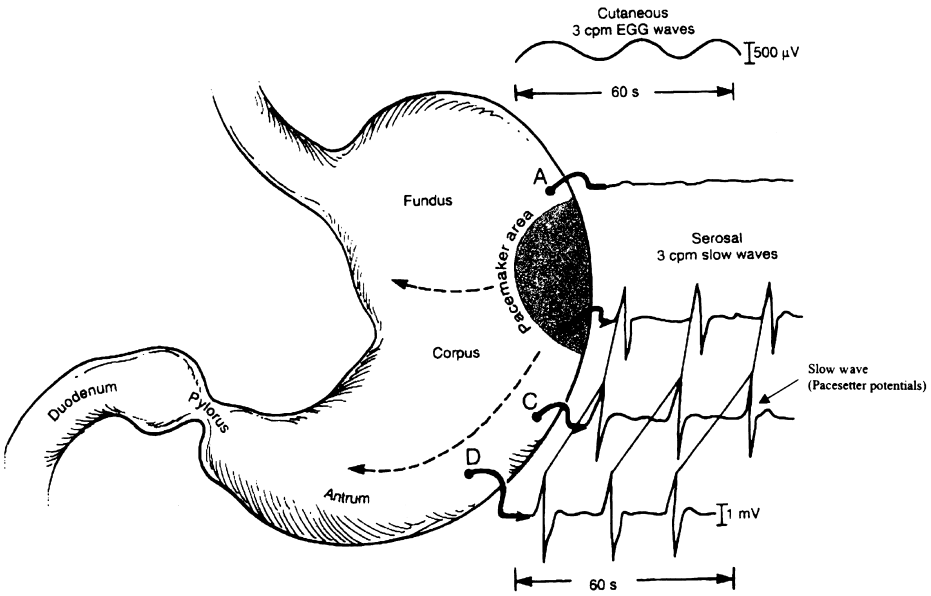

FIGURE 2 Gastric slow waves (pacesetter potentials) migrate circumferentially around the stomach and distally toward the pylorus at a rate of 3 cpm as recorded by the serosal electrodes (A–D). The fundus is electrically silent. The 3 cpm EGG waves recorded from electrodes placed on the surface of the epigastrium summate electrical events and yield a 3 cpm wave pattern.

electrocardiogram (EKG)-type electrodes placed on the epigastrium. These signals are termed electrogastrograms. During the fasted state, the electrical activity from the stomach reflects predominantly the gastric pacesetter potential activity. The EGG activity during fasting may be relatively unstable. In contrast, after a homogenous meal, such as water, barium, or yogurt, rhythmic gastric peristaltic contractions are evoked and the accompanying gastric electrical and EGG activity has greater amplitude and regularity than in the fasting condition.

RECORDING AND ANALYSIS OF ELECTROGASTROGRAMS

Recording EGGs

Electrogastrograms are recorded by placing EKG-type electrodes on the surface of the epigastrium as shown in Fig. 4. The first EGG was recorded in 1922 by Alvarez, who reported rhythmic 3 cpm electrical activity in a thin woman. The amplitude of the EGG signal ranges from 100 to 500 μV and the signal must be properly amplified and filtered. To reduce baseline drift and to filter out cardiac and respiratory signals, a 0.016 Hz high-pass filter and a 0.25 Hz low-pass filter are used. These filters create a window from approximately 1 to 15 cpm through which myoelectrical signals pass during the EGG recording. The normal EGG rhythm is approximately 3 cpm (2.5–3.7 cpm), whereas bradygastrias are signals from approximately 1.0 to 2.5 cpm and tachygastrias are from 3.7 to 10.0 cpm. The duodenal pacesetter potential frequency is approximately 12–14 cpm. Occasionally, the respiration rate is less than 15 breaths per minute and this respiratory frequency may be recorded in the EGG signal.

The EGG signal is digitized for computer analysis by using analog to digital technology. Digitization rates range from 1 to 4.267 Hz. The digital files are subjected to fast Fourier transform to extract the frequency information present in the EGG signal. Displayed over time the frequencies are often presented as running spectral analysis. Computer analysis allows for quantitative expression of the EGG signal as described below.

To avoid movement artifact, EGGs must be recorded in quiet rooms with the subject seated in a comfortable chair. A baseline EGG is recorded and is followed by a provocative test to assess the gastric myoelectrical activity responses and sensations or symptoms. Provocative tests using water loading stimulate the relaxation capacity (stretch) of the stomach, as well as the gastric myoelectrical response, without the confounding effects of a caloric meal. Caloric meals are also used to assess the effect of specific foods on EGG activity. Respiration rate must be recorded on a separate channel.

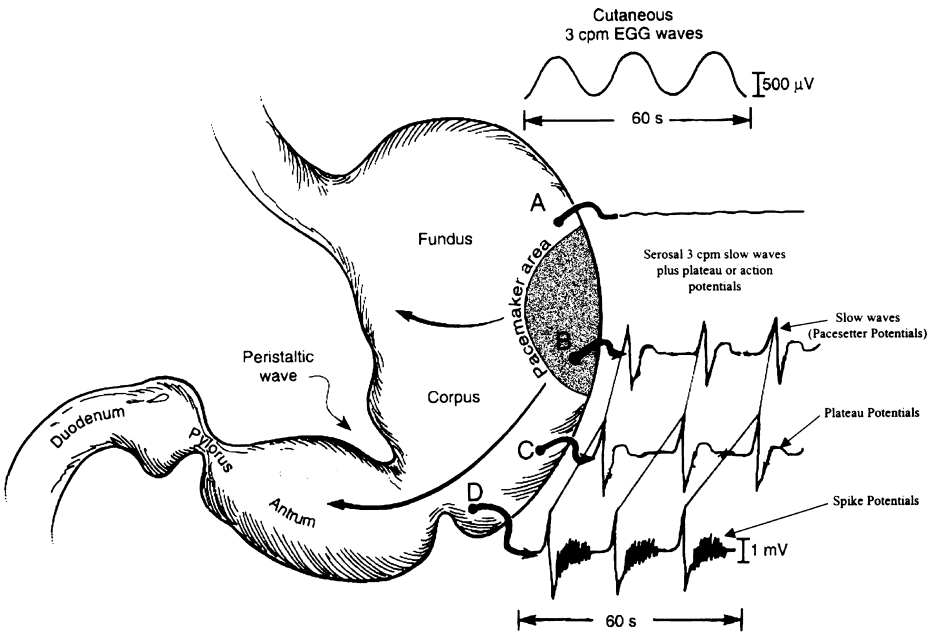

FIGURE 3 Gastric peristaltic waves during circular muscle contraction occur when plateau potentials or spike potentials occur and are linked with the propagating slow waves. Generally, there is an increased amplitude of the EGG wave during these electrical events associated with gastric peristaltic contractions.

Analysis of the EGG Signal

Visual Analysis

Proper analysis of the EGG requires visual inspection of the EGG signal. The EGG signal is reviewed for the presence of normal 3 cpm activity, tachygastrias, or bradygastrias (Fig. 5). It is extremely important to identify artifacts in the EGG signal, which may be created by movement of the limbs, deep breathing, coughing, or talking. An overall EGG diagnosis of normal versus abnormal EGG is made on the basis of the EGG rhythm strip.

Computer Analysis

Frequencies in EGG signal Computer analysis of the EGG signal emphasizes the frequency components. The frequency component is the most reliable and stable of the EGG parameters that can be quantified. The human gastric pacesetter potential activity is approximately 3 cpm and 2 standard deviations around the mean is the normal EGG frequency range of 2.5–3.7 cpm. Normative ranges for EGG activity have been defined in response to the water load test or test meals. The EGG response is reproducible in response to the water load test.

Percentage distribution of EGG power A certain percentage of the overall EGG activity occurs in four relevant frequency ranges: the normal range and the bradygastria, tachygastria, and duodenal frequency ranges. Thus, a useful method of expressing the EGG activity is to determine the percentage distribution of the total EGG power in these ranges. Power is the log of the microvolts squared (log μV^2) of the frequencies present in the EGG signal. Normal values in control subjects and patients with upper gastrointestinal symptoms have been reported.

Power ratio The postprandial to preprandial ratio of 3 cpm EGG power is generally >1 and indicates a normal increase in the 3 cpm activity after ingestion of a test meal. This parameter is also used to assess normal and abnormal neuromuscular activity of the stomach in response to test meals.

NORMAL ELECTROGASTROGRAM PATTERNS

Fasting

The neuromuscular activity of the stomach during the fasting state is unstable compared with that in the postprandial state. Contractile patterns in the stomach during fasting range from quiescence (phase I) to intermittent contractions (phase II) to sustained regular antral contractions (phase III). Thus, the electrical

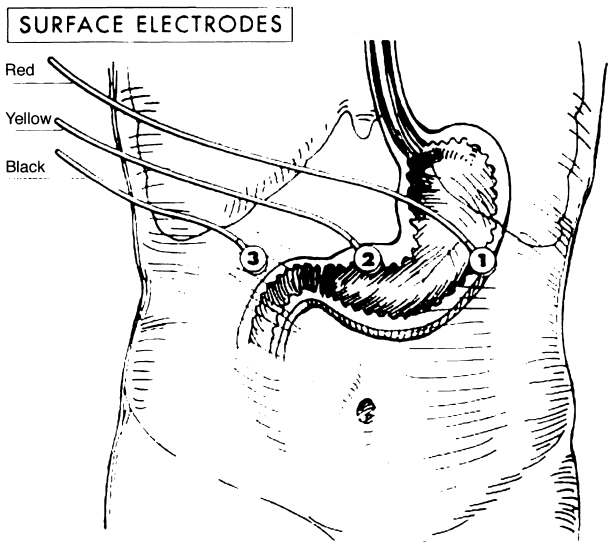

FIGURE 4 Position of electrodes on the surface of the epigastrium for recording electrogastrograms.

activity during fasting is also unstable in that the 3 cpm electrical activity is inconsistent. Phase III contractile activity also is reflected in increased 3 cpm EGG activity 50% of the time.

Postprandial EGG Patterns

Barium Meals and Water Load Test

The fasting EGG pattern, which may be unstable, is normally converted to regular 3 cpm activity when the stomach is loaded with a variety of nutrient or nonnutrient test meals. Figure 6 shows the effect of a barium meal on EGG activity. The barium meal stimulates regular 3 cpm EGG waves that correspond to the peristaltic gastric waves. Loading the stomach with water also stimulates regular 3 cpm waves after an initial period of suppression of 3 cpm waves (Fig. 7). This example also shows the EGG frequency response as a running spectral plot. (See legend to Fig. 7 for details.)

Yogurt and Caloric Meals

A variety of test meals ranging from yogurt to soup to milk to scrambled eggs also stimulate increased 3 cpm EGG activity and an increased power ratio in the normal frequency range. The exact pattern of onset of 3 cpm activity and other frequencies depends upon the caloric content of the meals and the proportions of fat and carbohydrate.

ABNORMAL ELECTROGASTROGRAM PATTERNS

Gastric Dysrhythmias

Tachygastrias

Tachygastrias are abnormally rapid gastric electrical events from 3.7 to 10.0 cpm. High-amplitude tachygastrias occur during the acute onset of motion sickness. Tachygastrias are frequently low-amplitude EGG signals recorded from patients with chronic nausea conditions such as morning sickness, functional dyspepsia, unexplained nausea, or idiopathic gastroparesis. The tachygastria frequency is often very unstable and may range from 4 to 7 to 9 cpm within a 30 min recording period. Other tachygastria patterns are fixed at a single frequency (e.g., 6 cpm) (Fig. 5). Tachygastrias have been recorded from the antrum with serosal electrodes. The presence of tachygastrias is associated with decreased rates of gastric emptying. The cause of tachygastrias is unknown but they have been induced by vagotomy, epinephrine, glucagon, and hyperglycemia.

Bradygastrias

Bradygastrias are abnormally slow EGG frequencies from approximately 1 to 2.5 cpm. Bradygastrias

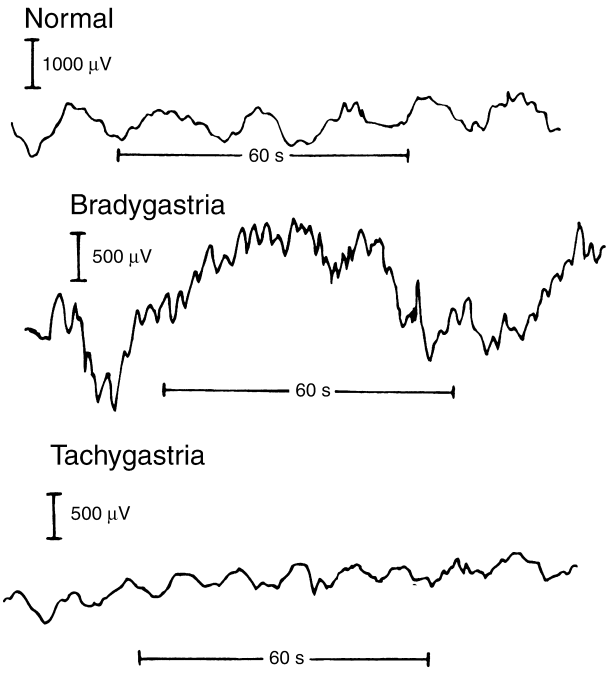

FIGURE 5 Normal 3 cpm EGG recording showing 3 cpm waves; bradygastria example shown as a 1 cpm EGG wave with superimposed respiratory rhythm and tachygastria example shown as 6 cpm regular, low-amplitude waves.

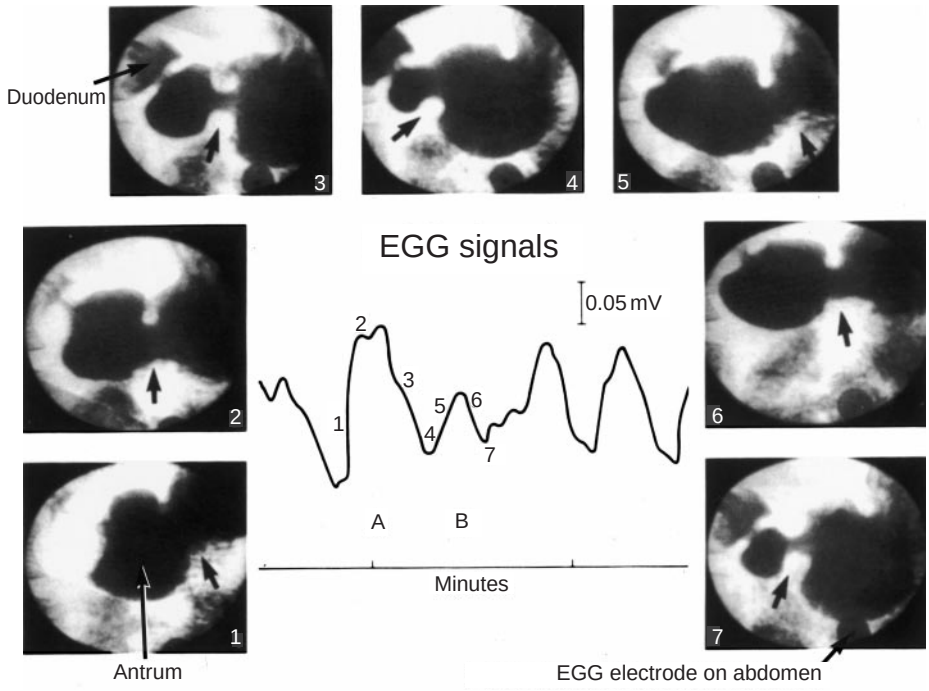

FIGURE 6 EGG waves (A and B) recorded during fluoroscopy of the barium-filled stomach. EGG wave A is numbered 1, 2, 3, and 4 to illustrate the relationship between this EGG wave and the gastric peristaltic wave shown in radiographic panels 1, 2, 3, and 4. In the radiographic panels, the arrow indicates a circular contraction that is migrating from the corpus (1) to the mid-antrum (2, 3) and finally to the distal antrum (4). EGG wave B is numbered 5, 6, and 7 and is similarly associated with the next gastric peristaltic wave shown in radiographic panels 5, 6, and 7. Reprinted from Koch *et al.* (1987), Effect of barium meals on gastric electromechanical activity in man. *Digest. Dis. Sci.* **32**, 1217–1222, with permission from Kluwer Academic.

are high-amplitude 1 to 2 cpm EGG waves or low-amplitude waves (Fig. 5). The bradygastrias have been recorded from the gastric corpus with several electrodes. Bradygastrias are present in a variety of patients with unexplained nausea, dyspepsia symptoms, and gastroparesis.

Mixed Dysrhythmia

EGG recordings that do not clearly fit into a tachygastria or bradygastria pattern are termed mixed (nonspecific) dysrhythmias. These patients have combinations of tachygastria and bradygastria, abnormal patterns that are brought out by provocative testing with the water load test or test meals.

Decreased Power Ratio

The power ratio is a calculation of the EGG power in the postprandial period compared with the preprandial EGG power. An abnormal power ratio is 1 or less and indicates failure of the expected increase in 3 cpm electrical activity after the provocative test. An abnormal power ratio of the signal at 3 cpm is associated with delayed gastric emptying.

GASTRIC DYSRHYTHMIAS AND CLINICAL DISORDERS

The measurement of EGG patterns in response to provocative testing is a clinical test to evaluate gastric myoelectrical activity in patients with suspected gastric motility disorders. The EGG pattern complements the solid-phase gastric emptying test, which tests the efficiency of the global muscular work of the stomach. The EGG reveals the mechanisms that underlie gastroparesis. Thus, the combination of EGG and gastric emptying studies reveals pathophysiological conditions of the stomach that may cause the patient's symptoms. In the sections below, the EGG patterns found in a variety of clinical conditions are reviewed.

Nausea of Pregnancy

Gastric dysrhythmias ranging from tachygastria to bradygastrias have been recorded in women with nausea

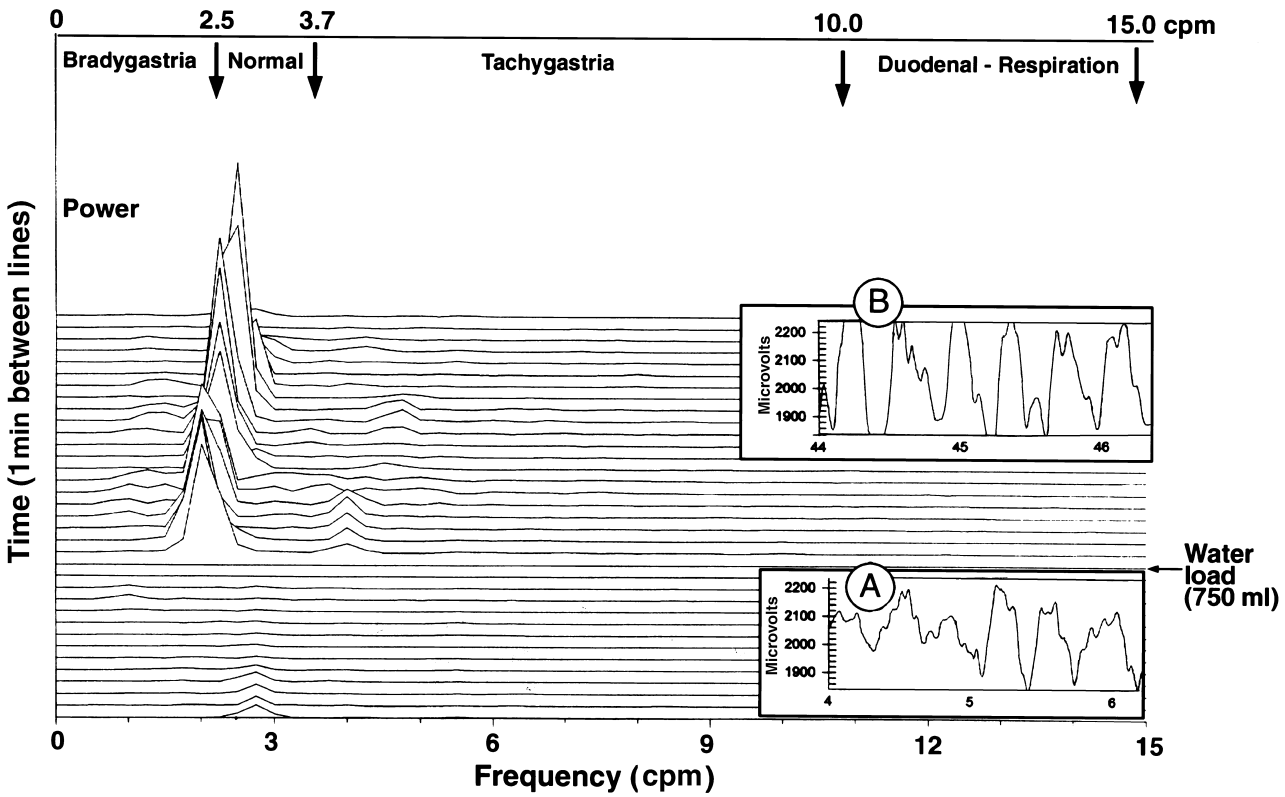

FIGURE 7 Running spectral analysis of the frequencies in the EGG signal recorded before and after a water load test in a healthy subject. The insets show the EGG signal. At baseline (A), some 3 cpm rhythm is seen in the EGG. After the water load was ingested, there is higher amplitude and more regular 3 cpm activity (B). The running spectral analysis is the frequency analysis of the EGG. The *X* axis displays the frequencies in the EGG in cycles per minute. The *Y* axis indicates time, with each line representing 4 min of EGG signal with 75% overlap. The *Z* axis represents the power (log of the μV^2) of any frequencies contained in the EGG signal from 0 to 15 cpm. The four relevant frequencies are indicated at the top of the graph. In this healthy subject, there are several low-power peaks near 3 cpm at baseline. After ingestion of water, there is a frequency shift to approximately 2 cpm after ingestion of 750 cc of water. Thereafter, there is a progressive increase in power in the peaks as they enter the normal range of 2.5 to 3.7 cpm.

of pregnancy. Pregnant women with no nausea had normal 3 cpm EGG patterns. Thus, the presence or absence of gastric dysrhythmias is associated with the presence or absence of nausea. Administration of estrogen and progesterone also produces gastric dysrhythmias.

Dysmotility-like Functional Dyspepsia

Gastric dysrhythmias have been recorded in approximately 60% of patients with dysmotility-like functional dyspepsia (unexplained nausea and vomiting, upper abdominal discomfort, early satiety, bloating, and fullness). Endoscopic examinations in these patients reveals no mucosal abnormalities and ultrasound or computerized tomography scans of the abdomen reveal no structural abnormalities to account for symptoms. Thus, gastric dysrhythmias are a pathophysiological mechanism for these symptoms. Correction of gastric dysrhythmias (which range from bradygastria to tachygastria) is associated with improved upper gastrointestinal (GI) symptoms. A minority of patients with gastric dysrhythmias have frank gastroparesis. These patients have a severe electrical and contractile abnormality of the stomach.

Gastroparesis

Gastroparesis indicates severely impaired emptying of meals from the stomach. The gastric emptying test does not reveal the cause of the gastroparesis. The EGG test diagnoses the presence of gastric dysrhythmias or normal myoelectrical signals in these patients.

Diabetic Gastroparesis

Patients with diabetic gastroparesis have a high incidence of gastric dysrhythmias. Patients with

predominantly bloating and distension symptoms in the upper abdomen after eating may also have delayed emptying, but normal 3 cpm electrical activity. Hyperglycemia also induces tachygastrias and bradygastrias.

Ischemic Gastroparesis

Patients with gastroparesis and those with histories of peripheral vascular disease, smoking, and weight loss may have ischemic gastroparesis. Abdominal bruits are present in approximately 50% of these patients. The median accurate ligament may obstruct the celiac artery and produce ischemic gastroparesis. Bypass of the obstructions in the mesenteric arteries results in resolution of the gastric dysrhythmias, gastroparesis, and other symptoms.

Obstructive Gastroparesis

Patients with gastric outlet obstruction due to pyloric stenosis or postbulbar obstructions have high-amplitude, consistently normal 3 cpm EGG activity despite the presence of gastroparesis. This discordance between normal EGG rhythm and delayed emptying suggests that mechanical or functional obstruction may account for the gastroparesis.

Idiopathic Gastroparesis

In patients with idiopathic gastroparesis, gastric dysrhythmias are commonly present. The dysrhythmias range from bradygastria to tachygastria. The origins of idiopathic gastroparesis are unknown but range from degenerative disorders of the enteric nervous system, damage to the interstitial cells of Cajal, and myopathies of various severity. Damage to the neuromuscular apparatus of the stomach may be a sequelae to a previous viral infection.

Drug-Induced Gastric Dysrhythmias

Gastric dysrhythmias and nausea are induced by hormones such as glucagon, epinephrine, estrogen, and progesterone. The narcotic drug morphine induces a variety of gastric dysrhythmias ranging from bradygastrias to tachygastrias. Nicotine induces gastric dysrhythmias and nausea.

Motion Sickness

Nausea is one of the most noxious symptoms of motion sickness. Nausea reported during vection-induced motion sickness is accompanied by tachygastrias and increased plasma vasopressin and epinephrine levels. Gastric dysrhythmias and motion sickness symptoms are reduced by carbohydrate meals, acustimulation, ginger, and a variety of other treatments.

CLINICAL APPLICATIONS OF ELECTROGASTROGRAPHY

EGG tests are obtained in patients who have persistent upper GI symptoms despite normal upper GI barium studies, endoscopy, and ultrasound examinations. In these patients, the presence of a gastric dysrhythmia provides a diagnosis of gastric neuromuscular dysfunction, whereas a normal EGG test is associated with normal gastric emptying and suggests the possibility of other pathophysiological mechanisms causing the symptoms.

The noninvasive diagnosis of gastric dysrhythmias with the EGG test has analogies to the noninvasive diagnosis of cardiac dysrhythmias with the EKG test. The EGG test provides a diagnosis of gastric dysrhythmia or eugastria in response to a provocative test and is an objective finding of neuromuscular abnormality of the stomach for patients with unexplained nausea and functional dyspepsia symptoms. The gastric dysrhythmias may reflect relatively mild gastric neuromuscular disorders that underlie symptoms. On the other hand, the gastric dysrhythmia may be associated with significant contractile abnormality of the stomach and frank gastroparesis. A normal or eugastric EGG pattern suggests that other pathophysiological mechanisms may account for the upper GI symptoms (e.g., gallbladder disease). Gastric visceral hypersensitivity, gastric electro-contractile abnormalities, or obstruction must also be considered.

RESEARCH APPLICATIONS OF ELECTROGASTROGRAPHY

Electrogastrography methods are used to identify patient populations with upper GI symptoms, such as nausea and gastric dysrhythmias (versus symptoms and normal EGGs). A variety of drugs, such as domperidone, metoclopramide, and cisapride, eradicate gastric dysrhythmias and the eradication of the dysrhythmia is associated with improvement in upper GI symptoms. Drug or nondrug therapies with potential anti-arrhythmic or prokinetic effects may be studied at baseline and with follow-up noninvasive EGG recordings. EGG testing may be performed multiple times without discomfort or adverse effects for the subject.

Emesis

IVAN M. LANG, REZA SHAKER

Medical College of Wisconsin, Milwaukee

blood–brain barrier Physiological and anatomical barriers to the free diffusion of larger molecules from the vascular system to the neural circuits of the brain.

circumventricular organs Group of brain areas lining the cerebral ventricles; have no blood–brain barrier and may have chemosensory or secretory functions.

electrical control activity Ongoing spontaneous changes in membrane potential of the gastrointestinal smooth muscle that controls the timing of contractions.

electrical response activity Electrical activity of gastrointestinal smooth muscle associated with contractions.

enteric nervous system Set of integrative neural circuitry of the digestive tract that includes the myenteric and submucosal plexuses.

enterochromaffin cells Subset of hormone- or paracrine-secreting cells of the mucosa of the digestive tract that contain serotonin.

prodromata Set of autonomic responses that accompany and often precede emesis or nausea.

Emesis refers to the specific set of physiological responses associated with retching and vomiting that culminate in the expulsion of gastric contents. Emesis does not accurately refer to the act of expulsion of substances from the stomach, because this can occur during belching, regurgitation, rumination, coughing, and perhaps other situations. Nausea is a sensation that accompanies emesis or is activated by emetic stimuli.

INTRODUCTION

Emesis acts to protect an organism from ingested noxious substances. The protective function of emesis is signaled by two sets of receptors located at different levels of the absorptive pathway. A preabsorptive set of receptors is located in the digestive tract and a postabsorptive set is located within the vascular system.

Emesis

IVAN M. LANG, REZA SHAKER

Medical College of Wisconsin, Milwaukee

blood–brain barrier Physiological and anatomical barriers to the free diffusion of larger molecules from the vascular system to the neural circuits of the brain.

circumventricular organs Group of brain areas lining the cerebral ventricles; have no blood–brain barrier and may have chemosensory or secretory functions.

electrical control activity Ongoing spontaneous changes in membrane potential of the gastrointestinal smooth muscle that controls the timing of contractions.

electrical response activity Electrical activity of gastrointestinal smooth muscle associated with contractions.

enteric nervous system Set of integrative neural circuitry of the digestive tract that includes the myenteric and submucosal plexuses.

enterochromaffin cells Subset of hormone- or paracrine-secreting cells of the mucosa of the digestive tract that contain serotonin.

prodromata Set of autonomic responses that accompany and often precede emesis or nausea.

Emesis refers to the specific set of physiological responses associated with retching and vomiting that culminate in the expulsion of gastric contents. Emesis does not accurately refer to the act of expulsion of substances from the stomach, because this can occur during belching, regurgitation, rumination, coughing, and perhaps other situations. Nausea is a sensation that accompanies emesis or is activated by emetic stimuli.

INTRODUCTION

Emesis acts to protect an organism from ingested noxious substances. The protective function of emesis is signaled by two sets of receptors located at different levels of the absorptive pathway. A preabsorptive set of receptors is located in the digestive tract and a postabsorptive set is located within the vascular system.

Copyright 2004, Elsevier (USA). All rights reserved.

A number of motor and secretory events of the respiratory and digestive tracts occur before, during, and after emesis. The brain contains the vascular chemoreceptive area as well as the pattern generators for the motor and secretory responses, and pharmacological agents may block emesis at the sensory or integrative areas.

SENSORY MECHANISMS

Digestive Tract

Mechanoreceptors

Mechanical stimulation of the digestive tract from the pharynx to the small intestine by stroking the mucosa, distension, compression, or obstruction can activate nausea and vomiting. Slowly or rapidly adapting mechanoreceptors located in the mucosa, muscularis, or serosa may be involved in mechanical stimulation-induced emesis. Serosal slowly adapting mechanoreceptors, in particular, may be responsible for obstruction- or peritonitis-induced emesis.

Chemoreceptors

Noxious stimulation of the digestive tract using a variety of chemical substances, including acidic or alkaline solutions, $CuSO_4$, hypertonic saline, and hydrogen peroxide, can activate nausea and vomiting by stimulation of mucosal chemoreceptors of the stomach or duodenum.

Nonphysiological Stimulation of Receptors

Two clinically important treatments for cancer, cytotoxins and X-radiation, activate emesis probably by damage to physiological receptors or their afferent pathways. These emetic stimuli may activate vagal afferents directly or indirectly through the release of serotonin from enterochromaffin (EC) cells.

Chemoreceptor Trigger Zone

The chemoreceptor trigger zone (CTZ) is located in the area postrema (AP), one of the circumventricular organs of the brain. The CTZ is similar to other vascular chemoreceptors except that it functions as a postabsorptive receptor for the protection of the organism from ingested noxious substances. The CTZ has no blood–brain barrier and responds to numerous chemicals and hormones, including dopaminergic, α2-adrenergic, and opioid agonists, and cardiac glycosides, cytotoxins, and $CuSO_4$.

MOTOR RESPONSES OF THE DIGESTIVE TRACT

The digestive tract from pharynx to rectum is involved in the responses associated with emesis. The increase in salivation and swallowing prior to emesis probably functions to assist in the buffering of gastric juice. Salivary secretions protect the esophagus against swallowing-associated gastric reflux and probably do the same for emesis-associated gastric reflux. The subsequent digestive tract responses are organized into two sets of responses that occur in a hierarchical fashion. The gastrointestinal responses occur first and have a lower initiation threshold compared to the pharyngoesophageal responses, such that the gastrointestinal responses may occur without the pharyngoesophageal responses.

Gastrointestinal Responses

Motor Responses

The first gastrointestinal responses are relaxation of the gastric fundus and lower esophageal sphincter (LES), and these responses last the duration of the vomiting episode (Fig. 1A). A retrograde giant contraction (RGC) of the gastrointestinal tract (Fig. 1B) then empties the contents of the upper half of the small intestine into the stomach, thereby removing the offending noxious substance from the absorptive areas of the digestive tract. This RGC, in its progression through the duodenum, also empties the Brunner's glands and deposits its secretions into the stomach. The Brunner's gland secretions have significant buffering capacity, therefore, like salivary secretions, these Brunner's gland secretions may assist in protecting the esophagus during vomiting. Simultaneous with the RGC is the activation of a series of contractions of the lower half of the small intestine (Fig. 1B) that propagate distally. These contractions are of similar amplitude and duration as the usual spontaneous contractions, but they propagate distally a longer extent. These contractions act to milk the contents of the lower part of the small intestine into the colon. Defecation often follows emesis, therefore the contents of the lower half of the small intestine are eliminated from the organism just as vomitus expulsion eliminates noxious substances from the stomach and small intestine.

Myoelctric Responses

The electrical control activity (ECA), also known as electrical slow waves, of the entire gastrointestinal tract is altered during this phase of emesis (Fig. 2B). The ECA of the stomach becomes highly disorganized or highly regular at elevated (tachygastria) or reduced (bradygastria) frequencies before or during the

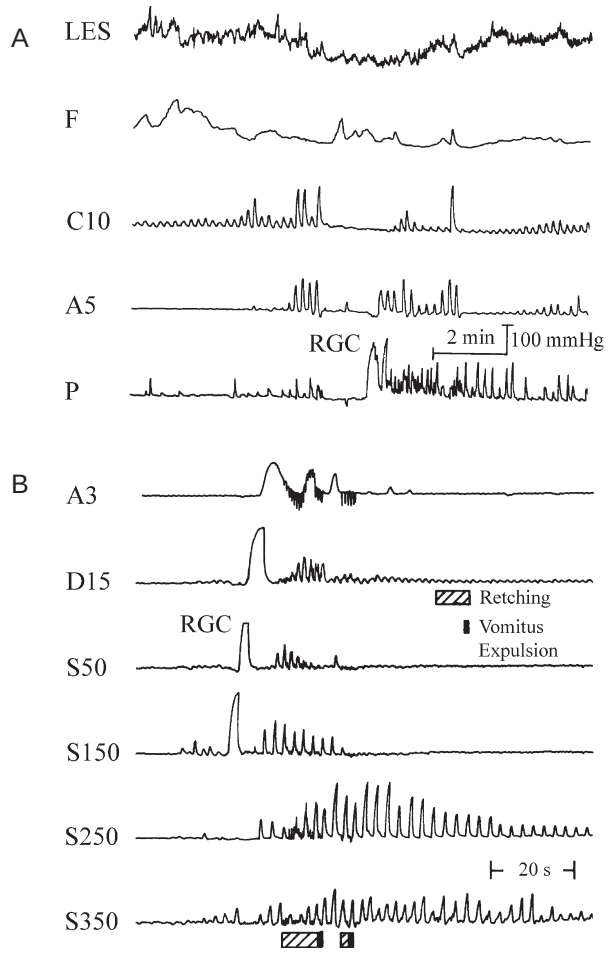

FIGURE 1 Gastrointestinal motor responses associated with emesis. (A) Gastric responses; (B) intestinal responses. LES, Lower esophageal sphincter; F, fundus; C, corpus; A, antrum; P, pylorus; D, duodenum; S, small intestine; RGC, retrograde giant contraction. The numbers next to abbreviated terms indicate the distance in centimeters of recording site from P. Note that LES and F relax before the occurrence of the RGC (A), the RGC occurs in upper small intestine only (B), and after the RGC a series of phasic contractions occur, especially in the distal small intestine (B).

vomiting episode. Contractions are not associated with tachygastria or bradygastria, and these electrical changes may be associated with active inhibition of the muscle. The RGC is associated with the highly irregular pattern of electrical activity, and this change may represent the electrical response activity (ERA) of the stomach. The ECA of the upper small intestine ceases (for up to 30 s) before and during the propagation of the RGC. This cessation of ECA is necessary for propagation of the RGC, because the ECA controls the normal orthograde propagation of contractions and this must be eliminated before this retrograde contraction can occur. The ECA of the lower small intestine slows significantly and becomes more entrained (time locked) in a distal direction, and this change in ECA is responsible for the increased propagation distance of the stripping contractions of the distal small intestine.

Pharyngoesophageal Responses

After intestinal contents have been refluxed into the stomach, the upper digestive tract responses begin. The pharyngoesophageal responses are coordinated closely with respiratory movements of retching and vomitus expulsion. The first response occurs just prior to

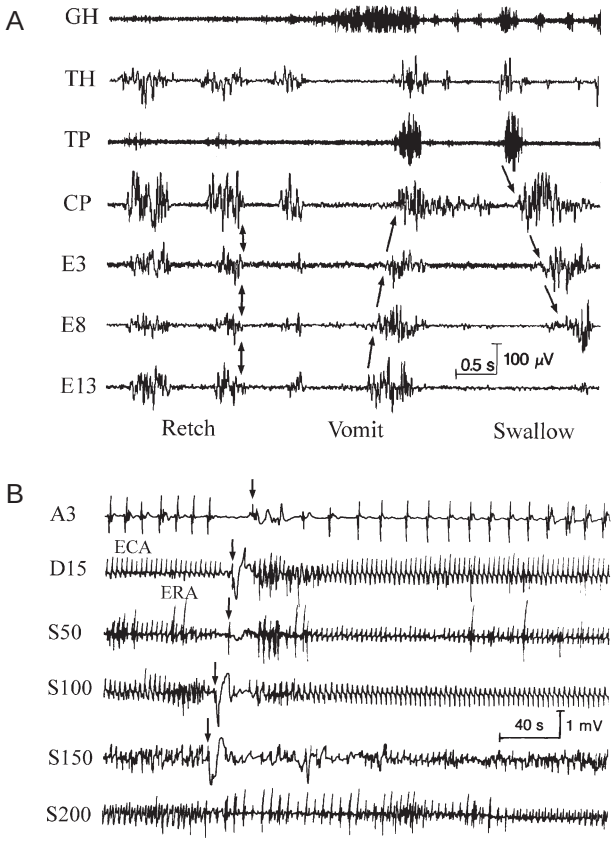

FIGURE 2 Gastrointestinal and esophagopharyngeal myoelectrical responses associated with emesis. (A) Esophagopharyngeal responses; (B) gastrointestinal responses. GH, Geniohyoideus; TH, thyrohyoideus; TP, thyropharyngeus; CP, cricopharyngeus; E, esophagus; A, antrum; D, duodenum; S, small intestine; ECA, electrical control activity; ERA, electrical response activity. The numbers next to abbreviated terms indicate the distance of recording site from CP (A) or A (B). Note that a retrograde propagated electrical event of E occurs at the end of the vomit (A), the retrograde myoelectric response of the gastrointestinal tract is associated with a loss of ECA (B), and the ECA frequency decreases after the retrograde myoelectrical response, especially in the distal small intestine (B).

retching and consists of longitudinal contraction of the striated muscle portion of the esophagus such that the LES rises into the chest. The effect of this action in conjunction with prior relaxation of the LES and fundus is to eliminate the gastroesophageal angle that forms a physical barrier between stomach and esophagus. Retching then occurs about once per second as a series of simultaneous contractions and relaxations of the diaphragm and abdominal muscles. The stomach rises and falls during retching, which mixes gastric contents with intestinal secretions, imparts a momentum to the gastric bolus to assist expulsion, and may stimulate gastric receptors that signal vomiting. Some gastric contents may be expelled during retching, but this is limited by contraction of the diaphragmatic hiatus that pinches off the gastroesophageal junction. Vomitus expulsion occurs when diaphragmatic dome and abdominal muscles contract strongly and simultaneously with relaxation of the diaphragmatic hiatus. These events always occur between retches when the stomach is rising and the gastric contents are already moving orad. As the bolus is expelled to the esophagus, a retrograde contraction of the striated muscle portion of the esophagus captures the bolus, assisting its transport to the pharynx and preventing the bolus from returning to the stomach (Fig. 2A). When the bolus reaches the upper esophageal sphincter (UES), the UES is maximally pulled open by anterior traction of the suprahyoid (Fig. 2A) and infrahyoid muscles and by posterior traction of the suprapharyngeal muscles.

NEURAL CONTROL

Afferent Pathways

The vagus nerves are the primary afferent nerves mediating emesis due to stimulation of the digestive tract. Splanchnic afferent nerves seem to serve little or no role in emesis, although they may mediate peritonitis-induced emesis and provide a significant afferent pathway for radiation-induced emesis.

Efferent Pathways

The gastrointestinal motor correlates of vomiting are controlled by vagal efferent fibers that are transmitted to the jejunum and ileum through the celiac branch of the vagus nerve and the mesenteric nerves. The innervation of the duodenum and stomach are through the duodenal and ventral branches of the vagus nerve, respectively. The neural pathway controlling initiation of the RGC descends about 20 cm within the intestinal wall, probably through the enteric nervous system, before innervating the muscle. The retrograde propagation of the RGC is controlled primarily by the central nervous system, but is modulated by the enteric nervous system. The upper digestive tract responses are controlled by branches of the vagus nerves, including the pharyngoesophageal, recurrent laryngeal, and superior laryngeal nerves.

Central Control

The central emetic pattern generator (CEPG), i.e., the area of the brain controlling the motor and secretory responses associated with emesis, may not be a single nucleus but may comprise a distributed network of brain nuclei. Some areas of the brain important for controlling emesis include the nucleus tractus solitarius, retrofacial nucleus, and dorsolateral reticular formation. However, the roles of specific areas of the brain in mediating and controlling emesis and the associated responses are unknown.

PHARMACOLOGY OF EMESIS

Emesis may be initiated from different sensory pathways, therefore specific types of emesis may be mediated by different neurotransmitters and blocked by different antagonists. Regardless of the emetic stimulus, all emesis is mediated by the CEPG, therefore some antagonists may block all forms of emesis.

Peripheral Control

Digestive tract-initiated emesis is mediated by multiple peripheral serotonergic (5-hydroxytryptamine) receptors. $CuSO_4$-induced and perhaps noxious chemical-induced emesis is mediated by 5-hydroxytryptamine isotype 4 (5-HT4) receptors, probably on chemosensory afferents, but radiation- or cytotoxin-induced emesis is mediated by 5-HT3 receptors, probably on vagal afferents supplying the EC cells. Presynaptic 5-HT3 receptors on vagal afferents supplying the AP may also mediate cytotoxin-induced emesis.

Chemoreceptor Trigger Zone

Numerous neurotransmitters activate emesis by stimulation of the CTZ, but emesis caused by these agonists is blocked only by the specific antagonists. Therefore, these neurotransmitters probably act at the level of the chemoreceptors rather than at the neurotransmitter level. Cholinergic or histaminergic antagonists block only motion sickness, therefore these agents may affect only the motion-sensing neural circuitry.

Central Pattern Generator

A few pharmacologic agents, because they block all forms of emesis, appear to block emesis at the level of the CEPG. The ability of agonists to block emesis suggests that there may be an endogenous emetic inhibitory mechanism. Perhaps the most powerful of the general antiemetic pharmacological agonists is opioid agonists, but cannabinoid and vanilloid receptor agonists may also be antiemetic. Neurokinin-1 receptor antagonists also block emesis due to a variety of emetic stimulants.

NAUSEA AND THE DIGESTIVE TRACT

Nausea is a sensation that is felt in the digestive tract, therefore investigators have sought a digestive tract source of this sensation for decades. Many digestive tract responses have been implicated, but all have subsequently been discarded. It has been recently suggested that changes in the gastric ECA, i.e., tachygastria, cause nausea. However, there is no one-to-one correspondence between tachygastria and nausea, changes in ECA occur at all levels of the gastrointestinal tract, and changes in ECA are just one of the many prodromata that accompany nausea. The prodromata do not cause the feeling of nausea, rather they are the result of the stimulus for nausea. It is probable that the unpleasant feeling in the digestive tract during nausea is a referred sensation similar to referred pain.

alpha cells Pancreatic islet cells that produce glucagon.
beta cells Pancreatic islet cells that produce insulin.
glucagon Hormone produced by alpha cells in the islets of Langerhans; acts to elevate blood glucose.
insulin Glucose-regulating hormone produced and secreted by beta cells in the islets of Langerhans; has broad anabolic effects on body metabolism.
islets of Langerhans Clusters of several hundred to several thousand endocrine cells embedded in the pancreas.
pancreatic duodenal homeobox factor-1 Patterning transcription factor; required for the differentiation of the pancreas.

The endocrine pancreas consists of the islets of Langerhans, which are scattered throughout the exocrine pancreas in all vertebrates evolutionarily higher than the bony fish (teleosts). Islets are complex structures of four primary endocrine cell types that function both separately as microorgans and in concert as the endocrine pancreas to regulate physiologic glucose homeostasis. Although the direct secretion of insulin and glucagon from islets into the portal vein has obvious advantages with respect to influence on hepatic function, it is not clear why the endocrine pancreas is dispersed throughout the exocrine pancreas. The most appealing suggestion is that the local insular–acinar portal system helps regulate the exocrine function of the pancreas.

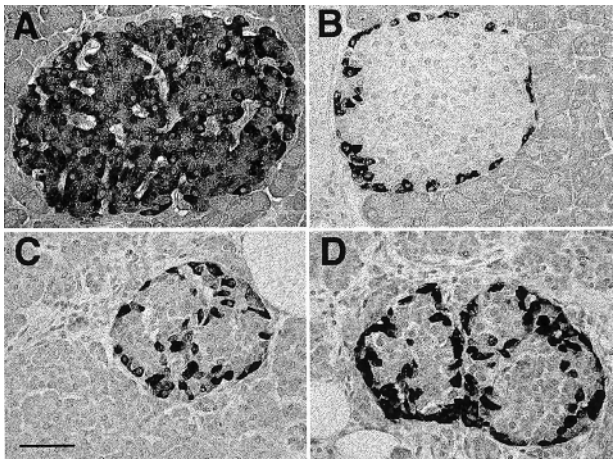

FIGURE 1 The islets of Langerhans of most species have a mantle of non-beta cells (consisting of glucagon-, somatostatin-, and pancreatic polypeptide-producing cells) and a core of insulin-producing beta cells. (A) Mouse islet immunostained for insulin, showing the extensive vasculature between the cords of endocrine tissue. (B) Mouse islet immunostained for glucagon, showing the incomplete mantle surrounding the core of beta cells. (C and D) Human islets immunostained for glucagon, showing a similar pattern of mantle/core but with greater complexity, suggestive of subunits similar to those in the rodent islet. Magnification bar = 50 μm.

INTRODUCTION

Four cell types of the endocrine pancreatic islets of Langerhans are common to all species: beta, or insulin producing; alpha, or glucagon producing; delta, or somatostatin producing; and pancreatic polypeptide (PP) producing. Each islet is a highly vas cularized cluster of these cells organized in a nonrandom manner, with the delta, alpha, and PP (the non-beta) cells occurring as a discontinuous mantle 1 to 3 cells thick around a central core of beta cells (Fig. 1). Islets of humans and other primates have a somewhat more complex arrangement. Sections of human pancreas show many different islet profiles, including oval and cloverleaf patterns, differences that have fueled controversy about whether they actually have a mantle–core arrangement (Fig. 1, C and D). Nonetheless, in three dimensions, human islets can be considered as composites of several mantle–core subunits or as lobulated with mantle–core lobules.

In the adult mammal, the islets make up 1–2% of the pancreatic mass. The relative volume of the islet cell mass varies with age, being much greater in fetuses and the young, presumably because the growth of the islet and exocrine tissues is discordant. The pancreas of an adult human has roughly 1 g of islet tissue, 500,000–1,000,000 islets, and contains about 200 units, or 8 mg, of insulin; the adult rat pancreas contains about 100 μg of insulin. The average rat islet is 150 μm in diameter and contains about 45 ng of insulin. Islet size can range from only a few cells and less than 40 μm in diameter to about 10,000 cells and 400 μm in diameter. Islets smaller than 160 μm in diameter represent 75% of the islets in number but only 15% of the islet

 Copyright 2004, Elsevier (USA). All rights reserved.

volume, whereas islets larger than 200 μm in diameter represent only 15% of the islets in number but 60% of the islet volume.

In adults, 70–80% of the islet consists of insulin-producing beta cells; 5% is somatostatin-producing delta cells, and 15–20% is either glucagon-producing alpha cells or pancreatic polypeptide-producing cells. However, at birth, the beta cells are usually only 50% of the islet, but with postnatal replication of the beta cells and an increase in cell volume, their proportion increases. The beta cell population is dynamic, undergoing compensatory changes in function and mass in order to maintain euglycemia.

PANCREATIC DEVELOPMENT

The pancreas is derived from outpocketings of the primitive gut. There are two or three pancreatic anlagen or primordia: a dorsal outpocketing of the gut across from the budding liver and, after a short temporal lag, one or two ventral buds (which fuse very early) from the base of the biliary floor of the gut. The dorsal anlage that gives rise to the splenic portion (tail and body) of the pancreas fuses to various degrees with the ventral anlage that gives rise to the head or duodenal portion of the pancreas. Islet cells are seen first as single cells along the terminal pancreatic tubules and then as clusters of cells within the epithelial basement membrane. These clusters become separated from the ductal epithelium to form islets.

The origin of the pancreas as separate primordia is thought to be the basis of the regional distribution of glucagon-producing and pancreatic polypeptide-producing cells. The dorsal pancreas, supplied with blood by the celiac trunk via the gastroduodenal and splenic arteries and drained by one main pancreatic duct, contains the glucagon-rich islets, with few pancreatic polypeptide-producing cells. The opposite distribution is found in the ventral pancreas, which is supplied with blood from the superior mesenteric artery via the inferior pancreaticoduodenal artery and is drained by a separate duct. Here the islets contain pancreatic polypeptide-producing cells and few, if any, glucagon-producing cells. The degree of fusion of these ducts differs among species.

The alpha cells appear before the others, followed by the beta cells and finally by the delta cells (PP cells have been reported several days before birth in rats). As they form, endocrine cells may express more than one hormone, with a progressive restriction to just one hormone. The finding that ablation of a homeobox transcription factor, pancreatic duodenal homeobox factor-1(pdx-1) [also known as insulin promoter factor-1 (IPF-1)], resulted in the failure to develop a pancreas brought great energy into defining the cascade of transcription factors involved in the differentiation of pancreas from endoderm and subsequently to the varied pancreatic cell types (exocrine and endocrine) (Fig. 2). Recent studies have shown that p48 [also known as pancreatic transcription factor-1 (PTF-1)], a transcription factor previously thought only to be the determinant for pancreatic acinar tissue, is also necessary for pancreatic formation.

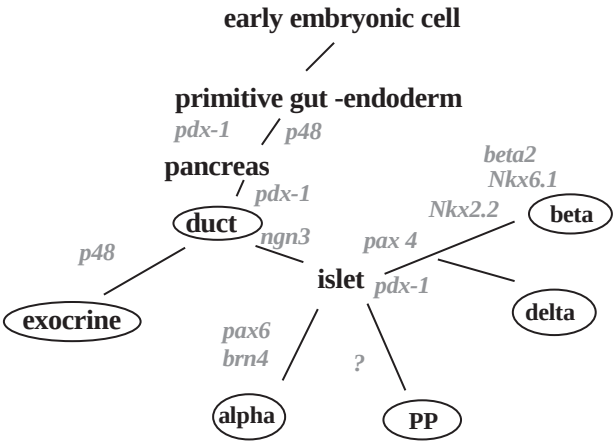

FIGURE 2 The cascade of transcription factors that are necessary for formation of the endocrine pancreas. Both pdx-1 and p48 are necessary for pancreas organogenesis, but each is limited to expression in certain cells in the mature pancreas, with pdx-1 expressed in insulin-producing beta cells and p48 expressed in acinar cells. Neurogenin 3 (ngn3) has been shown to be a marker of the endocrine progenitor cells. PP, Pancreatic polypeptide-producing cell. As indicated by the question mark, additional transcription factors remain to be placed in this schema.

COMPONENTS OF THE ISLETS OF LANGERHANS

Endocrine Cells

The four major endocrine cell types in mammalian islets are distinguished by ultrastructural and immunocytochemical techniques. The beta cells are polyhedral, being truncated pyramids, and are usually well granulated with secretory granules 250–300 nm in diameter. It has been estimated that each mouse beta cell is about 1000 μm^3 and contains about 10,000 insulin granules. Insulin granules can be found as mature granules that have an electron-dense core and a loosely fitting granule-limiting membrane with the appearance of a spacious halo, or as immature granules with little or no halo with moderately electron-dense contents (Fig. 3). Immature granules have been shown to be

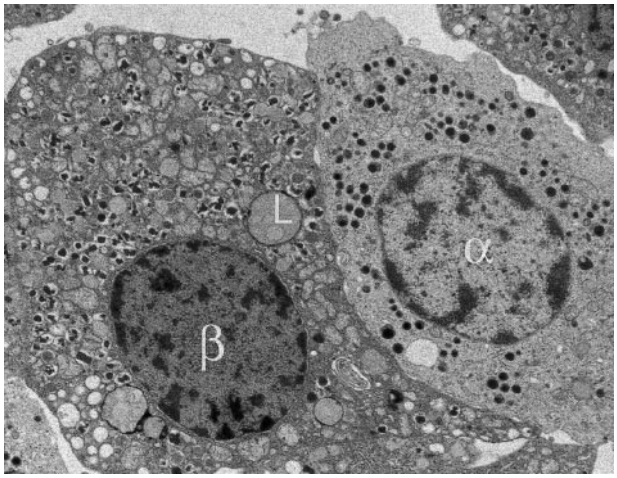

FIGURE 3 Insulin-producing beta cells and glucagon-producing alpha cells can be distinguished by secretory granule morphology. In a human islet, mature insulin granules in a beta cell have electron-dense crystalline cores and loosely fitting, granule-limiting membranes with the appearance of a spacious halo; immature granules have little or no halo and moderately electron-dense contents. Beta cells also contain lipid inclusions (L) that increase in numbers with cell age. In alpha cells, glucagon-containing granules are electron dense and have a narrow halo of less dense material and a tightly fitting, granule-limiting membrane.

the major, if not the only, site of conversion of proinsulin to insulin. In some species, the electron-dense core of the mature granule is visibly crystalline. Insulin is only one of at least 120 proteins in the granules.

The alpha cells are usually smaller and more columnar than the beta cells and well granulated with granules 200–250 nm in diameter. The granules are electron dense with a narrow halo of less dense material and a tightly fitting granule-limiting membrane; there is little species variation. The delta cells are usually smaller than either alpha or beta cells, are well granulated, and are often dendritic in shape. Within a delta cell, the electron density of granules varies greatly. Each granule, 200–250 nm in diameter, contains material of homogeneous moderate density that fills the granule-limiting membrane.

The PP cells are the most variable among species. In humans, the granules are elongated, very electron dense, and 120–160 nm in diameter, but in dogs and cats the granules are spherical, variable in electron density, and about 300 nm in diameter.

Microvasculature

The islets of Langerhans have a glomerular-like capillary network with a direct arteriolar blood supply. One to three arterioles penetrate each islet through discontinuities of the non-beta cell mantle and enter directly into the beta cell core, where each branches into a number of fenestrated capillaries. These capillaries follow a tortuous path, passing first through the beta cell core and then through the non-beta cell mantle. Often, a capillary will pass along the inside of the mantle before penetrating it to leave the islet. The pattern of microvasculature varies with islet size. In small islets ($<160\,\mu m$ in diameter), the efferent capillaries pass through exocrine tissue for 50 to 100 μm before coalescing into collecting venules. Large islets ($>200\,\mu m$ in diameter) are selectively located near the larger ducts and blood vessels. Their efferent vessels coalesce within the islet capsule, thus they probably have little effect on surrounding exocrine tissue. However, the vascular pattern of the small islets and their abundance would lead to an effective insuloacinar portal system.

The blood flow to the islets has been found to be disproportionately large (10–20% of the pancreatic blood flow) for the 1–2% of pancreatic volume. High concentrations of glucose have been shown to enhance pancreatic blood flow and to preferentially increase islet blood flow. Lymphatic vessels, although common in the pancreas, are not found within the islets.

Capsule

The islet capsule is only a single layer of fibroblasts and the collagen fibers laid down by these fibroblasts. Frequently, the capsule is discontinuous and is absent between islet and exocrine cells, such that the only separations between exocrine and islet cells are their respective basement membranes The capsule overlies the efferent blood vessels of the islet and thus defines a subcapsular interstitial space. On collagenase digestion for islet isolation, the capsule is disrupted and lost.

Nerves

The pancreas is innervated by sympathetic fibers via the celiac and superior mesenteric ganglia and by parasympathetic fibers from the vagus nerve. These parasympathetic fibers synapse in small ganglia dispersed in the pancreas; in some species, these ganglia are close to, or even within, the islets. They may act as pacemakers for the oscillations in hormone secretion that occur without extrinsic nervous connections, as in the isolated perfused canine pancreas. Within the islets, the nerves follow the blood vessels and terminate within the pericapillary space, within the capillary basement membrane, or closely apposed to the endocrine cells. Because no specialized synapses are found, it has been suggested that neurotransmitters released into

the interstitial space may affect a number of neighboring islet cells.

THE ISLET AS AN ORGAN

Functional Implications of Islet Organization

It is important to understand how the three-dimensional organization of the islet may determine islet function. Within the islet, endocrine cells are organized around the microvasculature. In the rat, 8 to 10 beta cells form a tube or rosette around a capillary, but each beta cell abuts a second capillary. In experimentally degranulated beta cells, the remaining granules are polarized toward the central "venous" capillary, suggesting an *in situ* polarity of the beta cells.

The interrelations of the islet cells and their relations with the microvasculature have functional implications. The microvascular pattern of the islet confers a directionality to the blood flow—from the point of arteriolar entry outward through the beta cell core to the peripheral non-beta cell mantle. Physiologic data from anterograde and retrograde passive neutralization perfusions of dog, rat, monkey, and human pancreases support a beta to alpha to delta (B—A—D) directional pattern of blood flow. This pattern of flow would favor insulin having an effect on the alpha and delta cells by its being transported in high concentrations from the core to the mantle. The reverse, that of the beta cells being influenced by local blood-borne somatostatin or glucagon, is not supported by the vascular pattern.

However, some paracrine effects may occur by simple diffusion through the interstitium. The dynamics and direction of flow of the interstitial fluid are not known, but we would expect it to be in the same direction as the blood flow. One could speculate that diffusion in the interstitial space allows somatostatin and glucagon to influence not only each other (adjacent cells) but also those adjacent beta cells. In large islets, there would be a central core of beta cells that would be isolated by their distance from the non-beta cells and thus from all but systemically circulating levels of the other islet hormones. In small islets, essentially all beta cells might be close enough to the non-beta cells to be influenced by their hormones diffusing into the interstitial fluid.

The intercellular contacts between the endocrine cells may also influence their function. Stimulated secretion is enhanced when beta cells have contact with at least one other beta cell. This enhancement is thought to be due to electrical coupling through gap junctions but may also involve cell adhesion molecules such as integrins.

Heterogeneity of Islets

We now realize that the islets within one pancreas are not all alike. Islets differ in cellular composition due to the regional distribution of the glucagon-producing alpha cell and the pancreatic polypeptide-producing cells. Increasing evidence suggests even that not all beta cells within an islet are identical. Studies on single islet cells have shown that individual beta cells may have different thresholds for glucose-induced insulin release; thus, with increasing concentrations of glucose, more beta cells are recruited in the response. This cellular heterogeneity has been extended to include the redox state and the threshold for glucose-induced biosynthesis of proinsulin and glucose-induced cytoplasmic free calcium concentration. It is unknown whether the heterogeneity is intrinsic and constant for a particular cell through its lifetime, is related to the age of the cell, or is imprinted by a factor from the environment. In addition, recent studies have questioned if such heterogeneity were artifactual.

Insular—Acinar Portal System

It has been hypothesized that one reason the endocrine pancreas is dispersed as islets throughout the exocrine pancreas is that the islet hormones regulate exocrine function and growth locally through an insuloacinar portal system. Microvascular corrosion casts show efferent vessels from islets passing through the exocrine tissue before coalescing into venules; these vessels comprise an insuloacinar portal system. Such vessels are mostly from smaller islets (160 μm in diameter and smaller) that are usually embedded in exocrine tissue. The efferent vessels of the larger islets are postcapillary and collecting venules that are considered the "leakiest" or most permeable in other tissues, thus allowing diffusion of the hormones into the surrounding acinar tissue. The presence of periinsular halos of enlarged and highly granulated exocrine cells adjacent to islets has been cited as histological evidence of tropic effects of islet hormones on the exocrine pancreas.

LIFETIME CHANGES IN THE ENDOCRINE PANCREAS

For many years, the accepted concept was that all the pancreatic beta cells present throughout life were present at birth. Many researchers thought that insulin resistance would lead to diabetes without change in the beta cells. However, evidence over the past decade has

been compelling; in most cases, the beta cells can, and do, compensate for added demand arising from pregnancy, obesity, or insulin resistance. It is important to remember that only 15–20% of obese or severely insulin-resistant humans become diabetic; the others maintain normoglycemia due to beta cell compensation. The new concept is that the beta cell mass is dynamic, with increases and decreases both in function and mass maintaining the glycemic level within a very narrow physiological range. The changes in mass can be both in number (hyperplasia) and in individual volume of beta cells (hypertrophy). When the mass cannot increase adequately, diabetes ensues.

During embryonic development, multipotent cells of the primary pancreatic buds differentiate into specific pancreatic phenotypes of ductal, acinar, and the four endocrine islet cells. Until late gestation, most beta cells result from the differentiation of ductal precursor cells to islet cells, a process called neogenesis. Shortly before birth, replication becomes the major mechanism for adding new beta cells, but both neogenesis (the differentiation process) and replication continue throughout adult life. In rodents, during the first days after birth, many new islets are formed, and a second wave of neogenesis occurs around the time of weaning. Beta cell replication is significantly higher during late gestation and the neonatal period compared to the period following weaning, with little change in replication rates occurring beyond 30 to 40 days of age.

From birth to adulthood, the volume of islet tissue with respect to that of the pancreas (relative volume) decreases, but the actual volume of islet tissue increases; the more slowly growing islet tissue is diluted by an exuberant postnatal growth of the acinar tissue. The beta cell mass has been shown to increase 12- to 15-fold from birth to adulthood. In fact, beta cell mass is linearly correlated with body weight in adult mice and rats and with body mass index (BMI) in humans. A longitudinal study shows that the addition of new cells accounts for the increase in beta cell mass throughout most of the life span of rats, but from 15 months onward hypertrophy of the beta cell is the main mechanism of for the expansion of beta cell mass.

The beta cell mass is dynamic in nature and increases or decreases in order to maintain euglycemia. Functional compensation, or changes in the amount of insulin each beta cell secretes, can be due to changes in the responsive threshold for glucose-induced insulin secretion, possibly caused by activation of glucokinase, or by recruitment of cells with heterogeneous response thresholds. The beta cell mass is the major factor in determining the amount of insulin that can be secreted. The mechanisms involved in this compensatory regulation are the determinants of beta cell mass: rate of replication, neogenesis and apoptosis, and cell size (hypertrophy vs. atrophy).

DETERMINANTS OF BETA CELL MASS

Neogenesis

Neogenesis is clearly the main pathway of beta cell increase during early to midgestation, but still occurs in the normal postnatal animal. In adults, islet cells of all types can be immunolocalized in the pancreatic ducts as occasional single cells or small budding islets. This process can be stimulated to form substantial numbers of new islets under numerous *in vivo* experimental conditions. Additionally, adult human ductal tissue can be differentiated into islets *in vitro*. In some experimental situations, such as the regeneration after partial pancreatectomy in the adult rodent, new lobes of pancreas (exocrine and endocrine) are added. There is some suggestion that new lobes of pancreas continue to form in adults.

Replication

Beta cell replication is significantly higher during late gestation and the neonatal period compared to the period following weaning, with little change in replication rates occurring beyond 30 to 40 days of age in rodents. The cell cycle has been determined using isolated rat islets synchronized in culture by exposure to hydroxyurea. A calculated cell cycle of 14.9 hours has been assumed to reflect that of the beta cell, the predominant cell of the islet. The length of the cell cycle does not change with glucose stimulation or with the age of the animals. Instead, the growth rate is regulated by the number of beta cells that can enter the division phase (G_1) from the resting (G_0) phase. Postnatal proliferation rate of beta cells is low, but the proliferation of differentiated beta cells must not be underestimated; it is adequate to maintain a slowly increasing beta cell mass. Replication can be further stimulated by prolactin, growth hormone, glucose, and glucagon-like peptide-1 (GLP-1). Replicating beta cells have been identified by bromodeoxyuridine and tritiated thymidine incorporation in cells immunolabeled for insulin, and numerous electron micrographs of mitotic figures in cells with insulin granules have been published. There may be functional differences in beta cells that can replicate and those that cannot, and as a cell enters the cell cycle, it may transiently lose function.

Hypertrophy

Hypertrophy, an increase in cell size without replication, can be an efficient and economical mechanism for rapid and transient compensation and has been recognized in many models, including late pregnancy.

Apoptosis

Apoptosis is a normal determinant of beta cell mass. The frequency of apoptotic beta cells in the adult rat has been found to be about 0.5%; this frequency cannot be equated with a rate because it is not known how long the apoptotic process takes nor how long apoptotic bodies are visible. The concept of beta cell turnover became evident with mathematical modeling of the beta cell mass. With beta cell replication of 2–3%/24 hours, as found in the adult rodent pancreas, the beta cell mass can double in about 1 month. Between 1 and 2, 2 and 3 months of age, the rat beta cell mass does almost double, but this monthly doubling does not continue, suggesting a loss of cells. The life span of a rat beta cell has been estimated as approximately 58 days. The slowly increasing beta cell mass results from the balance between cell formation and cell loss, such that the endocrine pancreas must be considered a slowly renewed tissue.

In the second week after birth, remodeling of the endocrine pancreas occurs simultaneous with a high rate of replication of beta cells and a high frequency of apoptosis. This remodeling coincides with marked changes in the message RNA levels of both insulin-like growth factor-1 and -2 (IGF-1 and IGF-2) as well as transient appearances of IGF binding protein-1 and -2 (IGFBP-1 and IGFBP-2), leading to the suggestion that an inadequate availability of survival factors, such as the IGFs, is the cause of the increased cell loss. This hypothesis is supported by evidence of the suppression of normal neonatal apoptosis by persistent IGF-2 in overexpressing transgenic mice. This remodeling may have significance in the priming of autoimmune diabetes, as seen in non-obese, diabetic (NOD) mice, BioBreeding (BB) rats, and humans, because apoptotic bodies are highly immunogenic.

Sources of Cells for Renewal: Progenitor and Stem Cells

With the acceptance of the concept of postnatal growth of the beta cell mass, interest in the adult "pancreatic stem cell" has increased. The characterization of such a stem/progenitor cell has been elusive. One likely source of progenitor cells is the pancreatic ducts, because adult duct epithelium retains the ability to give rise to all the differentiated cell types of the pancreas. Current research is focused on characterizing the cells capable of generating new islet cells in the adult pancreas.

GLUCOSE EFFECTS ON BETA CELLS

The effects of elevated glucose levels can be both beneficial, as in stimulation of beta cell proliferation, and detrimental, as in cell death; the term "glucose toxicity" has been used to describe the latter effect. There are a number of secondary effects of a hyperglycemic environment, including the loss of glucose-induced insulin secretion and even loss of specific beta cell differentiation. Additionally, beta cells in some strains or species undergo apoptosis when exposed to hyperglycemia, but in other strains, beta cells can have more adaptive responses and maintain a stable mass, even with chronic hyperglycemia.

antibody A Y-shaped immunoglobulin protein on the surface of B cells that is secreted into the blood or lymph in response to an antigenic stimulus.

celiac sprue (gluten-sensitive enteropathy) A malabsorptive disorder in which there is an atrophic and inflamed proximal small intestinal mucosa that usually improves morphologically and clinically on treatment with a gluten-free diet but relapses when gluten is reintroduced.

Antibodies to gliadin, reticulin, endomysium, and tissue transglutaminase have been detected in patients with celiac sprue. Studies have shown that endomysial antibodies, tissue transglutaminase antibodies, and anti-gliadin antibodies seem to be the most useful in screening patients for celiac sprue.

ENDOMYSIAL ANTIBODIES

Endomysial antibody (EMA) is directed against endomysium, a connective tissue protein found between myofibrils in the smooth muscle cells of the gastrointestinal tract of primates. Once EMAs were found to be associated with gluten-sensitive enteropathy, further tests were developed to detect them. An indirect immunofluorescence assay was implemented in which the binding of the serum EMAs to a tissue substrate produces a characteristic staining pattern. The initial tissue substrate used for the indirect immunofluorescence assay, primate esophagus, is limited in supply. However, now with more readily available human umbilical cord as the tissue substrate, wider application of serum EMA testing has been possible. Most patients with celiac sprue have a serum EMA of the immunoglobulin A (IgA) subtype. However, EMA of the IgG_1 subtype has also been employed for diagnosis (mostly in IgA-deficient patients). The sensitivity and specificity of IgA EMAs are reported to be 85–98% and 97–100%, respectively. Thus, serum EMA testing has a high positive predictive value.

TISSUE TRANSGLUTAMINASE

The target autoantigen for EMA in celiac disease has been identified as a tissue transglutaminase (tTG). Autoantibodies (IgA and IgG) to tissue transglutaminase have also been recently detected via more easy-to-perform enzyme-linked immunosorbent assays (ELISAs). Studies have shown that the sensitivity of IgA tissue transglutaminase antibodies (TTAs) is 90–98% and the specificity is 95–97%. These high positive and negative predictive values of IgA TTA have led more investigators to recommend the IgA TTA as the initial screening serologic test to diagnose celiac sprue, followed by EMA testing if IgA TTA is borderline, followed by a small intestinal biopsy if either EMA or TTA or both are positive. However, it is not yet clear how extensively TTA and EMA results overlap since both seem to bind to the same substrate, namely, tissue transglutaminase.

ANTI-GLIADIN ANTIBODIES

Finally, anti-gliadin antibodies (AGAs) are antibodies to wheat gliadin and have also been extensively studied in celiac sprue. Two anti-gliadin antibody subtypes exist, IgA and IgG. The sensitivity of IgG AGAs is 75–85% and the specificity is 75–90%. The sensitivity of IgA AGAs is 80–90% and the specificity is 85–95%. Therefore, IgA AGAs are more sensitive and specific than IgG AGAs and a negative IgA AGA result has a high negative predictive value. Interpretation of positive AGAs, however, must be scrutinized carefully because other conditions, such as cow's milk intolerance, IgA nephropathy, Crohn's disease, eosinophilic enteritis, and tropical sprue, may raise AGA levels.

In patients with celiac disease who are also IgA-deficient, all IgA antibody-based tests are negative. In these patients, elevated levels of IgG_1 EMAs and IgG TTAs support the diagnosis of celiac sprue.

The benefit of screening for asymptomatic celiac disease is debatable, but potential advantages include reducing the risk of enteropathy-associated T-cell lymphoma, reducing the risk of nutritional deficiency states, preventing mild intestinal symptoms, and improving general well-being, assuming adoption of and strict adherence to a gluten-free diet.

Although the IgA TTA assay has a high positive and negative predictive value and is an easy-to-perform ELISA-based test, it is relatively new. EMA testing has been the primary screening tool through the years and thus continues to be a comfortable initial assay with

which to screen populations with a high pretest probability of celiac sprue. EMAs in combination with TTAs or AGAs have positive and negative predictive values approaching 100%. Therefore, if either test is positive, the patient or the screened individual should be referred for diagnostic biopsy of the small intestine. If both tests are negative, it is highly unlikely that the individual has celiac disease. These serologic markers are useful not only in supporting the diagnosis but also in following the response to a gluten-free diet because it has been shown that these tests often but not always revert to negative when patients with celiac sprue comply with a gluten-free diet.

aspiration, endoscopic ultrasound can guide needle biopsies of tumors, lymph nodes, and other lesions that are in close proximity to the gastrointestinal tract. This has greatly expanded diagnostic capability, and new indications continue to evolve.

INTRODUCTION

Endoscopic ultrasound (EUS) was originally designed in 1980 to better image the pancreas. Early echoendoscopes were big, bulky, and difficult to maneuver, and image quality was poor. With technologic advances over the past decade, these scopes are now smaller, more flexible, and provide high-quality endoscopic and ultrasound images.

Certain substances (fluid, blood) transmit or conduct ultrasound, whereas others reflect the sound waves (air, bone). Ultrasound images are created by sound waves that are reflected back to the transducer by objects or tissue components in the wave path. These reflected sound waves are termed "echoes." The detail of the image (resolution) and the depth of ultrasound (US) penetration into the tissue are a function of the ultrasound frequency. Low-frequency sound waves have an increased tissue penetration capability, but image resolution is less defined. High-frequency sound waves increase the image resolution, but the penetration depth is much less. EUS employs frequencies between 5 and 20 MHz., with penetration depths ranging from 1 to 7 cm. In contrast, transabdominal ultrasound utilizes lower frequency sound waves (2.5–5.0 MHz) to visualize more distant internal organs.

EQUIPMENT

EUS utilizes specialized endoscopes, called echoendoscopes, that incorporate ultrasound transducers on the distal tip. There are two types of echoendoscopes, defined by the orientation of the ultrasound transmission with respect to the shaft of the endoscope. The optical or endoscopic image is generated from fiber-optic or computerized video technology.

Radial Scanning Echoendoscopes

The radial scanning echoendoscope uses a mechanical rotating transducer that creates a 360° image in a circular plane perpendicular to the shaft of the scope (Fig. 1). A small balloon is placed over the transducer, so that a water bath can be created to enhance US transmission, or acoustic coupling. The viewing optics are located just proximal to the transducer and are oriented at a 60° oblique angle. Current radial echoendoscopes

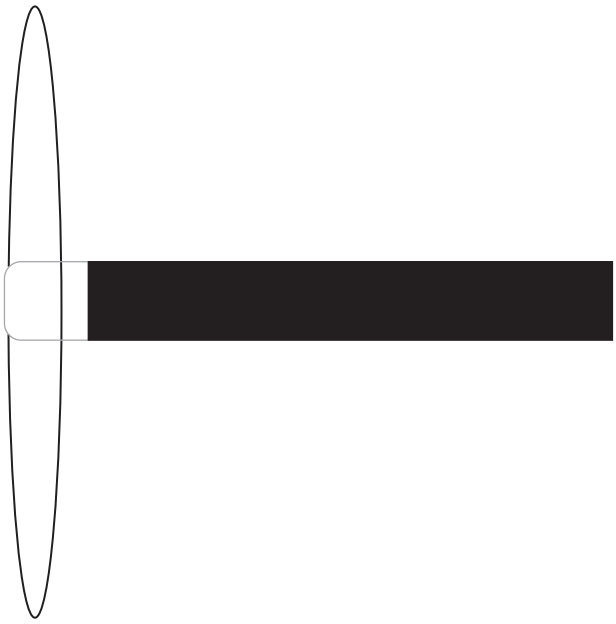

FIGURE 1 Diagram of radial scanning echoendoscope showing the US scanning plane perpendicular to the shaft of the scope. Reproduced with permission from Rosch and Classen (1992).

(Fig. 2) have switchable ultrasound frequencies of 5, 7.5, 12 and 20 MHz. The 360° ultrasound image resembles a computed tomography (CT) scan image.

A transverse array echoendoscope also exists; in this system, an electronic transducer creates a 270° image in a plane that is perpendicular to the shaft of the scope. This instrument has forward-viewing optics and switchable frequencies (5, 7.5, and 10 MHz). Although current

FIGURE 2 The tip of the radial scanning echoendoscope. Courtesy of Olympus America, Inc.

experience with this instrument is limited, it appears to be a promising addition to the EUS armamentarium.

Curved Linear Array Echoendoscopes

The curved linear array (linear) echoendoscope uses an electronic transducer that scans sagitally in a narrow viewing plane that is parallel to the shaft of the scope (Fig. 3). The major advantage of the linear scanner is the ability to perform fine needle aspiration (FNA). The needle exits the scope in the ultrasound plane, therefore it can be sonographically visualized as it is advanced into a target lesion. Additionally, the linear scanner has Doppler capability so that vascular structures can be identified and avoided during FNA. Two linear echoendoscope models are available; one with switchable frequencies between 5 and 7.5 MHz and a 120° scanning angle (Fig. 4), and one with switchable frequencies between 5, 7.5, and 10 MHz and a 180° scanning angle (Fig. 5).

Miniprobes

Specialized high-frequency radial "miniprobes" are available; these can be passed through the operating channel of a standard endoscope to provide detailed imaging of mucosal and other superficial lesions. Available frequencies range from 12 to 30 MHz.

EUS PROCEDURE

In the vast majority of cases, EUS is performed as an outpatient procedure using conscious sedation. If a patient cannot be adequately sedated, then general anesthesia is required to perform the exam. Depending on the indication, the duration of the exam can range from 10 to 90 minutes. The echoendoscope is introduced through the mouth or anus and is maneuvered to the area of interest. By positioning the ultrasound transducer in certain locations within the digestive tract, particular organs or structures may be viewed in great detail. As sound waves are reflected by air, excess air within the gut lumen is continuously suctioned through the scope. As previously mentioned, a small balloon surrounds the transducer to allow for creation of a water bath to enhance acoustic coupling. Additionally, water can be instilled into the gut lumen to decrease air artifact and enhance imaging.

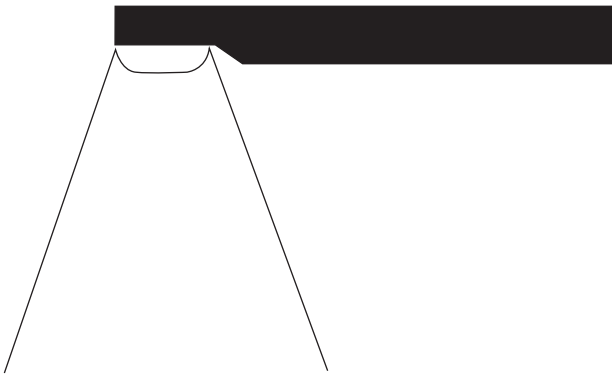

FIGURE 3 Diagram of the linear array echoendoscope showing the US scanning plane parallel to the shaft of the scope. Reproduced with permission from Rosch and Classen (1992).

FIGURE 4 Tip of a linear array echoendoscope with FNA needle. Courtesy of Pentax Precision Instruments, Inc.

EUS-GUIDED FINE NEEDLE ASPIRATION

Utilizing linear array echoendoscopes, FNA can be performed under real-time ultrasound guidance. Needle devices (19, 22, or 25 gauge) can be passed down the operating channel of the echoendoscope, and when an abnormality has been targeted, the needle can be advanced through the gut wall and into the lesion under constant ultrasound guidance. Doppler analysis is employed to ensure that the path of the needle is clear of intervening blood vessels. Once the needle is in position, suction is applied and the needle is moved to and fro within the lesion to obtain a cytologic sample. Slides are prepared within the endoscopy room, and a cytologist provides immediate feedback on the sample. In clinical practice, one to seven biopsies may be performed to obtain the diagnosis. Both solid and cystic lesions can be aspirated; cyst fluid is generally sent for tumor marker analysis in addition to cytology.

FIGURE 5 Tip of a linear array echoendoscope with a stent protruding from the operating channel. Courtesy of Olympus America, Inc.

The overall diagnostic yield for EUS-guided FNA is 77%. The complication rate (significant bleeding) associated with this technique is 1–2%.

INDICATIONS FOR EUS

EUS is most commonly performed to diagnose and stage malignancies of the gastrointestinal (GI) tract. However, indications for this sophisticated procedure continue to expand with improvement in technology. Listed in Table I are the more common indications for EUS.

Staging of Gastrointestinal Malignancies

The gastrointestinal wall is viewed in great detail as a five- layer structure (Fig. 6), with the EUS layers corresponding to the histopathologic layers of the gut wall. The ability to obtain such detailed wall layer imaging has made EUS the most accurate staging modality for several GI malignancies. Cancer survival correlates with the stage of disease, and accurate staging directly guides treatment, be it minimally invasive endoscopic therapy, surgery with/without chemoradiation, or palliation alone. The information obtained by EUS serves as a cornerstone for this decision process.

TABLE I Indications for Endoscopic Ultrasound[a]

Staging of esophageal, gastric, and rectal cancer
Evaluation of abnormalities of the gastrointestinal wall or adjacent structures (submucosal masses, extrinsic compression)
Evaluation of thickened gastric folds
Diagnosis (FNA) and staging of pancreatic cancer
Evaluation of pancreatic abnormalities (suspected masses, cystic lesions including pseudocysts, suspected chronic pancreatitis)
Staging of ampullary neoplasms
Diagnosis and staging of cholangiocarcinoma
Evaluation of suspected choledocholithiasis
Celiac plexus neurolysis for chronic pain due to intraabdominal malignancy or chronic pancreatitis
Staging of non-small-cell lung cancer (subcarinal and posterior mediastinal lymph nodes)
Evaluation/diagnosis of posterior mediastinal masses

[a] Courtesy of the *North Carolina Medical Journal*.

The tumor/node/metastasis (TNM) staging system is universally employed for cancer staging; tumor staging (T stage) for luminal malignancies generally consists of four different stages: T1, tumor extension limited to the mucosa or submucosa; T2, tumor invades the muscularis propria, but does not extend into the adventitia or serosa; T3, tumor invades through the muscularis propria into the adventitia or serosa; and T4, tumor invades adjacent organs or major blood vessels.

Nodal (N) staging is represented by the presence (N1) or absence (N0) of lymph node metastases. EUS criteria have been developed to suggest malignant lymphadenopathy: (1) size greater than 1 cm, (2) round or oval shape, (3) hypoechoic echo pattern, and (4) well-demarcated borders. If all four criteria are met, accuracy rates for predicting lymph node metastasis range from 70 to 80%. CT scanning is capable only of evaluating lymph node size. EUS-guided FNA of suspicious nodes further increases the accuracy to approximately 90%.

Esophageal Cancer

EUS is the most accurate modality to determine the locoregional stage of esophageal cancer. Because it is the only modality that can actually delineate gut wall layers, it can determine local tumor extension (T stage) with an accuracy ranging from 76 to 89%. Node stage accuracy is 72–80% for EUS using the established criteria. In comparison, the accuracy of computed tomography for locoregional staging of esophageal cancer ranges from 50 to 60% (T stage) and 45 to 60% (N stage). Computed tomography still remains invaluable as a staging modality, and should be the first study performed after diagnosis to rule out distant metastases, the presence of which significantly changes management. Because EUS has only limited depth penetration, it frequently cannot determine the presence of distant metastases. Many large centers are now using neoadjuvant chemoradiation for the treatment of locally advanced esophageal cancer. This decision is directly influenced by EUS evaluation.

Gastric Cancer

Surgical resection is the main treatment for gastric cancer. Disease stage still reflects survival, and

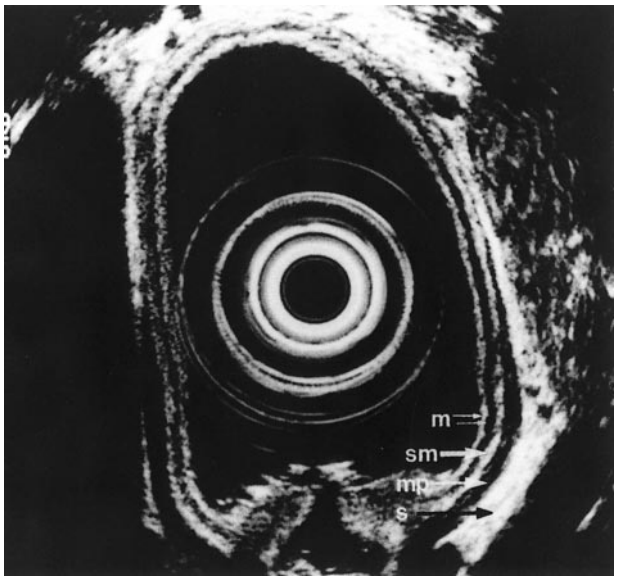

FIGURE 6 Radial image of the normal five-layer structure of the GI tract wall. Layer 1, superficial mucosa (m); layer 2, deep mucosa (m); layer 3, submucosa (sm); layer 4, muscularis propria (mp); and layer 5, serosa/adventitia (s). Reprinted courtesy of the *North Carolina Medical Journal*.

historically, adjuvant chemotherapy has not improved survival in gastric cancer. A new study has suggested a modest survival benefit using chemotherapy in a neoadjuvant fashion. EUS again remains a valuable tool in guiding treatment decisions, specifically in the setting of neoadjuvant protocols. Additionally, EUS can guide endoscopic mucosal resection (EMR) of superficial cancers. The accuracy of EUS-determined T (92%) and N (78%) stages is superior to that of CT scanning (42 and 48%, respectively).

Rectal Cancer

Patients with locally advanced rectal cancer ($\geq$T3, or N1 disease) are best treated with neoadjuvant chemoradiation prior to surgical resection. Given the detailed wall layer imaging achieved, EUS is well suited for the staging of rectal cancer. The accuracy of T and N staging is 84 and 84%, respectively. For superficial tumors (T1) without evidence of nodal disease, EUS can direct transanal excision or endoscopic resection. EUS does not play a role in colon cancer staging. There is little impact on therapy, because treatment of colon cancer is surgical resection with possible adjuvant chemotherapy pending the pathologic stage.

Evaluation of the Pancreaticobiliary System

Originally developed more than 20 years ago to better image the pancreas, EUS has had a tremendous impact on the diagnosis and evaluation of pancreatic pathology. Given the anatomic relationships, placement of the transducer within the duodenum and stomach allows for detailed imaging of the pancreas and bile duct.

Pancreatic Cancer

EUS provides highly accurate staging information in the evaluation of pancreatic cancer. In the absence of distant metastases, EUS is used to assess resectability based on local vascular invasion. EUS has an accuracy rate on the order of 80–95% and 65–85% for T and N staging of pancreatic cancer, respectively. New dual-phase helical CT scanning is also quite accurate for tumor and nodal staging (86 and 77%, respectively). A major advantage of EUS is the ability to accurately stage and diagnose via FNA a pancreatic mass in a single procedure. Accuracy rates for EUS-guided FNA of pancreatic masses range between 85 and 95%. EUS is also more sensitive in detecting small pancreatic tumors $<$2 cm in size, which can be missed by CT.

EUS-guided FNA offers several advantages over percutaneous CT-guided biopsies. These include shorter needle tracks (with less concern for peritoneal seeding), smaller diameter needles, use of real-time color Doppler analysis to avoid blood vessels, and better access to

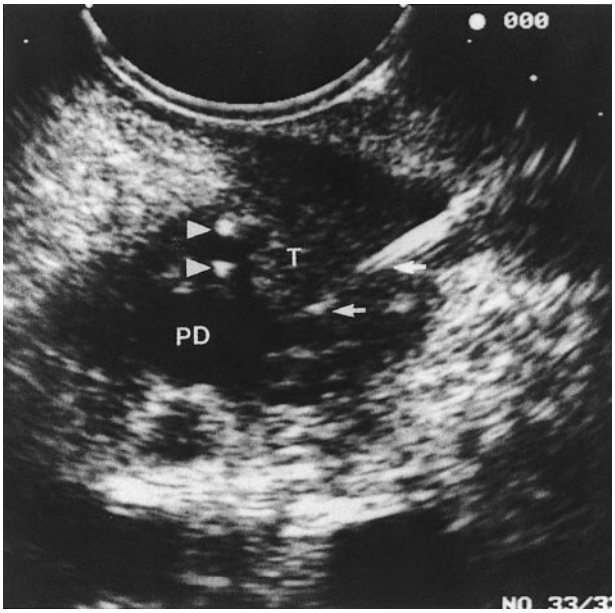

FIGURE 7 Linear image of a small 2-cm hypoechoic tumor (T) in the head of the pancreas. A biliary stent (white arrowheads) is in the common bile duct, above a dilated pancreatic duct (PD). Fine-needle aspiration reveals adenocarcinoma (white arrows, the needle tip). Reprinted courtesy of the *North Carolina Medical Journal*.

smaller lesions (Fig 7). Additionally, small hepatic metastases that may have been missed by CT can be detected by EUS.

Neuroendocrine Tumors

Given its ability to detect small pancreatic lesions, EUS is perhaps the most sensitive modality to localize neuroendocrine tumors of the pancreas. Sensitivity for detection of islet cell tumors ranges between 79 and 93%. Additionally, simultaneous FNA can be performed for definitive diagnosis.

Cystic Lesions of the Pancreas

Pancreatic cysts are rare, but they are being discovered more frequently due to increased utilization of CT. On discovery, anxiety generally mounts due to the possibility of a premalignant cystic neoplasm. Previously, the patient could be offered surgical resection or radiologic surveillance. Now, EUS is very helpful in characterizing pancreatic cystic lesions, because morphologic detail can be assessed and cyst fluid can be aspirated for cytology and tumor markers. Cyst infection is a potential risk, and prophylactic antibiotics are warranted.

EUS evaluation of pancreatic pseudocysts is helpful in guiding endoscopic drainage. The gastric wall can be surveyed and marked for cyst gastrostomy. EUS guidance can lower the risk of transgastric stent placement, because blood vessels can be avoided.

Chronic Pancreatitis

The diagnosis of chronic pancreatitis is obvious in the setting of parenchymal calcifications or intraductal stones as seen on abdominal radiograph, CT, or endoscopic retrograde cholangiopancreatography (ERCP). These findings are also easily seen on EUS. However, there are patients with symptomatology suggestive of chronic pancreatitis, yet imaging modalities are normal or nondiagnostic. This cohort of patients may have early or minimal-change chronic pancreatitis. EUS can accurately assess for subtle parenchymal and ductal changes in these patients. Defined EUS criteria, which have been correlated to excised pathologic specimens, exist for the diagnosis of chronic pancreatitis. Histologic confirmation is the gold standard for the diagnosis of chronic pancreatitis, and new needle systems are being developed that will allow for a core pancreatic biopsy via EUS guidance.

Choledocholithiasis

EUS is an excellent modality to visualize the biliary tract, given the proximity to the duodenal bulb. EUS is superior in the detection of common bile duct stones (choledocholithiasis) as compared to CT and transabdominal US. This is particularly true in patients with small stones and normal-caliber bile ducts. The sensitivity for the detection of bile duct stones is equivalent to that of endoscopic retrograde cholangiopancreatography (95%). Given the risk of pancreatitis associated with ERCP, EUS can be helpful in evaluating patients in whom there is a low suspicion for choledocholithiasis. It is useful in evaluating pregnant patients with suspected bile duct stones, because unnecessary fetal exposure to radiation can be avoided. EUS cannot replace ERCP as the test of choice in patients with a high suspicion of choledocholithiasis, because ERCP can offer therapeutic removal of the stone.

Celiac Plexus Neurolysis

Celiac plexus neurolysis is a therapeutic application of EUS. The celiac plexus cannot actually be visualized by EUS, but its ganglia straddle the celiac trunk. Given the ability to visualize the takeoff of the celiac trunk from the aorta, anesthetic or neurolytic agents can be injected with excellent localization and, therefore, minimal morbidity (Fig. 8). Injection of absolute alcohol has proved effect in relieving the pain associated with pancreatic cancer. Temporary blocks using anesthetics and steroids have been performed to decrease pain caused by chronic pancreatitis. Results have been less promising,

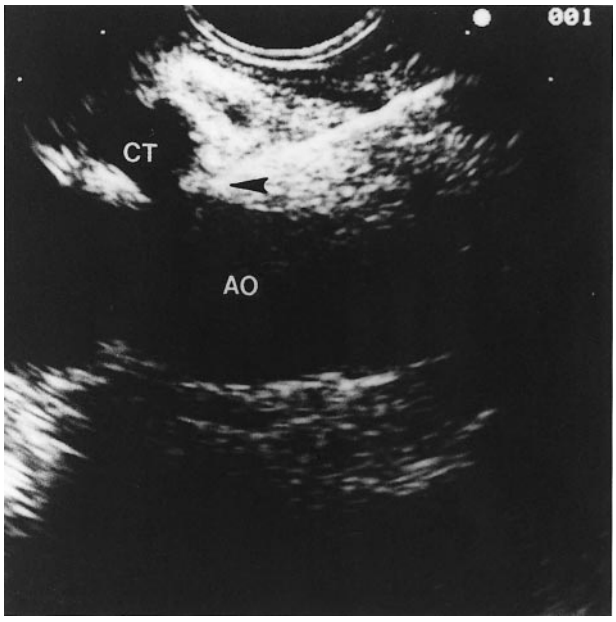

FIGURE 8 Linear image representing celiac plexus neurolysis in a patient with intractable pain from pancreatic cancer. The needle tip (arrowhead) is seen at the takeoff of the celiac trunk (CT) from the aorta (AO). Reprinted courtesy of the *North Carolina Medical Journal*.

but approximately 50% of patients do experience transient improvement in their pain.

Intramural Tumors and Extrinsic Compression

EUS can accurately distinguish between intramural masses and extrinsic compression in the GI tract. Intramural masses such as cysts, lipomas, and stromal cell tumors have defining echo characteristics and arise from characteristic gut wall layers. Foregut duplication cysts appear as anechoic submucosal cysts, whereas lipomas image as hyperechoic submucosal masses. These are both benign entities. Gastrointestinal stromal cell tumors (GISTs) are hypoechoic and arise from the muscularis propria (Fig. 9). Defined EUS criteria that raise suspicion for malignancy can guide recommendations for surgical resection. Extrinsic compression of the GI lumen can result from normal organs (liver, spleen), adjacent tumors, or cysts.

Lung Cancer Staging

The staging of non-small-cell lung cancer is an indication for which EUS and FNA have proved very useful. EUS is an excellent modality for imaging the posterior mediastinum, therefore enlarged lymph nodes can easily be sampled. The accuracy of diagnosing malignant mediastinal lymph node involvement for CT- and EUS-guided FNA ranges from 49 to 74% and 96 to 100%, respectively. EUS is able preferentially to access the aortopulmonary (AP) window and subcarinal space (American Thoracic Society stations 5 and 7). These are the two most difficult stations to access with mediastinoscopy. EUS-guided FNA is most helpful in the preoperative evaluation of patients with suspicious contralateral mediastinal or bulky subcarinal lymph nodes, because malignant involvement drastically alters management (Fig. 10). Some centers now consider EUS-guided FNA as the technique of choice for sampling the subcarinal space and AP window. Routinely, the left adrenal gland is sought when staging lung cancer, and adrenal metastases have been diagnosed via EUS-guided FNA.

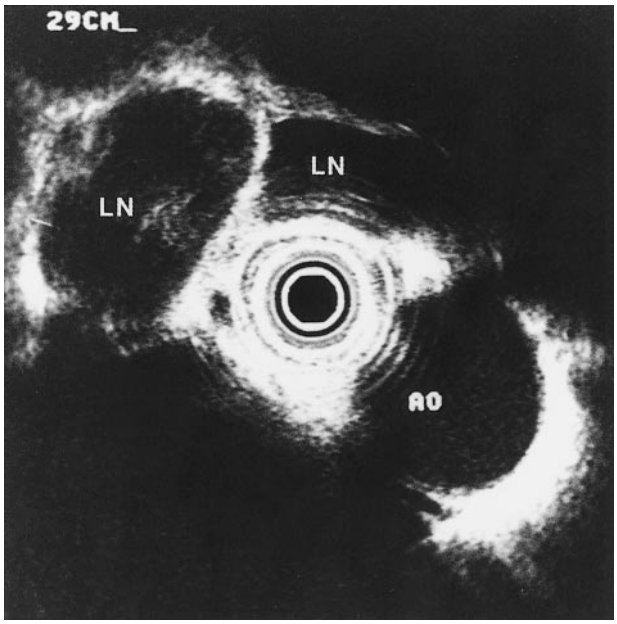

FIGURE 10 Radial image of two bulky subcarinal lymph nodes (LN) in a patient with non-small-cell lung cancer (AO, aorta). Reprinted courtesy of the *North Carolina Medical Journal*.

Evaluation of Mediastinal Masses

Mediastinal masses can be evaluated with EUS, given the fact that the esophagus traverses the mediastinum. Posterior mediastinal masses are most easily seen, because tracheal air artifact can obscure imaging of superior and anterior mediastinal tumors. Posterior mediastinal masses are amenable to EUS-guided FNA, with an accuracy rate for a cytologic diagnosis of 83–89%. As an outpatient procedure, this takes 20 to 30 minutes and requires conscious sedation only. It is a cost-effective and minimally invasive alternative to mediastinoscopy for posterior mediastinal mass evaluation.

LIMITATIONS OF EUS

Endoscopic ultrasound is not without its limitations. Understaging of malignancies can occur due to microscopic invasion that is not apparent on EUS examination. Perhaps the biggest drawback of EUS is the inability, based on imaging alone, to distinguish between benign and malignant tissues, therefore overstaging due to peritumor inflammation can occur.

EUS and EUS-guided FNA are technically challenging procedures that are operator dependent. Advanced training in EUS is a requirement for proficiency in performing this procedure. Additionally, the equipment is quite costly, therefore, at this juncture, EUS tends to be limited to academic medical centers.

SUMMARY

EUS has rapidly emerged as a valuable asset to the practice of gastroenterology. EUS accurately stages GI malignancies, evaluates intramural tumors, and diagnoses pancreatic cancer via FNA. Essentially, any mass lesion in close proximity to the reach of the echoendoscope can be biopsied for diagnostic purposes. Interventional EUS currently incorporates celiac plexus neurolysis and cyst gastrostomy, but this field will likely expand in the future to include EUS-guided radiofrequency ablation and injection therapy (chemotherapy, attenuated viruses) for the treatment of gastrointestinal malignancies.

Endoscopy, Complications of

MICHAEL F. BYRNE, ROBERT M. MITCHELL, AND JOHN BAILLIE
Duke University Medical Center

colonoscopy A flexible video (or fiber-optic) endoscopy that allows direct visualization of the lining of the rectum and colon.

endoscopic retrograde cholangiopancreatography (ERCP) An endoscopic procedure that permits detailed radiological imaging of the pancreaticobiliary ductal system. One can also perform interventional procedures during ERCP such as removal of stones, placement of stents, and tissue sampling.

endoscopic ultrasound An endoscopic technique that utilizes an endoscope with an ultrasound probe at its tip. This allows the physician to see beyond the endoscopic image provided by standard endoscopes. It is particularly useful for cancer staging.

esophagogastroduodenoscopy A flexible video (or fiber-optic) endoscopy that allows direct visualization of the lining of the esophagus, stomach, and proximal duodenum.

pancreatitis An inflammatory process in which pancreatic enzymes autodigest the gland. It is a well-described complication of endoscopic retrograde cholangiopancreatography.

percutaneous endoscopic gastrostomy (PEG) An endoscopic procedure during which a feeding tube is placed between the stomach and the anterior abdominal wall to allow for direct feeding into the stomach. The most common indications for PEG tube placement are neurologic conditions associated with impaired swallowing and neoplasms of the oropharynx, larynx, and esophagus.

polypectomy A procedure used to remove a polyp(s). If polyps are detected during endoscopy, these will be removed by passing a snare or biopsy forceps through the endoscope and severing the attachment of the polyp from the intestinal wall, sometimes with the use of cautery.

There is a risk of complication with any endoscopic procedure, many of which are inherent to the techniques used. It is critical that endoscopists be aware of the potential complications with each endoscopic procedure performed, that they know how to limit the chance of such complications occurring, and that they recognize and treat complications when they arise. In this article, some general complications applicable to all gastrointestinal endoscopy are described. This is followed by a more detailed overview of the risks associated with diagnostic and therapeutic upper gastrointestinal endoscopy, colonoscopy, endoscopic retrograde cholangiopancreatography, and endoscopic ultrasound.

GENERAL COMPLICATIONS

Complications of Conscious Sedation

Gastrointestinal (GI) endoscopy is performed under conscious sedation in the United States and many parts of Europe. The most common practice is to use intravenous doses of benzodiazepines, usually midazolam, and opiates such as meperidine (demerol) or fentanyl. However, morbidity rates of 1:200 to 1:2000, and occasional mortality, usually due to cardiorespiratory complications, have been reported using these agents. Thus, the American Society of Anesthesiologists (ASA) and the American Society of Gastrointestinal Endoscopy (ASGE) devised more formal practice guidelines for conscious sedation that included the use of supplemental oxygen and revised dosing guidelines recommending titration of sedative medications rather than bolus doses.

Midazolam is a good agent to use for endoscopy as it has both anxiolytic and amnestic effects, but its use also results in residual sedative effects and anterograde amnesia. Propofol (2,6-diisopropyl phenol), an intravenous anesthetic agent often used with other agents for delivery of general anesthesia, can be used in lower doses to induce conscious sedation. For this latter indication, propofol has some advantages over benzodiazepines and opiates such as shorter half-life and quicker hepatic clearance, resulting in quicker recovery from sedation and less hangover effects. However, there is significant debate regarding the safety of propofol use by personnel who are not anesthesiologists. For example, significant respiratory depression can occur during propofol-induced conscious sedation and one can inhibit the gag and cough reflexes at higher doses. It is also important to be aware that, unlike the benzodiazepines, propofol has no specific antagonist that can be employed to reverse its effects.

In general, whichever conscious sedation protocol is used, one needs to be aware of the risk of respiratory depression, aspiration, hypotension, paradoxical

 Copyright 2004, Elsevier (USA). All rights reserved.

agitation, and anaphylaxis. Special care should be taken in the very young and elderly.

Cardiopulmonary Complications during Endoscopy

Most of the cardiopulmonary complications during endoscopy are medication related, as described above. However, some of these complications can be attributed to vagal- or sympathetic-mediated changes associated with endoscopy. Simple arrhythmias, such as sinus tachycardia, and transient hypoxia are common during endoscopy. Current guidelines recommend that supplemental oxygen and pulse oximetry are used throughout endoscopy. It has also been suggested by some that capnography be used to detect early respiratory depression, especially if propofol is used, but the place of capnography in endoscopic practice remains to be determined. Cardiac ischemia is rare after endoscopy and recent myocardial infarction is not a contraindication to endoscopy. However, one should consider each such case individually. Tachydysrhythmias and heart block should be treated before endoscopy, whenever possible.

Complications of Topical Oropharyngeal Medication

Topical oropharyngeal anesthesia is used routinely by many endoscopists for upper GI endoscopy. Topical lignocaine and benzocaine are used most commonly and usually are safe. However, topical anesthesia can increase the risk of aspiration as the gag reflex is suppressed. One needs to be aware of this, particularly if there are significant amounts of blood or food in the stomach. In addition, there have been a limited number of reports of methemoglobinemia induced by topical anesthesia, a condition treated by use of supplemental oxygen and intravenous methylene blue.

Consent

Commonly occurring complications of endoscopy should be discussed with the patient prior to endoscopy when gaining informed consent.

Infection—General Comments

Infectious complications of endoscopy can result from the procedure itself or from contaminated equipment. Risk of infection is higher with particular endoscopic techniques, particularly therapeutic procedures, and this is discussed in the relevant sections below. Transient bacteremia may occur after endoscopic procedures but the risk of infective endocarditis or other infectious complications is low. ASGE guidelines for the use of antibiotic prophylaxis for endoscopy include high-risk patients (such as those with prosthetic heart valves, synthetic vascular grafts, history of endocarditis) undergoing high-risk procedures [such as sclerotherapy, stricture dilation, or endoscopic retrograde cholangiopancreatography (ERCP) in the setting of biliary obstruction]. It also appears that transmission of infection from the endoscope to the patient is rare. This is a concern, especially in the era of human immunodeficiency virus, hepatitis C, and other viruses. However, although iatrogenic infection transmitted by endoscope has been shown for several bacteria, including *Pseudomonas, Salmonella,* and *Helicobacter pylori*, there is little convincing evidence of viral transmission. If published guidelines on cleaning and disinfection of endoscopic equipment are followed, the risk of infection is low.

UPPER GASTROINTESTINAL ENDOSCOPY

Diagnostic upper GI endoscopy is very safe, with an overall complication rate of less than 0.1%. However, although rare, aspiration and perforation during upper GI endoscopy can be fatal. Most of the complications associated with upper GI endoscopy result from intervention.

Perforation

This is a rare but potentially serious complication of diagnostic upper GI endoscopy. Perforation rates are as low as 1 in 5000. Perforation is particularly concerning in the debilitated and elderly. It is more common in the presence of certain predisposing factors such as Zencker's diverticulum, esophageal stricture and malignancy, and anterior cervical osteophytes. Perforation of the esophagus has a particularly high mortality, at approximately 25% overall, with mortality higher for perforation of the intrathoracic esophagus. Perforation in the cervical esophagus is more common with rigid esophagoscopy. Upper gastrointestinal perforations present with pain and one or more of the following symptoms: pleuritic chest pain, leukocytosis, fever, and surgical emphysema. Any perforation related to endoscopy is best managed in cooperation with surgeons.

Bleeding

Significant bleeding is a rare complication of diagnostic upper GI endoscopy, even in the setting of

coagulopathy or thrombocytopenia. However, significant coagulopathy and severe thrombocytopenia should be corrected before biopsies are taken. Mallory–Weiss tears occur rarely (<0.01%) during routine upper endoscopy and are usually related to struggling and retching during the procedure.

Complications of Hemostatic Procedures

Injection Therapy

Epinephrine, at a dilution of 1:10,000, is the most commonly used injection agent for the treatment of bleeding peptic ulcers. This is a safe practice overall, with no reports of perforation but tissue necrosis and ulceration at the site of injection may occur. Epinephrine injection directly into a blood vessel can cause transient tachycardia, which usually resolves within 30–60 s. The risk of complications is higher if sclerosants are used but this practice is becoming less common.

Thermal Hemostasis

Hemostasis of bleeding peptic lesions can be achieved using thermal methods such as bipolar or multipolar electrocoagulation or the heater probe. These are fairly safe hemostatic methods as the low-powered thermal energy causes tissue desiccation rather than vaporization. For example, the perforation rate for multipolar electrocoagulation is reported to be between 0 and 2%. Bleeding may also occur during delivery of therapy, but this is rarely significant. Another problem with these probes is tissue sticking as coagulum builds up. Repeated cleaning by removal of the probe or with the water jet may be necessary; this probably lessens the chance of posttreatment bleeding as the probe does not adhere to the treatment site. Repeat thermocoagulation within 24–48 h may be associated with an increased perforation rate and is best avoided.

Laser Hemostasis

Delivery of heat to a site of bleeding or potential bleeding by the Nd:YAG laser causes tissue erosion. Theoretically, this should result in a higher rate of perforation than for the other thermal methods described above, but this does not appear to translate into significant risk in clinical practice.

Treatment of Varices

The two main techniques for treatment of esophageal varices are endoscopic sclerotherapy and banding. Sclerotherapy has an overall significant complication rate between 20 and 40%, with a mortality of up to 2%. Risks of sclerotherapy include esophageal perforation, ulceration, stricture, and motility disturbances. Less common complications include spinal cord paralysis, pneumothorax, bacteremia, and pleural effusion. If sclerotherapy is performed, a second session should not be performed earlier than 7 days after initial treatment, as this appears to lessen the risk of ulceration. The recent literature favors the use of band ligation on grounds of clinical efficacy and safety. The overall complication rate for banding is approximately half that of sclerotherapy. In particular, the rate of stricture formation and ulceration is much lower with banding.

Complications of Dilation Procedures

Esophageal dilation is relatively safe but can be complicated by perforation. Overall, the risk of perforation is less than 1%, but the rate depends upon whether dilation is performed for benign strictures, malignant strictures, or achalasia. For dilation of benign esophageal strictures, there appears to be no difference in the rate of perforation whether balloon dilators or wire-guided polyvinyl dilators (such as Savary-Gilliard) are used; blind use of Maloney dilators does increase the risk of perforation and this practice should be discouraged. For achalasia, the risk of perforation after pneumatic balloon dilation is approximately 5%, although there is evidence that a graded-dilation technique may limit this risk. Dilation of malignant strictures results in perforation in perhaps up to 10% of cases.

For patients with pyloric outlet obstruction caused by benign pyloric stenosis, balloon dilation carries a perforation rate between 0 and 6% and is comparable in safety to wire-guided push-type dilators. However, a high stenosis recurrence rate suggests that this procedure should be reserved for patients of high surgical risk.

Esophageal Stenting

This procedure is performed for palliation of malignant strictures. Originally, use of rigid Silastic plastic stents resulted in a complication rate of approximately 20%, with risk of bleeding, perforation, tumor ingrowth, and stent migration. These risks are significantly less with the more recent practice of using expandable metal stents.

Treatment of Esophageal Malignancies

There are several endoscopic options for debulking esophageal tumors. Injection with sclerosants such as 95% ethanol using a sclerotherapy needle is effective but there is a risk of extensive tissue necrosis, predisposing to perforation and mediastinitis. This is more

likely with injections over 10 ml in volume. All of the thermal energy delivery methods described above for treatment of hemostasis (heater probe, bipolar/multipolar coagulation, and laser therapy) have been used for tumor ablation; it is reported that perforation and fistula development may occur in up to 10% of cases. Photodynamic therapy (PDT) is a technique that is being used in both tumor destruction and ablation of Barrett's mucosa. In theory, targeted tumor therapy is achieved using PDT as malignant tissue preferentially concentrates the photosensitizer given prior to treatment. However, perforation, bleeding, fistula, and stricture development have all been reported with this technique. Patients should be warned about the risk of cutaneous photosensitivity after ingesting photosensitizers.

Foreign Body Retrieval

Food boluses that become impacted in the esophagus can often be gently pushed into the stomach using the tip of the endoscope, but sometimes they must be removed. A particular concern is loss of the bolus in the region of the larynx. Use of an overtube limits the risk of aspiration, but carries a risk of perforation and bleeding. Papain-based enzyme preparations to tenderize meat boluses can result in severe pulmonary complications and should never be used. Sharp objects should be removed using an overtube or a sleeve over the end of the endoscope. Irregular, hard, or sharp foreign bodies (e.g., dental plate) should be removed by rigid esophagoscopy, usually under general anesthesia, otherwise there is a significant risk of perforation and bleeding on foreign body removal. One should also resist the temptation to attempt endoscopic removal of condoms or plastic bags containing narcotics, as these are easily ruptured with disastrous consequences. Surgical removal is the only safe option.

Percutaneous Endoscopic Gastrostomy

Percutaneous endoscopic gastrostomy (PEG) is a technique used increasingly for the delivery of nutritional support to a range of patients. It is an excellent feeding option in many neurological conditions and also allows bowel decompression proximal to any malignant intestinal obstruction. However, major complications are reported in 2.7% of cases and minor complications in up to 7% of cases. The mortality rate for this procedure is approximately 0.7%.

The major complications of PEG tube placement include perforation, aspiration, hemorrhage, peritonitis, and gastrocolic fistula. Aspiration is the most commonly reported PEG complication, probably due to the underlying neurological defect with poor or absent oropharyngeal reflexes, delayed gastric emptying, and reflux of feeds. Taking certain feeding precautions, such as elevation of the head during feeding, will limit the risk of aspiration. Peritonitis can occur if the gastrostomy tube becomes dislodged, if there is an unrecognized perforation, or if there is leakage of stomach contents into the peritoneal cavity around the stoma site. A through-the-tube water-soluble contrast study will aid in the diagnosis and management of PEG tube leaks. Potential infectious complications of PEG tube placement include wound infection and necrotizing fasciitis. Use of prophylactic antibiotics significantly reduces the risk of stomal infections. Necrotizing fasciitis is a concern in patients with diabetes mellitus, alcoholism, malnutrition, and those who are immunosuppressed. Occasionally, one may puncture the colon during PEG tube placement, if there is a loop of colon anterior to the stomach, resulting in a gastrocolocutaneous fistula. Migration of the feeding tube and impaction in the abdominal wall ("buried bumper syndrome") can occur if there is significant traction on the internal bumper, resulting in mucosal ulceration and eventual erosion through the mucosa. Once the fistulous tract is mature, loosening of the external bumper will help prevent this complication. There have been reports of development of metastases at the PEG insertion site, raising concern that placement of a PEG tube using the oropharyngeal route in patients with oropharyngeal cancers may facilitate metastasis. A direct introducer method may be preferable in these cases, if the primary tumor cannot be removed.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Endoscopic retrograde cholangiopancreatography carries many of the risks associated with all endoscopic techniques as well as having complications particular to this technique. Risks specific to instrumentation of the pancreaticobiliary system include pancreatitis, cholangitis, bleeding, retroduodenal perforation, and stent dysfunction.

Pancreatitis

The serum amylase level is elevated in up to 50% or more of asymptomatic patients after ERCP, but the clinical syndrome of post-ERCP pancreatitis occurs in only 3–10% of cases on average. In the majority of cases, post-ERCP pancreatitis is mild and self-limiting but it can be severe (Fig. 1) and occasionally fatal. Factors that appear to increase the risk of pancreatitis include

FIGURE 1 CT scan of the abdomen showing severe post-ERCP pancreatitis.

overfilling or acinarization of the pancreatic parenchyma, multiple cannulations of the pancreatic duct, endoscopic sphincterotomy, and manometry (risk of pancreatitis as high as 20%). Measures that show promise in preventing post-ERCP pancreatitis are still under investigation but there are some encouraging early data regarding the prophylactic use of the protease inhibitor, gabexate (not currently available in the United States), intravenous somatostatin (or its synthetic analogue, octreotide), and interleukin-10, and the placement of pancreatic stents.

Bleeding

Sphincterotomy can cause significant bleeding (Fig. 2). The incidence of complications after sphincterotomy ranges from 5 to 10% (9.8% in the Freeman multicenter study). In particular, uncontrolled (or "zipper") cuts predispose to bleeding. Fortunately, bleeding from a sphincterotomy site is more often venous than arterial. It is rare for a patient to require a blood transfusion after a sphincterotomy bleed, possibly because of the widespread use of blended rather than pure-cut current. If bleeding occurs when the cannulotome is still in the duct, one can often achieve hemostasis with a brief application of coagulation current. If oozing continues, flushing the site with dilute epinephrine solution may arrest bleeding, but injection of epinephrine into the sphincterotomy site may be required. Using an inflated stone-extraction balloon to tamponade the site may also be effective. If bleeding persists and it proves impossible to deliver local therapy, celiac angiography with subsequent embolization of the offending vessel should be performed but, in some cases, surgery is necessary. Delayed bleeding is a rare but potentially serious complication of sphincterotomy, particularly as many patients are discharged home within hours of ERCP. Rarely, ERCP may provoke hemobilia from trauma to friable hilar tumors or a guide-wire penetrating the bile duct wall, creating a biliovenous fistula.

Perforation

Perforation can occur with any endoscopic procedure as described earlier. During ERCP, perforation is associated with sphincterotomy. However, the risk is still low, at less than 1% of sphincterotomies. In this setting, perforations are usually retroduodenal (Fig. 3) but can occasionally communicate with the peritoneal cavity. The risk of perforation is greater the larger the sphincterotomy (Fig. 4) and the more the cut deviates from the axis of the bile duct. The risk of perforation may be even greater if a precut papillotomy is performed.

Retroduodenal perforation may be recognized during the procedure as a diffuse leak of contrast behind the duodenum, but it is not uncommon to miss this at the time of ERCP as they are often small. The radiologic appearances are often subtle. Patients may take several hours or even days to develop abdominal pain, elevated white count, and fever, suggestive of occult sepsis. One should be especially suspicious of perforation if a patient, behaving as if he or she has post-ERCP pancreatitis, has a normal serum amylase. Most retroduodenal

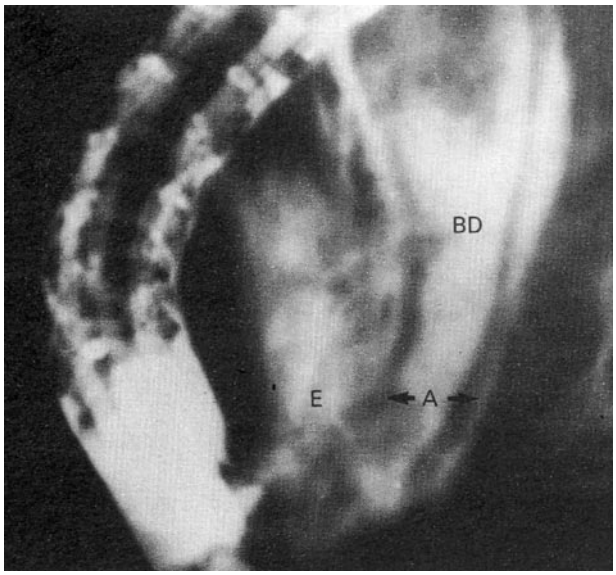

FIGURE 3 A retroperitoneal perforation after endoscopic sphincterotomy. A, air outside the bile duct wall (free air); E, retroduodenal extravasation of contrast; BD, common bile duct containing contrast. Reprinted from Baillie, J. (1992). "Gastrointestinal Endoscopy: Basic Principles and Practice." Butterworth-Heinemann, Oxford, UK, with permission.

perforations can be managed conservatively, although percutaneous or surgical drainage is required if a retroperitoneal abscess develops.

Sepsis

Cholangitis is a particular concern if ERCP is performed in patients with biliary obstruction. Sepsis after ERCP can be fatal. Patients with biliary obstruction should be given broad-spectrum antibiotics prior to instrumentation. The risk of significant post-ERCP sepsis can be decreased by avoiding injection of large volumes of contrast into an obstructed bile duct. Aspirating bile before injecting contrast should be encouraged in all cases. It is critical to relieve biliary obstruction if contrast has been injected, whether that is by removal of stones, stenting in cases of tumor or retained stones, or placement of a nasobiliary drain. If none of these measures is successful, percutaneous or surgical drainage should be performed as soon as practically possible, and certainly within 48 h, or earlier if possible. The patient should be kept on intravenous antibiotics until adequate biliary drainage is achieved.

Pathogenic organisms may be introduced by the unsuspected use of contaminated duodenoscopes and catheters. One should be alerted to this possibility of iatrogenic infection when *Serratia* or *Pseudomonas* species are cultured from bile or blood after ERCP. Thorough disinfection of all instruments used at ERCP and a regular review of infection control practices is indicated. A series of cases involving the same organism in particular raises concern regarding the possibility of endoscope contamination.

Occasionally, patients may develop acute cholecystitis after ERCP. This may occur within the first 10 days or so, but more commonly it is delayed months or even years. Inability of the gallbladder to contract and clear bacteria that reflux into the biliary system after sphincterotomy or stent placement is a possible cause. Standard management of acute cholecystitis should be employed.

Stenting

Polyethylene stents placed during ERCP commonly occlude or kink, causing stent failure. Stent occlusion is felt to be due to clogging with sludge and bacterial infection may play a part in this. In addition, plastic stents occasionally migrate from their original position. Complications such as these result in the need for repeated procedures. Placement of self-expanding metal stents appears to result in fewer stent failures but careful patient selection is critical. Metal stents should only be used to palliate malignant strictures. They are

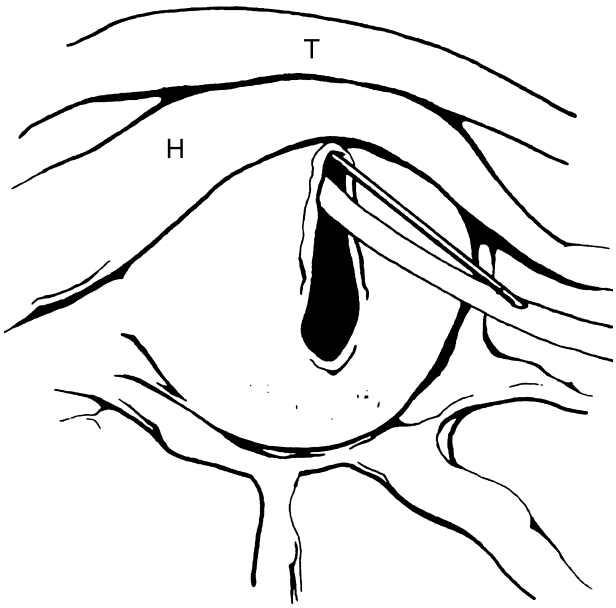

FIGURE 4 Papillotomy in progress. The cut may proceed across the hooding fold (H) but the transverse fold (T) is often the upper limit for a safe papillotomy. Reprinted from Baillie, J. (1992). "Gastrointestinal Endoscopy: Basic Principles and Practice." Butterworth-Heinemann, Oxford, UK, with permission.

cost-effective only if the patient's projected survival is greater than 2 months.

COLONOSCOPY

Overall, colonoscopy carries a complication rate of approximately 0.1%, with a mortality rate between 0.008 and 0.02%. The risk of a complication is increased in the setting of interventional procedures such as polypectomy. The main risks of colonoscopy are bleeding and perforation.

Perforation

This is the most feared of colonoscopic complications. It occurs in approximately 0.05% of examinations. Perforation can be either a mechanical or a pneumatic injury. Significant forces are often exerted on the bowel wall by a colonoscope and occasionally these forces can result in a transmural tear. Advancing the colonoscope forcibly through a loop can overcome the compliance of the colon (Fig. 5). During diagnostic procedures, this most commonly occurs in the rectosigmoid area. The practice of "sliding by" in the sigmoid colon has also been reported to increase the risk of perforation. Mechanical perforation can also occur with use of biopsy forceps (particularly in the cecum) and polypectomy or dilation (see below). Pneumatic perforation is less common than mechanical perforation but can occur (usually on the anti-mesenteric aspect of the colon), especially with excessive insufflation of the colon proximal to a stricture (Fig. 6).

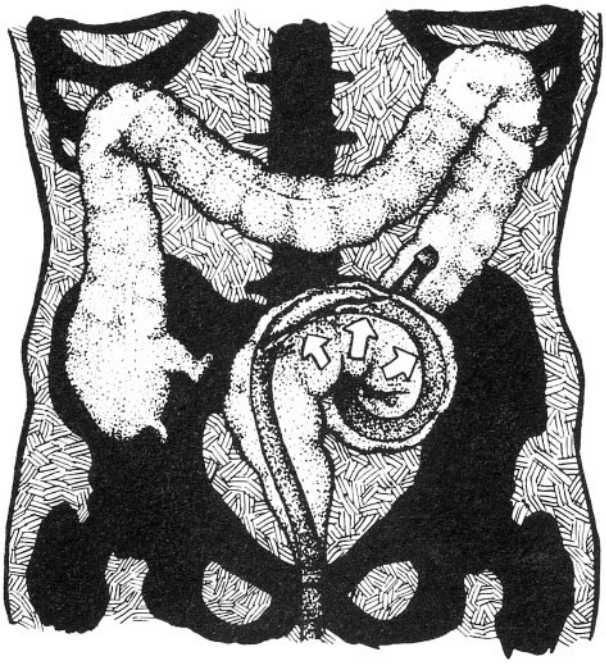

FIGURE 5 Linear tear (perforation) of the sigmoid colon caused by excessive force used to advance through a loop. Reprinted from Baillie, J. (1992). "Gastrointestinal Endoscopy: Basic Principles and Practice." Butterworth-Heinemann, Oxford, UK, with permission.

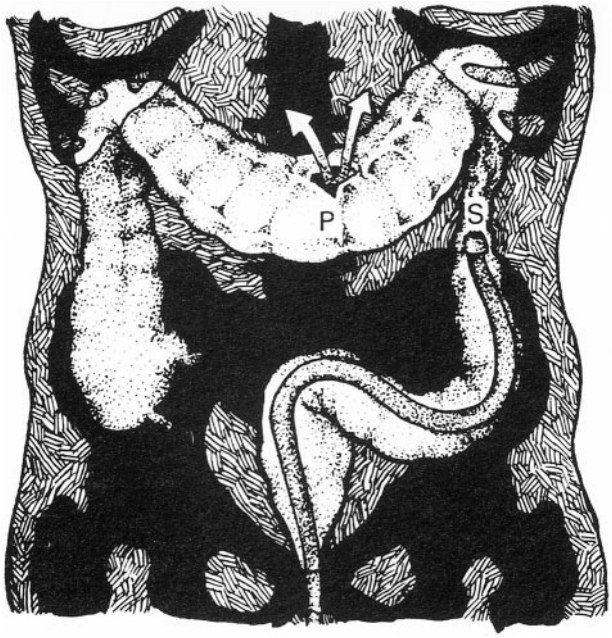

FIGURE 6 Pneumatic perforation of the colon. The site of perforation (P) is proximal to a stricture (S) that cannot be negotiated by the colonoscope. Reprinted from Baillie, J. (1992). "Gastrointestinal Endoscopy: Basic Principles and Practice." Butterworth-Heinemann, Oxford, UK.

Bleeding

Hemorrhage is the most common serious complication of colonoscopy. Hemorrhage occurs in approximately 0.02% of diagnostic colonoscopies, with this figure rising to 1.6% if polypectomy is performed. Bleeding may be immediate or delayed. Immediate bleeding after biopsy or polypectomy usually ceases spontaneously but occasionally, especially after polypectomy has been performed with suboptimal coagulation of the polyp stalk, local measures to arrest bleeding are necessary. These measures include injection of epinephrine, electrocoagulation, or placement of endoscopic clips. More rarely, angiography with embolization or surgery is required to achieve hemostasis. Delayed bleeding (up to 1 month after the procedure) occurs either after sloughing of the eschar formed by coagulation or when the initial mucosal "injury" erodes over time into a deeper blood vessel. Reversal of anticoagulation or correction of a known coagulopathy prior to the procedure will

obviously decrease the incidence of significant bleeding, as will discontinuation of aspirin (ASA) and NSAIDs that impair platelet function. Patients should be advised to avoid ASA and NSAIDs for 7–10 days after colonoscopic polypectomy.

Complications of Bowel Preparation

Poor bowel preparation often leads to inability to reach the cecum or, even if the cecum is reached, poor visualization of the mucosa. Thus, pathology may be missed, repeat examinations may be scheduled at earlier intervals than otherwise planned, and the procedure is more difficult and often more time-consuming to perform. In addition, poor bowel preparation can increase the risk of significant complications. The endoscope may inadvertently be introduced into diverticula obscured by feces. Perforation resulting from this or from other maneuvers has graver consequences in the setting of inadequate bowel preparation, as there is increased risk of peritoneal contamination. A rare complication that should never occur these days is combustion of bowel gases when electrocautery is used in the setting of inadequate bowel preparation (i.e., residual feces).

The two predominant bowel cleansing regimens currently employed involve the use of polyethylene glycol-electrolyte lavage solutions or oral sodium phosphate. Sodium phosphate is the more easily completed preparation and may be preferable in patients without comorbidities such as renal insufficiency or congestive cardiac failure that preclude the safe use of sodium phosphate.

Postpolypectomy Syndromes

Postpolypectomy coagulation syndrome (otherwise known as transmural burn or serositis) presents with abdominal pain, fever, and leukocytosis but no evidence of free perforation. It is more common after removal of sessile rather than pedunculated polyps. It is a reaction to thermal damage to the colonic wall deep to the submucosa; it usually settles spontaneously but keeping the patient nil by mouth and using broad-spectrum antibiotics are recommended measures.

Microperforation of the colon is also recognized as a complication of polypectomy. This is essentially an intermediate between the deep thermal damage as described above and "free" perforation in which there is escape of bowel contents and frank peritonitis. Most cases of microperforation do well with conservative management. If the patient does not improve significantly within 24 h, the possibility of more extensive perforation and the need for surgery should be considered.

Tattooing

There have been some concerns about the safety of injection of India ink to label colonic lesions or polypectomy sites, as it appears to promote histological inflammation. There have been a few reports of abscesses and perforation but, overall, it appears that as long as small volumes of sterile ink are used, colonic tattooing is relatively safe.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) carries the same general risks of all endoscopic procedures such as perforation, bleeding, and sedation reactions. One procedure increasingly used during EUS is that of EUS-guided fine-needle aspiration (FNA). EUS–FNA is usually performed using linear-array echoendoscopes as the whole length of the needle can be seen in real time. EUS-guided FNA using linear array has a complication rate less than 1%. FNA is possible using radial array systems but is technically more difficult, carries a higher complication rate for bleeding and perforation, and is not recommended. A recent study described a low complication rate (0.5%) for FNA of solid lesions but a higher rate of 14% for FNA of cystic lesions, predominantly due to infectious or hemorrhagic events after puncturing cystic lesions. Prophylactic antibiotics should be given for FNA of cystic lesions. The theoretical risk of tumor seeding has not yet been reported.

Another problem with EUS and staging of esophageal cancers arises with advanced and stenotic lesions. It may prove impossible to advance the EUS probe through the stenosis and in this situation some authors have suggested dilating the stricture to allow for EUS evaluation. Although an increased incidence of perforation has been reported, study results vary and it now appears to be safe if general principles of esophageal dilation are applied.

CONCLUSION

There have been a great number of advances in the fields of diagnostic and therapeutic gastrointestinal endoscopy over the last number of years. Although these techniques have contributed greatly to diagnosis and disease treatment, there are attendant complications, some of which are common to all endoscopic techniques and others are associated with particular endoscopic interventions. Undoubtedly, with the advances in interventional EUS, endoscopic fundoplication, and widespread colorectal cancer screening, there will be an increasing number of endoscopies performed.

Being aware of the types of complications that may arise, and their early recognition, is a standard to which all endoscopists should adhere.

disease-specific formula An enteral formula designed to treat a specific disease.

enteral formula The nutrition product delivered via tube into the stomach or intestines. Usually, the formula is synthesized commercially from fixed ingredients. Rarely, the formula may consist of blenderized food.

enteral nutrition The provision of nutrition and nutrients directly by tube into the gastrointestinal tract, bypassing normal eating mechanisms.

immune-enhancing formula An enteral formula with added substrates (often arginine, ω-3 fatty acids, ribonucleic acids, and glutamine). Such formulas are postulated to enhance intestinal immune function.

parenteral nutrition The provision of nutrients directly into the venous side of the vascular system.

predigested formula An enteral formula consisting of amino acids and/or short peptides and/or hydrolyzed protein plus simple sugars plus minimal fat. These products are fiber-free and require less digestion by the gastrointestinal system, but still require intact intestinal absorptive function.

Enteral nutrition is the provision of nutrients directly into the gastrointestinal tract via a tube. As such, it is nonvoluntary, or nonvolitional, and is regarded as a substitute for eating in individuals with functional gastrointestinal tracts, but who cannot eat for a variety of reasons. Many commercial nutritional products are available for gastrointestinal infusion. However, enteral nutrition is an invasive technology associated with a degree of risk.

invasion. Although usually considered equivalent to eating, enteral nutrition differs from simple eating:

- Enteral nutrition bypasses normal eating mechanisms of smell, taste, chewing, and swallowing as well as the cephalic phase of digestion.
- Enteral formulas are usually fixed, defined, and unvaried, as opposed to the wide variety of nutrients in food.
- Enteral feeding is involuntary, or nonvolitional, and often delivered continuously, as opposed to the intermittent and voluntary intake of oral food.
- Enteral nutrition is associated with risks and complications.

This article will focus on tubes and access to the gastrointestinal tract, types of enteral formulas, indications, complications, and drug–formula interactions.

ACCESS AND TUBES

Access into the gastrointestinal tract is generally through the nose or through the abdominal wall. Tubes through the nose may be placed into the stomach (nasogastric) or beyond the pylorus into the proximal small intestine (nasointestinal or nasoenteric). Passage of tubes into the stomach is usually done "blindly." Although intestinal passage may be done blindly at the bedside, more often nasointestinal tubes are passed with the assistance of gastrointestinal endoscopy or fluoroscopy. The use of nasoenteric tubes is somewhat controversial, as it is not clear that the clinical outcome is always enhanced or that complications are prevented. Additionally, nasoenteric passage is more difficult and costly and the tubes often are displaced into the stomach. As opposed to the stiff polyvinyl chloride composition of traditional large-bore (5–6 mm) nasogastric tubes, nasogastric and nasoenteric feeding tubes are usually manufactured from polyurethane and are narrower (2–4 mm), are softer, and have a larger proportional internal diameter. Tubes placed through the abdominal wall may go into the stomach (gastrostomy), through the stomach into the jejunum (jejuno-gastrostomy), or directly into the jejunum (jejunostomy). Currently, the most common technique for direct abdominal wall insertion is via a percutaneous approach using gastroendoscopic guidance. Percutaneous insertion may be achieved also with radiologic guidance. Open or laparoscopic surgical insertion of tubes also occurs. Gastrostomy and jejunostomy tubes are usually of larger diameter (6–10 mm) than nasogastric or nasointestinal tubes, are composed of silicone, and are more flexible. These tubes are designed to be more permanent than those used through the nose, but may deteriorate over time.

ENTERAL FORMULAS

A host of enteral formulas exist. Table I lists important differentiating features that can be used for the selection and administration of enteral feeding products.

INDICATIONS

It is generally assumed that enteral nutrition is the same as eating, but this is not necessarily true, as enteral formulas are not the same as food and delivery may result in complications. Additionally, there are some data indicating that enteral formulas may not have the same effect on gastrointestinal function and structure as real food. Because of the difference between food and enteral formulas and because of the risk involved from inserted tubes, enteral nutrition should be thought of as an invasive medical intervention with potential benefits and risks.

Since prolonged starvation is not considered beneficial, enteral nutrition may be initiated in clinical situations in which normal eating is not possible for at least a week, in which there is possible and safe access to a functional gastrointestinal tract, and in which there is a clinical condition for which prolonged nonvolitional feeding is thought to provide a benefit.

Prospective clinical trials have suggested benefit from enteral nutrition after hip fractures. Enteral nutrition appears to be better than placebo for primary treatment of Crohn's disease (regional enteritis), but is not as good as corticosteroids. Enteral nutrition appears to be associated with less infectious morbidity after acute abdominal trauma and in acute pancreatitis when compared to parenteral intravenous feeding. Nonvolitional enteral feeding with "immune-enhancing" formulas may also result in less infectious morbidity in certain clinical situations. Increasing evidence indicates that gastrostomy feeding provides no benefit for patients with dementia of the Alzheimer's type. Some patients recovering from strokes have enhanced rehabilitation when gastrostomy feeding is added to total care. Gastrostomy or jejunostomy feedings may improve response to therapy in patients with head and neck or esophageal carcinomas and may provide palliation for selected individuals with advanced, but not terminal obstructing cancers.

TABLE I Considerations in Enteral Nutrition Formula Composition

Water	Origin	Macronutrient content	Added substrates	Disease specific[a]
Sufficient free water (1 kcal/cc formulas) vs concentrated formulas with free water removed (1½ −2 kcal/cc)[b]	Blenderized whole food[c] vs defined nutrient substrates	Intact protein vs amino acids and/or peptides[d] Complex carbohydrates vs simple sugars[d] "Normal" fat content vs reduced fat +/− medium-chain triglycerides[d] Lactose-free[e]	Soluble fiber "Immune-enhancing" nutrients: ω-3 fatty acids, RNA, arginine, +/− glu- tamine Modules of protein, carbohydrate, or fat can be added prior to patient administration to increase protein or energy content	Liver Pulmonary Renal Diabetes Critical care

[a] Formula substrates are modified to "treat" various disease states; there is little documentation that these modifications provide clinical benefit.

[b] Free-water-removed formulas may cause dehydration.

[c] Commercial blenderized formulas are rarely utilized.

[d] Formulas with amino acids and/or peptides, simple sugars, and low-fat +/− medium-chain triglycerides are "predigested," in that they do not need normal pancreatic and intestinal digestive processing; however, they still require intact intestinal absorptive function.

[e] Virtually all commercial "nutritionally complete" formulas are lactose-free.

COMPLICATIONS

Complications from nasogastric or nasoenteric feeding tube insertion include the following: inadvertent passage through the tracheobronchial tree into the lungs (resulting in pneumonia, pneumothorax, or hydropneumothorax), esophageal perforation, laryngeal injury, and even cranial insertion. Nasogastric and nasoenteric tubes often "fall" out or are pulled out by patients, resulting in a "nuisance" need to reinsert the tube with the repeated potential for insertion-related complications and the need for additional chest X rays to assess proper placement. Complications from indwelling nasoenteric feeding tubes include nasal alar pressure necrosis, sinusitis and otitis, and esophageal stricture. Major complications from percutaneous gastrostomy or jejunostomy insertion may occur in 5−10% of insertions and include the following: death, bleeding, esophageal laceration or perforation, gastric and colonic perforation, liver laceration, cellulitis, peritonitis, necrotizing fasciitis, exit site leakage, migration of tubes out of the stomach into the peritoneal cavity, and migration of balloon gastrostomy tubes into the pylorus causing gastric outlet obstruction. Enteral formula delivery-related complications include the following: pulmonary aspiration and aspiration pneumonia (gastrostomy and jejunostomy do not reduce the risk of aspiration), intravenous administration of formula, tube occlusion, glucose and electrolyte abnormalities, and dehydration from "concentrated, free-water-removed" formulas. When the intestine is normal, diarrhea is generally not a complication related to enteral formulas, but more likely results from concomitant medication administration, antibiotic-associated diarrhea, *Clostridium difficile* colitis, liquid medications formulated with sorbitol, intestinal "failure" in the intensive care unit as part of multiorgan failure, and rarely, bacterial contamination of the enteral product consequent to a prolonged "hang-time" at room temperature or inappropriate handling.

Nutrition support teams, composed of multidisciplinary health care professionals with expertise in the delivery of enteral and parenteral nutrition, reduce complications associated with enteral nutrition.

DRUG−NUTRIENT INTERACTIONS

Solid pills generally do not go through narrow feeding tubes and medications often are not formulated to be delivered directly into the jejunum. For these and other reasons, it is necessary to be cognizant of some basic issues surrounding the administration of medications via feeding tubes. Ideally, only medications available in liquid form should be administered through a feeding tube. Even if in liquid form, if the tube is in the small intestines, it should be ascertained that the liquid formulation is safe to infuse directly into the small bowel. Often, solid medications are "crushed" for delivery through a feeding tube. Protocols should be followed to safely liquefy solid medications. Medications formulated in delayed-release form should not be crushed for feeding delivery, as crushing will nullify the sustained release mechanisms and may result in

gastrointestinal tract toxicity or excessive delivery of medication.

With respect to several specific medications, Dilantin (phenytoin) is inactivated by enteral nutrition formulas and must be administered with tube feeding "turned off." The vitamin K content in enteral products may alter anti-coagulation responses to Coumadin. Sucralfate- and fiber-containing formulas can produce esophageal, gastric, and intestinal bezoars with complete obstruction.

potentials within single neurons and chemical transmission of information at the points of contact (i.e., synapses) between neurons. Action potentials transmit coded information from one region of the neuron to another. Synapses at the boundaries transform the action potential codes into chemical codes. Action potential codes arriving in the presynaptic neuronal terminals are transformed to chemical signals for transmission across the synapse and are then retransformed as action potentials in the postsynaptic neurons. Postsynaptic neurons integrate large numbers of synaptic inputs and represent the fundamental component in the computation and processing of neural information.

The enteric microcircuits in the various specialized regions of the digestive tract are wired with large numbers of neurons and synaptic sites where information processing occurs. Multisite computation generates output behavior from the integrated circuits that could not be predicted from properties of their individual neurons and synapses. Emergence of complex behaviors is a fundamental property of the neural networks of the ENS, in the same way as in the brain and spinal cord.

As in the brain and spinal cord, the enteric circuitry processes information and generates patterns of signals that determine the timing and sequence of behavior of the muscles and other effector systems. Processing of information in the circuits is a function whereby computation of input signals results in output to the effectors that is a meaningful transform of the input. Like electronic calculators, which receive numbers as input and calculate outputs according to specific equations preprogrammed into the circuits, the neural circuits receive sensory signals and compute outputs that control behavior of the effectors in ways adapted for overall performance of the specialized regions of gut.

Processing of sensory signals is one of the major functions of the ENS neural networks. The sensory signals are generated by sensory nerve endings and coded in the form of action potentials. The code may represent the status of an effector system (e.g., tension in a muscle) or may signal a change in a parameter in the environment, such as luminal acidity. Sensory signals are deciphered by the neural networks to generate output signals that initiate homeostatic adjustments in the behavior of the effector system.

MYENTERIC AND SUBMUCOSAL PLEXUSES

The ENS consists of ganglia, primary interganglionic fiber tracts, and secondary and tertiary fiber projections to the effector systems (i.e., musculature, glands, and blood vessels). Two ganglionated plexuses are the most obvious structures of the ENS (Fig. 1). The myenteric plexus, also known as Auerbach's plexus, is located between the longitudinal and circular muscle layers of most of the digestive tract. The submucosal plexus, also known as Meissner's plexus, is situated in the submucosal region between the circular muscle and mucosa. The submucosal plexus is most prominent as a ganglionated network in the small and large intestine. It does not exist as a ganglionated plexus in the esophagus and is sparse in the submucosal space of the stomach. In larger mammals (e.g., humans), the intestinal submucosal plexus consists of an inner submucosal network (Meissner's plexus) located at the serosal side of the muscularis mucosae and an outer plexus (Schabadasch's plexus) adjacent to the luminal side of the circular muscle coat. In human small and large intestine, a third intermediate plexus lies between Meissner's and Schabadasch's plexus.

Most motor innervation of the intestinal circular and longitudinal muscle coats originates from motor neurons that have their cell bodies in the myenteric plexus. Motor innervation of the intestinal secretory glands (i.e., crypts of Lieberkühn) and villi originates in the submucosal plexus. Neurons in submucosal ganglia send fibers to the myenteric plexus and also receive synaptic input from axons projecting from the myenteric plexus. The interconnections link the two networks into a functionally integrated nervous system.

Structure, function, and neurochemistry of enteric ganglia differ from those of other autonomic ganglia. Unlike most sympathetic or parasympathetic autonomic ganglia, for which function is mainly relay-distribution centers for signals transmitted from the brain

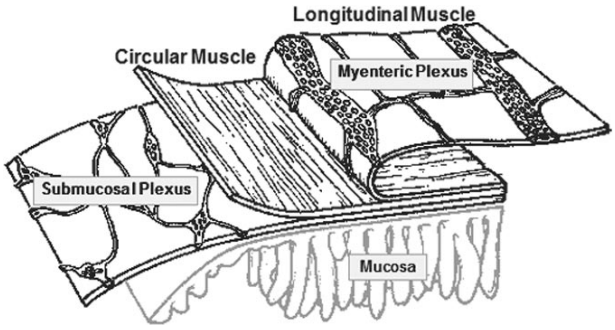

FIGURE 1 Structural relations of the intestinal musculature and the enteric nervous system. Longitudinal and circular muscle coats are the main components of the musculature involved in propulsive motility. Ganglia and interganglionic fiber tracts of the myenteric and submucosal plexuses are the main constituents of the enteric nervous system. The myenteric plexus is situated between the circular and longitudinal muscle coats; the submucous plexus is between the mucosa and circular muscle coat.

and spinal cord, enteric ganglia are interconnected to form a nervous system with mechanisms for integration and processing of information like those found in the brain and spinal cord. In view of this, the ENS is sometimes referred to as "the brain-in-the-gut."

HEURISTIC MODEL OF THE ENS

The heuristic model for the ENS is the same as for the brain and spinal cord (Fig. 2). In fact, the ENS has as many neurons as the spinal cord. Like the central nervous system, sensory neurons, interneurons, and motor neurons are connected synaptically for flow of information from sensory neurons, to interneuronal integrative networks, to motor neurons, to effector systems. The ENS organizes and coordinates the activity of each effector system into meaningful behavior of the integrated organ. It is integrated with the central nervous system and bidirectional communication occurs between the centers in the central nervous system and the ENS.

NEURONAL TYPES

Dogiel Types I and II are the principal morphological classes of neurons in the ENS. The German neuroanatomist, A. S. Dogiel, described two morphological types of enteric ganglion cells that have been named for him. These two types are each distributed in both myenteric and submucosal plexuses. Both types of neurons are distributed in a two-dimensional plane (i.e., the cell bodies are not stacked one on the other). This may adapt the ENS for the changing forces within the gut wall experienced during contraction of the musculature or stretching of the wall as the hollow organs fill.

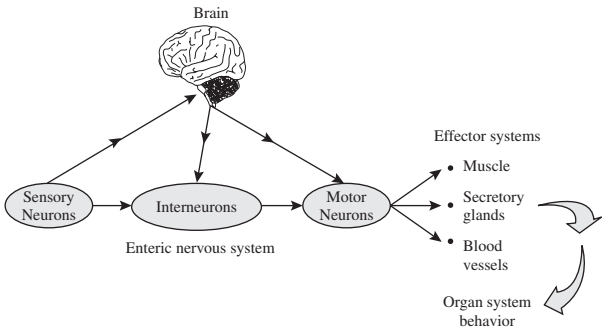

FIGURE 2 Sensory neurons, interneurons, and motor neurons are synaptically interconnected to form the integrated microcircuits of the enteric nervous system. Like the central nervous system, sensory neurons, interneurons, and motor neurons are connected synaptically for flow of information from sensory neurons to interneuronal integrative networks, to motor neurons, to effector systems. The enteric nervous system organizes and coordinates the activity of each effector system into meaningful behavior of the whole organ. Bidirectional communication occurs between the central and the enteric nervous system.

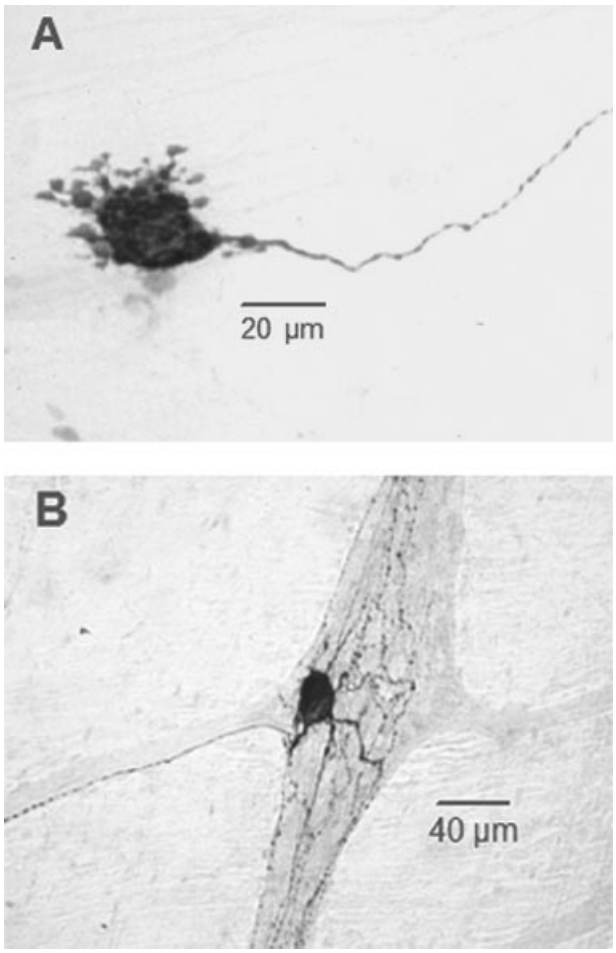

FIGURE 3 Dogiel Type I and Type II morphologies represent the major neurons in the enteric nervous system. (A) Dogiel morphologic Type I neuron in the submucosal plexus of the small intestine of the guinea pig. Dogiel Type I neurons have multiple short dendrites at the edges of the cell body and a single axon. (B) Dogiel morphologic Type II neuron in the myenteric plexus of the guinea pig small intestine. Dogiel Type II neurons have multiple long processes of variable length that ramify throughout the ganglion and into interganglionic fiber tracts. These neurons were marked by the injection of biocytin from micropipettes that also served as recording microelectrodes.

Dogiel Type I neurons have cell bodies with many short processes and a single long process (Fig. 3). These are flat neurons with the processes extending from the cell body in the circumferential and longitudinal planes of the wall. The short processes are dendrites, which receive synaptic input; the long process is an axon. The axon of Dogiel Type I neurons projects for relatively long distances through interganglionic fiber tracts and many rows of ganglia. Still, the projections are

not long in absolute length; the longest known projections of any enteric ganglion cell are only about 2–3 cm. Dogiel I neurons projecting in a specific direction may express a specific neurotransmitter. Aborally projecting Dogiel I axons release nitric oxide and vasoactive intestinal polypeptide as neurotransmitters; those projecting in the oral direction release substance P and acetylcholine. Some of the Dogiel Type I neurons are motor neurons to the musculature and secretory epithelium; others are interneurons.

The cell bodies of ENS neurons with Dogiel Type II morphology have smooth surfaces with long and short processes arising in a variety of configurations (Fig. 3). The long processes may extend through interganglionic fiber tracts across several rows of ganglia in either the circumferential direction, oral direction or aborally. Shorter processes may only project within the home ganglion. Almost all Dogiel Type II neurons in the myenteric plexus project a process to the submucosa/mucosa. Dogiel Type II processes in the mucosal regions are fired by mechanical and chemical stimulation of the mucosa. Dogiel Type II neurons are involved at an early stage in the handling of sensory information, as well as interneuronal functions in the microcircuits of the ENS. They express the neurotransmitters, substance P and acetylcholine.

ELECTRICAL BEHAVIOR OF NEURONS

Intracellular microelectrodes are used to record the electrical and synaptic behavior of enteric neurons in preparations removed from the various organs of the digestive tract. Differences in electrical and synaptic behavior are a basis for classification of enteric neurons into two main subgroups, AH type and S type. The S-type neurons were first identified on the basis of nearly universal occurrence of fast excitatory postsynaptic potentials and the AH-type neurons were identified based on the occurrence of long-lasting after-hyperpolarization associated with the action potential (see Figs. 4 and 5). Electrophysiological behavior of the AH type is found mainly in enteric neurons with Dogiel Type II morphology, and S-type behavior is found mainly in Dogiel Type I neurons.

Repetitive action potential discharge always can occur in S type; repetitive discharge generally does not occur in AH-type enteric neurons (Fig. 4). Membrane excitability is higher in S-type as compared to AH-type enteric neurons. The S-type neurons fire repetitively during the intraneuronal injection of long-duration depolarizing current pulses through the recording microelectrode. The frequency of the repetitive spike discharge increases in proportion to the amplitude of the depolarization produced by the injected pulses. The AH-type neurons do not fire repetitively during sustained membrane depolarization when they are in a resting state. Irrespective of the strength of a depolarizing pulse, these neurons fire only one or two spikes at the onset of the pulse. During slow synaptic excitation (see Fig. 5), AH neurons become hyperexcitable and fire repetitively like S-type neurons.

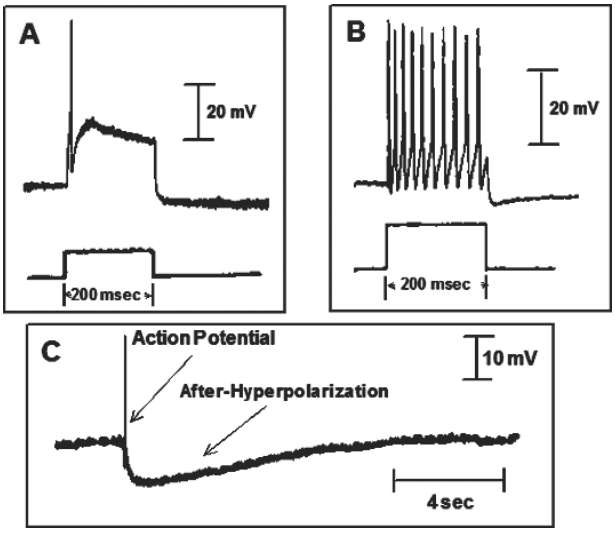

FIGURE 4 Enteric neurons are classified as S-type 1 or AH-type 2 based on their electrophysiologic behavior. (A) An AH-type 2 neuron that had low excitability, as reflected by discharge of only a single action potential during intraneuronal injection of a 200-msec depolarizing current pulse. (B) An S-type 1 neuron that had relatively high excitability, as reflected by repetitive discharge of action potentials during intraneuronal injection of a 200-msec depolarizing current pulse. The bottom traces in A and B show the current pulses and the top traces show the neuronal responses to the depolarizing current pulses. (C) The AH-type 2 neurons are characterized by long-lasting membrane hyperpolarization (i.e., after-hyperpolarization) following the discharge of an action potential.

In the guinea pig, which is the most commonly studied model, the occurrence of AH-type neurons is limited to the gastric antrum and small and large intestine. The S-type neurons are found throughout the digestive tract, including gastric corpus and antrum, gall bladder, esophagus, and pancreas.

NEUROTRANSMISSION

Synaptic events in the ENS are basically the same as in the brain and spinal cord. Excitatory postsynaptic potentials, inhibitory postsynaptic potentials, and presynaptic inhibition and facilitation are the principal synaptic events in the enteric minibrain. Both slow

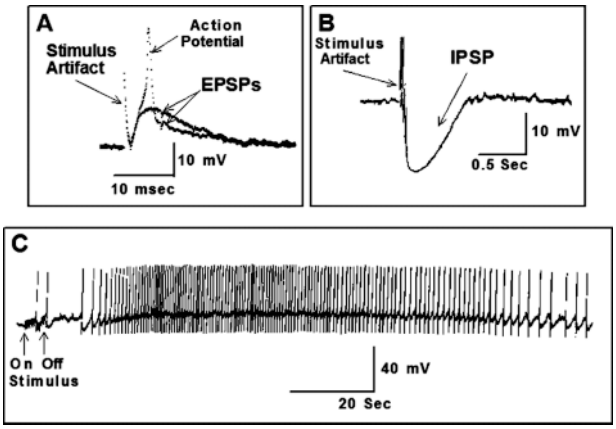

FIGURE 5 Fast and slow excitatory postsynaptic potentials (EPSPs) and slow inhibitory postsynaptic potentials (IPSPs) are the main kinds of synaptic potentials in enteric neurons. (A) Two fast EPSPs were evoked by successive stimuli and are shown as superimposed records. Only one of the EPSPs reached threshold for discharge of an action potential. The time course of the EPSPs is in the millisecond range. The fast EPSPs were evoked by single electrical shocks applied to the axon that formed the synapse with the recorded neuron. (B) Slow IPSP evoked by stimulation of an inhibitory input to the neuron. This is a hyperpolarizing synaptic potential that will suppress excitability (i.e., decrease probability of action potential discharge), as compared with enhanced excitability during slow EPSPs. (C) Slow EPSP evoked by repetitive electrical stimulation of the synaptic input to the neuron. Slowly activating depolarization of the membrane potential continues for more than 2 min after termination of the stimulus. Repetitive discharge of action potentials reflects enhanced neuronal excitability during the slow EPSP.

and fast synaptic mechanisms are operational. Fast synaptic potentials have durations in the millisecond range; slow synaptic potentials last for several seconds or minutes. Fast synaptic potentials are usually excitatory postsynaptic potentials. The slow synaptic events may be either excitatory postsynaptic potentials or inhibitory postsynaptic potentials.

Fast Excitatory Postsynaptic Potentials

Fast excitatory postsynaptic potentials are membrane depolarizations with durations less than 50 msec (Fig. 5). They are found at synapses in ENS microcircuits in myenteric and submucosal plexuses, where they are most prominent in neurons with S-type electrical behavior in all of the specialized organs of the digestive tract. Most of the fast excitatory postsynaptic potentials are mediated by acetylcholine at nicotinic postsynaptic receptors. The actions of serotonin at the serotonergic receptor subtype 3 and of purine nucleotides at P_{2X} purinergic receptors behave much like fast excitatory postsynaptic potentials.

Slow Excitatory Postsynaptic Potentials

Slow excitatory postsynaptic potentials are involved in neurotransmission in both the myenteric and submucosal plexuses and in both AH- and S-type neurons. They are most dramatic in Dogiel morphologic Type II neurons with AH-type electrophysiologic behavior when conversion from hypo- to hyperexcitability is involved. Neurons with slow excitatory synaptic inputs are found in the small and large intestine and gastric antrum, but not the gastric corpus or gallbladder. They seem to be associated with specialized regions in which propulsive motility is a significant function.

Slowly activating membrane depolarization continuing for several seconds to minutes after termination of release of the neurotransmitter from the presynaptic terminal identifies slow excitatory postsynaptic potentials (EPSPs) (Fig. 5). Enhanced excitability, reflected by long-lasting trains of impulses, is the hallmark of slow excitatory postsynaptic neurotransmission. Enhanced excitability is apparent experimentally as repetitive spike discharge during depolarizing current pulses. The AH-type neurons, which fire only a single spike at the beginning of a depolarizing current pulse in the inactivated state, will fire repetitively in response to depolarizing pulses when the slow EPSP is in effect. When activated by slow synaptic inputs, behavior of AH-type neurons is much like that of S-type neurons and may be confused as such, if the AH-type neurons happen to be in an activated state due to ongoing release of the transmitter. Postspike hyperpolarization in AH-type neurons is suppressed during slow excitatory neurotransmission. Suppression of the after-hyperpolarization is part of the mechanism that permits repetitive spike discharge at increased frequencies during the enhanced state of excitability.

Slow excitatory postsynaptic potentials are a mechanism for long-lasting activation or inhibition of gastrointestinal effector systems. The prolonged neuronal firing during a slow excitatory postsynaptic potential drives the release of neurotransmitter from the neuron's axon for the duration of the spike discharge. Prolonged inhibition, or excitation at neuronal synapses in the processing circuits and at neuroeffector junctions, is the functional outcome of slow synaptic excitation. This governs the functional behavior of the effector systems. Compared to twitches of skeletal muscles, contractile responses of the gut musculature are sluggish events that last for several seconds from start to completion. The prolonged trainlike firing during

slow excitatory postsynaptic potentials is the neural correlate of long-lasting excitatory or inhibitory responses of the muscle groups in the functioning gastrointestinal tract. Prolonged secretory responses in the intestinal crypts are also related to the sustained firing during slow synaptic excitation.

Several messenger substances found in neurons, endocrine cells, or immune cells of the brain and gut mimic slow EPSPs when applied experimentally to enteric neurons. Receptors for more than one of the messenger substances may be present on the same neuron. The current list of substances (and their receptor subtypes, in parentheses) includes the following compounds: (1) acetylcholine (muscarinic M_1), (2) cholecystokinin (A), (3) bombesin, (4) calcitonin gene-related peptide, (5) thyrotropin releasing hormone, (6) 5-hydroxytryptamine (5-HT1P), (7) norepinephrine, (8) pituitary adenylate cyclase activating peptide, (9) interleukin-1β, (10) tumor necrosis factor, (11) adenosine (A_2), (12) histamine (H2), (13) vasoactive intestinal peptide, (14) cerulein, (15) gastrin-releasing peptide, (16) tachykinins (NK_3 and NK_1), (17) corticotropin releasing hormone, (18) γ-aminobutyric acid, (19) motilin, (20) glutamate (group I metabotropic), (21) interleukin-6, (22) platelet-activating factor, and (23) bradykinin (B_2).

Slow Inhibitory Postsynaptic Potentials

Slow inhibitory postsynaptic potentials are hyperpolarizing synaptic potentials found in neurons in both myenteric and submucosal plexuses of the small and large intestine and in myenteric neurons of the gastric antrum. Slow inhibitory postsynaptic potentials activate relatively slowly and continue for several seconds after termination of the stimulation (Fig. 5). The characteristics of slow synaptic inhibition are inverse to those of slow synaptic excitation in that hyperpolarization instead of depolarization of the membrane potential occurs (e.g., a change from −50 to −75 mV). Hyperpolarization of the membrane potential decreases excitability and the probability that the neuron will fire impulses. Inhibitory postsynaptic potentials are more readily demonstrated in the submucous than in the myenteric plexus of animal preparations.

Several putative neurotransmitters evoke responses similar to slow inhibitory postsynaptic potentials when experimentally applied to enteric neurons. Some of these substances are peptides, others are purine compounds, and another is norepinephrine. Receptors for two or more of these substances may be localized to the cell body of the same neuron. Substances (and their receptor subtypes, in parentheses) that may be found in enteroendocrine cells, as well as in enteric neurons, include (1) acetylcholine, (2) 5-hydroxytryptamine (5-HT1A), (3) neurotensin, (4) somatostatin, (5) adenosine (A_1), (6) nociceptin, (7) opioid peptides, (8) norepinephrine (α2), (9) cholecystokinin, (10) ATP, and (11) galanin. These substances, which are present both in the brain and in the gastrointestinal tract, simulate slow synaptic inhibition when applied experimentally to enteric neurons.

Enterochromaffin-like (ECL) Cells

CHRISTIAN PRINZ
Technische Universität, Munich

chromogranin A protein present in cellular storage granules or vesicles containing bioactive amines such as histamine and norepinephrine.

enterochromaffin-like (ECL) cells Neuroendocrine cells in the gastric epithelium that control the peripheral regulation of acid secretion by releasing histamine as a paracrine stimulant.

enterochromaffin-like (ECL) cell carcinoid A tumor of gastric ECL cells that usually does not metastasize, but can infiltrate into deeper layers of the gastric wall. Elevated plasma gastrin levels (hypergastrinemia) play a crucial role in the development of these tumors.

gastrin Gastrointestinal hormone released from G cells in the gastrin antrum in response to food.

histamine Paracrine regulator derived from the amino acid histidine.

pituitary adenylate cyclase-activating peptide A neuropeptide present in the vagal nerve endings innervating the gastric mucosa.

Enterochromaffin-like cells are neuroendocrine cells in the gastric mucosa that control acid secretion by releasing histamine as a paracrine stimulant. Their name derives from their resemblance to chromaffin cells, which stain with chromium salts. They also synthesize and secrete other biogenic amines.

PHYSIOLOGY

During food intake, endocrine and neural signals such as gastrin and PACAP (pituitary adenylate cyclase-activating peptide), which directly stimulate enterochromaffin-like (ECL) function, are released. Gastrin is released from antral G cells in response to meal stimulation, reaches the ECL cell via the systemic circulation, and binds to cholecystokinin-B (CCK-B; gastrin) receptors on ECL cells. PACAP is a neural mediator and is released from neural endings of the vagus nerve that are activated during the cephalic as well as gastric phases of digestion. Stimulation of ECL cells induces both secretion of histamine and its synthesis, the latter through transcriptional regulation of the histidine decarboxylase gene, which codes for the enzyme that converts histamine to histidine. Prolonged stimulation of ECL cells can lead to cell growth and division.

Secretion of histamine by ECL cell stimulation is mediated by a rise in intracellular calcium resulting from the release of intracellular stored calcium and entry of calcium across the plasma membrane from extracellular fluid. L-type voltage-gated calcium channels are activated upon stimulation by gastrin. Blockage of L-type channels can decrease histamine release. K^+ and Cl^- channels have also been identified in gastric ECL cells and act to maintain the intracellular negative membrane potential at -60 mV. Histamine available for secretion in ECL cells is stored in membrane-bound vesicles. V-type ATPases transport protons into these vesicles to maintain a low pH. The proton gradient serves to energize vesicular monoamine transporters of subtype 2, which mediate the uptake of histamine into the vesicles. Secretion occurs by exocytosis and involves interacting proteins on the vesicle and the plasma membrane. In addition to histamine, the secretory vesicles contain peptides of the chromogranin family, including pancreostatin, that have been used as histological markers for the presence of ECL cells and to assess the number of ECL cells. Furthermore, circulating pancreostatin has been used as a functional marker for ECL cell secretion.

PATHOPHYSIOLOGY

The gastric mucosa is frequently infected with *Helicobacter pylori*, leading to elevated mucosal levels of pro-inflammatory cytokines such as tumor necrosis factor α (TNFα) or interleukin 1 β (IL-1β). These pro-inflammatory cytokines inhibit the secretory response of ECL cells and prevent *de novo* histamine synthesis. Furthermore, IL-1β and TNFα can induce ECL cell apoptosis. These findings may explain the clinical observations that *H. pylori*-positive patients with or without duodenal ulceration have significantly lower gastric histamine concentrations and histidine decarboxylase activity than *H. pylori*-negative subjects. Part of the

inhibitory response may be mediated by the release of prostaglandin E2 from ECL cells, which in turn prevents histamine secretion from this cell type.

TUMORIGENESIS: ECL CELL CARCINOIDS

The distribution of the vesicular monoamintransporters in embryonal and adult cells suggests that ECL cells arise from cells within the neural crest. ECL cell growth is differentially regulated from other gastric epithelial or parietal cells that derive from gastric mucosal stem cells. Most importantly, the life cycle and the proliferative response are directly controlled by the antral hormone gastrin, which stimulates the proliferation of ECL cells. Hypergastrinemia is observed during conditions of gastric mucosal atrophy, such as autoimmune gastritis (AIG). The destruction of mucosal cells during AIG can therefore be associated with tumors of ECL cells (type 1 ECL cell carcinoids). In contrast, type 2 carcinoids are associated with multiple endocrine neoplasia and type 3 carcinoids occur sporadically. The development of carcinoids during AIG has not been explored; however, it appears that hypergastrinemia may increase the production of growth factors such as epidermal growth factor or basic fibroblast growth factor in ECL cells, which in turn prevents ECL cell apoptosis and favors the persistence and proliferation of ECL cells in the chronically inflamed gastric mucosa. Furthermore, mutations of the CCK-B receptor with continuous intrinsic activity may play a role in this tumorigenesis.

TREATMENT OF CARCINOIDS

Endoscopic resection can be performed to dissect carcinoid tumors; however, gastric antrectomy may be the treatment of choice to remove the gastrin-producing cells and to close this vicious cycle of achlorhydria, hypergastrinemia, and the resulting proliferation and carcinogenesis of ECL cells. Future research may provide specific, long-acting CCK-B receptor antagonists in order to prevent gastrin activity and to enable medical treatment of these tumors.

Enteroglucagon

JENS JUUL HOLST
University of Copenhagen

differential processing Formation of different processing products from the same prohormone in different tissues.

dipeptidyl peptidase IV A proteolytic enzyme occurring in the plasma membranes of many cells, including vascular endothelial cells, as well as in a soluble form in plasma. It is responsible for rapid inactivation of the glucagon-like peptides 1 and 2.

enterogastrones Gastrointestinal hormones that inhibit gastric motility and/or secretion.

ileal brake An endocrine mechanism, elicited by the presence of nutrients in the ileum, that causes inhibition of upper gastrointestinal secretion and/or motility.

incretin hormones Insulinotropic intestinal hormones responsible for enhanced insulin secretion after oral as opposed to intravenous glucose administration.

L cells The endocrine cell type in the intestinal mucosa that expresses the glucagon gene and secretes the proglucagon-derived peptides.

proglucagon-derived peptides Secreted products of proglucagon processing, including those from the pancreas (glicentin-related pancreatic polypeptide, glucagon, and major proglucagon fragment) and those from the gut (glicentin, oxyntomodulin, and glucagon-like peptides 1 and 2).

prohormone The biosynthetic precursor for a peptide/protein hormone. By cleavage of the prohormone, the mature hormone is produced.

prohormone convertases Enzymes responsible for the proteolytic processing (cleavage) of prohormones.

Enteroglucagon derives its name from the fact that the gene encoding the hormone glucagon is expressed not only in the pancreas but also in the gut. However, here the gene products (peptides) differ from those produced in the pancreas and the main products are the glucagon-like peptides 1 and 2.

HISTORY AND CHEMISTRY

The hormone glucagon was discovered in 1923 as a hyperglycemic substance derived from the pancreatic islets. However, in 1948 it was found that a similar hyperglycemic substance could be extracted from the gastric mucosa. Subsequent immunochemical studies confirmed the existence of "glucagon-like immunoreactivity" in gut extracts and detailed studies revealed that a specific, open (i.e., with apical cytoplasmic processes reaching the gut lumen) endocrine cell type, designated the L cell, was responsible for the immunoreactivity. A large number of reports from the 1970s and early 1980s contained descriptions of the secretion of "enteroglucagon," particularly after the introduction of radioimmunoassays that could distinguish pancreatic glucagon from the "total" glucagon immunoreactivity in plasma. By subtraction, one obtained enteroglucagon [also called "gut glucagon" or "gut GLI" (gut glucagon-like immunoreactivity)]. It was soon established that enteroglucagon was itself heterogeneous and composed of at least two components, complicating the interpretation of the results. Eventually, the two main components were purified from intestinal extracts and sequenced. The larger component was named glicentin, "gli-" for "glucagon-like imunoreactivity" and "-cent-" because it was originally thought to be composed of 100 amino acid residues. Eventually, it was discovered to consist of only 69 amino acids. Residues 33 to 61 corresponded exactly to the sequence of pancreatic glucagon. The smaller form was called "oxyntomodulin" and corresponded to glucagon plus the same 8 additional amino acids at the C-terminus as in glicentin; it was therefore considered to be a fragment of glicentin (see Fig. 1). Because of the presence of the entire glucagon sequence, it was assumed that glicentin might actually represent, if not the entire biosynthetic precursor of glucagon (known as "proglucagon"; glicentin was too small), then at least a fragment thereof. This notion was supported by the discovery in pancreatic extracts of a peptide that corresponded exactly to residues 1–30 of glicentin and was secreted in parallel with glucagon. This could also suggest that the intestinal and pancreatic glucagons could be products of the same gene. This turned out to be the case. In 1983, the sequence of mammalian proglucagon was deduced from a hamster islet cDNA library and subsequently the human gene was cloned and sequenced (see Fig. 1). The human proglucagon sequence included from the N-terminus the full glicentin sequence (in which the glucagon sequence occupies positions 33–61) and in addition contained two

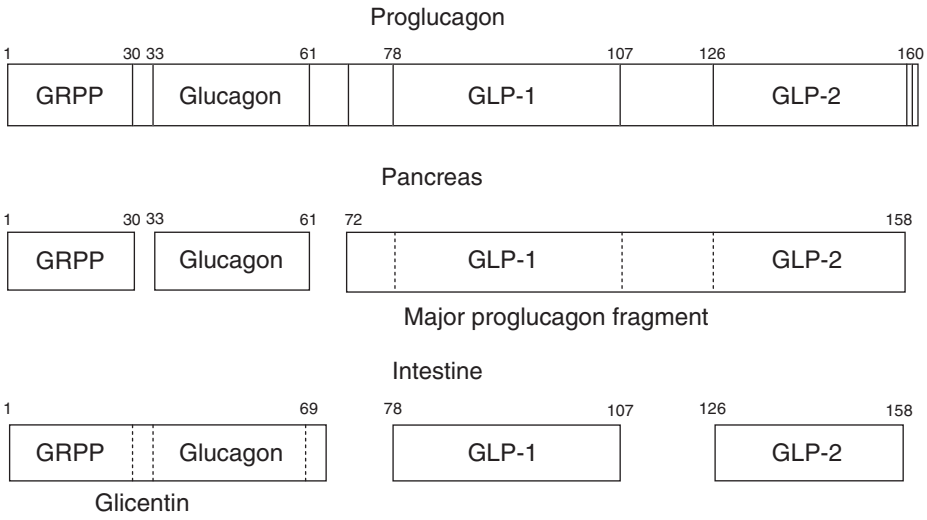

FIGURE 1 Schematic representation of the structure of proglucagon and its processing products in the pancreas and in the intestine. The numbers refer to the positions of the amino acids in the proglucagon sequence. The vertical lines indicate the major sites of proteolytic cleavage. GRPP, glicentin-related pancreatic polypeptide; GLP, glucagon-like peptide. See text for details.

glucagon-like sequences (designated glucagon-like peptides 1 and 2), flanked by pairs of basic amino acids (typical cleavage sites for prohormone processing enzymes, the so-called convertases) and occupying positions 72–108 and 126–160. Further studies confirmed that in mammals only a single gene could be identified and, furthermore, that only a single mRNA was produced in gut and pancreatic tissues (this is quite unlike the situation in birds and fish). The different proteins generated in the alpha cells of the pancreas and the L cells of the gut therefore had to result from differential processing of the prohormone in the two tissues, with the formation of glucagon in the pancreas and of glicentin in the gut. But what about the glucagon-like peptides? Detailed studies of the processing and secretion of the proglucagon-derived peptides from the pancreas and the gut revealed that the pancreatic products include proglucagon (PG) 1–30 (designated glicentin-related pancreatic polypeptide, GRPP), glucagon, and the so-called major proglucagon fragment comprising PG residues 72–158 (Fig. 1). The intestinal products include glicentin (PG1–69), oxyntomodulin (PG33–69; small amounts of GRPP are therefore also formed in the gut), and the glucagon-like peptides 1 and 2, which were apparently cleaved from the major proglucagon fragment. For some time, both of the new glucagon-like peptides seemed biologically inert, showing no glucagon-like biological activities, but natural GLP-1, isolated from intestinal extracts, was found to powerfully stimulate insulin secretion in a perfused pancreas preparation. Sequence analysis of the naturally occurring GLP-1 revealed that the peptide corresponded to PG78–107 (and was C-terminally amidated), indicating that it was cleaved out of proglucagon at the single basic amino acid residue at position 77 of PG. Natural GLP-2 was found to correspond to PG126–158. The peptide positioned between GLP-1 and GLP-2, the so-called intervening peptide 2, was found to correspond to residues 111–123 (and also to be C-terminally amidated); this peptide is also secreted, but thus far nothing is known about its physiology. The differential processing of proglucagon in the two tissues was thought to be due to expression of different processing enzymes (prohormone convertases; PCs) in the two cell types, and subsequent studies, including studies in mice with targeted deletions of the genes encoding the most prominent convertases, PC2 and PC1/3, indicated that PC2 is essential and apparently sufficient for the cleavage of proglucagon to release glucagon and that PC1/3 is essential for processing of PG to GLP-1, whereas it is still unclear whether PC1/3 is also sufficient to explain the full processing of PG into glicentin, GLP-1, and GLP-2. In agreement with these findings, PC2 is expressed in the pancreatic alpha cells and PC1/3 in the L cells.

With the complete knowledge of the intestinal processing of proglucagon and the structure of the products, it became possible to analyze their physiology and pathophysiology. Whereas glicentin (and oxyntomodulin) is currently thought to play a limited role in metabolism, GLP-1 turned out to be an important regulator of gastrointestinal functions and insulin secretion

and GLP-2 acts as a potent regulator of intestinal growth and repair. In the remainder of this article, emphasis will be placed on the glucagon-like peptides.

SECRETION OF THE PROGLUCAGON-DERIVED PEPTIDES

In principle, it should be possible to monitor L-cell secretory activity by measuring any of its products. Apparently, the three main products, glicentin, GLP-1, and GLP-2, are formed in equimolar amounts and their secretion is synchronous. The GLPs are eliminated rather rapidly, whereas glicentin seems to metabolized more slowly and, in theory, glicentin assays should be superior for monitoring of L-cell secretion. Specific assays for glicentin that are suitable for measurements of endogenous glicentin in plasma do not exist. Instead, assays directed against a midsequence of the glucagon constituent have been employed, but these require, as mentioned above, corrections for the contribution of glucagon, derived from the pancreas, and are therefore somewhat inaccurate and cumbersome. Nevertheless, since the secretion of gut-derived proglucagon-derived peptides (PGDPs) is often opposite to the secretion of pancreatic glucagon, many of the early reports of enteroglucagon/gut glucagon/gut GLI secretion are probably perfectly valid. In general, secretion is low in the fasting state (although not absent, as indicated by inhibitory effects of exogenous somatostatin administration). Ingestion of mixed meals elicits a robust secretion and it has been established that in particular, carbohydrates and lipids stimulate secretion. However, proteins are not without effect. Secretion seems to be determined mostly by the exposure of the gut lumen with nutrients, as reflected by a tight correlation between the gastric emptying rate and PGDP secretion. Furthermore, administration of α-glycosidase inhibitors (e.g., acarbose) increases the secretion of the PGDPs and reduces the secretion of proximal gastrointestinal hormones [such as gastric inhibitory polypeptide (GIP)], presumably by reducing the proximal concentration of stimulatory monosaccharides while increasing the load of nutrients to the distal small intestine, where the density of the L cells is higher. It has been suspected that only absorbable and metabolizable carbohydrates stimulate secretion, but currently it is not known whether the absorption and metabolism should take place in the L cells or in neighboring enterocytes, which could then signal to the L cells. Despite the higher density of L cells in the distal gut (in fact, there are numerous L cells even in the colon, but nothing is known about their function), the response to meal ingestion may be rapid (noticeable within 5–10 min), which has raised suspicion that secretion might be regulated by neural or hormonal mechanisms. It has been established that activation of the sympathetic nerve supply to the gut inhibits secretion, but the parasympathetic division seems to play a minor role, if any, and hormones with a clear influence on GLP-1 secretion have not been identified (these statements are based mainly on findings in humans and pigs; findings in rodents may be different).

METABOLISM OF INTESTINAL PROGLUCAGON-DERIVED PEPTIDES

The actual plasma concentrations of glicentin and the GLPs are influenced not only by their rate of secretion but also by their individual elimination rates. GLP-1 is metabolized with unique rapidity. Its primary metabolism is due to the ubiquitous enzyme dipeptidyl peptidase-IV (DPP-IV), which is located in the plasma membranes of many cell types, including vascular endothelial cells, and which also exists in a soluble form in plasma. The enzyme cleaves off the two N-terminal amino acids, leaving behind a truncated, inactive metabolite. Interestingly, this metabolite may even act as an antagonist at the GLP-1 receptor. Subsequently, both GLP-1 and the metabolite are cleared from the plasma, mainly in the kidneys, by a combination of filtration and peritubular uptake. The initial clearance of GLP-1 exceeds cardiac output and hence GLP-1 is significantly degraded while circulating, in agreement with the expression of the enzyme on vascular endothelial cell membranes. The apparent elimination half-life is on the order of 1–2 min (but there is no steady state, so the figure has little meaning). The disappearance half-life of the metabolite is approximately 4–5 min. The concentrations of intact GLP-1 are therefore very low (a few picomoles per liter), whereas those of the primary metabolite three to five times higher. GLP-2 is also cleaved by DPP-IV, but much more slowly than GLP-1. The elimination half-life of the intact GLP-2 (1–33) in humans is 7 min and that of the metabolite, GLP-2 (3–33), is 27 min. In humans, therefore, the plasma concentration of glicentin is usually the highest, that of intact GLP-2 is somewhat lower, and that of intact GLP-1 is very low. Because of the intravascular degradation of GLP-1, its rate of secretion cannot be ascertained from measurements of plasma concentrations of the intact hormone. Instead, one can use the sum of the metabolite and the intact hormone concentrations as a measure of L-cell secretion. In humans, where most of the GLP-1 molecules carry a C-terminal carboxyamidation, assays against the amidated carboxy-terminus will

provide a measure of this sum. Alternatively, L-cell secretion can be estimated by measurements of enteroglucagon or GLP-2 levels. Clearly, however, if the purpose is to estimate the biological potential of a certain concentration of GLP-1 in plasma, it is necessary to employ assays for the intact molecule.

BIOLOGICAL EFFECTS OF THE PROGLUCAGON-DERIVED PEPTIDES

There have been some controversies with respect to the biological effects of glicentin. The intact molecule seems to have little effect in humans on glucagon-responsive systems, such as gastric acid secretion, intestinal motility, and insulin secretion. Oxyntomodulin has clear glucagon-like actions, such as inhibition of acid secretion, stimulation of insulin secretion, and interaction with the hepatic glucagon receptors. However, its potency is generally much lower (approximately 1/50 of that of glucagon), and given that it also circulates in very low concentrations, it seems unlikely that it exerts major metabolic functions.

Both of the GLPs interact with specific receptors. The receptors belong to a subgroup of highly related G-protein-coupled receptors to which the glucagon, VIP, and secretin receptors, and also the PTH and calcitonin receptors, belong. The fact that both of the GLPs interact with a specific receptor also explains the finding that their actions diverge despite their close sequence homology.

Actions of Glucagon-like Peptide 1 on the Beta Cell

One of the prominent actions of GLP-1 is to potentiate glucose-induced insulin secretion. The intracellular machinery activated by GLP-1 has not been fully elucidated, but accumulation of cyclic AMP and elevation of intracellular Ca^{2+} are essential components. All steps of insulin biosynthesis are stimulated by GLP-1, including expression of the insulin genes and the genes required for the beta cell to react to glucose with increased insulin secretion, such as the glucose transporter (GLUT-2) and glucokinase genes. Furthermore, in numerous rodent studies, GLP-1 has been found to stimulate beta-cell replication and differentiation of progenitor cells into new beta cells in the pancreatic ducts. Also, beta-cell apoptosis rates are inhibited by GLP-1. GLP-1's function as an incretin hormone (the gastrointestinal hormones that enhance insulin secretion above that elicited by elevated postprandial substrate concentrations) has been proven in experiments with receptor antagonists and in mice with a targeted deletion of the GLP-1 receptor gene. These mice become glucose intolerant and the male mice may develop fasting hyperglycemia, i.e., diabetes. GLP-1 also inhibits glucagon secretion (the mechanism is thus far unknown) and the combined action on the islets therefore is to enhance insulin secretion and inhibit glucagon secretion. This in turn inhibits hepatic glucose production, which is regulated by the ratio of these hormones, and this inhibition, in combination with the stimulatory actions of elevated insulin concentrations on peripheral glucose uptake, ensures effective disposition of the absorbed carbohydrates.

Gastrointestinal Actions of Glucagon-like Peptide 1

GLP-1 powerfully inhibits upper gastrointestinal secretion and motility, inhibiting gastric acid and pancreatic enzyme secretion, gastric emptying of both liquids and solids, and intestinal transit (see Fig. 2). Because of these actions, GLP-1 is usually regarded as an important member of the enterogastrone hormones of the so-called ileal brake mechanism, an endocrine mechanism that inhibits upper gastrointestinal secretion and motility when unabsorbed nutrients are present in the ileum. Thus, on infusion into the ileum of lipids or carbohydrates in amounts that correspond to "physiological malabsorption," GLP-1 secretion is inversely correlated

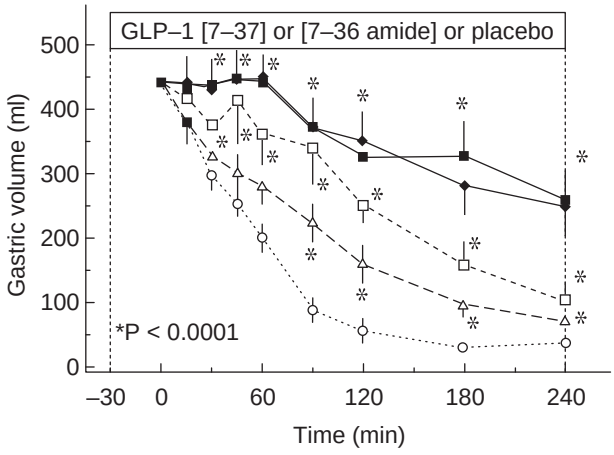

FIGURE 2 Effect of different rates of intravenous infusion of GLP-1 on gastric emptying of a liquid meal (measured as volume remaining in stomach) in healthy volunteers. Both the amidated and the nonamidated forms of GLP-1 were infused at the highest rate. (◯) Placebo; (■) GLP-1 [7–36 amide] 1.2 pmol · kg^{-1} · min^{-1}; (□) GLP-1 [7–36 amide] 0.8 pmol · kg^{-1} · min^{-1}; (△) GLP-1 [7–36 amide] 0.4 pmol · kg^{-1} · min^{-1}; (◆) GLP-1 [7–37] 1.2 pmol · kg^{-1} · min^{-1}. Data from Nauck *et al.* (1997). Glucagon-like peptide 1 inhibition of gastric emptying outweighs its insulinotropic effects in healthy humans. *Am J. Physiol. Endocrinol. Metab.* **273**, E981–E988. Reprinted with permission of the American Physiological Society.

with an inhibition of gastropancreatic secretion and motility. The inhibitory actions of GLP-1 seem to be mediated via interaction with parasympathetic outflow from the central nervous system. Thus, the inhibition of acid secretion by GLP-1 is lost in vagotomized subjects, whereas GLP-1 strongly inhibits purely neurally stimulated secretion, as elicited by "sham feeding." How GLP-1 interacts with the cerebral regulation of parasympathetic activity is not known. Circulating GLP-1 can gain access to the brain via leaks in the blood–brain barrier in the subfornical organ and the area postrema, where GLP-1 receptors are expressed, but there is also evidence that GLP-1 may affect sensory afferent neurons traveling to the brain stem. This may provide a clue to understanding its efficiency despite the surprisingly extensive degradation by DPP-IV as discussed above. Investigations have shown that a substantial percentage of the GLP-1 molecules, between 50 and 75%, are already truncated by DPP-IV and thereby inactivated before they leave the gut. Apparently, newly secreted GLP-1 molecules traverse the basal lamina of the gut epithelium and enter the lamina propria, where they may interact with nerve endings of sensory afferent neurons (see Fig. 3). Subsequently, GLP-1 enters the capillary system of the villi, where it is immediately degraded by DPP-IV, which is expressed on the endothelial surface of the vessels. According to this view, GLP-1 may physiologically act more as a paracrine regulator than as a true hormone. If, on the other hand, the exposure of the gut to unabsorbed nutrients is extensive, as seen after large meals or accelerated gastric emptying, GLP-1 secretion is enhanced and more intact hormone escapes to the systemic circulation. This allows the hormone to interact with the pancreatic islets in an endocrine fashion, thereby facilitating deposition of the substrates absorbed from this very large meal. According to this view, GLP-1 may be regarded as a second-in-line incretin hormone (GIP is the first), which is mainly activated during nutritional abundance and acts to diminish further intake (see below) and processing of nutrients and to promote disposition of already absorbed nutrients.

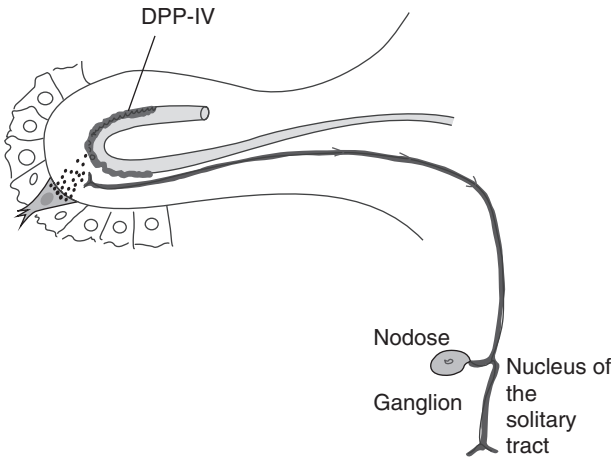

FIGURE 3 Secretion of GLP-1 from an endocrine cell in a villus of the intestinal mucosa and possible mechanism of activation of afferent sensory nerve fibers as well as inactivation of the hormone on entry into the capillaries. The peptide is secreted by exocytosis from the basal aspect of the open-type endocrine cell on lumenal stimulation. The peptide crosses the basal lamina and diffuses into the lamina propria, where it may interact with nerve endings of sensory nerves. Subsequently, it reaches the capillaries and is degraded by the enzyme dipeptidyl peptidase IV, localized on the endothelial surface of the capillaries.

Effects of Glucagon-like Peptide 1 on Appetite and Food Intake

Interestingly, GLP-1 infused intravenously also inhibits appetite and food intake. It is not known whether this is due to its inhibitory effect on gastrointestinal motility or whether it principally involves some of the brain centers regulating food intake. GLP-1 administered into the cerebral ventricles also inhibits food intake and investigations have shown that the GLP-1 receptor is expressed at numerous locations of the brain, including hypothalamic nuclei involved in appetite regulation. As mentioned above, these receptors are not immediately accessible to peripheral GLP-1, but are likely targets for GLP-1, produced in neurons of the nucleus of the solitary tract, the fibers of which project to the hypothalamus and other brain regions. According to studies of early gene expression (cFos), these neurons are not activated by extensive food intake but rather by interoceptive stress, harmful stimulation of the inner organs, e.g., elicited by administration of lipopolysaccharides or lithium chloride. Thus, intracerebrovascular (icv) administration of the GLP-1 receptor antagonist exendin 9-39 abolished the inhibition of food intake elicited by lithium chloride. The antagonist, however, also enhances spontaneous food intake as well as neuropeptide Y-induced food intake, suggesting that GLP-1 may nevertheless be tonically involved in the regulation of food intake. The mechanisms whereby peripheral GLP-1 and central GLP-1 inhibit food intake are apparently not related. Thus, the inhibitory effect of central GLP-1 on food intake is lost in animals neonatally treated with monosodium glutamate, a model of hypothalamic obesity in which the arcuate nucleus is destroyed, whereas peripheral GLP-1 is still effective. However, these findings do not exclude the possibility that neurons activated by GLP-1 on

food ingestion may transmit satiety signals, only that they do not transmit to GLP-1-producing neurons of the brain stem. Alternatively, brain GLP-1 receptors may differ with respect to transmission of mainly satiety signals and enteroceptive stress signals. Mice in which the GLP-1 receptor has been knocked out do not become obese, suggesting either that GLP-1 is not essential for the regulation of body weight or that other regulatory mechanisms compensate for the loss of the inhibitory peptide.

Biological Effects of Glucagon-like Peptide 2

The exact structure of human GLP-2 was only recently determined and synthetic GLP-2 with the correct structure has not been available until recently. The early assays for GLP-2 were unable to discriminate between GLP-2 and other GLP-2-containing products of proglucagon. In addition, using the available C-terminally extended synthetic GLP-2, most workers were unable to find biological activities for the peptide, although an early report claimed that there was activation of adenylate cyclase in sections of the hypothalamus. It has been hypothesized that GLP-2 could have a supportive role in the ileal brake mechanism and GLP-2 has been demonstrated to inhibit gastric motility and vagally induced acid secretion, but GLP-2 appears less potent than GLP-1. The GLP-2 receptor is expressed in the intestinal epithelium and also in the ventromedial nucleus of the hypothalamus and icv administration of GLP-2 was recently demonstrated to cause inhibition of food intake. It is possible therefore that GLP-1 and GLP-2 interact with respect to this cephalic action. Evidence for what appears to be the major biological activity of GLP-2 was provided by Drucker *et al*. in 1996, when they discovered that mice harboring subcutaneous glucagonomas expressing proglucagon-derived peptides in a gut-like pattern developed intestinal villous hyperplasia. Among the various proglucagon-derived peptides subsequently tested (GLP-1, glicentin, oxyntomodulin, and GLP-2), GLP-2 was the only one with significant intestinotropic activity.

The expansion of the villous epithelium was attributable both to increased crypt cell proliferation and to decreased enterocyte apoptosis. The major effect was seen in the small bowel epithelium, in which a marked increase in villus height and small bowel mass was observed, following treatment with GLP-2 for 7–10 days. Thus, it seems that GLP-2 is in fact the intestinal growth factor of the L cell predicted to exist from numerous animal experiments in which an association between adaptive growth and increased L-cell secretion was observed.

THERAPEUTIC APPLICATIONS OF GLUCAGON-LIKE PEPTIDE 1 AND GLUCAGON-LIKE PEPTIDE 2

Taken together, the actions of GLP-1 should make it ideally suited to therapy of type 2 diabetes mellitus and indeed, in such patients, infusions of GLP-1 may completely normalize blood glucose, presumably by a combined action of stimulated insulin secretion, inhibited glucagon secretion (thereby decreasing hepatic glucose production), and flattened meal-induced glucose excursions (due to the inhibition of gastric emptying). It could also be expected to inhibit food intake and thus promote a weight loss, which per se would be expected to enhance insulin sensitivity and improve glucose tolerance. Finally, and most importantly, its effect on beta-cell replication and differentiation raises the hope that with GLP-1, the effect on blood glucose regulation will be more long-lasting than that observed with conventional therapy, which generally fails after some years of treatment. The major problem associated with therapeutic application of GLP-1 is its rapid degradation and inactivation by DPP-IV. Several approaches are currently being investigated to circumvent this problem, including the use of resistant analogues of GLP-1 and administration of inhibitors of DPP-IV. Both approaches are currently undergoing clinical testing, inspired by successful experiments in animal models of diabetes where such approaches have resulted in lasting improvements in glucose tolerance, near normalization of glycated hemoglobin concentrations, and reductions of body weight. The fact that age-induced deterioration of glucose tolerance in rats can be prevented by GLP-1 suggests that its tropic effects can also be exploited clinically. Recently, in 2002, the efficacy of GLP-1 in diabetes treatment was documented by Zander *et al*. in a study in which GLP-1 was administered for 6 weeks by continuous subcutaneous infusion to patients with severe type 2 diabetes. In these patients, average plasma glucose values were lowered by approximately 5 mmol/liter, the concentrations of free fatty acids were lowered, and the concentration of glycated hemoglobin fell by 1.3%. In addition, the patients lost 2 kg of body weight and both their insulin sensitivity and beta-cell function were markedly improved. The treatment was without side effects. These observations have greatly increased interest in developing therapies based on GLP-1 receptor activation. Because GLP-1 does not cause hypoglycemia, it can also be given to euglycemic subjects and it is therefore hoped that GLP-1 can also be used to treat obesity.

Because of its intestinotropic effects, GLP-2 is currently being considered as treatment for a number of

gastrointestinal diseases associated with insufficient intestinal mucosal function. Thus, it has been shown that the mucosal atrophy associated with total parenteral nutrition could be prevented by administration of GLP-2 and that the adaptive growth responses to major intestinal resections can be augmented by GLP-2 treatment. Furthermore, in mice with dextran sulfate- or indomethacin-induced enteritis, their injuries, weight loss, and mortality may be significantly attenuated by GLP-2 treatment. Similarly, GLP-2 significantly enhanced mucosal repair after experimental intestinal ischemia. In a 2001 study in patients with short bowel syndrome, Jeppesen and co-workers demonstrated that GLP-2 significantly reduced malabsorption and promoted weight gain. In agreement with the finding that GLP-2 is less extensively degraded by DPP-IV than GLP-1, native GLP-2 can be used for these therapeutic applications. Thus, GLP-2 also seems to have an interesting spectrum of clinical applications.

Eosinophilic Gastroenteritis

JON A. VANDERHOOF AND ROSEMARY J. YOUNG
University of Nebraska Medical Center, Omaha

eotaxin Specific eosinophil chemoattractant that is important in the process of eosinophil production.
mucosal eosinophilic gastroenteritis Eosinophilic infiltration primarily in the mucosal layer, resulting in vomiting, diarrhea, and abdominal pain.
muscular eosinophilic gastroenteritis Eosinophilic infiltration extending into the muscular layer of the gastrointestinal tissues, resulting in obstructive symptoms and stricture formation.
serosal eosinophilic gastroenteritis Eosinophilic infiltration extending into the serosal layer of the gastrointestinal tract, resulting in symptoms such as abdominal distension and pain.

Eosinophilic gastroenteritis is a rare disorder characterized by the infiltration of eosinophils in the gastrointestinal tissues. The location of the eosinophils, number of eosinophils, and depth of eosinophilic infiltration all are factors in the varied manifestations of this disorder. Classification of this condition can be related to the depth of the eosinophilic infiltration, such as mucosal, muscular, or serosal infiltration, and as either primary (immune-mediated) enteropathy, which is the subject of this article, or secondary enteropathy, which may occur in parasitic infections.

INTRODUCTION

Visual endoscopic findings in eosinophilic gastroenteritis may reveal prominent mucosal folds, hyperemia, and nodularity. Small numbers of eosinophils are normally present in the lamina propria of the gastrointestinal tract, thus there is no general agreement on what increased level constitutes a pathological condition. The presence of eosinophils in mucosal/submucosal, muscular, or serosal layers is considered abnormal. Attempts to grade the severity of eosinophilic gastroenteritis have been based on density of eosinophils, and it is generally agreed that greater than 20 eosinophils per high-power microscopic field is needed for histological diagnosis. It has also been noted that eosinophilic gastroenteritis can be patchy in nature and requires multiple biopsy specimens for identification. Superficial biopsy specimens lacking the muscular and serosal layers may also obscure findings and, therefore, full-thickness gastrointestinal biopsies may be desirable.

PATHOGENESIS

Epidemiologic studies to identify the frequency of eosinophilic gastroenteritis have not been done. It has been noted that this condition affects all age groups and races. The most frequent form affects the mucosal layer of the gastrointestinal tract. There is a definite association between patients having a personal or family history of other allergic disorders, such as asthma or eczema, and there is a slight male preponderance.

Eosinophils are thought to be recruited in excess numbers by eotaxin, a chemoattractant released from mast cells after stimulation by irritants or certain food antigens. Eosinophils accumulate and initiate mast cell degranulation and further release of eotaxin and other cytokines, such as histamine, platelet-activating factor, and leukotriene B4. The cytotoxic products cause tissue injury and subsequent development of symptoms. The up-regulation of eotaxin mRNA also occurs in eosinophilic gastroenteritis, but the mechanism that stimulates the eotaxin is not well understood.

Diagnosis of eosinophilic gastroenteritis generally relies on a combination of gastrointestinal symptoms and the demonstration of eosinophilic infiltration on biopsies. Many cases exhibit peripheral eosinophilia and Charcot–Leyden crystals in the stools. Absence of parasitic infestation and the lack of involvement of organs outside the gastrointestinal tract are also cited as diagnostic factors. The differential diagnosis of eosinophilic gastroenteritis includes parasitic infections, particularly with helminths, early inflammatory bowel disease, celiac disease, connective tissue diseases, immunological disorders (including malignancies), and adverse effects of pharmacological agents such as enalapril.

CLINICAL PRESENTATION

Signs and symptoms of eosinophilic gastroenteritis are dependent on the portion of the gastrointestinal tract involved and are highly variable. Some patients exhibit

 Copyright 2004, Elsevier (USA). All rights reserved.

symptoms only in response to certain trigger factors, such as food, whereas seasonal variations are noted in other patients. Oftentimes, the course of the disease starts out mild and variable, making the diagnosis difficult. Many times, severity of the symptoms increases over time and may become debilitating, regardless of treatment.

Typically, patients with eosinophilic esophagitis present with dysphagia, anorexia, and/or heartburn. Patients with eosinophilic duodenitis or enteritis have abdominal pain with or without diarrhea. Eosinophilic colitis may present with abdominal pain and/or diarrhea. Mucosal/submucosal infiltration often results in pain, nausea, vomiting, diarrhea, and weight loss. Eosinophilic infiltration in the rectum, recently described in children, may present as constipation. Muscular layer eosinophilia results in partial obstruction in the pylorus or intestine. The esophagus may appear with multiple contractions or rings, often called trachealization of the esophagus. Abdominal computer tomography (CT) and X-ray findings in this disorder may reveal areas of a thickened gastrointestinal bowel wall. Serosal layer disease involving the entire bowel wall is extremely rare, and these patients typically present with eosinophilic ascites.

TREATMENT

Because the etiology of eosinophilic gastroenteritis is not known, treatment of the condition primarily relies on management of symptoms. Because of the highly variable presentation, management often becomes a trial-and error-process. Younger children may outgrow the symptoms. Dietary and/or medication therapy are generally utilized.

Avoidance of certain foods is an initial mode of therapy. In younger children, cow's milk protein is most often an offending agent; however, restrictive elimination diets may be required for symptom control. A completely elemental diet based on free amino acids may also be required if symptoms are severe and triggered by multiple dietary components. Direct skin testing is not helpful due to a high false positive rate and the failure of a negative skin test to exclude a delayed hypersensitivity reaction. In children with identified allergic constipation, restriction of all dairy products has been shown to be of significant value.

Acid-reducing medications may be used for patients with mucosal/submucosal eosinophilic infiltration of the upper gastrointestinal tract. Medications such mesalamine may provide topical antiinflammatory effects for colonic eosinophilia. Other medications specifically targeting control of eosinophils have demonstrated some success. Case reports of sodium cromoglycate (Gastrocrom), montelukast (Singulair), and systemic steroids (Prednisone) have indicated positive benefits. If symptoms are severe, initiation of therapy with systemic steroid therapy may be required, with later weaning, and maintenance of remission with less potent antiinflammatories and diet therapy. Systemic steroids may intermittently be required if symptoms return. Most recently, the benefits of fluticasone (Flovent), an inhalable corticosteroid that is swallowed, has been shown to be of particular benefit for eosinophilic esophagitis. Additional medications for other symptoms, such as nausea, may include medications such as ondansteron hydrochloride (Zofran) or prokinetic agents such as metaclopromide (Reglan). Ketotifen (which inhibits secretion of mast cell mediators such as histamine) and suplatast tosilate (a selective T helper-2 cytokine interleukin-4 and interleukin-5 inhibitor) have been used with success in some cases of eosinophilic gastroenteritis.

CONCLUSION

Although previously considered to be rare, eosinophilic gastroenteritis is increasingly being diagnosed due to enhanced awareness of characteristics and better diagnostic methods. Pain control and chronic malnutrition are the major issues to be dealt with and fatality is uncommon unless obstructive symptoms occur. Placebo-controlled studies of various treatment modalities have been lacking due to small patient numbers and highly variable symptoms. Further research is needed to identify the exact etiology and the most appropriate therapy.

cytokines Regulatory proteins released by inflammatory and noninflammatory cells that act as mediators of immune responses.
ions Elements that have a positive (cationic) or negative (anionic) charge due to the loss or gain of one or more electrons.
kinase Enzyme that catalyzes the transfer of phosphate from ATP to substrates.
phosphatase Enzyme that catalyzes the hydrolysis of phosphate groups from substrates.
plasma membrane Semipermeable lipid bilayer that encloses the cytoplasm of a cell.

The gastrointestinal epithelium forms a selective and regulated barrier, allowing the uptake of nutrients while restricting pathogen access to underlying tissue compartments. Epithelial barrier function relies on the formation of cell–cell junctions, namely, the apical tight junction. The tight junction is the major structure that defines barrier function and selective paracellular transport. The tight junction and the underlying adherens junction form what is referred to as the apical junctional complex, which is linked to cytoskeletal elements via scaffolding and linker proteins. These complexes act to regulate tight junction structure and function. Alterations in epithelial barrier function occur in both physiologic and pathologic conditions.

GASTROINTESTINAL TRACT EPITHELIAL BARRIER

The epithelial lining of the gastrointestinal tract is an important barrier that separates two very distinct environments with different molecular compositions. Thus, the epithelium interfaces with and separates luminal contents from underlying tissue compartments. The epithelial barrier is not a static structure but is a dynamic barrier that is tightly regulated to control movement of fluid and solutes between the two environments. The epithelium permits uptake of luminal nutrients, ions, and water while restricting access of pathogens to the underlying tissue compartments. Transport across the epithelium occurs through both transcellular and paracellular pathways. Transcellular transport is an energy-dependent, directional transport mechanism that relies on the cell-specific transporters and channels positioned on the apical and basolateral cell membranes. Paracellular transport is also a regulated process that complements the transcellular transport pathway. The most apical intercellular junction in epithelial cells, referred to as the tight junction (TJ), is a major player in regulating paracellular permeability. In addition to regulating paracellular permeability, the TJ separates apical and basolateral plasma membrane domains, thereby

Epithelial Barrier Function

BRIAN A. BABBIN AND ASMA NUSRAT
Emory University

cytokines Regulatory proteins released by inflammatory and noninflammatory cells that act as mediators of immune responses.
ions Elements that have a positive (cationic) or negative (anionic) charge due to the loss or gain of one or more electrons.
kinase Enzyme that catalyzes the transfer of phosphate from ATP to substrates.
phosphatase Enzyme that catalyzes the hydrolysis of phosphate groups from substrates.
plasma membrane Semipermeable lipid bilayer that encloses the cytoplasm of a cell.

The gastrointestinal epithelium forms a selective and regulated barrier, allowing the uptake of nutrients while restricting pathogen access to underlying tissue compartments. Epithelial barrier function relies on the formation of cell–cell junctions, namely, the apical tight junction. The tight junction is the major structure that defines barrier function and selective paracellular transport. The tight junction and the underlying adherens junction form what is referred to as the apical junctional complex, which is linked to cytoskeletal elements via scaffolding and linker proteins. These complexes act to regulate tight junction structure and function. Alterations in epithelial barrier function occur in both physiologic and pathologic conditions.

GASTROINTESTINAL TRACT EPITHELIAL BARRIER

The epithelial lining of the gastrointestinal tract is an important barrier that separates two very distinct environments with different molecular compositions. Thus, the epithelium interfaces with and separates luminal contents from underlying tissue compartments. The epithelial barrier is not a static structure but is a dynamic barrier that is tightly regulated to control movement of fluid and solutes between the two environments. The epithelium permits uptake of luminal nutrients, ions, and water while restricting access of pathogens to the underlying tissue compartments. Transport across the epithelium occurs through both transcellular and paracellular pathways. Transcellular transport is an energy-dependent, directional transport mechanism that relies on the cell-specific transporters and channels positioned on the apical and basolateral cell membranes. Paracellular transport is also a regulated process that complements the transcellular transport pathway. The most apical intercellular junction in epithelial cells, referred to as the tight junction (TJ), is a major player in regulating paracellular permeability. In addition to regulating paracellular permeability, the TJ separates apical and basolateral plasma membrane domains, thereby

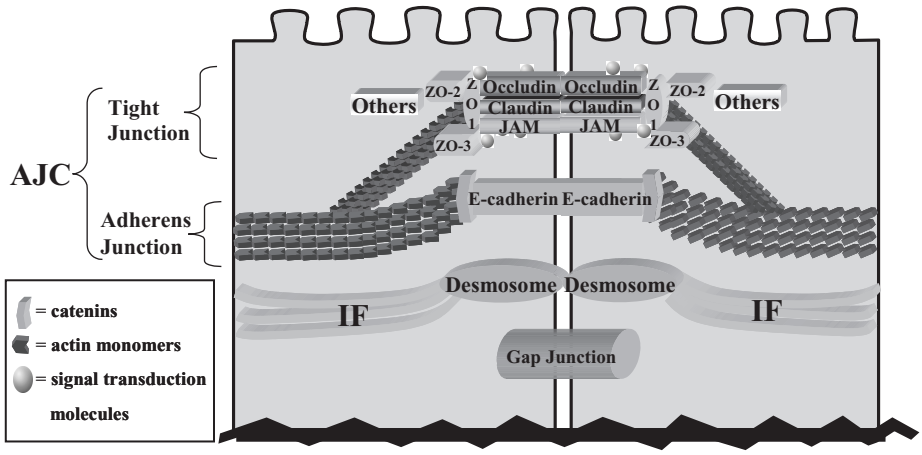

FIGURE 1 Epithelial intercellular junctions. The apical junctional complex (AJC) consists of the tight junction and underlying adherens junction. Both junctions consist of transmembrane proteins linked to the perijunctional actin cytoskeleton via linker or scaffolding proteins. Occludin, claudin(s), and junction adhesion molecules (JAMs) of the tight junction are linked to the cytoskeleton via the zonula occludens (ZO) proteins. E-Cadherin affiliates with the cytoskeleton via the catenins. Desmosomes anchor cell–cell junctions that bind intermediate filaments (IFs). Gap junctions form conduits in which molecules can pass from the cytosol of one cell to the cytosol of another cell. Figure courtesy of Thomas Brown.

contributing to epithelial cell polarity. Immediately subjacent to the TJ is the adherens junction (AJ), and these two intercellular junctions constitute the apical junctional complex. The development, stabilization, and regulation of the TJ appear to be dependent on interaction with the underlying actin cytoskeleton that encircles the apical perijunctional region of epithelial cells. Other intercellular junctional complexes in epithelial cells include the desmosomes and gap junctions (see Fig. 1). Because TJs are key structural elements that regulate epithelial paracellular permeability/barrier function, the focus of the remainder of this discussion is on these intercellular junctions.

TIGHT JUNCTION STRUCTURE

TJs were first identified by ultrathin-section electron microscopy as a series of discrete sites of apparent membrane fusion ("membrane kisses") involving the outer leaflet of adjacent plasma membranes (see Fig. 2). On freeze-fracture electron microscopy, these junctions appear as anastomosing strands or fibrils in the plasma membrane, with complementary grooves in the extracytoplasmic membrane leaflet. At sites of membrane kisses, the TJ strands in one cell are in close apposition with strands in the adjoining cell. The intervening grooves create aqueous permeation routes, or pores, in which certain solutes can diffuse. This netlike meshwork demonstrates ion and size selectivities of solutes that are dependent on the biochemical composition of the TJ and the aqueous pore size, which are regulated under both physiologic and pathologic conditions.

In recent years, the molecular composition of the TJ has begun to be elucidated. The basic biochemical structure of TJs consists of integral membrane proteins that are linked to the underlying actin cytoskeleton via linker or scaffolding proteins (see Fig. 1). The TJ multiprotein complex appears to be affiliated with distinct lipid-rich membrane microdomains, "membrane rafts," which cluster signal transduction proteins to allow for efficient regulation of TJ function. The TJ multiprotein complex consists of three major transmembrane proteins. These include occludin, claudin(s), and the junction adhesion molecule (JAM). Occludin, a 65-kDa protein, is predicted to consist of four transmembrane domains, two extracellular loops, a short cytosolic N terminus, and a long cytoplasmic C-terminal tail of approximately 255 amino acids. Both the N- and C-terminal domains are high in serine and threonine residues that are hyperphosphorylated when the protein is in its active form. The C-terminal domain interacts with the postsynaptic protein-95/discs-large/zonula occludin-1 (PDZ) domains of TJ cytoplasmic plaque proteins in the zonula occludens (ZO) family, namely, ZO-1 and ZO-3.

The claudin family of transmembrane proteins consists of over 20 members. Evidence supports that claudins are the major structural component or "backbone" of TJs. They localize to TJs of epithelial and

FIGURE 2 Electron micrograph of epithelial intercellular junctions. The arrows indicate the site of the tight junction where membranes of adjoining cells are in close apposition. The brackets outline the adherens junction with subjunctional actin filament condensation. The desmosomes are apparent beneath the adherens junction.

endothelial cells and their expression patterns vary among different tissues. Claudin-1, -2, and -4 are expressed in the gastrointestinal tract. In the rat gut, claudin-4 has been identified to be exclusively expressed on the colonic surface epithelium, whereas claudin-2 demonstrates a crypt-to-villous decrease in expression. Claudins are also predicted to have four transmembrane domains with a cytoplasmic N and C terminus, and two extracellular loops. They show no sequence homology with occludin; however, like occludin, they interact with the ZO proteins. Distinct species of claudins can polymerize to form "heteropolymers," and between adjacent cell strands, claudins adhere to each other in either a homotypic or heterotypic manner. The extracellular loops of claudins vary in the amount and nature of charged residues, suggesting that these loops and their positions in the TJ influence ion passage. It has recently been demonstrated that claudins create a charge-selective barrier. Claudin-4 has been shown to selectively alter paracellular flux of Na^+ in Madin–Darby canine kidney (MDCK) epithelial cells. Because the extracellular loops of occludin lack charged amino acid side chains and have a high tyrosine and glycine content, it is unlikely that this protein directly determines the ion selectivity of TJs. Rather, occludin is likely to have a regulatory role in assembly and maintenance of TJs.

The last major transmembrane component of TJs is JAM.Three JAM-related protein belong to the immunoglobulin superfamily. They have a single transmembrane domain. The extracellular domain of JAM is thought to be folded into two immunoglobulin-like domains. JAM has been demonstrated to be involved in cell adhesion, TJ assembly, and extravasation of monocytes across the endothelium. *In vitro* experiments have suggested that JAM also associates with TJ cytoplasmic plaque proteins such as ZO-1, acute lymphocytic leukemia fusion-6 (AF-6), and partitioning-defective protein 3 (PAR 3), implicating its role in the establishment of cell polarity.

The scaffolding proteins linking the transmembrane proteins to the underlying cytoskeleton also couple tight junctions to cytoplasmic regulation, intracellular signal transduction, cell polarity, and vesicle targeting. ZO-1 was the first TJ protein to be identified, and related ZO-2 and ZO-3 have subsequently been identified. In addition to their localization in the cytoplasmic plaque of TJs, the ZO proteins have also been identified in the nucleus of growing cells, suggesting a role in transcriptional events. They are members of the membrane-associated guanylate kinase-like homologues (MAGUKs). These proteins are characterized by one or more PDZ domains, a src homology (SH3) domain, and a guanylate kinase-like (GUK) domain. The have been demonstrated to link the TJ protein complex to the apical perijunctional actin–myosin ring. This affiliation is important in regulating paracellular permeability. Numerous additional proteins have been discovered in TJs. These include atypical protein kinase C (PKC) isotype-specific interacting protein (ASIP), symplexin, the phosphoprotein cingulin, Sec 6/8, vesicle-associated membrane protein-associated protein (VAP), and AF-6, as well as PAR. Details of mechanisms by which these proteins regulate TJ structure and function are still incompletely understood. What appears to be clear, however, is that affiliation of the TJ protein complex with the underlying actin cytoskeleton is important in regulation of TJ function. Numerous signal transduction pathways have been implicated in regulation of TJ function/paracellular permeability, as discussed in the following sections.

REGULATION OF TJ FUNCTION IN HEALTH AND DISEASE

Signal Transduction Pathways Regulating TJ Function

The tight junction is a dynamic intercellular junction that regulates paracellular permeability. It is

therefore not surprising that TJ function is regulated by a broad spectrum of signal transduction proteins that serve to maintain and regulate the association of the TJ multiprotein complex with the underlying actin cytoskeleton, which in turn controls movement of fluid and solutes in the paracellular pathway. There are key signaling mechanisms involved in regulation of paracellular permeability.

The G proteins encompass a growing family of signal transduction molecules with inducible activities that are dependent on reversible interactions with guanine nucleotides. Heterotrimeric and the small Ras superfamily of G proteins have been implicated in the regulation of TJ function. Of the many Ras family members, Rho, Rab 3B, and Rab 13 have been shown important in TJ regulation. It has been shown that the *Clostridium botulinum* toxin C3 transferase, which selectively blocks Rho effector coupling, results in reorganization of the perijunctional F-actin ring, disassembly of TJs, and increased paracellular permeability. Furthermore, studies using transfected epithelial cells expressing mutant Rho GTPases have documented the role for these proteins in TJ regulation. One group of downstream effectors mediating Rho signaling events includes the family of serine/threonine kinase isoenzymes, termed p160ROCK (ROCK I) and Rho kinase (ROCK II). These kinases are important in many cellular processes that involve actin cytoskeletal rearrangements, such as stress fiber formation, axonal growth, tumor cell invasion, and platelet activation. ROCK activity has been attributed to inactivation of myosin phosphatase and phosphorylation of myosin light chain kinase, leading to actin–myosin contraction. It has been previously shown that modification of ROCK function is associated with enhanced paracellular permeability without changes in organization of TJ proteins, occludin, JAM, and ZO-1. It is therefore likely that ROCK mediates its influence on TJs via modifications in the actin cytoskeleton and that the assembly of the TJ multiprotein complex requires other downstream effectors of Rho. The Rab proteins (Rab 11, Rab 3B) are implicated in the maintenance of intercellular junctional structures.

Affiliation of TJ proteins with each other, the plasma membrane, and the underlying actin cytoskeleton has previously been shown to require phosphorylation/dephosphorylation events. Although details of kinases and phosphatases involved in such events are still lacking, numerous studies have focused on proteins in the protein kinase C family. PKCs are phospholipid-dependent serine/threonine protein kinases that can be classified into three groups based on the structure of their regulatory domains [classical (cPKC), novel (nPKC), and atypical (aPKC)]. Numerous PKCs have been implicated in regulation of TJ structure/function. These include PKCs in the novel and atypical category. Physical association of PKC-ζ, an aPKC, with the cytoplasmic tail of the TJ transmembrane protein, occludin, has been documented. Studies in LLC-PK1 and MDCK cell lines have demonstrated that PKC activation regulates the phosphorylation and localization of occludin. In addition to TJs, PKCs have been implicated in endocytosis and recycling of the subjacent AJ transmembrane protein E-cadherin, implicating a more diverse regulatory role of these proteins.

Physiologic Regulation of Paracellular Permeability by Luminal Glucose

The first example of physiologic regulation of TJs by an extracellular stimulus was described in 1987. In these experiments, the addition of intraluminal glucose segments of rodent small intestine caused a significant increase in permeability to small molecules and a simultaneous decrease in transepithelial resistance (TER). Na^+–glucose cotransport-dependent TJ regulation has subsequently been demonstrated *in vivo* in healthy human subjects. Intrajunctional tight junction dilations and dissociation of ZO-1 have been observed during Na^+–glucose transport. Studies to define mechanisms by which luminal glucose regulates paracellular permeability have suggested that a Na^+–glucose cotransport-dependent activation of the Na^+/H^+ exchanger (NHE3) leads to alkalinization of the cytoplasm and subsequent myosin light chain phosphorylation, causing contraction of the perijunctional actomyosin ring, leading to increased paracellular permeability.

Modifications in Epithelial Paracellular Permeability by Leukocytes

Active inflammation in the gastrointestinal tract and patient symptoms are histologically correlated with transmigration of polymorphonuclear neutrophils (PMNs) across the epithelium. PMNs migrate across the epithelium from the basolateral to the apical/luminal compartments. Interactions of PMNs with epithelial cells have been demonstrated to alter barrier function in a manner that is dependent in part on the number of PMNs actively crossing the epithelium. With large-scale PMN migration, the resultant epithelial discontinuities may be the precursors for erosions and ulcers seen in many inflammatory conditions. However, low-density PMN transmigration is associated with little loss of barrier function, which recovers rapidly. The TJ serves as the rate-limiting step in PMN transmigration, and therefore mechanisms for PMNs to facilitate their migration

across this junction are likely to be important in minimizing deleterious effects of epithelial barrier disruption. The cross-talk between epithelial cells and PMNs is an area of intense investigation. A number of different epithelial intercellular junction proteins and lateral membrane proteins appear to play an essential role in this process. CD11b/CD18 (PMN β2-integrin) and CD47 (integrin-associated protein) are some key proteins in PMNs and epithelial cells that mediate interaction(s) between these two cell types. Interestingly, *in vitro* studies using model intestinal epithelial cells (T84 cells) and PMNs have shown that epithelial−PMN contact prior to PMN transmigration is sufficient to induce epithelial cell phosphorylation events that enhance paracellular permeability. This provides evidence that regulation of transepithelial migration is, at least in part, mediated by sequential signaling events between migrating PMNs and the epithelium.

Intraepithelial lymphocytes (IELs) comprise one of the largest lymphocytic populations in the body. IELs comprise a distinct T lymphocyte population that resides in close proximity with epithelial cells. Increased IELs are observed in a number of chronic inflammatory conditions, such as celiac sprue and lymphocytic colitis. E-Cadherin has been identified as the counterreceptor for the IEL-expressed integrin, αEβ7-integrin, which is important in the interactions between these two cell types. Affiliation with the epithelium, as well as elaboration of cytokines by IELs, may play a role in modifying epithelial barrier function.

Cytokine Regulation of Epithelial Barrier Function

The extracellular signals of many different cytokines and growth factors in a variety of physiologic and pathologic conditions influence TJ structure and function. Key proinflammatory cytokines such as interferonγ (IFNγ)and tumor necrosis factor α (TNFα) enhance paracellular permeability by influencing TJ structure. Studies have demonstrated that IFNγ induces displacement of occludin, ZO-1, and ZO-2 away from the apical lateral membrane with alterations of the perijunctional F-actin ring. TNFα has been shown to reduce the number of tight junction strands and induce loss of submembranous cortical F-actin with an increase in G-actin content.

Numerous other cytokines such as interleukin (IL)-1, IL-4, IL-13, insulin-like growth factor-1 (IGF-1), and vascular endothelial growth factor (VEGF) have been shown to decrease barrier function of endothelial and epithelial cells. Transforming growth factor-β (TGF-β)produced by platelets, lymphocytes, macrophages, and endothelial cells, in contrast, has been shown to increase the barrier function of epithelial cells and promote intestinal epithelial wound closure. In addition to inducing increased epithelial barrier function, TGF-β has additional protective effects by curtailing the influence of barrier-reducing cytokines such as IFN-γIL-4, and IL-10.

Disease Entities Influencing Epithelial Barrier Function

Idiopathic Inflammatory States

Impaired epithelial barrier function has been observed in diverse idiopathic pathologic conditions of the gastrointestinal tract. These entities range from microscopic colitis to inflammatory bowel disease (IBD). In IBD, numerous mechanisms have been described to explain the decrease in epithelial barrier function. These include release of proinflammatory cytokines, PMN transepithelial migration, and innate increased paracellular permeability not completely accounted for by the former mechanisms. Altered barrier function in microscopic colitis may be due to IEL−epithelial cell interactions.

IBD encompasses ulcerative colitis (UC) and Crohn's disease (CD), which display a waxing and waning course, with flares of disease activity correlating with active PMN transepithelial migration. Inflammatory mediators such as TNFα and IFN-are known to be elevated in these disorders and contribute to impairment of barrier function. This impairment is most pronounced in areas of active inflammation, and less so in quiescent areas. Innate differences in epithelial barrier function have been described in patients with IBD. Redistribution of TJ proteins in this disorder has been observed both in areas of active inflammation and in quiescent regions. Application of targeted gene deletion and transgenic approaches has revealed potential genetic factors that could contribute to the development of IBD. Models that include deletions of IL-2, IL-10, and TGF-β, as well as T cell receptor rearrangements, have resulted in chronic inflammatory bowel disease. However, these manipulations of single genetic loci are modulated by other genetic factors as well as environmental factors. Thus, it appears that IBD results from an environmental stimulus in a genetically predisposed individual.

Collagenous and lymphocytic colitis, also known as microscopic colitis, are characterized by watery diarrhea and a normal-appearing colonic mucosa during endoscopic examination. Histologically, these entities are associated with an increase in intraepithelial lymphocytes or thickening of epithelial basement membrane and epithelial damage. Diarrhea in these

patients may be attributed to reduced net ion absorption secondary to alterations in barrier function. These alterations could result from direct IEL–epithelial interaction as well as elaboration of cytokines by IELs. In collagenous colitis, the thickened subepithelial collagen plate may act as a diffusion barrier, decreasing ion uptake.

Pathogen-Induced Epithelial Damage and Decreased Epithelial Barrier Function

Many infectious agents, such as *Salmonella*, *Shigella, Clostridium difficile, Escherichia coli* (enterohemorrhagic strains), and *Campylobacter*, are capable of breaching the epithelial barrier and inducing disease. Some pathogens secrete toxins that specifically interact with TJ proteins or regulatory molecules in TJs, thereby enhancing paracellular permeability (see Table I). As an example, *C. difficile* elaborates two toxins (A and B). These toxins specifically glucosylate Rho GTPases and inhibit Rho effector coupling, resulting in modifications in TJ structure and enhanced paracellular permeability. The latter in turn exposes underlying tissues to luminal antigens/pathogens, resulting in further epithelial damage and influx of PMNs. Monocytes exposed to *C. difficile* toxins have been shown to secrete the PMN chemoattractant interleukin-8. In addition, specific TJ transmembrane proteins have been documented to function as receptors for viral pathogens. These include claudin-4, which is a receptor for *Clostridium perfringens* enterotoxin (CPE). This single polypeptide induces displacement of claudin-4 from the TJ, with subsequent degradation in MDCK cells. Viral receptors in TJs include JAM, which is the reovirus receptor, and the coxsackievirus and adenovirus receptor (CAR) protein. Thus, both bacterial and viral pathogens not only target TJ proteins and influence paracellular permeability, but also utilize TJ proteins as receptors or conduits for internalization and epithelial damage.

SUMMARY

TJs are dynamic structures that are regulated to control epithelial barrier function and selective paracellular transport of solutes. They also serve to segregate apical and basolateral membrane domains that are important in cell polarity. A variety of factors regulate TJs in physiologic and pathologic conditions. In inflammatory states, alterations in these structures are a major factor in the development of diarrhea. Although our understanding of these structures has greatly advanced over recent years, questions regarding the regulation of the TJ barrier, incorporation of TJ proteins into the tight junctions, and apical polarization of TJs have yet to be answered.

TABLE I Enteric Pathogens that Alter Barrier Function/Tight Junctions[a]

Enteric pathogen	Virulence factor	Cell lines/tissue studied	Proposed mechanism	TJ structural modification and pathophysiology
Clostridium difficile	Toxin A, toxin B	T84, human colon, rabbit ileum, Caco-2	Monoglucosylation of Rho at threonine 37	Alteration of apical F-actin with decreased TER in 2–4 hours
Clostridium perfringens	Enterotoxin	MDCK I	Cleavage of claudin-3 and claudin-4	Loss of claudins at TJs with decreased TER starting at 4 hours
Vibrio cholerae	Zonula occludens toxin	Rabbit ileum	Protein kinase C activation	Decreased numbers of TJ strands with decreased TER by 1 hour
	Hemagglutinin	MDCK I	Cleavage of occludin	Occludin degradation; ZO-1 and F-actin reorganization with decreased TER after 1 hour
Bacteroides fragilis	Metalloprotease toxin	T84, Caco-2, MDCK, human colon	Cleavage of E-cadherin	Dissociation of occludin and ZO-1 from TJ, absent E-cadherin with decreased TER starting in 15 minutes
Escherichia coli	Cytotoxic necrotizing factor 1	Caco-2	Deamination of Rho at glutamine 63	Alteration of actin filament formation with decreased TER in 1 hour

[a] Abbreviations: MDCK, Madin–Darby canine kidney; TER, transepithelial resistance.

apoptosis Evolutionarily conserved method of programmed cell death; also referred to as "cell suicide."
base One of the two functional zones of the gastric unit, found at the bottom of the gastric gland; site of cells producing the acid and enzymes necessary for breakdown of food in the gastric lumen.
cell cycle Series of four phases that a dividing or proliferating cell goes through. G_1 is the first of two growth phases and is the longest portion of the cell cycle, S phase is the period during which a cell's genetic material is replicated, G_2 is the second growth phase, and M phase is when a cell divides into two genetically identical cells.
columnar epithelium Classification of epithelium in which cell height is larger than cell width.
crypt of Lieberkühn Zone of proliferation in the small intestine, located underneath the villi. Crypts provide the cells that replace the epithelium of the villi of the small intestine.
deoxyribonucleic acid Genetic material of a cell.
differentiation Process of a cell maturing and acquiring a particular, specific function within the body, usually accompanied by a loss of the ability to proliferate.
foveolae Opening of the gastric unit into the lumen of the stomach.
goblet cell Responsible for the production and secretion of mucus into the lumen of the small intestine and colon.
homeostasis Ability of an organism to maintain an internal balance or equilibrium (i.e., a balance between cell loss and cell production).
hyperplasia Increase of proliferation to a level that is higher than normal.
hypoplasia Decrease of proliferation to a level that is lower than normal.
metaplasia Process of converting one tissue type to another.
Paneth cell Normally found only at the base of the crypt of Lieberkühn in the small intestine; responsible for secreting lysozyme and antimicrobial factors.
parietal cell One of the cell types of the gastric epithelium; responsible for acid production and secretion into the gastric lumen.
pit One of the two functional zones of the gastric unit, located superior to the gastric gland; site of pit cells that produce the protective mucus of the gastric epithelium.
restitution Ability of epithelium to rapidly replace or repair sections of denuded epithelial tissue.
squamous epithelium Flat type of epithelium classified by cells with a width much larger than their height.
stem cell Has the ability to self-replicate and ultimately produce multiple distinct types of differentiated cells.
villus Functional zone of the small intestinal epithelium; composed of columnar epithelium that projects into the lumen of the small intestine.
zymogenic cell One of the cell types of the gastric epithelium, found within the base; responsible for secreting enzymes needed in the chemical breakdown of food.

The gut epithelium is one of the most rapidly dividing tissues within the body. Rapid cellular renewal in the gastrointestinal tract is protective, serving to prevent bacterial infection or other diseases of the epithelial layer. However, alterations in gut proliferation may lead to a variety of diseases, including cancer and inflammatory bowel disease.

INTRODUCTION

The gastrointestinal epithelium serves several important roles within the body. It provides a physical barrier against infections and protects the body from the harsh environment of the gut lumen, exemplified by the stomach's highly acidic environment. It also serves as the major barrier against luminal carcinogens, toxins, or pathogens. In addition, the gastrointestinal epithelium provides a surface layer for selective absorption of nutrients and water from ingested foods.

Although specific details vary along the length of the gastrointestinal tract, the gut epithelium can generally be subdivided into two zones: a proliferative zone and a functional zone. In the proliferative zone, a small number of multipotent stem cells create transit daughter cells, which further divide, expanding the number of cells available to the epithelium. These cells then migrate to the functional zone, where they differentiate into their final form to perform a specialized function (such as producing mucus or absorbing nutrients) and lose their ability to divide.

CELL CYCLE AND METHODS FOR STUDYING PROLIFERATION

Proliferating cells progress through four stereotypical phases, called the cell cycle, as they undergo the journey from being a single cell to having identical cellular offspring (Fig. 1). The presynthetic gap phase (G_1) is the

 Copyright 2004, Elsevier (USA). All rights reserved.

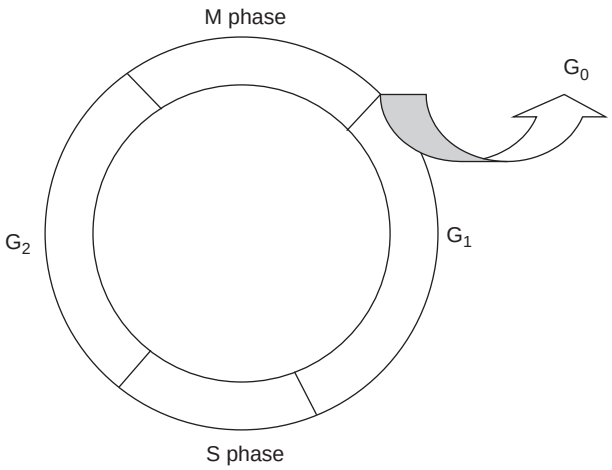

FIGURE 1 The cell cycle of proliferating cells. Once cells enter the functional zone, they lose the ability to proliferate and are in G_0.

first and longest portion of this cycle and is a period of cell growth. This is followed by a synthesis (S) phase in which the cell's DNA is replicated, leading to a doubling of the cell's genetic material. The postsynthetic gap phase (G_2) follows next and is another growth phase, during which the cell is preparing to undergo division. The final step of the cell cycle is the mitosis (M) phase. During M phase, the cell divides into two daughter cells that are genetically identical to the original parental cell. When a cell migrates from the proliferative zone of the gastrointestinal epithelium to the functional zone, where it can differentiate to perform specialized processes, it loses the ability to proliferate. Differentiated cells that lack the ability to divide under normal circumstances are said to be in the G_0 phase.

Of the four parts of the cell cycle, mitosis is the easiest to detect; it is the only phase detectable on conventional light microscopy without specialized staining. Mitotic cells have a characteristic morphology, including the presence of mitotic spindles. This is readily apparent on hematoxylin and eosin staining, the simplest histologic technique for evaluating tissue microscopically.

Although there is no clear way to detect cells in G_1 or G_2 by means of conventional microscopy, several methods exist for identifying proliferating cells in the S phase of the cell cycle. These techniques are more specialized than the visual identification of M phase cells on simple histologic sections and are typically utilized in animal or cell culture research. Bromodeoxyuridine (BrdU) is a material similar to the DNA building block thymidine. Subcutaneous injection of BrdU leads all cells in S phase to mistakenly incorporate this molecule in replicating DNA. The incorporated BrdU can be visualized using standard staining techniques with antibodies to the molecule. A similar approach involves proliferating cell nuclear agent (PCNA), a small protein that is needed for the cell's DNA replication machinery to function. Cellular staining allows for the identification of this protein when levels are highest to indicate cells that are in S phase.

The S phase cells can also be identified as cells that incorporate tritiated thymidine, a radiolabeled building block of DNA, into their genetic material. Identification involves either using autoradiography, a photographic technique similar to X rays wherein radioactive emission from labeled cells causes a darkening of a silver-coated film that is laid over a section of tissue, or using a quantitation technique that counts radioactive emissions using a scintillation counter.

ORAL CAVITY AND ESOPHAGUS

The epithelium of the oral mucosa and esophagus provides protection to the salivary glands and muscles within the esophagus. It also serves as a barrier against cytotoxic agents and possible carcinogens in ingested substances. The hard palate and gingiva are protected by the presence of a keratinized epithelia in areas where mechanical breakdown of food occurs. Keratin, a family of scleroproteins also seen in nails, hair, and horn tissue, adds additional strength to this portion of the gastrointestinal epithelium. All other mucosa of the oral cavity and esophagus consists of a softer, nonkeratinized epithelium. The epithelium also serves as a flexible sheath to help transfer food to the stomach via peristaltic contractions of smooth muscles in the esophagus.

Epithelium of the oral mucosa and the esophagus is characterized as stratified squamous epithelium. Stem cells are located in the basal layer of the epithelium. Cells migrate upward from the basal layer to the superficial layer, the surface of the epithelium. As cells migrate toward the epithelial surface they begin to differentiate and lose the ability to divide. To ensure that the epithelial layer does not get too thick, cells are sloughed off into the oral cavity or into the lumen of the esophagus. Homeostasis is therefore maintained, and cell loss in the superficial layer is balanced by proliferation in the basal layer.

STOMACH

The stomach contains thousands of invaginations called gastric units; these have the greatest spatial and geographic complexity of any epithelia in the gastrointestinal tract. Like all epithelium in the gastrointestinal tract except for oral mucosa and esophagus, the gastric epithelium is a columnar epithelium. Its gastric units

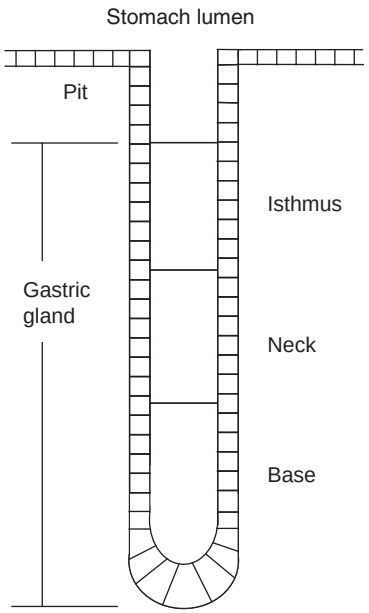

FIGURE 2 Gastric unit of the stomach epithelium. Multipotent stem cells that give rise to all the cell types of the gastric epithelium proliferate in the isthmus.

open into the lumen of the stomach via the foveolae. Each gastric unit can be divided into two subunits, the pit and the gastric gland, with the pit located superior to the gastric gland (Fig. 2). The gastric gland is further subdivided into three subunits (in descending order from the junction with the pit)—the isthmus, the neck, and the base. The proliferative zone of the gastric unit is located in the isthmus of the gastric gland. Multipotent stem cells located in the isthmus are capable of producing the three cell lineages found within the gastric epithelium—mucus-producing pit cells, acid-producing parietal cells, and enzyme-producing zymogenic cells.

Although gastric units exist throughout the stomach, differences exist in the fundus, corpus (body), and antrum, the stomach's three main anatomical regions (from proximal to distal). The two functional zones of the stomach's epithelium are located at the opening of the gastric unit to the lumen and at the base of the gastric gland. The functional zone located near the opening of the gastric lumen is called the pit, which is composed primarily of pit cells, responsible for secreting a protective layer of mucus, and a few acid-producing parietal cells. The base of the gastric gland is the location of the second functional zone of the gastric unit and contains parietal cells and/or zymogenic cells, depending on its anatomic location.

The neck region of the gastric gland in the corpus serves as a transitional zone for zymogenic cells. As prezymogenic cells travel through the neck, they undergo a process of maturation and lose the ability to divide. This process of maturation and migration downward from the isthmus to the base takes prezymogenic cells approximately 14 days. Migration for pit cells is much more rapid; they travel from the isthmus to the pit in 12 hours. Parietal cells exhibit a bidirectional migratory pattern, with mature parietal cells being found in all compartments of the gastric unit.

Although stem cells lead to daughter cells and eventually differentiated cells throughout the stomach, local geographic influences lead to differences in gastric unit size and type throughout the stomach. For instance, the gastric unit of the corpus is smaller than the gastric unit of the antrum. In mice, gastric units in the corpus contain 200 cells, compared to 250 cells in the antrum. The length of the pit also varies between gastric units within the corpus and the antrum, with the pit being much larger in the antrum. The base also differs between regions; zymogenic cells are present in the corpus but are absent in the antrum. Therefore, even though stem cells can give rise to each of the differentiated cell types of the gastric epithelium, local environmental factors can influence what type and how many cells are produced.

Turnover rates of cells in the gastric epithelium vary depending on the cell type. Parietal cells have an average life span of 54 days, whereas zymogenic cells live an average of 194 days, after which they are eliminated in an unclear fashion, potentially by being engulfed by macrophages in the extracellular matrix. In contrast, pit cells are rapidly renewed and have a turnover rate of 3 days, after which they are shed into the gastric lumen. Despite the obvious disparity in life span of differentiated epithelial cells, stem cells and their resultant daughter cells are able to match cell loss with cell production to maintain gastric homeostasis.

SMALL INTESTINE

The primary function of the small intestine is absorption of water and nutrients from ingested foods. Enzymatic digestion occurs within the small intestine whereas mechanical (and to a lesser degree chemical) breakdown occurs in the stomach. In order to increase the surface area of the small intestine for greater absorption, the intestinal epithelium is divided into hundreds of thousands of fingerlike projections, villi, into the lumen. Each villus is supplied with cells from the small intestine's proliferative units, flask-shaped invaginations called the crypts of Lieberkühn (crypts) (Fig. 3). Proliferation has been studied extensively in the small intestine; the mechanisms underlying this process are well delineated in mice and are more completely understood in humans than they are for other locations in the

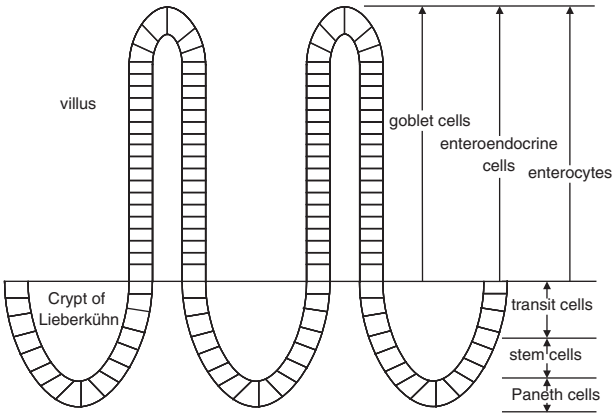

FIGURE 3 Crypt–villus unit of the small intestinal epithelium. Multipotent stem cells are located three to five positions above the crypt base. These give rise to a transit cell population and ultimately to all four cell lineages of the small bowel.

gastrointestinal tract. All cells within the small intestinal epithelium are produced in the crypts. Each crypt has an average cell population of 450, and although the average number of crypts per intestine is unknown in humans, it is approximately 1×10^6 in mice. An individual crypt supplies two to three villi. In contrast, each villus is supplied by approximately six crypts.

Multipotent stem cells that supply the entire small intestinal epithelium are located near the base of the crypt at approximately three to five cell positions above the base of the crypt. The number of stem cells in each crypt is unclear, with estimates ranging from 4 to 16, accounting for less than 5% of crypt cells. Stem cells divide approximately once every 36 hours or greater and give rise to a zone of rapidly dividing transit or daughter cells in the region immediately superior to the stem cell niche. There are six or greater generations of transit cells per crypt, and the cell cycle takes 20–73 hours to complete in this population. Cumulatively, a human's small intestinal crypts produce approximately 50×10^6 cells/minute, a total of 0.25 kg/day.

Although human studies examining how a multipotent stem cell gives rise to multiple differentiated villus cells are obviously difficult to perform, experiments performed in mice demonstrate that this is an extremely complex process. The daughter transit cells resulting from the stem cell vary in both their life span as well as in the type of cells they can produce. Daughter cells can be short-lived, with a life span of less than 10 days, or long-lived, with a life span of over 100 days. In addition, some transit cells can parent both columnar-shaped enterocytes and mucus-producing goblet cells, whereas other types can produce only a single cell type.

As animals age, their intestines become larger. As such, intestinal homeostasis is a process in continual evolution, with production of both new crypts and new villi as well as continued division of existing crypt cells and migration into existing villi. The crypt/villus ratio increases over time, with a disproportionate increase in new crypts. Up to 10% of crypts are estimated to be dividing at any given time, after the number of cells contained inside reaches a certain, as yet unknown, threshold.

Stem cells inside a crypt are capable of producing all four cell lineages of the small intestinal epithelium. Three cell types (absorptive enterocytes, mucus-producing goblet cells, and enteroendocrine cells) migrate toward the villus apex. As cells travel up the crypt, they begin to differentiate into their final form. Once an epithelial cell passes the crypt–villus junction, it is fully committed into its mature state and can no longer divide. It then takes between 3 and 5 days for a differentiated cell to migrate to the villus tip. Epithelial cells are removed from the villus primarily by extrusion into the intestinal lumen, although a small subset undergoes apoptosis before reaching the villus apex. Proliferation studies of both mouse and human intestines suggest that the entire epithelium of the small intestine renews every 3 to 5 days.

The fourth small intestinal cell lineage, Paneth cells, differentiate as they migrate toward the base of the crypt, where they reside for approximately 3 weeks. Paneth cells produce lysozyme and other antimicrobial factors. The downward migration of this cell lineage takes approximately 5 to 8 days, and cells are ultimately eliminated by either apoptosis or by being phagocytosed by macrophages within the extracellular matrix or basement membrane.

COLON AND RECTUM

The function of the large intestine is absorption of the water in what remains of the ingested nutrients after their passage through the small intestine. The large intestine is also responsible for helping to maintain the balance of sodium and other minerals within the body. Like the small intestinal and gastric epithelium, the colonic epithelium is columnar in organization. Unlike the small intestine, the colon has no formal villi to reach into the lumen—each unit ends in a hexagonal cuff of cells ringing the opening of the crypt.

The epithelium of the large intestine has three cell types—mucus-producing goblet cells, enteroendocrine cells, and columnar cells, which are also referred to as colonocytes. Because no Paneth cells exist in the large intestine, stem cells are located at the base of the colonic crypt, with transit cells found above. Like the small intestine, multipotent stem cells can ultimately produce

all three cell types found in the colonic epithelium. However, colonic crypts are much larger than their small intestinal counterparts, with an average of 2250 cells per crypt. Stem cells divide every 36 hours or greater, and daughter transit cells take 36–96 hours to divide. The proliferative region occupies the basal two-thirds of a colonic crypt, and there are greater than five to nine daughter transit cell generations, although the exact number is not known. The top third of the crypt is the zone of maturation, with the luminal surface being the functional zone of the crypt. The epithelial surface of the colon is replaced in mice every 8 days. Nearly all cells exit the colonic epithelium through extrusion into the lumen.

Organization of the rectal epithelium is identical to that seen in the colon. The epithelial layer is flat, without villi, and the proliferative zone comprises the basal two-thirds of the crypt, with stem cells located at the extreme base leading to production of columnar, goblet, and enteroendocrine cells. Cells at the top of the rectal crypt are eliminated by being sloughed into the gut lumen. Murine studies indicate that the rectal epithelium is replaced every 4–5 days.

FACTORS INFLUENCING EPITHELIAL PROLIFERATION

The presence and passage of food through the gastrointestinal tract are important stimuli for epithelial proliferation and thickness. Animal data suggest that mechanical passage of food through the esophagus stimulates cell production in the basal layers of the esophageal epithelium. Direct feeding into the stomach also causes an increase of esophageal epithelial proliferation over baseline via the hormone gastrin, suggesting that factors produced in the stomach can stimulate epithelial proliferation in distant anatomic locations. However, direct gastric feeding results in a less robust proliferative response compared to normal ingestion and illustrates that mechanical passage of food plays an important role in esophageal proliferation. Experiments in mice demonstrate that bypassed sections of the small intestine undergo substantial hypoplasia compared to those sections that receive luminal nutrition. This point is further supported by animal models that show general hypoplasia throughout the gastrointestinal tract during intravenous feeding. Regrowth of an atrophied epithelium occurs rapidly when luminal nutrition is reintroduced.

Injuries to the gastrointestinal epithelium may also affect proliferation. Brief treatment of rat gastric mucosa with 100% ethanol denudes the epithelium. Within moments after stopping the ethanol treatment, new epithelial cells begin to migrate toward the gastric lumen. An intact epithelial layer is reestablished within 1 hour of injury; this phenomenon is called restitution. Restitution has also been described in the colon of rabbits and humans.

Critical illness can affect gastrointestinal epithelial proliferation in disparate ways. Both *Pseudomonas aeruginosa* pneumonia and burn injury in mice cause decreases in small intestinal proliferation as measured by BrdU. These animals also have simultaneously elevated epithelial apoptosis resulting from their injuries. In contrast, a mouse model of ruptured appendicitis causes increased small intestinal epithelial proliferation in rats measured with tritiated thymidine.

A number of molecular mediators are also involved in the control of epithelial proliferation. Epithelial growth factor (EGF) is a strong inducer of epithelial proliferation and maturation in the small and large intestines, and also plays a role in intestinal development in both fetuses and infants. Transforming growth factor (TGF) also increases epithelial proliferation, although in a less potent fashion than EGF. Prostaglandins increase proliferation and influence cell migration in the gastric epithelium. Prostaglandins also impart a protective benefit on gastric epithelium and appear to play a role in gastric mucosal wound healing. Prostaglandins appear to stimulate proliferation in the small intestine but have no effect on proliferation in the colon. Gastrin, a hormone produced by the gastric epithelium, stimulates proliferation in the esophageal epithelium as previously outlined. Cells neighboring wounds within the gastrointestinal epithelium secrete trefoil peptides, small stable signal proteins with a distinctive three-dimensional configuration. Trefoil peptides are thought to be important in the process of restitution by influencing cell migration and possibly stimulating proliferation. Corticosteroids reduce both the rate of proliferation and cell migration within the gastrointestinal epithelium and may play a role in the development of ulcers in this tissue.

DISEASES OF THE GASTROINTESTINAL EPITHELIUM INVOLVING ABNORMAL PROLIFERATION

Although the proliferation rate is high in both the small intestine and the colon, colorectal cancer is the third most common type of neoplasia in the United States but small intestinal cancer is rare. The differential sensitivities of the two organs to crypt apoptosis are one potential explanation for this paradox. Theoretically, decreased programmed cell death coupled with

increased or abnormal proliferation could yield an increase in cancer risk. Evidence that supports this involves increased expression of the antiapoptotic protein, Bcl-2, in the stem cell compartments of the colonic and rectal epithelium, compared to the stem cell compartments in the small intestine, and the fact that it is much more common to see apoptotic crypt cells in the small intestine than in the colon. Some carcinogenic agents can also extend the proliferative zone into the functional zone of the colonic crypt or induce the production of an increased proliferative cell population.

Ulcerative colitis is primarily a disease of the rectal epithelium that may spread proximally into the colon. Symptoms of ulcerative colitis include bloody diarrhea and a thinning of the rectal mucosa. The rectal mucosa has an increased proliferative rate in ulcerative colitis, leading to a reduction in turnover time for the rectal epithelium from the typical 4–5 days down to 2–3 days. In addition, the proliferative zone of the affected rectal or colonic crypt extends to include the entire crypt, in contrast to the basal two-thirds seen in normal epithelium.

Gastric metaplasia involves both an increase in proliferation and an abnormal pattern of gastric epithelium. In this disorder, the gastric epithelium undergoes a shift in appearance to one resembling the small intestine, and the proliferation zone extends toward the base of the gastric gland. This enlargement of the zone of proliferation is accompanied by a marked increase in proliferation to two to three times the normal rate. Small intestine epithelial cell lines also begin to appear, with both Paneth and goblet cells present in the gastric epithelium. This can ultimately lead to gastric dysplasia and invasive cancer.

SUMMARY

The gastrointestinal epithelium is one of the most rapidly dividing organs in the body. In keeping with the gut's multiple functions, its epithelium is rapidly renewable and replaces itself on a routine basis. Multipotent stem cells located in the proliferative region of the gastrointestinal tract produce daughter or transit cells that eventually mature into each of the specialized cell types that make up the functional portion of the gastrointestinal epithelium. Because gut stem cells can differentiate into a number of cell types, they have attracted substantial research interest both for treatment of disorders of the gastrointestinal tract and for answering basic scientific questions about how epithelial cells proliferate. Further understanding of stem cell function and signaling may allow future manipulations of gut epithelial proliferation for therapeutic gain.

columnar epithelium A classification of epithelium composed of a type of cell whose height is larger than its width.
restitution The ability of epithelium to rapidly replace or repair sections of denuded epithelial tissue.
squamous epithelium A flat type of epithelium classified by a type of cell whose width is much larger than its height.

Epithelial repair or restitution is the process by which small superficial defects in a mucosal surface are sealed by coordinated epithelial cell migration. Restitution occurs throughout the gastrointestinal tract as a necessary response to noxious injury in both simple columnar and stratified squamous epithelia. Adequate restitution prevents bacteria and other foreign antigens from invading deeper mural tissues. Inadequate restitution, induced either by persistent noxious stimuli or by failure of epithelial responses, contributes to the production of persistent and larger breaches in the mucosal barrier and clinically significant ulcerative diseases. Therefore, restitution is central to the pathophysiology of many common ulcerative disorders including gastroesophageal reflux disease, duodenal ulceration, enteric infections, idiopathic inflammatory bowel disease, and ischemia. For the purposes of this article, epithelial restitution in each compartment of the gastrointestinal tract will be considered separately. In each section, existing knowledge concerning coordinated epithelial cell migration will be considered, underlying molecular mechanisms will be discussed, migration-enhancing and -inhibiting factors will be summarized, and the contribution of stromal factors will be assessed where appropriate.

EPITHELIAL RESTITUTION IN THE ESOPHAGUS

The human esophagus is lined by a stratified squamous epithelium. Numerous exogenous and endogenous stimuli may damage this barrier, most commonly reflux of low pH stomach contents in gastroesophageal reflux disease (GERD). The presence of such gastric contents is directly toxic to the esophageal epithelium, producing small defects or erosions in the mucosal surface and exciting an inflammatory response including intraepithelial eosinophils. These erosions heal by coordinated squamous epithelial cell migration into the eroded areas and subsequent basal cell proliferation to regenerate the normal barrier.

Most studies of epithelial restitution, including studies of esophageal epithelium, have relied on simple *in vitro* culture models of rabbit esophageal cells. Wounds in epithelial monolayers are made mechanically, thereby stimulating neighboring epithelial cells to migrate in coordinated sheets with preserved intercellular junctions into the wound space. Experiments using such a model have demonstrated that epithelial restitution decreases markedly in direct response to a falling pH and increased length of time of acid exposure. These conditions closely model the conditions of the lower esophageal epithelial surface in patients with GERD. This profound inhibition of restitution might explain why prolonged acid suppression is necessary for healing patients with esophagitis and ulcer disease.

At the molecular level, the role of growth factors such as hepatocyte growth factor (HGF) and epidermal growth factor (EGF) is controversial. Initial *in vitro* studies had demonstrated restitution-enhancing effects of HGF and EGF in a rabbit esophageal model, noting a greater sensitivity to these stimuli in esophageal epithelia than in gastric epithelia. However, a subsequent study, also of cultured rabbit esophageal epithelial monolayers, failed to detect a restitution-enhancing effect from HGF or EGF but instead detected enhanced cell proliferation. Of interest, tumor growth factor-β_1 (TGF-β_1) inhibited both restitution and cell proliferation. Overall, given evidence in other epithelial systems, it seems highly likely that several cytokines and growth factors play a critical role in modulating restitution. The likely complex interplay between restitution-enhancing and restitution-inhibiting growth factors has not been unraveled. More critically, the identity of central regulatory factors, likely targets for therapeutic intervention, is not known.

In contrast, the role of epithelial–stromal interactions has not been studied in the esophagus and specific proteins crucial in cell migration, such as the focal adhesion complex proteins, have not yet been intensively studied. Such investigations will be necessary

to further explore the role of restitution in the pathophysiology of GERD.

EPITHELIAL RESTITUTION IN THE STOMACH

The human stomach is lined by a simple mucus-producing columnar epithelium. Although well adapted to the low pH environment of the stomach lumen, the gastric mucosa nevertheless is commonly affected by toxic stimuli that produce mucosal defects or gastric erosions. Such noxious stimuli may be locally derived, such as chronic active gastritis driven by *Helicobacter pylori* or by exogenous chemical injury such as that caused by alcohol, nonsteroidal anti-inflammatory drugs (NSAIDs), and bile reflux. Failure to achieve restitution can result in the development of large or confluent erosions and eventually deep ulcer formation.

Studies performed in rats demonstrated that superficial erosions heal by migration of flat to low cuboidal epithelial cells from within gastric pits to the gastric surface. This process is rapid with migrating cells from pits extending lamellipodia over denuded basal lamina and moving at approximately 1–2 μm/min. These studies correlate well with *in vitro* studies of frog mucosa that demonstrate flattened cells migrating from gastric pits during restitution. Typical junctional complexes were present between adjacent cells. Subsequent studies demonstrated that lumenal ammonia, potentially derived from *H. pylori*, retarded restitution of guinea pig gastric mucosa *in vitro*.

Growth factors, as in other compartments of the gastrointestinal tract, have been associated with enhancing gastric epithelial cell migration and thus restitution. Acceleration of gastric epithelial restitution by platelet-derived growth factor (PDGF) has been demonstrated *in vitro*. HGF has also been shown to be a potent stimulant of rabbit gastric epithelial cell migration and proliferation, possibly via cyclooxygenase 2. In addition, EGF has been found to contribute to gastric mucosal restitution via stimulation of basolateral EGF receptors. EGF effects are at least in part produced by the stimulation of basolateral Na^+/H^+ exchangers, by formation of actin stress fibers, and via effects on focal adhesion complex proteins, notably focal adhesion kinase (FAK) and tensin. In culture models of canine oxyntic mucosa EGF, transforming growth factor-α (TGF-α), insulin-like growth factor-I, and interleukin-1 all enhanced cell migration and restitution. Finally, cytokines, such as PDGF derived from subepithelial fibroblasts, may not only influence epithelial function but also may have crucial autocrine effects on stromal cells during larger wound repair. It is likely that further growth factors and cytokines will be shown to regulate gastric restitution.

Although all of the early studies noted the coordinated, cohesive nature of gastric epithelial cell migration, few studies have concentrated on cell–cell adhesion and cell–cell communication during restitution. Increased expression of E-cadherin during cell migration and inhibition of cell migration by anti-E-cadherin antibodies demonstrated the critical role of this intercellular adhesion molecule in a culture model of rat gastric epithelial restitution. However, simple up-regulated linkage between migrating gastric epithelial cells is not the whole story. Inhibition of intercellular communication via gap junctions significantly inhibits gastric epithelial restitution in rats. This correlated with abnormal patterns of gap junction expression as evidenced by connexin 32 expression. Intercellular communication possibly via gap junctions may be necessary to coordinate the sheet-like movement of cells observed during migration.

The extracellular matrix also plays an important role in gastric epithelial restitution. This is adequately demonstrated by elegant studies of the differing effects of matrix components on gastric epithelial cell migration. At a molecular level, focal adhesion complexes serve to anchor the actin cytoskeleton of epithelial cells to the extracellular matrix. Focal adhesion complexes also serve as potent signal transducers between the extracellular matrix and the intracellular milieu. As noted above, the restitution-enhancing effects of EGF are associated with effects on focal adhesion complexes. Furthermore, the NSAID indomethacin delayed gastric restitution in association with inhibition of FAK phosphorylation. Clearly, extensive cross talk between gastric epithelial cells and their underlying matrix is vital in gastric epithelial restitution whether it occurs via direct stromal focal adhesion complex interaction or via other paracrine effectors, such as growth factors.

One of the most exciting fields of study in gastrointestinal epithelial restitution is the function of trefoil peptides. Their roles are well characterized in intestinal restitution but their role in the stomach is less certain. Trefoil peptides have been shown to stimulate canine gastric epithelial restitution *in vitro*. However, trefoil factor family 2 (TFF2) does not appear to affect restitution in studies of knockout mice. Instead, TFF2 influences gastric proliferation, acid secretion, and susceptibility to NSAID injury. Finally but importantly, a recent study has analyzed the energy dependence of gastric epithelial restitution and determined that the glycolytic pathway is essential for restitution after injury in the bullfrog gastric mucosa and that almost all repair

occurs in the absence of mitochondrial respiration, serving to highlight the rapidity of restitution. Pulling these various strands of information together, it is clear that cytokine stimulation, epithelial–stromal interactions, and efficient cell–cell communication are all likely to be required for gastric epithelial restitution. It is hoped that some of these recent advances in the understanding of gastric epithelial restitution and in particular the precise molecular mechanisms by which noxious stimuli affect restitution may well stimulate the discovery of novel therapies for gastric mucosal erosions and ulcers.

EPITHELIAL RESTITUTION IN THE INTESTINE

In direct contrast to the esophagus and stomach, an enormous volume of research has been performed on mechanisms of epithelial restitution in the intestine. This is no doubt due to the numerous diseases that produce mucosal erosions in the intestine, including enteric infection, ischemia, and idiopathic inflammatory bowel disease. It is not possible in this article to deal with the many and varied avenues of research into the intestinal restitution process and therefore certain general areas of promising research will be highlighted with reference to existing excellent reviews of the subject matter.

The mucosa of the intestines serves a vital function as a barrier between the highly noxious potentially pathogenic environment of the intestinal lumen and the vulnerable deeper tissues. Breaches in this epithelial barrier must be rapidly resealed by coordinated epithelial cell migration from surrounding uninjured mucosa in order to prevent the development of serious disease. Due to the wide variety of potential noxious stimuli, it is not surprising that the human small bowel and intestines have evolved a variety of mechanisms to protect against mucosal breaches and affect their rapid resealing.

Morphology of Epithelial Restitution in the Colon

No matter what the cause of the epithelial injury, areas of lamina propria denuded of epithelial cells provoke a rapid response from surrounding colonic epithelial cells. These epithelial cells flatten out in a coordinated fashion and migrate from all sides in a sheet to re-cover the exposed areas of lamina propria. Histopathologically, snapshots of this process may be identified in routine sections of erosions detected in biopsy material from patients with idiopathic inflammatory bowel disease or ischemia. In damaged colonic crypts, epithelial cells assume a flattened-out phenotype and extend long thin processes into the denuded areas. Importantly, they do not separate from their adjacent viable epithelium. The use of experimental models to analyze the molecular mechanism underlying these histopathological appearances will now be examined.

Intestinal Epithelial Restitution: Models of Repair

Most models of intestinal epithelial restitution are culture-based models composed of a monolayer of intestinal epithelial cells grown over a collagen-coated porous membrane. The existing commonly utilized models, both *in vivo* and *ex vivo*, are eloquently summarized by Wilson and Gibson in their review. The authors extensively discuss the benefits of simple *in vivo* model systems of intestinal epithelial cell migration. Such models allow the dissection of complex molecular pathways without the confounding and potentially confusing issues of host–pathogen or epithelial–stromal interactions. Then again, the limitations of using transformed cell lines that, however well differentiated, cannot precisely mimic normal epithelium is recognized. In addition, the particular difficulties surrounding the growth of model epithelia on matrix components are noted.

Intestinal Epithelial Restitution: Role of Peptides

A massive body of work now exists on the role of peptides in the modulation of intestinal epithelial restitution. These are excellently summarized in the review by Wilson and Gibson already mentioned but also in the excellent reviews by Podolski and by Dignass. Briefly, the role of peptide growth factors in intestinal epithelial restitution is now thought to be crucial. Numerous studies have recognized the central roles of TGF-β in this process. Importantly, numerous other restitution-enhancing growth factors, such as TGF-α, EGF, HGF, fibroblast growth factor, interleukin-1, interleukin-2, and interferon-γ, have been demonstrated to enhance restitution through a TGF-β-dependent pathway. However, the relative importance of each individual growth factor in enhancing restitution in a particular disease setting, such as idiopathic inflammatory bowel disease, remains to be determined.

Of equal importance in intestinal epithelial restitution is the role of trefoil factors or peptides. Members of this peptide family are differentially expressed throughout the gastrointestinal tract. Numerous investigators have determined the critical role of these peptides in recovery for mucosal injury and it appears that their effects are entirely independent of the TGF-β pathway.

Of great clinical interest is the fact that trefoil production is enhanced in sites as diverse as the stomach, small bowel, and colon. Dysregulation of trefoil peptide production has been demonstrated in both peptic ulceration and Crohn's disease. It is likely therefore that these peptides may provide useful therapeutic targets in healing such diseases.

Intestinal Epithelial Restitution: Role of Nonpeptide Factors

Again the reader is referred to the excellent reviews noted above. A wide variety of nonpeptide factors have been shown to modulate intestinal epithelial restitution. These include short-chain fatty acids, glutamine, nucleotides, bile salts, lysophosphatidic acid, trace elements, and numerous pharmacological agents. The extensive list of nonpeptide regulators serves as a reminder that, in the *in vivo* setting, each individual factor is a small part of a very complex puzzle. It has not been possible using *in vitro* models to assess in detail the complex interactions between numerous peptide and nonpeptide regulatory factors in governing epithelial restitution. Such studies are keenly awaited.

Intestinal Epithelial Restitution: Role of the Extracellular Matrix

Another fertile area of study has been the interaction between the intestinal epithelial cell and its supportive matrix. This has been excellently summarized in a recent review by Basson. This critical review notes that the extracellular matrix may influence restitution not only as a physical substrate but also by modulating relevant intracellular proteins, such as focal adhesion complex proteins, and by modulating the receptors for soluble factors derived from the extracellular environment. In this process, it appears that FAK plays a central role in integrating signals derived from the extracellular matrix. These signals are modulated in order to produce changes necessary to affect a phenotypic shift from a tall stationary columnar phenotype to a migratory flattened phenotype. Indeed, it is the rapid assembly and disassembly of focal adhesion complexes to integrins and thus to the extracellular matrix on one hand, and their linkage to the actin cytoskeleton providing contractile force on the other, that may serve as a trigger point for the influences of the many modulators of intestinal epithelial cell migration whether matrix or cytokine derived. Further studies have emphasized the role of subepithelial myofibroblasts enhancing epithelial migration. On a cautionary note, due to the difficulty of manipulating the extracellular matrix of the human intestinal lamina propria *in vivo*, the vast majority of studies of epithelial–stromal interaction are performed *in vitro*.

Intestinal Epithelial Restitution: Molecular Mechanisms

Due to the enormous variety of factors, both peptide and nonpeptide, that have been shown to modulate intestinal epithelial cell restitution, it is not surprising that the downstream molecular mechanisms by which these factors affect their responses are of great interest. Influencing a final common pathway governing cell migration would be of great therapeutic value. The role of focal adhesion complexes as signal integration sites is discussed above. Not surprisingly, the role of actin, critical in the formation of lamellipodia and intimately related to focal adhesion complexes, has been emphasized by several authors.

Similarly, the extensive junctional complexes between intestinal epithelial cells including the adherence junction complex may also serve as critical sites for the integration of numerous signals during restitution. Interestingly, recent studies have suggested that TFF3-modulated epithelial cell adhesion and migration occur via perturbing complexes between E-cadherin and β-catenin. The role of tight junctions and gap junctions in this regard remains to be studied. However, as epithelial migration occurs in a coordinated fashion, some intercellular signaling via gap junctions is to be expected. This has already been discussed with regard to gastric epithelium restitution. The role of the tight junction is less clear as preservation of mucosal integrity depends on the preservation of an intact tight junction during coordinated epithelial cell migration. However, this does not exclude the possibility of modulation of such junctions during migration. It could certainly be hypothesized that greater tractional force is exerted on tight junctions during monolayer migration than in the stationary setting. The expanding list of tight junction component proteins may yet contain critical agents necessary for reinforcing or otherwise altering tight junction function during migration. Clearly, much further study of junctions during migration is required.

CONCLUSION

Epithelial restitution throughout the gastrointestinal tract displays some recurring themes. First, restitution is a rapid, energy-dependent process. It occurs in a coordinated fashion and therefore inherently involves cell–cell adhesion complexes and molecules. Furthermore, the nature of epithelial–stromal interactions is crucial in modulating the restitution response. Finally,

peptide growth factors, trefoil peptides, and numerous other exogenous factors provide a busy information highway to the cell in regulating migration and thus restitution. Critical junctions on this highway at which integration of information occurs include focal adhesion complexes and intercellular junctions. A better understanding of these complex pathways may lead to the development of novel therapeutic strategies to enhance epithelial restitution and thus alleviate patient diseases.

Erosive and Hemorrhagic Gastritis (Gastropathy)

RAJEEV JAIN
Presbyterian Hospital of Dallas

gastritis Gastric mucosal disorder associated with an inflammatory infiltrate.
gastropathy Gastric mucosal disorder without significant microscopic inflammatory infiltrate.

The classification of erosive and hemorrhagic gastritis (gastropathy) is based on endoscopic findings related to acute chemical or irritant injury to the stomach without associated microscopic inflammation. Depending on the etiologies of erosive and hemorrhagic gastritis, it is recommended that diagnoses be further defined (e.g., reactive gastritis, chemically induced gastritis).

HISTOLOGY

Although the term "gastritis" is often used to both describe clinical symptoms and endoscopic findings, the histologic definition of acute gastritis is mucosal injury associated with an inflammatory neutrophilic infiltrate. Chronic gastritis is characterized by an inflammatory infiltrate of mononuclear cells such as lymphocytes, plasma cells, and macrophages. Causes of gastritis include *Helicobacter pylori* and other infectious agents, allergic and hypersensitivity reactions, or drugs. In comparison, erosive and hemorrhagic gastritis (gastropathy) denotes endoscopic findings in which mucosal injury has occurred but no significant inflammatory infiltrate is seen microscopically. In response to mucosal injury, the gastric mucosa can display cellular regeneration with reactive changes of foveolar hyperplasia. Erosions are superficial mucosal breaks involving necrosis that does not extend beyond the muscularis mucosa, whereas ulcers penetrate through the muscularis mucosa.

ENDOSCOPY

The endoscopic findings of the gastropathy of erosive and hemorrhagic gastritis vary from petechial hemorrhages to erosions and ulcers. The hemorrhagic lesions can vary in intensity and distribution based on the causative agent. The erosive changes are typically manifested by multiple erosions that can progress to ulcer formation.

The endoscopic and histologic findings of gastritis are frequently discordant. For example, the endoscopic findings suggestive of inflammation are frequently incorrect when gastric biopsies are examined. Also, the mucosa can appear normal at endoscopy but biopsies reveal inflammation. Therefore, when describing endoscopic findings, the term "gastropathy" is preferred over "gastritis."

ETIOLOGIES

Alcohol

Acute ingestion of alcohol can cause subepithelial hemorrhages in the stomach. The histological characteristics of acute alcohol injury include superficial hemorrhage and edema. The correlation between chronic alcoholism and gastric mucosal injury is unclear because of factors such as *H. pylori* infection and concomitant aspirin and/or nonsteroidal antiinflammatory drug use.

Antineoplastic Therapy

Radiation injury to the stomach affects the parietal and chief cells by causing edema and necrosis. Of patients receiving 5500 cGy of radiotherapy to the stomach, 50% will develop ulceration, which typically is solitary and located in the antrum. Chemotherapy agents infused through the hepatic artery can inadvertently injure the stomach and cause gastric ulceration with marked epithelial atypia.

Bile Reflux

Bile salts can reflux from the proximal small intestine into the stomach through an operative stoma or because of an incompetent pylorus or abnormal duodenal motility. Bile acts as a topical irritant, leading to gastric mucosal breakdown. The gastric histologic

 Copyright 2004, Elsevier (USA). All rights reserved.

findings documented in a group of patients with gastroenteric anastamosis-associated bile reflux include both hyperplasia and fibrosis of the lamina propria with foveolar hyperplasia. Endoscopically, the mucosal changes are most prominent in the distal stomach or proximal to the gastroenteric anastamosis. The clinical presentation of bile reflux gastropathy can vary from no symptoms to nausea, vomiting, abdominal pain, and weight loss. Medical therapy with ursodeoxycholic acid, sucralfate, misoprostol, and cholestyramine has shown limited benefit. In some reports, patients with bile reflux related to a gastroenteric anastamosis have improved after undergoing surgery with a Roux-en-Y gastrojejunostomy designed to divert bile from the stomach.

Cocaine

Crack cocaine use can cause exudative erosions throughout the stomach, sometimes with complications of bleeding and perforation. It is believed that these lesions are caused by vasoconstriction and resultant mucosal ischemia.

Ischemia

Ischemic gastropathy has been described in patients with chronic mesenteric ischemia, most typically related to atherosclerosis, atheromatous embolization, and extreme athletic activity, as seen in long-distance runners, who can present with gastrointestinal hemorrhage and anemia.

Mechanical Prolapse

Mechanical injury to the gastric cardia occurs in some patients, with retching and vomiting when the gastric cardia prolapses into the esophageal lumen. At endoscopy, prolapse can be observed, with gastric cardia injury manifested by erosions and ulceration.

Medications

Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) are the leading etiology of gastropathy. These agents injure the gastric mucosa by both topical and systemic routes. Topical injury occurs because aspirin and many NSAIDs are weak acids and can pass through the gastric mucus barrier into the surface epithelium. Also, some NSAIDs are prodrugs that the liver converts to acidic active drugs, which are secreted in bile. Topical injury from biliary excretion occurs when the active acidic metabolite refluxes into the stomach from the duodenum. Systemic injury is related to prostaglandin inhibition in the gastric mucosa, which causes decreased mucus and bicarbonate secretion and reduces mucosal blood flow, with subsequent impairment of mucosal protection. Within minutes of ingestion of aspirin and NSAIDs, histologic changes of mucosal cell injury can be noted. Endoscopic findings of subepithelial hemorrhages and erosions can be seen within a few hours of ingestion. The entire stomach is vulnerable to injury, with most erosions and ulcers found in the antrum. The primary treatment and prevention of gastropathy is discontinuation and avoidance of the injurious agent. If aspirin or NSAIDs cannot be discontinued, active treatment requires antisecretory therapy with histamine-2 receptor antagonists or proton pump inhibitors. Prophylactic strategies include misoprostol and proton pump inhibitors.

Oral potassium and iron therapy have also been shown to cause gastric petechial hemorrhage and erosions.

Portal Hypertension

The findings of congestive gastropathy in the setting of portal hypertension are recognized at endoscopy as mucosal red spots in a mosaic pattern. This endoscopic appearance is attributed to mucosal congestion and edema, with the grooves surrounding the area gastrica displayed as pale lines, producing the typical mosaic pattern. Microscopically, superficial venular and capillary ectasia with or without organizing microvascular thrombi is seen. Clinically, patients can be asymptomatic or present with occult bleeding and anemia. Nonselective beta-blockers and decompressive shunts have been used to treat refractory cases of bleeding.

Stress

Stress gastropathy is seen in critically ill patients who require mechanical ventilation and/or have a coagulopathy. Other risk factors for stress injury include previous gastrointestinal bleeding, hypotension, trauma, burn injury (>35% of body surface), central nervous system injury, renal failure, hepatic failure, organ transplantation, and sepsis. Erosions and ulcerations develop from a multifactorial process, with the primary insult being gastric ischemia. In endoscopic studies, mucosal injury is found in greater than 75% of critically ill patients within 24 hours of admission. The typical mucosal injury seen is multiple, diffuse, superficial erosions in the gastric fundus and body; however, focal, deep ulceration can also be seen in both the stomach and duodenum. Patients in the intensive care unit can experience significant bleeding, which

is associated with increased mortality. Preventive strategies have focused on acid suppression with histamine-2 receptor antagonists and mucosal protection with sucralfate. Based on the available data, stress ulcer prophylaxis is warranted only in high-risk critically ill patients such as those requiring mechanical ventilation or those with significant coagulopathy. Intravenous histamine-2 receptor antagonists or proton pump inhibitors are the preferred preventive strategy in these high-risk patients.

Overall, the survival for esophageal cancer is poor, because a majority of patients at diagnosis are found to have advanced disease.

INTRODUCTION

Approximately 12,000 people in the United States are diagnosed annually with esophageal cancer. Although considered a comparatively uncommon cancer in Western countries, esophageal cancer represents a major cause of cancer-related mortality worldwide. In

Copyright 2004, Elsevier (USA). All rights reserved.

developed countries over the past three decades, a substantial shift in relative incidence of the two major histologic types has been observed. Adenocarcinoma is now diagnosed more frequently than squamous cell carcinoma in the United States and western Europe. The reason for this change remains unclear, but is likely associated with the parallel increase in incidence of gastroesophageal reflux disease and, in turn, Barrett's metaplasia.

Solid food dysphagia is the most common clinical manifestation of esophageal carcinoma. Most patients present with advanced disease, because esophageal cancer appears to metastasize early in disease progression. Overall survival is directly dependent on the stage of disease at diagnosis, regardless of the histologic type of cancer. Five-year survival rates range from approximately 60% in patients with carcinoma *in situ* to less than 4% in patients with distant metastases. Because survival correlates closely to extent of disease, precise clinical staging is a critical component of determining appropriate treatment options. Endoscopic ultrasound has emerged as the most accurate diagnostic modality for locoregional staging. In select patients with limited disease, curative surgical resection represents a potential therapeutic approach.

SQUAMOUS CELL CARCINOMA

Epidemiology and Risk Factors

The incidence of esophageal squamous cell carcinoma varies greatly according to geographic location. The region extending from northern Iran across central Asia to northern China exhibits annual incidence rates exceeding 100 per 100,000 new cases. Additional high-incidence regions included Puerto Rico, South Africa, and India. Men and women appear to be equally effected in these high-incidence regions, whereas, in low-incidence regions, such as the United States and parts of Europe, men are more likely to be affected. In the United States, the annual incidence is approximately 3 to 4 per 100,000. African Americans have a fourfold increased risk as compared to European Americans. Further, most persons diagnosed with squamous cell carcinoma are over the age of 50 years. Such geographic differences in epidemiology suggest that dietary and environmental factors may play a central role in pathogenesis. A majority of cases in the United States and Europe are attributed to alcohol and tobacco consumption, but in endemic regions of Asia, exposure to foods containing carcinogenic nitrosamines and fungal contaminants has been implicated.

The presence of underlying esophageal disease also increases the risk for squamous cell carcinoma. Such disease processes include achalasia, chronic esophageal strictures, and previous caustic injuries to the esophagus. In addition, an association exists with rare diseases such as Plummer–Vinson syndrome, characterized by spoon-shaped concave fingernails, angular stomatitis, and esophageal webs, and tylosis, an autosomal-dominant disorder marked by hyperkeratosis of the soles and palms. As well, the infection of squamous cells with DNA viruses, including Epstein–Barr virus and human papilloma virus, has been linked to malignant transformation.

Pathology

Most squamous cell cancers arise from the middle esophagus. Early lesions may begin as small, focal areas of thickened mucosa. Over a period of months to years, these areas may progress to clinically overt disease (see Fig. 1). Gross features of advanced disease are generally characterized as polypoid, ulcerative, or infiltrating. In terms of spread, squamous cell cancers typically invade to the submucosa early in the disease process. As a consequence of an abundant network of submucosal lymphatics in the esophagus, dissemination to regional lymph nodes occurs rapidly. Common sites of such dissemination include the cervical, paratracheal, mediastinal, and celiac groups. Direct invasion of surrounding structures may also occur with further disease progression. Reported consequences of this process include gastrointestinal bleeding due to erosion into the aorta and aspiration as a result of tracheoesophageal fistula formation.

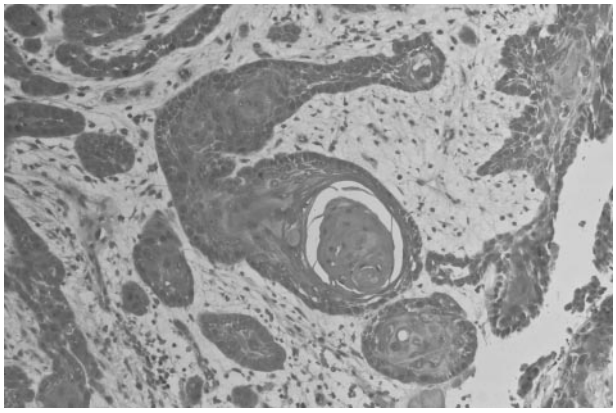

FIGURE 1 High-power microscopic view of a well-differentiated squamous cell carcinoma with a characteristic keratin pearl and invading nests of malignant squamous cells.

ADENOCARCINOMA

Epidemiology and Risk Factors

Several studies using population-based cancer registry data have suggested that incidence rates of adenocarcinomas of the esophagus have been increasing since 1970. This upward trend has been observed particularly in Caucasian men of developed countries such as the United States, Denmark, Sweden, and the United Kingdom. Among Caucasian males in the United States, the incidence of adenocarcinoma surpassed that of squamous cell carcinoma around 1990. Squamous cell carcinoma, however, remains the more common esophageal cancer worldwide.

Affected patients generally present in their middle sixties. Approximately 95% of patients are Caucasian, and males outnumber females 5 : 1. Unlike patients with squamous cell carcinoma, those with adenocarcinoma do not generally have a history of heavy tobacco or alcohol use. A strong correlation with obesity and adenocarcinoma has also been consistently found.

Barrett's esophagus is the most important risk factor for adenocarcinoma. This condition occurs when normal stratified squamous mucosa is replaced by columnar-lined epithelium that extends upward from the gastroesophageal junction (see Figs. 2 and 3). It is an acquired metaplastic process in response to recurrent mucosal injury, commonly the result of long-standing gastroesophageal reflux. Additional undetermined factors clearly play a role in this process, as suggested by findings that fewer than 50% of patients with adenocarcinoma have pathologic evidence of esophagitis, and that neither antireflux pharmacologic therapy nor surgery has been shown to result in reversion of metaplastic epithelium to normal squamous epithelium. Because of the association between Barrett's esophagus and adenocarcinoma, endoscopic screening is recommended in patients with established Barrett's esophagus.

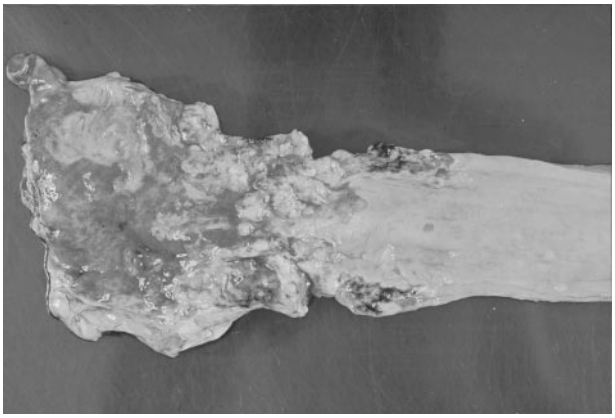

FIGURE 2 Gross view of an ulcerated adenocarcinoma of the distal esophagus, originating from Barrett's esophagus.

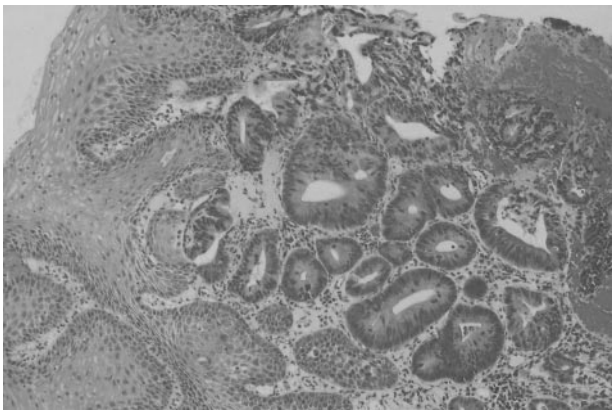

FIGURE 3 Low-power microscopic view of a well-differentiated adenocarcinoma with some distortion of glandular architecture.

Pathology

Adenocarcinomas typically arise from the distal third of the esophagus. Initially, they tend to appear as flat or raised patches of otherwise intact mucosa at or near the gastroesophageal junction. The general morphologic features of advanced disease are similar to those of squamous cell carcinoma; they can be polypoid, ulcerative, or infiltrating. Microscopically, most adenocarcinoma tumors are mucin-producing with intestinal-type features. As with squamous cell carcinoma, metastases to adjacent or regional lymph nodes occur early in the course of the disease process. Direct invasion of surrounding structures can also occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Squamous cell carcinoma and adenocarcinoma have similar clinical presentations. Obstruction of the lumen of the esophagus by tumor generally causes progressive food dysphagia. Patients may initially experience an intermittent sensation of friction or slow food passage, which may evolve into complete solid food intolerance. Accompanying weight loss, due to tumor anorexia and poor nutritional intake as a result of dysphagia, suggests advanced disease. The presence of odynophagia or retrosternal discomfort may indicate mediastinal involvement. Hoarseness may occur in the setting of recurrent laryngeal nerve involvement. Chronic gastrointestinal blood loss with iron deficiency anemia as a consequence of luminal epithelium disruption is common. Acute gastrointestinal blood loss is rare

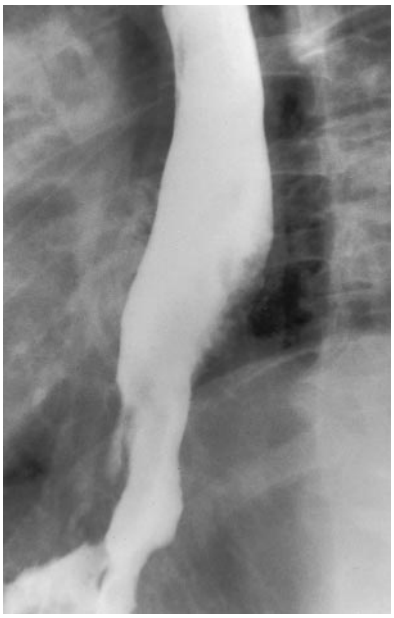

FIGURE 4 Barium esophogram, demonstrating a circumferential adenocarcinoma of the distal esophagus.

but has been reported in the context of tumor invasion into the aorta or pulmonary arteries. Aspiration pneumonias due to tracheobronchial fistula formation can occur as a late manifestation of tumor progression.

A diagnostic workup for esophageal cancer should be initiated in patients with dysphagia in the setting of risk factors for esophageal cancer. Barium studies are useful in detecting findings consistent with advanced lesions, such as high-grade strictures or fistulas, but often fail to identify early esophageal cancers (see Fig. 4). Endoscopy with biopsies is the most effective means of establishing the diagnosis. It must be performed even for patients with normal barium studies due to the limited sensitivity of barium studies. Multiple endoscopic biopsies increase the accuracy of diagnosis; when employed in conjunction with cytology brushings, the diagnostic yield exceeds 90%.

STAGING AND SURVIVAL

The ultimate prognosis is strongly dependent on the stage of disease at diagnosis. An accurate assessment of extent of disease is therefore necessary in the process of formulating treatment strategies. The initial step in staging typically begins with a CT scan of the chest and abdomen to evaluate for evidence of local and distant metastases. Patients without evidence of metastatic disease generally should have endoscopic ultrasound (EUS) in an effort to further delineate the extent of locoregional disease. For patients found to have proximal tumors, bronchoscopy is generally carried out to assess for evidence of spread to the trachea. Bone scanning is indicated for patients with clinical or laboratory findings suggestive of bone metastases.

EUS employs a high-frequency ultrasound transducer to assess the extent of invasion into the esophageal wall, which is depicted as a five-layered structure. EUS is also highly accurate in assessing for involvement of regional lymph nodes. Examination of the celiac nodes is particularly important, because evidence of spread to this group implies distant metastatic disease and therefore unresectability. The use of fine-needle aspiration (FNA) biopsy increases the staging accuracy of EUS by providing cytological evidence. With surgical resection specimens as a gold standard, the sensitivity for EUS FNA exceeds 85% in terms of detecting regional metastatic disease.

The TNM staging system of the American Joint Committee on Cancer (AJCC) for esophageal cancer is widely used (Table I). The important components of the system are extent of tumor invasion (T) and the presence of metastatic (M) disease in regional lymph nodes (N) or solid organs. Metastases in regional lymph nodes are either absent (N0) or present (N1).

TABLE I TMN Staging System for Cancer of the Esophagus

Primary tumor (T)			
TX: Primary tumor cannot be assessed			
T0: No evidence of primary tumor			
Tis: Carcinoma *in situ*			
T1: Tumor invades lamina propria or submucosa			
T2: Tumor invades muscularis propria			
T3: Tumor invades adventitia			
T4: Tumor invades adjacent structures			
Lymph node (N)			
NX: Regional lymph nodes cannot be assessed			
N0: No regional lymph node metastasis			
N1: Regional lymph node metastasis			
Distant metastasis (M)			
MX: Presence of distant metastasis cannot be assessed			
M0: No distant metastasis			
M1: Distant metastasis			
Stage grouping			
0	Tis	N0	M0
I	T1	N0	M0
IIA	T2	N0	M0
	T3	N0	M0
IIB	T1	N1	M0
	T2	N1	M0
III	T3	N1	M0
	T4	N1	M0
IV	Any T	Any N	M1

As well, organ metastases are either absent (M0) or present (M1). Resultant TNM classifications in turn correspond to disease stage. Esophageal cancer usually presents in an advanced stage, and, as a consequence, the overall prognosis is poor. Tumor histology does not appear to have an important impact on prognosis. Survival, moreover, is closely related to extent of tumor invasion and metastatic spread and thereby decreases sharply with increasing stage. Patients with T1 disease are reported to have a 5-year survival rate approaching 46% versus only 7% in patients with T4 disease. When stratified by TNM subtype, the 5-year survival rates for stages I, II, III, and IV disease are 60.4, 31.3, 19.9, and 4.1%, respectively.

TREATMENT STRATEGIES

Surgical resection with the intent to cure represents the only treatment strategy that has repeatedly been shown to result in prolonged survival. Radical surgery is the approach of choice for localized stage I and stage II disease. Surgery does not appear to have a role in advanced disease, particularly with distant metastases. Resection of the esophagus is achieved by various surgical techniques that differ in the type of incision, the extent of resection, the conduit for reconstruction, and the method of reanastomosis. Unfortunately, the majority of patients at presentation are not found to have resectable disease after staging. With potential resection candidates, a careful preoperative assessment of the patient's overall medical and performance status is essential. Even in high-volume centers, postoperative mortality and morbidity rates approach 10 and 75%, respectively.

Since the implementation of surgical resection, many postoperative patients have been found to develop systemic metastases without local recurrence. It has been proposed that this pattern of recurrent disease may be the consequence of present but undetectable metastatic disease at the time of diagnosis. Therefore, to improve overall survival in operative candidates, various chemotherapy and chemoradiation regimens have been investigated as a means of obliterating presumptive micrometastases. In general, clinical trial outcomes have been disappointing, because little additional benefit has been shown to be gained by the use of such treatment modalities. Single-modality chemotherapy or radiation therapy before or after surgery has not been shown to confer a significant survival benefit. There are, however, several small early-phase trials that suggest that neoadjuvant chemoradiation may improve short-term survival over surgery alone.

Because the majority of patients after staging are not candidates for a curative approach, palliation remains an important component to the management of esophageal cancer. In patients with obstructive symptoms, esophageal bypass surgery represents a means of reestablishing gastrointestinal continuity without the associated morbidity and mortality seen with surgical resection. In the less severe situation of esophageal stricture formation, repeated endoscopic dilations or expandable metal stent deployment can be undertaken to maintain patency. In selected patients, additional endoscopic modalities may be effective in treating dysphagia. These include photodynamic therapy, endoscopic laser therapy, and bipolar coagulation. Palliative radiation and chemotherapy also have important roles. Randomized trials have indicated that chemoradiation with cisplatin and fluorouracil-based regimens is superior to radiation alone. This approach has evolved into the standard of care for patients with unresectable disease.

SUMMARY

Over the past 30 years, there have been significant changes in the epidemiology of esophageal cancer. Adenocarcinoma is now the most common type of esophageal cancer in most developed countries. Nevertheless, extent of disease at diagnosis remains the most important prognostic factor. Advances with regard to imaging have greatly enhanced the accuracy of disease staging. In particular, endoscopic ultrasound has evolved into an important means of evaluating for locoregional spread of disease. In the minority of patients without advanced disease, radical surgery is a potential curative therapy. The utility of chemotherapy and/or radiotherapy in patients with either resectable or unresectable disease remains an area of debate. Trials examining new cytotoxic agents in different combined modality regimens are in process.

Esophageal Cancer Surveillance and Screening: Barrett's Esophagus and GERD

STUART JON SPECHLER
Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

Barrett's esophagus The condition in which an abnormal columnar epithelium replaces the stratified squamous epithelium that normally lines the distal esophagus.
dysplasia A constellation of histological abnormalities that suggest that one or more clones of cells have acquired genetic damage rendering them neoplastic and predisposed to malignancy.
gastroesophageal reflux disease A disease that occurs when the passage of stomach contents into the esophagus results in symptoms or signs such as chest pain, esophagitis, chronic cough, or recurrent pneumonia.

Barrett's esophagus develops when refluxed gastric juice injures the esophageal mucosa and the injury heals through a metaplastic process in which columnar cells replace reflux-damaged squamous cells. Specialized intestinal metaplasia, the epithelium that characterizes Barrett's esophagus, is composed of a variety of columnar cell types that can have gastric, small intestinal, and colonic features. This abnormal columnar epithelium may be more resistant to gastroesophageal reflux disease (GERD) than the native squamous mucosa, but the metaplastic cells are predisposed to malignancy. GERD and Barrett's esophagus are the major recognized risk factors for esophageal adenocarcinoma, a lethal malignancy that has increased profoundly in frequency over the past few decades in Western countries.

INTRODUCTION

The diagnosis of Barrett's esophagus is made by endoscopic evaluation. Columnar epithelium in the esophagus has a characteristic dull, reddish appearance that can be distinguished readily from the glossy, pale squamous epithelium. The diagnosis of Barrett's esophagus is established when biopsy specimens of the esophageal columnar epithelium show specialized intestinal metaplasia. Barrett's esophagus can be further categorized according to the extent of the metaplastic lining. Patients who have >3 cm of specialized intestinal metaplasia have long-segment Barrett's esophagus, a condition that usually is associated with severe gastroesophageal reflux disease (GERD). Patients with <3 cm of metaplasia have short-segment Barrett's esophagus, a disorder often associated with only mild GERD. Although it is not clear whether these two types of Barrett's esophagus have the same risk for carcinogenesis, patients with short- and long-segment Barrett's esophagus are managed similarly.

Published estimates on the annual risk of cancer in patients with Barrett's esophagus have ranged from 0.2 to 2.9%, with an average risk of approximately 1%. The studies on which those estimates were based involved primarily patients referred to tertiary care

Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

Barrett's esophagus The condition in which an abnormal columnar epithelium replaces the stratified squamous epithelium that normally lines the distal esophagus.
dysplasia A constellation of histological abnormalities that suggest that one or more clones of cells have acquired genetic damage rendering them neoplastic and predisposed to malignancy.
gastroesophageal reflux disease A disease that occurs when the passage of stomach contents into the esophagus results in symptoms or signs such as chest pain, esophagitis, chronic cough, or recurrent pneumonia.

Barrett's esophagus develops when refluxed gastric juice injures the esophageal mucosa and the injury heals through a metaplastic process in which columnar cells replace reflux-damaged squamous cells. Specialized intestinal metaplasia, the epithelium that characterizes Barrett's esophagus, is composed of a variety of columnar cell types that can have gastric, small intestinal, and colonic features. This abnormal columnar epithelium may be more resistant to gastroesophageal reflux disease (GERD) than the native squamous mucosa, but the metaplastic cells are predisposed to malignancy. GERD and Barrett's esophagus are the major recognized risk factors for esophageal adenocarcinoma, a lethal malignancy that has increased profoundly in frequency over the past few decades in Western countries.

INTRODUCTION

The diagnosis of Barrett's esophagus is made by endoscopic evaluation. Columnar epithelium in the esophagus has a characteristic dull, reddish appearance that can be distinguished readily from the glossy, pale squamous epithelium. The diagnosis of Barrett's esophagus is established when biopsy specimens of the esophageal columnar epithelium show specialized intestinal metaplasia. Barrett's esophagus can be further categorized according to the extent of the metaplastic lining. Patients who have >3 cm of specialized intestinal metaplasia have long-segment Barrett's esophagus, a condition that usually is associated with severe gastroesophageal reflux disease (GERD). Patients with <3 cm of metaplasia have short-segment Barrett's esophagus, a disorder often associated with only mild GERD. Although it is not clear whether these two types of Barrett's esophagus have the same risk for carcinogenesis, patients with short- and long-segment Barrett's esophagus are managed similarly.

Published estimates on the annual risk of cancer in patients with Barrett's esophagus have ranged from 0.2 to 2.9%, with an average risk of approximately 1%. The studies on which those estimates were based involved primarily patients referred to tertiary care

 Copyright 2004, Elsevier (USA). All rights reserved.

centers; however, the patients whose cancer risk may have exceeded that for patients treated in primary care practices. Furthermore, a recent report has provided compelling evidence that the cancer risk in Barrett's esophagus has been overestimated for years because of publication bias, the selective reporting of studies that have positive or extreme results. Modern studies suggest that patients with Barrett's esophagus develop esophageal cancer at a rate of approximately 0.5% per year.

SCREENING AND SURVEILLANCE FOR PATIENTS WITH BARRETT'S ESOPHAGUS

To decrease mortality from esophageal adenocarcinoma, authorities have proposed that patients with chronic GERD symptoms should have endoscopic screening for Barrett's esophagus. Long-segment Barrett's esophagus can be found in 3 to 5% of such patients, whereas 10 to 15% have short-segment Barrett's esophagus. In patients with GERD, risk factors for adenocarcinoma in Barrett's esophagus include male gender, white ethnicity, obesity, advanced age, and long duration of GERD symptoms. However, any screening program that targets only such individuals can have only limited impact on cancer mortality rates because 40% of patients with esophageal adenocarcinoma have no history of GERD symptoms whatsoever. Currently, there is little evidence that screening programs have prevented deaths from esophageal adenocarcinoma. Among patients found to have these tumors, fewer than 5% are known to have had Barrett's esophagus before they presented with symptoms of esophageal cancer.

A number of medical societies, including the American College of Gastroenterology, have recommended regular endoscopic cancer surveillance for patients with Barrett's esophagus in order to decrease mortality from esophageal cancer and thereby prolong survival. The need for such surveillance has been questioned, however, because the practice has not been proved to decrease cancer mortality and available studies suggest that Barrett's esophagus does not even affect longevity. Studies on survival in Barrett's esophagus have consisted predominantly of older patients who often succumbed to comorbid illnesses rather than to esophageal adenocarcinoma. Proponents of surveillance argue that the results of those studies may not be applicable to younger, healthier patients with Barrett's esophagus.

Retrospective studies have documented that endoscopic surveillance can detect curable neoplasms in Barrett's esophagus and that cancers discovered during surveillance are less advanced than those found in patients who present with cancer symptoms such as dysphagia and weight loss. Furthermore, computer models have suggested that endoscopic surveillance for patients with Barrett's esophagus can prolong life, provided that certain assumptions are met. For example, in one Markov model of 50-year-old patients who had an assumed annual cancer incidence rate of 0.4%, endoscopic surveillance every 5 years was found to be the preferred strategy, costing $98,000 per quality-adjusted life year gained.

DYSPLASIA IN BARRETT'S ESOPHAGUS

As in other organs, cancers in Barrett's esophagus are thought to evolve through a sequence of genetic (DNA) alterations that give the cells certain growth advantages (Fig. 1). These same DNA abnormalities also can cause morphological changes in the tissue that the pathologist recognizes as dysplasia. Dysplasia is a constellation of histological abnormalities that suggest that one or more clones of cells have acquired genetic damage rendering them neoplastic and predisposed to malignancy. Dysplasia can be categorized as low- or high-grade depending on the extent of cytological and architectural changes. Endoscopic surveillance in Barrett's esophagus is performed primarily to seek dysplasia, with the rationale that resection or ablation of the esophagus lined by dysplastic epithelium may prevent the progression to invasive malignancy.

Unfortunately, dysplasia is an imperfect marker for malignancy. For example, the grading of dysplastic changes is a subjective skill. Among experienced pathologists, interobserver agreement for the diagnosis of low-grade dysplasia in Barrett's esophagus is less than 50%, whereas interobserver agreement for high-grade dysplasia is approximately 85%. Approximately one-third

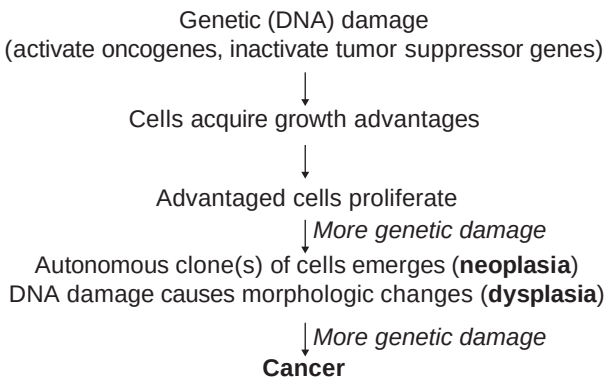

FIGURE 1 Carcinogenesis in Barrett's esophagus.

of patients who have esophagectomy for high-grade dysplasia have cancers found in the resected esophagus, cancers that were missed because of biopsy sampling error. Furthermore, the natural history of dysplasia in Barrett's esophagus is not well defined. Published estimates of the 5-year cumulative esophageal cancer incidence in patients with high-grade dysplasia range from 9 to 59%.

Researchers have been exploring alternative markers for cancer risk and preliminary data suggest that abnormalities in p53 expression and cellular DNA content (as assessed by flow cytometry) may be more sensitive and specific predictors of malignant potential than the histological finding of dysplasia. In addition, studies are evaluating the role of endoscopic techniques such as chromoendoscopy, endosonography, and fluorescence spectroscopy that enable the endoscopist to identify abnormal areas for biopsy sampling, rather than relying on random sampling to detect dysplasia. Currently, however, none of these tests or techniques has been shown to provide sufficient clinical information to justify its routine application in practice. Endoscopy with random biopsy sampling for dysplasia, despite all the shortcomings, remains the clinical standard for managing patients with Barrett's esophagus.

Patients who have verified high-grade dysplasia in Barrett's esophagus must choose among three management options: (1) esophagectomy, (2) endoscopic ablative therapy, or (3) intensive surveillance. Esophagectomy is the only therapy that clearly can prevent the progression from dysplasia to invasive cancer. Unfortunately, this procedure is associated with a 3 to 12% operative mortality rate and a 30 to 50% rate of serious operative complications. Endoscopic ablative therapies use thermal or photochemical energy to destroy the abnormal epithelium or localized lesions can be resected using a technique called endoscopic mucosal resection that is similar to colonoscopic polypectomy. Unfortunately, side effects of these therapies are frequent. For example, approximately one-third of the patients treated with photodynamic therapy using porfimer sodium develop esophageal strictures. Ablative therapies are expensive and they may not eradicate all of the tissue with neoplastic predisposition. As yet, no study has shown that these treatments decrease the long-term risk for cancer development and, currently, endoscopic ablative therapies should be considered experimental. Intensive endoscopic surveillance for high-grade dysplasia in Barrett's esophagus entails endoscopic examinations every 3 to 6 months, withholding invasive therapies until biopsy specimens reveal adenocarcinoma. Few published data directly support the safety and efficacy of this management strategy, however, and published reports suggest that 3 to 25% of cancers discovered in this fashion may be incurable.

MANAGEMENT RECOMMENDATIONS

The management of Barrett's esophagus that has been endorsed by the American College of Gastroenterology is as follows:

- Patients with Barrett's esophagus should have regular surveillance endoscopy to obtain esophageal biopsy specimens. GERD should be treated prior to surveillance to minimize confusion caused by inflammation in the interpretation of dysplasia.
- For patients who have had two consecutive endoscopies that show no dysplasia, surveillance endoscopy is recommended at an interval of every 3 years.
- If dysplasia is noted, the finding should be verified by consultation with another expert pathologist.
- For patients with verified low-grade dysplasia after extensive biopsy sampling, yearly surveillance endoscopy is recommended.
- For patients found to have high-grade dysplasia, another endoscopy should be performed with extensive biopsy sampling (especially from areas with mucosal irregularity) to look for invasive cancer and the histology slides should be interpreted by an expert pathologist. If there is focal high-grade dysplasia (defined as high-grade dysplastic changes involving fewer than five crypts), the condition may be followed with endoscopic surveillance performed at 3-month intervals. If there is verified multifocal high-grade dysplasia, intervention (e.g., esophagectomy) may be considered.

Although not specifically recommended in the practice guidelines, clinicians can consider the use of experimental ablative therapies such as photodynamic therapy for their patients with high-grade dysplasia in Barrett's esophagus, *provided the therapy is administered as part of an established, approved research protocol*. The use of ablative therapies outside of research protocols cannot be condoned at this time. Finally, the clinician should appreciate that no management strategy or patients with Barrett's esophagus has been verified by studies demonstrating that the strategy prolongs life.

Esophageal Strictures

WILLIAM G. PATERSON
Queen's University, Kingston, Canada

bougie A mercury-filled rubber tube that is passed by mouth and down the esophagus to dilate esophageal strictures.

proton pump inhibitors A class of drugs that block the H^+,K^+-ATPase ("proton pump") in the gastric parietal cell, thereby suppressing gastric acid secretion.

An esophageal stricture is a circumscribed narrowing of the esophageal lumen that may impede the passage of food to the stomach, thereby producing dysphagia.

ETIOLOGY AND PATHOGENESIS

Table I summarizes the major types of esophageal strictures categorized according to their presumed etiology or pathogenesis. By far the most common cause of esophageal stricture is gastroesophageal reflux disease (peptic stricture), accounting for at least 80% of cases. Peptic strictures result from recurrent reflux of acidic gastric juices up into the distal esophagus, with resulting inflammation, ulceration, and collagen formation. Inflammation triggered by virtually any agent is capable of causing stricturing of the esophagus. Lumenal narrowing from inflammation is typically due to thickening of all layers of the esophageal wall, with collagen deposition within the submucosa. Another common cause of lumenal narrowing is mucosal rings or webs, the most common type being the so-called "Shatski's ring." This is a prominent circumferential fold of mucosa at the junction between the squamous epithelium of the esophagus and the columnar epithelium of the stomach. An important cause of esophageal stricturing is malignant disease, the most common types being squamous cell cancer and adenocarcinoma. It is for this reason that patients presenting with new onset dysphagia require timely investigation.

CLINICAL PRESENTATION AND MANAGEMENT

Patients with esophageal strictures typically present with solid food dysphagia. Before these symptoms occur, the esophageal lumen usually has narrowed to <15 mm. The pattern of dysphagia may help the clinician predict the type of pathology present. Patients with unpredictable intermittent dysphagia to both solids and liquids are likely to have an esophageal motor disorder rather than a stricture as the cause. Rapidly progressive

solid food dysphagia with weight loss suggests malignant disease, whereas slowly progressive solid food dysphagia without weight loss is more in keeping with a peptic stricture. Sporadic dysphagia to meat suggests the presence of a Shatski's ring. Other symptoms may also be present depending on the underlying etiology of the stricture. For instance, patients with peptic strictures often relate a long history of heartburn and acid regurgitation before the onset of their dysphagia.

Esophageal strictures are diagnosed by performing barium contrast studies and/or endoscopy of the esophagus. In most instances, strictures diagnosed by X ray must also be assessed endoscopically, at which time mucosal biopsy may be performed. This is primarily to ensure that the stricture is not caused by a malignant neoplasm.

Many strictures can also be treated at the time of endoscopy by performing dilation with either a bougie or a balloon. This serves to stretch the lumen open, but it is important to then treat the underlying cause (if possible) in order to decrease the chance of the stricture recurring. For instance, to prevent recurrence of peptic strictures, patients should be placed on proton pump inhibitors to suppress reflux of gastric acid or undergo anti-reflux surgery.

Esophageal Surgery

YAEL REFAELY* AND RAPHAEL BUENO*,†

Brigham and Women's Hospital, Boston and †Harvard Medical School

achalasia Failure to relax.
Collis gastroplasty "Lengthens" the esophagus by transforming a portion of the upper stomach into an esophageal extension.
diverticula Small, balloon-like pouches that protrude from a hollow organ or structure.
esophagectomy Removal of the esophagus.
fundoplication Wrapping the stomach fundus around the esophagus.
gastroplasty Stomach-reducing surgery.

Operative techniques for treating esophageal disease have advanced considerably in recent years, both as a result of the improved understanding of esophageal anatomy and physiology and the successful introduction of minimally invasive approaches to esophageal surgery. Laparoscopic esophageal procedures for myotomy and antireflux procedures, as well as video-assisted thoracoscopic procedures for benign disorders and staging of esophageal cancer, have gained popularity and appear to be as effective as their open equivalents, while causing less postoperative morbidity. New anesthetic techniques, including the use of epidural catheters, and effective improvements in critical care have reduced perioperative mortality and made open surgical procedures safer. Despite the preponderance of minimally invasive techniques, open surgical procedures continue to make up an important component of esophageal surgery for the treatment of benign and malignant esophageal diseases.

SURGERY FOR BENIGN DISORDERS OF THE ESOPHAGUS

Antireflux Procedures

Gastroesophageal reflux disease (GERD) results from abnormal esophageal exposure to gastric acid. It is an exceedingly common disorder in the United States and usually responds well to abstinence from causative agents and pharmacological therapy. Patients with GERD refractory to maximal medical therapy may elect to undergo antireflux surgery. Whereas medical treatment concentrates on elevating the pH of the gastric acid and decreasing the incidence and duration of reflux episodes, surgical efforts are directed toward restoring normal function to the gastroesophageal junction (GEJ), which acts as a sphincter barrier between the acidic content of the stomach and the esophagus. This goal is achieved by reducing the GEJ to its normal intraabdominal position and tightening its sphincter function. A variety of techniques have been described to achieve these goals. The most common include (1) the Belsey–Mark IV antireflux repair, a partial fundoplication performed through a left thoracotomy, and (2) the Nissen fundoplication, which can be performed via a transthoracic, transabdominal, or laparoscopic approach. The Hill repair and other partial fundoplications are also surgical options that can be applied transabdominally.

Patients with severe, long-standing reflux disease often develop chronic inflammation and esophageal fibrosis that can lead to esophageal shortening. In these circumstances, the intraabdominal esophageal segment is insufficient and tension on the repair may lead to failure of the antireflux procedure. For patients with a foreshortened esophagus, a Collis gastroplasty is frequently performed to lengthen the intraabdominal esophagus and prevent postoperative failures.

Selection of the Optimal Antireflux Surgical Procedure

Patients with severe GERD who fail medical therapy require at the very least preoperative evaluation with endoscopy, manometry, and a pH probe. A barium swallow and gastric-emptying studies as well as careful psychological evaluation are occasionally warranted. For patients with normal esophageal motility and gastric emptying, most surgeons would opt to perform a laparoscopic transabdominal Nissen fundoplication. An open or laparoscopic drainage procedure is added for those patients with impaired gastric emptying. The transthoracic approach should be considered whenever any of the standard abdominal approaches carries an increased risk of failure or complication. For instance, the transthoracic approach would be appropriate in patients who have (1) associated esophageal motility disorder, (2) massive hiatal hernia, with the stomach pulled into the chest, (3) esophageal diverticula that require resection, or (4) profoundly foreshortened

 Copyright 2004, Elsevier (USA). All rights reserved.

esophagus, as well as (5) for patients who have undergone multiple previous abdominal operations or who have previously experienced failed antireflux procedures. The procedure of choice for patients with esophageal motility disorders, such as scleroderma or achalasia, is a partial as opposed to complete fundoplication in order to prevent postoperative obstruction. A partial fundoplication is any procedure in which the wrap is less than 360°, but more than 180°, such as the posterior Toupet fundoplication or the anterior Dor fundoplication.

Belsey–Mark IV Partial Fundoplication

The Belsey–Mark IV fundoplication is a 240° wrap that is usually performed through a left posterolateral thoracotomy incision, although it has also reportedly been performed thoracoscopically. The esophagus and both vagus nerves are exposed and mobilized followed by exposure of the right and left crura. The peritoneum is entered by dividing the phrenoesophageal membrane and the gastrohepatic ligament. The hiatal dissection is then completed, the hernia sac is excised, and a few short gastric arteries are divided. The esophagogastric junction is elevated into the chest for suture placement. When esophageal shortening is found, a Collis gastroplasty is performed utilizing a stapling device. The crura are approximated to close the hiatus snugly. The next step is the placement of three sutures in each of two to three rows or tiers to create a 240° fundoplication and concurrently reduce the wrap into the abdomen. In experienced hands, this operation is effective and durable. The major disadvantage is the requirement for thoracotomy.

Nissen Fundoplication

Nissen fundoplication (Fig. 1) is the most popular operation for GERD and considered to be the most effective. The procedure entails using a portion of the fundus of the stomach to create a 360° wrap around the lower 3–4 cm of the esophagus and then suturing it in place, so that the gastroesophageal sphincter passes through a short tunnel of the stomach. The wrap should be loose enough to accommodate a No. 48 to 56 French dilator within the esophagus after the procedure. To prevent axial slipping, the top of the wrap should be sutured to the side of the esophagus either separately or as part of the stitch securing the wrap. There are five major steps to this procedure: (1) crural dissection with the identification and preservation of both vagi, including the hepatic branch of the anterior vagus, (2) circumferential dissection of the esophagus, (3) crural closure, (4) fundic mobilization by division of the short gastric vessels, and (5) creation of a short (2–3 cm), loose fundoplication by enveloping the posterior and the anterior walls of the fundus. This operation can be performed transthoracically and transabdominally. The introduction of the laparoscopic approach has made this procedure far more common in the United States because of the minimal perioperative discomfort. Relief of typical reflux symptoms (i.e., heartburn, regurgitation, and dysphagia) is achieved in more than 90% of the patients following laparoscopic Nissen fundoplication. A lower incidence of symptom reduction is noted among patients with atypical reflux symptoms (i.e., cough, asthma, or laryngitis). These symptoms are relieved in only two-thirds of cases. However, recent reports indicate benefit in patients undergoing lung transplantation. Temporary dysphagia is common following this operation and may be seen in up to 50% of the patients; however, the dysphagia usually resolves after 3 months in most patients.

FIGURE 1 A picture of the Nissen wrap at the conclusion of a laparoscopic procedure. The sutures are evident in the middle of the wrap. The esophagus is underneath and cephalad to the wrap.

Collis Gastroplasty

In performing the Collis gastroplasty for a short esophagus, a stapler is used to form a 4- to 5-cm neoesophagus out of the proximal stomach, thereby effectively lengthening the esophagus and transposing the esophagogastric junction distally, below the diaphragm, where a high intraabdominal pressure, as opposed to a negative intrathoracic pressure, will reduce reflux. A large-caliber Maloney bougie (48 to 56 French) is placed in the esophagus to prevent narrowing of the lumen. The bougie is held against the lesser curvature, and the fundus is retracted away at a right angle to the esophagus. A stapler is applied immediately alongside

the bougie on the greater curvature side, simultaneously cutting and stapling the cardia. This procedure can also be performed thoracoscopically or laparoscopically.

Technical Complications of Antireflux Procedures

Early and late technical complications of the antireflux procedures are summarized in Table I. Late complications may cause failure of the repair and necessitate reevaluation and probable reoperation. Recurrent heartburn and regurgitation demand evaluation with contrast studies and esophagoscopy. Anatomic conditions determined to be responsible for failure of the fundoplication usually necessitate reoperation. Dysphagia unrelated to recurrent reflux or ulceration generally responds to dilatation and does not necessitate reoperation.

Surgery for Motility Disorders of the Esophagus

The act of swallowing is quite complex and requires the perfect coordination between the central nervous system and the various neural and muscular elements of the esophagus. Any discrepancy, such as hyperactivity or hypoactivity or discoordination, at any level of the esophagus can cause clinical symptoms. A number of motor disorders of the esophagus can cause a variety of adverse effects on swallowing; the most common disorders are described in the following sections.

TABLE I Technical Complications of Antireflux Procedures

Technical complications	Clinical manifestations
Early	**Early**
Injury to the spleen during short gastric ligation	Bleeding, splenectomy
Torsion of the fundus	Perforation and sepsis
Gastroplasty leak at the staple line	Perforation and sepsis
Late	**Late**
Injury to the vagi	Gastric dysfunction, gas-bloat syndrome
Poor crural approximation	Migration of the wrap into chest, paraesophageal hernia
Inadequate mobilization of the fundus	Tension on the wrap, later disruption, recurrent reflux
Inadequate fixation of wrap to esophagus (slipped Nissen)	Hourglass stomach; heartburn, regurgitation, dysphagia
Long wrap	Gas-bloat syndrome
Wrap that is too tight	Persistent dysphagia

Pharyngoesophageal (Zenker's) Diverticulum

The most common diverticulum of the esophagus, known as Zenker's diverticulum, usually occurs in elderly patients. It is a false diverticulum, with the esophageal mucosa (and not full-thickness esophagus) herniating between the oblique fibers of the inferior constrictor muscle of the pharynx and the transverse fibers of the cricopharyngeus muscle. Patients usually present with dysphagia and regurgitation. The radiographic appearance of the pharyngoesophageal diverticulum on a barium swallow is diagnostic. This disorder is thought to be caused by discoordination between relaxation and contraction of the pharynx and the upper esophageal sphincter. The preferred method of treatment is a single-stage resection with a concomitant myotomy. In this procedure, the esophagus is explored through a left neck incision by retracting the thyroid gland medially and the sternocleidomastoid muscle and carotid sheath laterally. Excess retraction is avoided to protect the recurrent laryngeal nerve. The mucosal sac is dissected up to its neck, such that the surrounding ring of the muscular defect is clearly defined. A curved clamp or a stapler is placed across the neck of the sac at a right angle to the long axis of the esophagus, and the sac is amputated. Interrupted fine silk sutures are placed in the mucosa as it is being incised. Alternatively, the diverticulum can be excised with a stapler. The operation carries a minimal risk and low recurrence rate. To prevent possible recurrences, a cricopharyngeal myotomy is routinely performed.

Epiphrenic Diverticulum

Epiphrenic diverticula are typically located within the distal third of the esophagus. This type of propulsive diverticulum arises because of abnormally elevated intraluminal esophageal pressures distally creating a functional obstruction. Patients usually present with dysphagia, regurgitation of previous meals, and frequently recurrent pneumonias. Relief of symptoms and prevention of aspiration pneumonia are the chief indications for resection of the diverticulum. The surgical approach is made through a left sixth or seventh interspace posterolateral thoracotomy. The diverticulum is mobilized to its base and amputated with a TA-30 stapler. A long, extramucosal esophagomyotomy is performed from the level of the diverticulum and sometimes from the aortic arch to the esophagogastric junction on the opposite wall of the esophagus. If an associated hiatal hernia or incompetent lower esophageal sphincter is found, an antireflux procedure should be added. Some surgeons advocate continuing

the myotomy below the GEJ and routinely add an antireflux procedure. A partial fundoplication procedure, such as the 240° Belsey—Mark IV, would be preferred, to obviate functional obstruction. The results of this surgery are usually excellent, even in the older patient population.

Cardiomyotomy for Achalasia (Heller Operation)

This operation was first described by Heller in 1914 for the treatment of esophageal achalasia. The operation originally consisted of two myotomies on opposite sides of the esophagus, performed through a laparotomy. Although some surgeons performed the operation through a laparotomy, others preferred a thoracotomy approach. The introduction of minimally invasive laparoscopic cardiomyotomy with its lower morbidity has resulted in the adoption of this minimally invasive technique by most surgeons. This operation is used primarily for the treatment of achalasia and is indicated in every patient diagnosed with achalasia who can tolerate general anesthesia. In the laparoscopic version, a myotomy is performed to a total length of approximately 3—5 cm. It is extended onto the stomach for a length of 1.5—2 cm. Its proximal extent is limited only by the operative exposure. The longitudinal and circular muscle fibers are divided while the esophagus is splayed over a bougie. Special attention is taken to protect the underlying mucosa from injury. The cut edge of the myotomy is gently dissected away, to be separated by at least one-third of the circumference of the esophagus, to prevent recurrence. Following completion of the myotomy, a partial antireflux procedure is usually added. This procedure can also be performed via a left open thoracotomy or a minimally invasive thoracoscopic approach. The myotomy is carried out from the level of the inferior pulmonary vein to just a few millimeters into the stomach and an antireflux procedure is not generally required.

The two most common fundoplications performed in conjunction with the Heller myotomy are, respectively, the posterior (Toupet) and anterior (Dor) 180° fundoplications. There are insufficient reports to measure the success rate of these fundoplication procedures, but it is clear that surgical myotomy is currently the best option for patients with achalasia. Relief of dysphagia and regurgitation may be expected in 85—90% of patients undergoing myotomy with or without fundoplication at 5 years. Chest pain is improved in 75—80%. Abnormal gastroesophageal reflux occurs in 15—25% of the patients.

Surgery for Benign Tumors of the Esophagus

Benign tumors of the esophagus are less common than malignant ones and usually are discovered incidentally. When symptomatic, large, or when the diagnosis is in question, these tumors should be surgically removed. Leiomyomas of the esophagus are the most common and usually grow within the muscular layer of the esophagus. They should not be endoscopically biopsied unless they have an intraluminal component because a mucosal injury during the biopsy will complicate surgical removal. These tumors can usually be enucleated without entering the esophageal lumen. Both open and minimally invasive thoracic approaches have been described. On rare occasions, esophageal resection is required for extirpation of esophageal leiomyomas.

Enteric (or esophageal) cysts are also common benign esophageal lesions. These are congenital and usually do not communicate with the esophageal lumen. Esophageal cysts, also known as esophageal duplications, may grow in size, become filled with mucus, and may hemorrhage or cause symptoms of pain, reflux, or obstruction. Unless their diagnosis is certain and there is no evidence of enlargement or symptoms, these should be removed, usually via video thoracoscopy.

SURGERY FOR CARCINOMA OF THE ESOPHAGUS

Esophageal Cancer

Esophageal cancer is a highly virulent malignancy; although rare, the incidence has recently been rising in the United States and Western Europe. In its earliest stages, esophageal cancer is readily curable by surgical treatment alone, with 5-year survival rates approaching 80%. By the time patients with esophageal cancer develop symptoms, however, this malignancy is usually moderately advanced in stage and more likely to be associated with metastatic lymph node involvement. The 5-year survival rates after surgical resection may be as high as 34% for patients with early nodal disease, but are more typically in the range of 10—15% for locally advanced lesions. It is unusual for patients with metastatic disease to survive 5 years after diagnosis.

There are two common histological types of esophageal cancer, squamous cell carcinoma and adenocarcinoma. Until recently, squamous cell carcinoma of the esophagus was the most common histological type seen. This disease is usually found in patients with the usual risk factors associated with other aerodigestive tract carcinomas. In particular, smoking and alcohol abuse are associated with a 5-fold increased risk of developing

squamous cell esophageal carcinoma. The combination of heavy smoking and drinking increases this risk 25- to 100-fold. African-Americans are five times more likely to develop squamous cell carcinoma than are members of any other racial or ethnic group, and the cancer is four to six times more likely to occur in males than females. Remarkably, a major shift has recently been observed in the histologic type of esophageal cancer. Since the early 1990s, the incidence of adenocarcinoma of the esophagus, located in the distal esophagus and gastroesophageal junction, has been gaining rapidly over the squamous cell variety. This change of prevalence is due to an increase in the incidence of adenocarcinoma without a change in the incidence of squamous cell carcinoma.

Surgical resection is the first-line therapy for the majority of patients with cancer of the esophagus and gastric cardia. Surgery remains the gold standard by which all other therapeutic modalities are measured. The main goals of surgery are (1) to extirpate the cancer by removing the primary tumor and lymph nodes with curative intention, (2) to relieve dysphagia, and (3) to maintain the continuity of the alimentary tract. The various types of surgical approaches may be combined with preoperative neoadjuvant chemotherapy and radiation therapy, although the data for their efficacy are limited at best. Chemotherapy or radiation therapy alone was not found to be effective in a neoadjuvant setting. Chemotherapy also has been used in many treatment protocols as an adjuvant therapy following surgery and has shown promise in cancer of the cardia and gastroesophageal junction.

Preoperative evaluation includes endoscopic documentation of cancer, chest and abdominal computer tomography (CT), a positron emission tomography (PET) scan to exclude metastatic disease, esophageal ultrasound for evaluation of the T and N stage, and a cardiorespiratory evaluation to ensure the patient's ability to withstand surgery. Laparoscopic and thoracoscopic surgical staging procedures have recently been advocated prior to esophagectomy or neoadjuvant therapy, given the limitation of other staging techniques.

The choice of operation for carcinoma of the esophagus depends on a number of factors, including preference of the surgeon, location of the tumor, body habitus, site of prior surgery, condition of the patient, choice of esophageal substitute, and history of prior radiation therapy. The two most important factors influencing the choice of procedure are the location of the tumor and the surgeon's preference. Cervical esophageal carcinoma is preferentially treated by chemotherapy and radiation at most centers. (Although some surgeons advocate pharyngolaryngectomy combined with extrathoracic esophagectomy and gastric interposition, these operations are beyond the scope of this article.) As for the more common cancers of the middle and lower thoracic esophagus and gastroesophageal junction, several types of operations are feasible, as listed in Table II. Esophageal resection should always be performed under careful monitoring that includes central venous pressure, arterial lines, electrocardiogram, end tidal CO_2, and O_2 saturation. A double-lumen endotracheal tube should be inserted in all cases, save for transhiatal esophagectomy, in order to collapse the lung on the operated side. Epidural analgesia is helpful for postoperative pain relief. A jejunostomy tube is often inserted for postoperative alimentation.

Options for Reconstruction After Esophagectomy

After a partial or complete esophagectomy, a conduit must be established to preserve the continuity of the digestive tract. The stomach, jejunum, and colon have all been successfully used as esophageal substitutes, but the stomach appears to be the conduit of choice because of ease of mobilization and ample vascular supply. The higher incidence of mortality reported with the use of the colon conduit is most probably related to the necessity of performing three anastomoses (i.e., coloesophagostomy, cologastrostomy, and

TABLE II Surgical Techniques to Resect and Replace the Esophagus in Malignant Disease

Technique	Surgeon (year)	Location of anastomosis
Left thoracoabdominal	Adams and Phemister (1938)	Left hemithorax
Ivor Lewis	Lewis (1946)	Right hemithorax
McKeown	McKeown (1976)	Left neck
Radical en bloc esophagogastrectomy	Skinner and co-workers (1982)	No limitations
Transhiatal esophagectomy	Orringer (1984)	Left neck
Three-hole esophagectomy	Swanson (2001)	Left neck

colocolostomy). The colon conduit is used if the patient has undergone partial or total gastrectomy previously, or if the tumor involves the stomach, precluding a 5-cm margin. Jejunal conduits can also be used, but they are least favorable due to their limited vascular supply and are therefore limited to short distal segmental replacement. A free jejunal segment may be used, usually in the neck, with reanastomosis of its blood supply and drainage to the carotid and jugular vessels. In rare circumstances, a musculocutaneous tube created from the pectoralis major muscle may be used as a replacement for the cervical esophagus.

Transhiatal Esophagectomy

The transhiatal esophagectomy technique was popularized by Orringer and Sloan in 1978, to avoid a thoracotomy and reduce the possibility of an intrathoracic anastomotic leak. The operation begins with the patient in a supine position, with the neck extended to the right side, exposing the left sternocleidomastoid muscle. The procedure is performed through left cervical and upper abdominal incisions. The resection begins with the abdominal dissection, followed by a blunt dissection of the thoracic esophagus from the abdominal and neck incisions until it is freed. The specimen is removed and a gastric tube is constructed and pulled up to the neck to create a cervical gastroesophageal anastomosis. The blind dissection increases the possibility of vascular or airway injury. It also limits the extent of the lymph node dissection. In expert hands, this procedure can be performed with morbidity and mortality as low as morbidity and mortality of other esophageal procedures and with similar long-term outcomes.

The steps in the abdominal dissection in esophagectomy are similar for most of the approaches. An upper midline incision is made from xiphoid to umbilicus. The peritoneal cavity is explored and inspected for metastases. If liver metastasis or other peritoneal spread is found, the resection is aborted and a jejunal feeding tube is inserted for palliative care of the patient. Following a negative inspection, total mobilization of the stomach is performed. The stomach is divided from its blood supply, preserving the right gastroepiploic artery. A gastric conduit based on this artery is created (see later) to replace the esophagus. The hiatus is then enlarged manually and the left lobe of the liver is mobilized from the diaphragm and gently retracted rightward for exposure. The distal esophagus is dissected under direct vision, and the middle esophagus is first palpable through the enlarged hiatus. Resectability is confirmed at this point. The most difficult area of dissection is the area immediately surrounding the tumor. Occasionally, a portion of the diaphragm is resected en bloc with the tumor. Local extension of the tumor involving the pleura, inferior pulmonary ligament, posterior pericardium, and so forth should be appreciated and treated accordingly. The cervical dissection is also similar for all neck approaches to the esophagus. The left cervical incision is made along the anteromedial border of the sternocleidomastoid muscle. The left is the preferred side of approach because the recurrent laryngeal nerve is less likely to be injured. A right-sided dissection can be substituted when needed for clinical reasons. The muscle and the carotid sheath are reflected laterally and no traction is placed on the trachea, to avoid injury to the left recurrent laryngeal nerve. The rest of the dissection is performed bluntly in a posterior dissection to get to the prevertebral fascia. The dissection then proceeds around the esophagus, which is freed from the trachea in the tracheoesophageal groove and encircled. The blunt dissection of the superior portion of the esophagus continues up to the level of the carina. Completion of the dissection is finally achieved through both incisions along the posterior mediastinum. The stomach conduit is than created by dividing the gastroesophageal junction along the lesser curvature of the stomach with multiple stapler firings. A Kocher maneuver is performed to allow the pylorus to reach the level of the hiatus and reduce tension. A pyloroplasty or pyloromyotomy is often performed to prevent future gastric-emptying difficulties, which are seen in up to 10% of patients undergoing esophagectomy. The specimen is removed from the field and the gastric conduit is then passed through the bed of the resected esophagus to the neck. The anastomosis is then performed in the neck. A feeding jejunostomy tube is placed routinely at the end of the operation.

The advantages to the transhiatal esophagectomy (THE) include the creation of a proximal surgical margin that is well away from the tumor site, an extrathoracic esophagogastric anastomosis that is easily accessible in the event of complications (e.g., anastomotic leak), and a reduced overall perioperative morbidity attributed to avoidance of the thoracotomy. The disadvantages to utilizing the THE are twofold: limited exposure increases the risk of injury to major structures in case of adherent or invasive tumor, and compromises are made in the mediastinal lymph node dissection (used mainly for staging and determination of response to treatment if given preoperatively).

Ivor Lewis Esophagectomy

The Ivor Lewis esophagectomy technique was proposed by Lewis in 1946 and immediately became the

most popular technique of esophageal resection. It combines two stages: abdominal laparotomy followed by right thoracotomy and intrathoracic anastomosis. The extent of resection is governed by the tumor location and includes at least a 5-cm margin proximal and distal to the tumor as well as to all the surrounding periesophageal tissue. This technique permits a partial or subtotal esophageal resection to be performed and provides exposure for complete regional lymph node dissection. The operation is performed in a specific order. First, the abdominal dissection is as for the THE. The thoracic dissection then follows. The patient is repositioned in a left lateral decubitus position for a standard right posterolateral thoracotomy. The esophagus is mobilized out of its bed and the tumor is carefully dissected off the posterior wall of the mainstem bronchus and pericardium. The esophagus is totally mobilized, beginning at the esophageal hiatus and extending just above the azygos vein. The already mobilized stomach is pulled into the thoracic cavity and the tumor is resected with at least a 5-cm margin. The lesser curvature of the stomach is divided and the gastric conduit is created. An end-to-side esophagogastric anastomosis is then performed, usually at the level of the azygos vein. The chest is closed in usual fashion, with a chest tube left in the pleural space and a nasogastric tube in the stomach conduit. This approach is ideal for lower and midesophageal lesions that are still lower than the carina, and provides excellent exposure for mediastinal lymph node dissection. It is limited only by the requirement of an intrathoracic anastomosis.

Left Thoracoabdominal Approach

The left thoracoabdominal approach is indicated for tumors in the lower third of the esophagus and the gastric cardia. The principal disadvantage is that the aortic arch limits the extent of the proximal dissection, rendering the intrathoracic anastomosis more difficult to perform. However, a third interspace left thoracotomy can always be added to gain additional proximal margin. This operation is frequently associated with significant esophagitis from bile reflux. Therefore, many surgeons prefer to resect the entire stomach and to create a Roux-en-Y jejunal interposition, which is anastomosed to the residual thoracic esophagus. The patient is positioned in the right lateral decubitus and a thoracotomy incision is made through the sixth intercostal interspace. The diaphragm is then incised peripherally, about 2 cm from the costal margins in order to reduce the risk of postoperative diaphragmatic paralysis. The pulmonary ligament is then divided and the esophagus is mobilized. Next, the stomach is mobilized as described above. Once adequately mobilized, the distal esophagus and stomach are resected and the anastomosis is carried out in the left hemithorax. The morbidity and mortality with this approach are similar to those of the Ivor Lewis approach. Gastric tip necrosis, which can be seen after a longer type esophagectomy, is less common with an intrathoracic anastomosis because the gastric tube is not unduly stretched.

The McKeown Operation and Three-Hole Esophagectomy (Abdominothoracicocervical Esophagectomy)

The conception of esophagectomy performed through three discrete incisions was first described by McKeown in 1972 and was aptly named the "three-stages esophagectomy," because it includes (1) an abdominal mobilization of the stomach, (2) a right thoracotomy to mobilize the esophagus, and (3) a cervical incision through which the esophagogastric anastomosis is performed. The first two stages are identical to those described for the Ivor Lewis approach except for mobilizing the entire intrathoracic esophagus. The third stage is carried out through a neck incision and includes passage of the stomach through the thoracic inlet and performance of cervical gastroesophageal anastomosis. This procedure results in a complete resection of the esophagus and its lymph node stations, with a "safe cervical anastomosis." A subtle variant of this approach has been recently popularized by the group at Brigham and Women's Hospital and has been named the "three-hole esophagectomy." It involves a right thoracotomy as an initial phase in the operation, with complete dissection of the intrathoracic esophagus with its lymph node stations, as described earlier. The chest is then closed and the remainder of the operation is performed as a transhiatal esophagectomy: Abdominal and cervical exploration and dissection are performed, the esophagus is divided proximally in the neck, and the stomach is divided to create a gastric tube that is pulled up to the neck for a cervical anastomosis. The advantage of this variant is in early determination of whether the tumors in the lower and midesophagus invade local structures, facilitating early assessment of tumor resectability. Video-thoracoscopic dissection can be substituted for the thoracotomy in order to minimize morbidity. A completely minimally invasive version of this procedure has also been described. The main benefits of both methods over THE include complete lymph node dissection and a safer visualized dissection of the intrathoracic esophagus.

Radical en Bloc Esophagectomy

Radical esophagogastrectomy was first described by Logan in 1963, but gained attention just after Skinner reported his experience in 1983. Skinner's results with 80 patients demonstrated that the operation can be performed safely, with an operative mortality of 11%, and that the survival rates are as good or better than previously achieved, with actuarial survival rates of 24% at 3 years and 18% at 5 years. The added benefit of radical esophageal resection is still controversial in Western countries and its use is limited to a few centers in the United States and Europe. In Japan, a more radical version of this approach is popular, including a three-field lymph node dissection (i.e., abdominal, thoracic, and cervical), as opposed to Skinner's technique, which involves only the abdominal and thoracic fields. Radical en bloc esophagectomy includes excision of the tumor-bearing esophagus, with 10-cm proximal and distal margins and a wide envelope of surrounding tissues, including the pericardium anteriorly, both pleural surfaces laterally, and the lymphatic tissues, inclusive of the thoracic duct wedged dorsally between the esophagus and the spine. Additionally, an upper mediastinal and abdominal lymphadenectomy is performed (two fields). Resection of tumors in the cardia or lower esophagus is performed through a thoracoabdominal incision, whereas for tumors in the thoracic esophagus, the operation is performed through a right thoracotomy and abdominal incision. Because the adequate proximal resection margin defined by this approach is 10 cm from the tumor and a clean margin from Barrett's esophagus, the anastomosis is performed in the neck whenever those two criteria meet high up in the thorax. The advantage of this procedure is the theoretical possibility of maximal locoregional control. Disadvantages include the facts that a survival benefit has not been proved and that the operation carries an increased risk for potential complications.

Complications of Esophageal Resection for Cancer

The operative mortality for esophagogastrectomy has significantly declined over the years, and in recent series it ranges between 2 and 10%. Centers with high volume report a 2% perioperative mortality. Other surgical complications are listed in Table III. Among them, the most common early complications are pulmonary (pneumonia and atelectasis), followed by cardiac, with arrhythmia occurring in 10% of the patients (most commonly atrial fibrillation). The occurrence of anastomotic leak ranges between 5 and 10% in different series. Although its incidence is not affected by the anastomotic site, it is easier to handle leakage from a neck anastomosis than from a thoracic anastomosis. Leak is more likely to occur in patients who are malnourished or diabetic and in those who have received preoperative radiation and have tension at the anastomosis site or a compromised blood supply to the conduit. Leak usually occurs within 10 days of the surgical procedure and most commonly these patients present with sepsis. For cervical anastomotic leakage, a conservative approach is advised, with open drainage of the cervical wound. Most of these patients ultimately develop esophageal stricture, requiring dilatation. In sharp contrast, intrathoracic anastomotic leaks are far more serious and carry a mortality of between 20 and 40%. Commonly, the patient will need another operation in order to inspect the anastomosis and drain the pleural space and mediastinum. In cases in which there is no necrosis and a relatively stable patient, attempts at repair with drainage are reasonable. Temporary exclusion is also possible. If a necrotic segment of stomach is discovered and the patient is in septic shock, debridement and takedown are performed. The viable stomach should be returned to the abdomen, and a cervical esophagostomy, as long as possible, is constructed for diversion. A decompressing gastrostomy is usually performed, and possible future reconstruction with substernal colon interposition will be required following recovery and absent recurrent cancer. Other complications include chylothorax from a thoracic duct injury, recurrent laryngeal nerve paresis, or paralysis and anastomotic strictures.

TABLE III Complications of Esophageal Resection

Early (perioperative)	Late
Atelectasis	Reflux
Acute respiratory distress syndrome	Regurgitation
Pneumonia	Dumping
Arrhythmia (usually atrial)	Anastomotic stricture
Myocardical infarction	Hiatal hernia
Anastomotic leak	
Conduit necrosis	
Pulmonary embolism	
Tracheobronchial injury	
Splenic injury	
Laryngeal nerve injury	
Chylothorax

Esophageal trauma is often a medical emergency requiring prompt attention and management. There are several types of esophageal injury. It can be iatrogenic in nature, resulting from endoscopic or other surgical procedures, it can occur spontaneously, or it can arise either from penetrating injury resulting in esophageal perforation or from caustic injury usually in the setting of attempted suicide. Prompt definitive treatment is required since delay can lead to decreased patient survival. This article focuses on the causes as well as the signs and symptoms of esophageal trauma. Management of the acute and chronic sequelae of these injuries is also discussed.

PERFORATING ESOPHAGEAL INJURY

Etiology

Esophageal perforation results from a variety of causes, including iatrogenic injury, spontaneous rupture, and both blunt and penetrating injuries. Iatrogenic injury typically results from injury sustained during endoscopic procedures, such as esophagogastroduodenoscopy (EGD) and transesophageal echocardiography. Iatrogenic injury is most commonly seen as a complication of endoscopic procedures. Spontaneous rupture typically occurs after prolonged vomiting. Perforation resulting from blunt and penetrating esophageal injuries is described in the trauma literature.

In patients with a normal esophagus, the cricopharyngeal portion of the proximal esophagus is the most commonly afflicted region. Mid and distal esophageal perforations typically result from endoscopic procedures including biopsy, stenting, and dilation used in the diagnosis or treatment of lesions of the esophagus, such as esophageal cancer. Less commonly, iatrogenic esophageal perforation may result from other types of instrumentation, such as nasogastric tube insertion, inadvertent esophageal intubation with an endotracheal tube, or injury during nonesophageal surgical procedures, such as tracheostomy and thyroidectomy.

Spontaneous rupture of the esophagus, known as Boerhaave's syndrome, is typically caused by prolonged vomiting usually in patients with a history of alcoholism. However, spontaneous perforation is also seen in patients with chronic esophageal injury resulting from severe reflux or severe candidal or herpetic infection. In these cases, esophageal perforation occurs posteriorly in the lower esophagus.

Penetrating injury to the neck can also result in esophageal perforation. Because of the posterior location of the esophagus in both the neck and chest, penetrating esophageal injury is rarely isolated and often accompanied by other more immediate life-threatening injuries to the trachea or carotid artery. Blunt trauma to the neck, such as might be sustained in high-speed motor vehicle accidents or blows to the neck, rarely

In patients with a normal esophagus, the cricopharyngeal portion of the proximal esophagus is the most commonly afflicted region. Mid and distal esophageal perforations typically result from endoscopic procedures including biopsy, stenting, and dilation used in the diagnosis or treatment of lesions of the esophagus, such as esophageal cancer. Less commonly, iatrogenic esophageal perforation may result from other types of instrumentation, such as nasogastric tube insertion, inadvertent esophageal intubation with an endotracheal tube, or injury during nonesophageal surgical procedures, such as tracheostomy and thyroidectomy.

Spontaneous rupture of the esophagus, known as Boerhaave's syndrome, is typically caused by prolonged vomiting usually in patients with a history of alcoholism. However, spontaneous perforation is also seen in patients with chronic esophageal injury resulting from severe reflux or severe candidal or herpetic infection. In these cases, esophageal perforation occurs posteriorly in the lower esophagus.

Penetrating injury to the neck can also result in esophageal perforation. Because of the posterior location of the esophagus in both the neck and chest, penetrating esophageal injury is rarely isolated and often accompanied by other more immediate life-threatening injuries to the trachea or carotid artery. Blunt trauma to the neck, such as might be sustained in high-speed motor vehicle accidents or blows to the neck, rarely

 Copyright 2004, Elsevier (USA). All rights reserved.

creates perforating injury and most often leads to an intramucosal hematoma and subsequent dysphagia. However, penetrating injury in this setting can be associated with high morbidity and mortality, since it is often missed and when present may be accompanied by airway injury. Hence, a high index of suspicion is always required in the evaluation of trauma patients, for if unrecognized, esophageal injury has an extremely poor prognosis.

Diagnosis

Signs and symptoms of esophageal perforation are fairly similar and depend more on the site of perforation than the mechanism of the injury. Signs of perforation include tachycardia, fever, subcutaneous air, and, with injuries of the thoracic esophagus, chest dullness. Symptoms include pain, vomiting, dysphagia, dyspnea, and malaise. Cervical signs and symptoms include neck pain and occasionally subcutaneous air, whereas signs and symptoms of abdominal and thoracic esophageal perforation include, respectively, subxiphoid or epigastric pain and retrosternal pain occasionally radiating to the back. Tachycardia and dyspnea are usually uniformly present in patients with esophageal perforation. Sepsis, hypotension, and shock can also occur, usually later in the course of the disease.

The best diagnostic studies in symptomatic patients vary with the potential cause and the degree of clinical suspicion. Often in cases of iatrogenic endoscopic injury, no further diagnostic studies are required as the injury is sufficiently large for direct endoscopic visualization. When the diagnosis is less certain, chest x-ray suggests the diagnosis in over 90% of cases. pneumomediastinum, subcutaneous emphysema, and left-sided pleural effusion are all suggestive of esophageal injury. An upper gastrointestinal series (UGI) with water-soluble contrast will also confirm the diagnosis in 90% of patients. Barium is to be avoided in patients suspected of having esophageal perforation since leakage of barium out of the esophagus can result in chemical mediastinitis. Chest computerized tomography (CT) enhanced with enteral water-soluble contrast is currently the most sensitive test as it often demonstrates the site of perforation as well as the associated pneumomediastinum and pleural effusions. Chest CT is reported to be over 95% sensitive for the diagnosis of esophageal perforation in most studies. EGD can also be used to increase the diagnostic sensitivity; however, if used alone, esophagoscopy may miss the site of injury. Esophagoscopy is further limited by the difficulty of seeing the site of injury due to the usual absence of inflammation early after perforation and by the angulation of the esophagus. EGD may also exacerbate the injury and increase contamination of the area. Hence, it is not recommended as the primary modality of diagnosis. Chest CT and water-soluble UGI are the two recommended diagnostic modalities.

Management

Treatment of esophageal perforation is dependent on etiology, location, and the length of time between diagnosis and treatment. Patient prognosis worsens with increasing delay in diagnosis as a result of the release of inflammatory mediators and the onset of septic physiology. Iatrogenic endoscopic perforation carries the best prognosis as diagnosis is immediate, whereas strain-related perforation from vomiting (i.e., Boerhaave's syndrome) carries the worst prognosis as diagnosis is often delayed.

Anatomic location of the perforation influences survival as well. Cervical perforations are better contained and result in less spillage with a resulting mortality of less than 10%, whereas thoracic and abdominal perforations lead to widespread contamination of the mediastinum and abdomen with a mortality of over 50% in most series.

Initial management of esophageal perforation involves the prevention of oral intake, fluid resuscitation with intravenous solutions, histamine 2 (H_2) blockers, or proton pump inhibitors, and the administration of broad-spectrum antibiotics to cover oral and gastrointestinal flora including fungal organisms. Nasogastric tube placement is avoided until the perforation is repaired to prevent further escalation of injury if operative intervention is imminent; otherwise it is placed for gastric decompression.

Nonoperative management with antibiotics and parenteral hyperalimentation carries a 20–40% mortality rate in most series. However, in carefully selected patients with a well-contained, internally drained esophageal perforation with no signs of mediastinal or abdominal contamination and no septic physiology, nonoperative management may be attempted with a low acceptable mortality, especially in poor operative candidates. Typically, these esophageal leaks are located in the cervical esophagus, whereas most thoracic and abdominal perforations require operative intervention.

Surgical intervention remains the primary treatment of choice in the management of esophageal perforation. Operative intervention consists of (1) primary repair; (2) diversion with concomitant exclusion; (3) T-tube drainage; or (4) esophagectomy with reconstruction, which may be immediate or staged. Regardless of the

exact surgical method, the main principles of operative intervention include containing the leak and draining the injury site.

Primary repair for esophageal perforation is typically reserved for cervical injury, which can be repaired and subsequently drained. Primary repair for thoracic and abdominal perforations can be considered when there is minimal mediastinal and intra-abdominal contamination, respectively, and with minimal devitalized tissue in a stable patient. Primary repair is most successful within 24–48 h of injury. Repairs may be reinforced with healthy and viable tissues such as muscle—platysma and intercostal—thick pleura, pericardium, or adjacent stomach. In the repair of thoracic esophageal injuries, it is usually prudent to debride and drain the entire mediastinum initially. The esophagus is then mobilized around the area of perforation, which may be posterior with respect to the site of thoracotomy. Careful dissection will usually reveal the site. It is important to open the muscle layers over the perforation to identify the full extent of the injury, which is often subtle. A two-layer repair is usually recommended and intercostal muscle or other viable tissues are used to buttress the repair. The chest is then irrigated and extensively drained. In the case of very low esophageal perforations, a fundoplication or a Thal patch using the stomach can be accomplished as well.

In the presence of widespread contamination and substantial devitalized esophageal tissue, options include exclusion and diversion, T-tube drainage, or esophagectomy. The exclusion and diversion technique involves the creation of a cervical esophageal fistula and a gastrostomy and jejunostomy with delayed reconstruction 3 months to 1 year later. In this procedure, the mediastinum is debrided, the perforation is repaired, and the flow of saliva and bile is diverted. A modification in the thoracic procedure involves the repair and drainage of the perforation with stapling of the esophagus above and below the injury. In this procedure, a nasogastric tube is placed above the staple line and a gastrostomy is used for gastric decompression. Over an interval of a few months, the peristalsis of the esophagus usually allows for recanalization, obviating the need for additional surgery.

Another approach utilizes a biliary T-tube positioned inside the perforation with the hole debrided and sewn around it. This drainage with a Silastic tube creates a controlled esophagocutaneous fistula and allows for the removal of the T-tube 6 months to 1 year later after resolution of the inflammatory state. At that point, the patient can be reevaluated and the remaining esophagus studied to consider whether any further reconstructive options are needed.

Esophagectomy, with or without immediate reconstruction, should be considered for perforation in the setting of carcinoma, severe stricture or stenosis, or mega-esophagus. Reconstruction techniques include creating a "neo-esophagus" from the stomach, jejunum, colon, or platysma. If delayed reconstruction is chosen in the setting of a septic patient in whom a short operative procedure is desired, a cervical esophageal fistula and gastrostomy and jejunostomy are created, as in the diversion and exclusion technique. Esophageal stenting of small perforations has also been described, but large studies to determine its efficacy are lacking.

Postoperatively, these patients require enteral nutrition through feeding gastromies or jejunostomies. In the setting of the ileus, parenteral nutrition is required until the perforation has been shown to be healed, if primarily repaired, or the reconstructed neo-esophagus has been shown to be patent. Typically, water-soluble UGI studies are done to evaluate the operative result in these cases.

CAUSTIC ESOPHAGEAL INJURY

Etiology

Caustic esophageal injury usually results from suicide attempts and its severity depends on the type of chemical ingested, the quantity ingested, and the duration of exposure to the caustic agent. Acid (e.g., battery acid, bleach) exposure to esophageal tissue leads to coagulative necrosis, whereas alkaline agents (e.g., lye) cause liquefactive necrosis and a more severe injury pattern. Regardless of the causative agent, treatment must be initiated immediately to prevent the early and late-term sequelae of this extremely morbid and often fatal injury.

Diagnosis

Diagnosis of caustic injury should be suspected in all patients brought to the emergency room after attempted suicide. Signs and symptoms include oropharygneal pain from burn injury, emesis, drooling, and dysphagia. If perforation has occurred, signs and symptoms of perforation will appear as outlined above. Chest X ray and either a UGI series or a chest CT are required, especially if perforation is suspected. These studies should be followed by esophagoscopy 12–24 h postinjury if esophageal perforation is not suspected in order to examine the extent of esophageal involvement and depth of injury. Bronchoscopy is often required to evaluate the airways when involved by aspiration during initial ingestion or vomiting.

Management

Successful management of caustic injury depends on identification of the caustic agent and early detection of esophageal perforation, as these patients have the highest mortality of all perforating esophageal injuries. Esophageal perforation caused by caustic agents is managed similarly to perforation for other etiologies as outlined above. Most cases of esophageal perforation from caustic injury require either exclusion and diversion or esophagectomy, since extensive esophageal injury sustained in these cases is not amenable to primary repair or T-tube repair technique.

In cases where esophageal perforation has not resulted from caustic exposure, management consists of preventing oral intake, fluid resuscitation with intravenous solutions, H_2 blockers, or proton pump inhibitors, and the administration of broad-spectrum antibiotics. Steroids to reduce edema and down-regulate the inflammatory response in both the airway and the esophagus may also be used. However, no studies have shown a mortality benefit. Nasogastric tube placement is avoided until perforation is ruled out.

Patients are kept NPO (L. *non per os;* nothing by mouth) for 24–72 h until EGD and UGI series with water-soluble contrast show no evidence of esophageal leak, and at that time oral intake can be resumed. If more extensive injury is found at the time of endoscopy, the patient can be maintained NPO on intravenous fluids and antibiotics and receive nutrition enterally via nasogastric feeding tubes or parenterally until repeat endoscopy in 72 h to 1 week shows sufficient esophageal healing. If at any time the patient shows signs of systemic sepsis, an endoscopy, UGI, and chest CT should be performed to search for an esophageal perforation.

Late complications of caustic injury include tracheoesophageal fistula and strictures. Esophageal strictures can often be treated symptomatically with dilation and now stenting, but severe strictures often require esophagectomy and reconstruction as outlined above for perforation. Tracheoesophageal fistula requires operative intervention. Other late complications include severe reflux, often unrelieved by maximal medical therapy requiring surgical intervention with fundoplication, or rarely, esophagectomy and reconstruction. Patients surviving caustic esophageal injury also have an increased incidence of esophageal carcinoma and, hence, must be monitored for this complication with surveillance EGD and biopsy.

Esophageal trauma may be caused by perforating injury, usually the result of iatrogenic endoscopic injury; it may arise spontaneously in certain disorders associated with prolonged vomiting; or it may be the result of caustic injury usually associated with attempted suicide. Several good diagnostic tools and surgical techniques are available for managing esophageal trauma. Regardless of the etiology, esophageal trauma carries a high risk of mortality and morbidity if not diagnosed and treated rapidly.

Esophageal Ulcers

KANTHI YALAMANCHILI AND MARK FELDMAN
Presbyterian Hospital of Dallas

dysphagia Difficulty in swallowing.
odynophagia Pain experienced when swallowing food or liquid.
ulcer A hole in the mucosal lining of the esophagus that often results in pain or heartburn.

An esophageal ulcer is a consequence of disruption of esophageal mucosal integrity leading to a local mucosal defect or excavation, often associated with active inflammation. Esophageal ulceration results from a breakdown of esophageal mucosal defense and repair. Symptoms of esophageal ulcers include odynophagia, dysphagia, and heartburn or chest pain that may be exacerbated by eating. Etiologies of ulcers are multiple and are sometimes idiopathic.

INTRODUCTION

Esophageal ulcers may result from gastroesophageal reflux disease, immunosuppression/infections, medication or chemical ingestion, tumors, or certain medical treatments and procedures (Table I).

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) occurs most often due to impaired lower esophageal sphincter function. As a result, stomach contents reflux into the esophagus. If left untreated, GERD may progress from esophageal erosions to formation of discrete esophageal ulcers. In some cases, such acid reflux may lead to Barrett's metaplasia.

IMMUNOSUPPRESSION-ASSOCIATED ESOPHAGEAL ULCERS

Esophageal ulcers may develop in early stages of HIV infection, when transient fever, chills, malaise, skin rash, and lymphopenia often occur; the ulcers tend to be multiple small aphthoid lesions. Later in the course of HIV infection (AIDS), deep ulcers extending up to several centimeters in size may be seen. These larger ulcers can result in fistula formation, perforation, hemorrhage, or stricture formation. Opportunistic infections in AIDS patients from *Candida* species or certain viruses (cytomegalovirus, herpes simplex virus, and rarely Epstein–Barr virus) may also result in esophageal ulcer formation. The pathophysiology of idiopathic esophageal ulcers in HIV patients is poorly understood, although it has been speculated that the squamous epithelial cells lining the esophagus undergo apoptosis as an "innocent bystander" effect of nearby HIV-infected T cell activity.

TABLE I Classification of Esophageal Ulcers[a]

Related to GERD (i.e., peptic ulcers), often with Barrett's esophagus
Related to HIV infection and other conditions with immunosuppression
Candida species
HSV
CMV
EBV
Idiopathic
Infections (immunocompetent hosts)
HSV
EBV (rare)
Mycobacterium tuberculosis
Candida—sometimes soon after antibiotic therapy (rare)
Pill or medication—induced, or ingestion of caustics
Antibiotics (especially tetracyclines)
Potassium chloride tablets
Iron tablets
NSAIDs
Bisphosphonates (e.g., alendronate)
Quinidine
Antivirals (e.g., zalcitabine)
Strong acids or alkalis (caustics)
Tumors with ulcers
Squamous cell cancer
Adenocarcinoma (often with Barrett's esophagus)
Other (metastatic, melanoma)
Following sclerotherapy or band ligation for esophageal varices

[a] Abbreviations: GERD, gastroesophageal reflux disease; CMV, cytomegalovirus; HSV, herpes simplex virus; EBV, Epstein–Barr virus; NSAIDs, nonsteroidal antiinflammatory drugs.

Organ transplant recipients and patients on potent antiinflammatory drugs (e.g., glucocorticoids and tumor necrosis factor inhibitors) can also develop opportunistic esophageal infections with ulcer formation.

IMMUNOCOMPETENCY-ASSOCIATED ESOPHAGEAL ULCERS

In immunocompetent persons, esophageal ulcerations can rarely complicate infectious mononucleosis. Herpes simplex virus (HSV) and *Mycobacterium tuberculosis* can also cause esophageal ulcers. These infections require confirmatory histopathologic diagnosis during esophagoscopy. HSV esophagitis and ulcers may occur spontaneously via reactivation and spread of HSV to the esophageal mucosa via the vagus nerve or may result from direct extension of the oropharyngeal infection into the esophageal mucosa.

MEDICATION-INDUCED ESOPHAGEAL ULCERS

Multiple medications have been linked to esophageal ulcers (Table I). Antibiotics taken as pills or tablets, especially doxycycline, potassium chloride, iron-containing pills, nonsteroidal antiinflammatory drugs (NSAIDs), quinidine, bisphosphonate medications, and antiviral drugs, comprise about 90% of all cases. Because the pharmacologic properties of these medications are so diverse, it is difficult to pinpoint a single unifying mechanism for pill-induced ulceration. Prolonged mucosal contact, the chemical nature of the drug, and drug solubility all contribute to the development of esophageal ulcers. The contact time is dependent on the size and shape of the pill and variations in esophageal anatomy. Coated pills, larger pills, pills taken at bedtime, and sustained-release formulations seem to enhance the chance of pill ulcerations. A preexisting swallowing disorder need not be present. However, there is a predisposition to pill ulceration in patients with preexisting esophageal strictures, tumors, and motility disorders such as achalasia and scleroderma. Symptoms of pill-induced ulcers of the esophagus include sudden onset of painful swallowing and retrosternal chest pain, which usually resolve 5 days to 2 weeks after discontinuation of the medication.

Diagnosis of NSAID-induced ulceration is one of exclusion based on elimination of reflux disease, cancer, or infections as possible causes in patients concurrently taking NSAIDs. Most common culprits are aspirin, ibuprofen, and naproxen. Bleeding is a common feature and there seems to be a prevalence of distal esophageal ulcers in these patients.

The bisphosphonates, which are often used for osteoporosis and Paget's disease may also cause esophagitis. Patients may report esophageal discomfort with the very first dose and a majority experience odynophagia within a week. Bleeding and perforation may result. This patient population tends to be older women who may not take precautions against esophageal injury, such as swallowing the pill with 6–8 ounces of water and then sitting upright for 30 minutes. Iron and potassium compounds in the sustained release preparations can also cause ulcerations. Patients usually do not experience pain with ingestion of iron and potassium and the onset of dysphagia is very slowly progressive.

Zalcitabine (dideoxycytidine, or ddC), a nucleoside analogue used as an antiviral agent, has been reported to cause oral and esophageal ulcers. The majority of these ulcerations resolve within 4 to 7 days even with continuation of the medication.

Caustic ingestions remain a worldwide problem. Two-thirds of household ingestions are accidental and occur in children younger than 6 years of age. Caustic agents may be alkaline or acidic, solid or granular. The concentration, quantity, and physical state of the agent along with the duration of exposure determine the degree of gastrointestinal injury, initially presenting as ulcers but sometimes progressing to severe bleeding, fibrosis with strictures, perforation, or (years later) carcinoma. In caustic ingestions, a poor correlation exists between upper endoscopy findings of gastrointestinal injury and clinical signs and symptoms, making upper endoscopy even more crucial to assess injury. However, the timing of an upper endoscopy after the caustic ingestion is debatable. Waiting 48 to 72 hours has been considered reasonable, although with flexible endoscopes, endoscopy may be performed even earlier if the patient is stable. Healing of injury is often associated with stricture formation.

TUMORS

Cancer of the esophagus with ulcer formation is relatively uncommon but extremely lethal if it occurs. Squamous cell esophageal carcinomas and adenocarcinomas cannot be distinguished endoscopically or radiographically. They mostly tend to cause symptoms in later stages when $>60\%$ of the esophageal lumen is infiltrated with the cancer. These malignancies cause

ragged, ulcerating changes in the esophageal mucosa. Therefore, esophagoscopy is crucial in visualizing the tumor and obtaining histopathologic confirmation.

ENDOSCOPIC BAND LIGATION, SCLEROTHERAPY, AND CHRONIC NASOGASTRIC TUBE PLACEMENT

Band ligation for treatment of esophageal varices in portal hypertension leads to superficial ulcers that occur where the bands are placed, but the frequency of deep esophageal injury is low. Many patients who undergo variceal sclerotherapy develop ulcers within the first few days of treatment because the injection of the sclerosant into and around the varices causes necrosis of esophageal tissue. Nasogastric tubes can cause local esophageal irritation and the ulcers that result may erode into adjacent structures such as major vessels. Studies have shown that even potent gastric acid suppressive therapies do not prevent esophageal damage associated with nasogastric tubes, incriminating local irritation as the key factor responsible.

TREATMENT AND PREVENTION

Proton pump inhibitors are the treatment of choice for esophageal ulcers due to GERD. High doses for 8–12 weeks may be needed to heal the ulcers. HIV associated idiopathic ulcers do not respond to antiviral or antifungal therapies but do respond to immunosuppressive regimens. Prednisone and thalidomide are the two most common agents used.

For pill induced ulcerations, patients with preexisting swallowing difficulties should take precautions such as sitting in the upright position, taking medications with food and water, and using liquid formulations if necessary. Lifestyle changes are key, such as taking pills with food or 6 ounces of water and avoiding recumbency immediately after pill ingestion. Speeding up healing is the only strategy for pill-induced ulcerations. Acid suppressive therapies may possibly allow for faster healing, but this has not been proved. In ulcerations related to ingestion of pill or tablet forms of antibiotics and other medications, epithelial inflammation resolves in 1 to 6 weeks after the medications are discontinued. Avoiding caffeine, alcohol, tobacco, and spicy foods may also possibly contribute to the healing of ulcers.

Infection-related esophageal ulcers respond to treatment of the specific infection. Goals of therapy after a caustic ingestion are to prevent perforation and avoid progressive fibrosis and stricture. Emergency surgery is the only option to treat perforation, but a variety of modalities, although unproved, have been speculated to prevent fibrosis and treat strictures; these include caustic neutralizing agents, corticosteroids, antibiotics, collagen synthesis inhibitors, heparin, early esophageal dilatation, and esophageal stents.

Esophagus, Anatomy

LORI A. ORLANDO* AND ROY C. ORLANDO*,†

** Tulane University School of Medicine and †New Orleans Veterans Administration Hospital*

Auerbach's plexus Network of neurons located between the circular and longitudinal muscle layers of the gastrointestinal tract; primarily involved with the transmission of motor information between the central nervous system and the peripheral end organ. Idiopathic achalasia and diffuse esophageal spasm are two esophageal disorders believed to reflect damage to this plexus.

Barrett's esophagus Existence of specialized columnar epithelium instead of the stratified squamous epithelium that normally lines the distal esophagus; a premalignant lesion that is believed to occur by metaplastic change during the course of reflux damage to squamous epithelium.

Meissner's plexus Network of neurons located within the submucosa of the gastrointestinal tract; primarily involved with the transmission of sensory information between the central nervous system and the peripheral end organ.

sphincter Ringlike band of muscle fibers that constricts a passage or closes a natural orifice; may be skeletal, as in the upper esophageal and external anal sphincters, or smooth, as in the lower esophageal and internal anal sphincters.

The esophagus is designed as a delivery system to transport food from the mouth to the stomach. A hollow tube, it conducts food through two mechanisms, gravity and peristaltic contractions of the surrounding musculature. Retrograde flow of food and gastric acid is prevented by two sphincters, the upper and lower esophageal sphincters, which open in response to a swallowed bolus. This effectively creates a hollow conduit with a one-way flow of contents into the stomach. Located within the posterior mediastinum, immediately behind the trachea but anterior to the aorta, the body of the esophagus extends from the upper esophageal sphincter in the pharynx at the cricoid cartilage to the lower esophageal sphincter in the right crus of the diaphragm at the T10 vertebral level.

MUCOSA

The innermost mucosa of the esophagus surrounded by three outer layers, the submucosa, the muscularis propria (the inner circular and outer longitudinal muscular layers) (see Fig. 1), and outermost adventitia. Each layer is structurally unique, with varying contributions by the vasculature, musculature, and neural innervation. Grossly, the esophageal mucosa is a smooth, pink expanse that ends at the gastroesophageal junction demarcated by the Z-line, an irregular white line. Histologically, the mucosa is composed of the epithelial layer (nonkeratinized stratified squamous epithelium) and the lamina propria and muscularis mucosae layers (Fig. 2). Metaplastic change from stratified squamous epithelium to a specialized columnar epithelium occurs in Barrett's esophagus, a

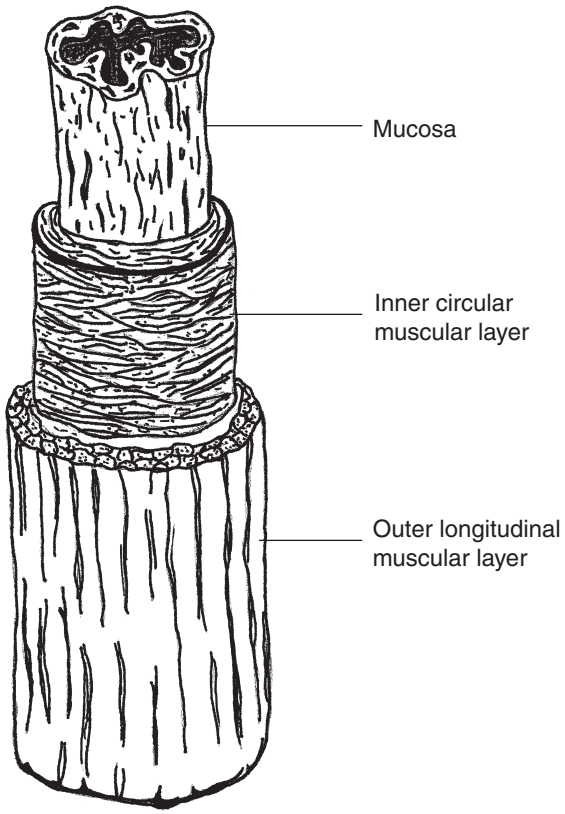

FIGURE 1 Anatomical relationship of the layers of the esophagus. The muscularis propria is made up of the inner circular and outer longitudinal muscular layers. Note the hollow lumen lined by the mucosa, which is collapsed between food boluses.

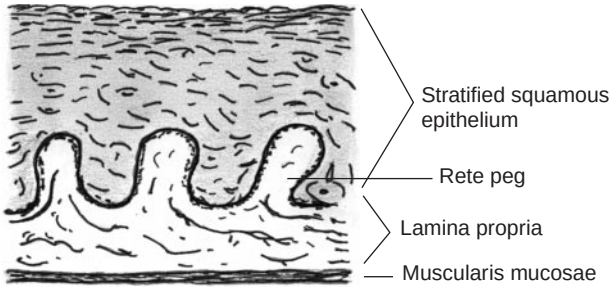

FIGURE 2 The three layers of the mucosa, depicting the superficial stratified squamous epithelium and the sequentially deeper lamina propria and muscularis mucosae. Note the rete pegs of the lamina propria projecting into the epithelial layer above.

premalignant condition. The lamina propria, a connective tissue and vascular layer, resides beneath the epithelium. Rete pegs, also known as dermal papillae, are rounded protrusions of the lamina propria into the epithelial layer above. Although rete pegs are normal, extension into the upper half of the epithelium is a marker for gastroesophageal reflux disease. The final mucosal layer, the muscularis mucosae, is composed of smooth muscle cells. It demarcates the mucosa from the submucosa. Neural structures are present in the mucosa, with sensory tufts extending into the epithelium; arterial and venous structures are present in the lamina propria (see later for discussion of venous drainage of the esophagus).

SUBMUCOSA

The submucosa, a dense network of connective tissue, blood vessels, lymphatics, neurons, and esophageal glands, primarily functions as a secretory layer. The glands are acinar, composed of cuboidal cells that, through a collecting system, secrete into the esophageal lumen mucus, bicarbonate, and epidermal growth factor. The mucus is primarily for lubrication because, unlike in the stomach, it does not form a definable viscoelastic protective layer over the squamous epithelium. The secreted bicarbonate protects the lumen by neutralizing refluxed acid, thereby raising pH to normal. Once esophageal damage has occurred, epidermal growth factor can bind to cell receptors and stimulate esophageal repair. Meissner's plexus, a neural network located within the submucosa, transmits sensory (afferent) stimuli to the central nervous system through both parasympathetic and sympathetic pathways.

MUSCULARIS PROPRIA

The muscularis propria provides the peristaltic contractions necessary to propel a food bolus from the oral cavity to the stomach. The proximal third of the muscularis propria is composed exclusively of skeletal (striated) muscle and the distal third is composed exclusively of smooth muscle; the middle third is a combination of both. Two layers, an inner circular muscular layer and outer longitudinal muscular layer, traverse the length of the muscularis propria (Fig. 1). The amplitude of peristaltic contractions, as measured by manometry, correlates with the efficacy of bolus clearance. Furthermore, inefficient peristaltic contractions can lead to dysphagia, as occurs in the swallowing disorder, achalasia. Innervation of the muscularis propria is complex and differs for the striated and smooth muscle cells. Vagal control of peristalsis occurs at two different nuclei, the dorsal motor nucleus for smooth muscle cells and the nucleus ambiguous for skeletal muscle cells. The Auerbach's (myenteric) plexus, located between the inner circular and outer longitudinal layers, provides preganglionic vagal parasympathetic innervation to smooth muscle cells, whereas the postganglionic vagal nerves end directly on the motor endplate of the skeletal muscle cells. Within the myenteric plexus, excitatory and inhibitory neurons coexist. The excitatory neurons have muscarinic M_2 receptors, which contract both layers of smooth muscle in response to acetylcholine stimulation. Inhibitory neurons induce inner circular smooth muscle cells to relax, probably through the release of nitric oxide and vasoactive intestinal peptide.

ADVENTITIA

The final layer of the esophagus, the adventitia, is a loose connective tissue network. Although all other digestive tract structures contain a serosal layer, the esophagus does not.

UPPER ESOPHAGEAL SPHINCTER

The upper esophageal sphincter (UES) marks the upper boundary and thus the beginning of the esophagus. It is created by the convergence of the inferior pharyngeal constrictor muscle and the cricopharyngeus muscle (Fig. 3). This band of striated muscle, innervated by the pharyngeal branch of the vagus nerve, is contracted at rest, creating a high-pressure zone about 1–2 cm in length. The primary function of the UES is to prevent aspiration of air into the esophagus during normal respiration. Relaxation occurs during the pharyngeal phase

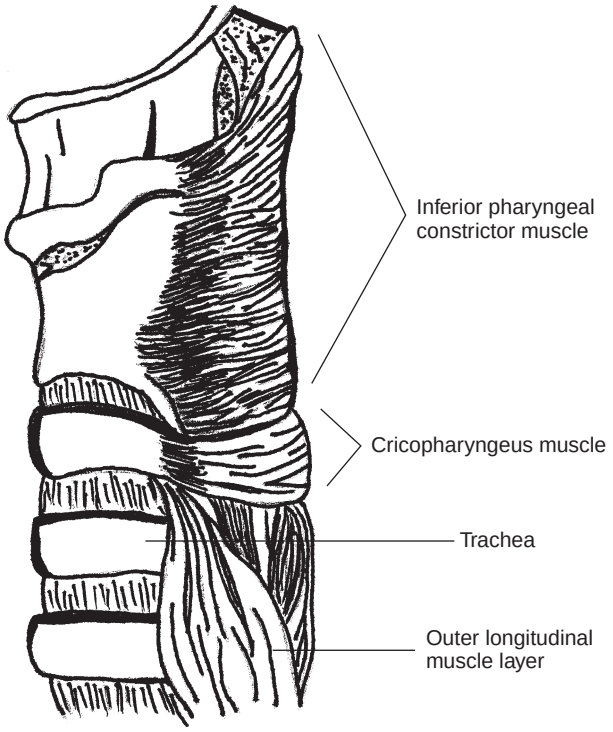

FIGURE 3 Anatomy of the upper esophageal sphincter.

of the swallow response, when elevation of the larynx and hyoid simultaneously close the airway and open the esophageal sphincter.

LOWER ESOPHAGEAL SPHINCTER

The lower esophageal sphincter (LES) forms the lower boundary of the esophagus, creating a barrier between it and the gastric fundus. Located within the right diaphragmatic crus, it is composed of asymmetrically thickened smooth muscle about 3–4 cm in length (Fig. 4). In addition, the fortuitous positioning of the LES within the diaphragm allows diaphragmatic contractions to make a significant contribution to the high-pressure zone at the esophagogastric junction. Esophageal sliding is limited by the phrenoesophageal ligament, which attaches the lower esophagus to the diaphragmatic fascia. Despite this preventive measure, the esophagus occasionally migrates orad, permitting a portion of the fundus to enter the thorax, the so-called sliding hiatal hernia, and allowing reductions in LES pressure. Normally, the LES is tonically contracted, resulting in manometric pressures that are about 20 mmHg greater than in the stomach. This creates a high-pressure zone that combats the reflux of gastric acid. Relaxation occurs in response to a swallowed food bolus, lasting about 5–7 seconds. Relaxation also occurs in response to gastric distension, as in the belch reflex, but lasts longer, at 10–20 seconds. Myenteric neurons convey parasympathetic vagal impulses to the LES, transmitting excitatory and inhibitory signals analogous to their actions within the muscularis propria. Neural innervation contributes greatly to LES pressure; however, many substances can influence pressure, either increasing or decreasing it. These substances range from food to medications to hormones.

CIRCULATION

The esophageal arterial blood supply arises from multiple vessels, which anastamose within the submucosa, forming extensive networks. The superior and inferior thyroid arteries supply the upper esophagus. The descending aorta and bronchial and right intercostal arteries supply the midesophagus, and the left gastric, left inferior phrenic, and splenic arteries supply the distal esophagus. The venous drainage is executed by a network of vessels within the esophageal wall (Fig. 5). Small intraepithelial vessels drain from the stratified epithelium of the mucosa into the superficial venous plexus within the two deeper layers, the lamina propria and muscularis mucosae. From the superficial plexus, blood is drained into the deep intrinsic veins located within the submucosa. Perforating veins traverse laterally through the muscularis propria to connect the deep intrinsic veins to the adventitial extrinsic

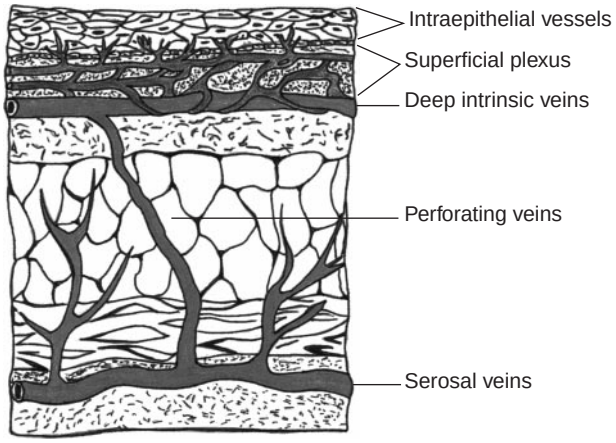

FIGURE 5 Venous drainage of the esophagus.

venous drainage system, which is composed of the serosal and periesophageal veins. Thereafter, drainage is variable, depending on the location. The upper esophagus drains to the superior vena cava, the mid-esophagus drains to the azygous veins, and the distal esophagus drains to the portal vein. Portal hypertension leads to dilation of the deep intrinsic veins, eventually displacing more superficial structures and protruding into the esophageal lumen. The lymphatic system is also segmental, with extensive submucosal anastomoses that account for the distant spread of most esophageal cancers.

atresia The congenital absence or closure of a normal body orifice or tubular organ, e.g., esophageal or biliary atresia.

diverticulum A circumscribed pouch or sac of variable size that may occur normally, as in embryologic development of the respiratory bud off the foregut, or pathologically, resulting from the herniation of the lining mucous membrane through a defect in the muscular wall of a tubular organ.

dysphagia A symptom in which the patient experiences trouble or difficulty swallowing. When the symptom occurs with solids only, it usually reflects a lumen-narrowing obstruction and when it occurs with both liquids and solids, it usually reflects an oropharyngeal or esophageal motor disorder.

Schatzki ring A thin circumferential ingrowth of mucosa at the squamocolumnar junction between esophagus and stomach. When the lumen is compromised to <15 mm, the ring may result in intermittent dysphagia for solids or an episode of acute esophageal food impaction.

sphincter A ringlike band of muscle fibers that constricts a passage or closes a natural orifice. The muscle may be skeletal as in the upper esophageal and external anal sphincters or smooth as in the lower esophageal and internal anal sphincters.

stenosis A pathologic narrowing or stricture of a duct or passage way that may be either acquired, e.g., by radiation injury to the esophagus, or congenital, e.g., esophageal stenosis.

Organ development is a complex and intricate process. A general understanding of esophageal embryology provides key information regarding esophageal disorders, as several commonly encountered abnormalities can be traced back to fetal life. This article describes the general process by which the esophagus emerges from precursor tissues and grows throughout childhood. Several important developmental anomalies are also reviewed.

EMBRYOLOGY

In the embryo, invagination of the endoderm-lined yolk sac into a hollow cylinder creates the primitive gut, which is separated into the pharyngeal, gut, foregut, midgut, and hindgut. Each segment ultimately matures into a separate portion of the digestive tract. The upper digestive tract and lower respiratory tract develop from the foregut. At gestational week 4, the respiratory bud appears as a diverticulum on the ventral surface of the foregut. The diverticulum elongates into a parallel hollow tube, which is gradually isolated from the dorsal portion by a thin membrane, the esophagotracheal septum. The ventral tube, the primordial respiratory tract, goes on to develop into the bronchi, bronchioles, alveoli, and visceral pleura. Meanwhile, the esophagus, the dorsal foregut tube, undergoes lumenal obliteration by proliferating ciliated columnar epithelium. Later, at week 10, the lumen recanalizes through the formation and coalescence of vacuoles. At week 16, stratified squamous epithelium replaces the columnar epithelial lining and the transformation is complete.

CHILDHOOD

Within a few days of birth, the neonate is able to reflexively swallow and breathe without choking, in part due to a fully functional and competent upper esophageal sphincter. The lower esophageal sphincter (LES) is another story. A majority of infants have gastroesophageal reflux, varying from asymptomatic to severe reflux esophagitis, as a consequence of LES incompetence. Factors associated with lower sphincter pressures include the angle of the gastroesophageal junction and the positioning of the sphincter within the abdomen instead of its correct location, being straddled by the diaphragm. In addition, the smaller capacity of the esophagus promotes vomiting in response to reflux more frequently in children than in adults. As the infant grows, the LES angle and location correct their position, leading to a fully competent sphincter and resolution of pathologic gastroesophageal reflux.

DEVELOPMENTAL ANOMALIES

Congenital anomalies of the esophagus are common, occurring in 1 in 3000 live births. They are associated with either genetic defects or intrauterine stresses that impede fetal maturation. Premature infants are prone to

 Copyright 2004, Elsevier (USA). All rights reserved.

developmental anomalies, with up to 50% having involvement of the vertebral, anal, cardiac, tracheal, esophageal, renal, and limb systems. Esophageal anomalies are particularly frequent.

Esophageal Atresia and Tracheoesophageal Fistulas

Esophageal atresia and tracheoesophageal fistulas are the most common developmental anomalies of the esophagus. The former results from the failure of the foregut to recanalize and the latter result from the failure of the lung bud to separate completely. Esophageal atresia occurs alone in 7% of cases, with tracheoesophageal fistulas accompanying the remainder of cases. In both forms, the esophagus is divided into two separate unconnected segments: the upper esophagus, which ends in a blind pouch, and the lower esophagus. In isolated atresia, the lower esophagus connects to the stomach, and in tracheoesophageal fistulas, it communicates with the trachea.

Congenital Stenosis

Esophageal stenosis is a rare anomaly, occurring in 1 in 25,000 live births. The stenotic segment, located in the distal two-thirds of the esophagus, varies from 2 to 20 cm in length. Although the etiology is unknown, one suggestion is that there is incomplete separation of the lung bud from the primitive foregut. Other hypotheses include fibromuscular hypertrophy or loss of muscle-relaxing myenteric neurons.

Esophageal Rings

The distal esophagus may contain two "rings," the A and B rings, which bound the proximal and distal esophageal vestibule and constrict the esophageal lumen. The A ring, a 4 mm band of hypertrophied muscle, is rare and marks the proximal border of the vestibule at the upper end of the LES. The B ring, also called the Schatzki ring, is common, found in up to 14% of the general population. A thin 2 mm membrane marking the distal border of the esophageal vestibule at the gastric cardia, it is associated with hiatal hernias. When present, it also demarcates the squamocolumnar junction. Classically, they remain asymptomatic until the esophageal lumen is narrowed to less than 15 mm, at which point intermittent dysphagia for solids and acute solid-food impactions can occur.

Esophageal Webs

Esophageal webs are congenital anomalies characterized by one or more thin horizontal membranes of stratified squamous epithelium within the upper and mid esophagus that protrude from the anterior wall and extend laterally. Ninety-five percent are symptomatic, usually with dysphagia. An association between cervical esophageal webs, dysphagia, and iron deficiency anemia occurs in Plummer-Vinson (or Paterson-Kelly) syndrome. Correction of iron deficiency may result in both anatomical correction of the web and symptom resolution.

Exocrine Pancreas

NINA W. FLAY AND FRED S. GORELICK
Yale University and Veterans Affairs Medical Center, Connecticut

acinar cells Pyramidal-shaped epithelial cells in the pancreas that synthesize and secrete digestive enzymes.
acinus Functional unit of the exocrine pancreas composed of acinar, centroacinar, and duct cells.
centroacinar cells Terminal duct cells bordering the acinar lumen that secrete bicarbonate into the lumen.
exocytosis Process by which secretory granules fuse with the plasma membrane and release their contents.
goblet cells Mucus-synthesizing and secreting cells found in the epithelium of pancreatic ducts.
islet–acinar portal system Specialized vascular system connecting the islets of Langerhans and the exocrine pancreas that delivers islet hormones to the acinar cells.
pancreatic stellate cells Cells of stellate morphology located between acini that contain vitamin A and respond to cytokines with the production of collagen, leading to fibrosis.
zymogen granules Mature secretory granules in acinar cells containing stored digestive enzymes or zymogens.

The pancreas is a mixed endocrine/exocrine gland enveloped by a thin layer of connective tissue. Connective tissue septa invade the gland, dividing it into lobules, serving as a support for tissue and providing a pathway for vasculature, nerve fibers, and lymphatic ducts. The pancreas lacks a complete fibrous capsule. As a result, cancerous tumor cells can spread to all of the structures located posteriorly to the pancreas by traveling along nerve sheaths. They facilitate their passage by generating proteases that degrade connective tissue. The exocrine portion of the pancreas takes up about 84% of the total organ; 2% of the organ is composed of the endocrine cells (islets of Langerhans). Blood vessels comprise about 4% of the pancreas and the remaining 10% of the pancreas is composed of the extracellular matrix (collagen fibers, reticular fibers, fibroblasts). Enhanced deposition of connective tissue within the pancreas is a feature of chronic pancreatitis of various etiologies. The collagen is probably synthesized and secreted from stimulated fibroblasts and a special class of vitamin A-storing cells known as pancreatic stellate cells. Also, under normal conditions, there is a considerable amount of fat scattered throughout the parenchyma of the human pancreas. Notably, this is the first tissue to show injury during the inflammatory disease of the pancreas known as pancreatitis.

FUNCTIONAL MORPHOLOGY OF THE EXOCRINE PANCREAS

The acinus is the basic functional unit of the exocrine pancreas. It is composed of acinar cells, centroacinar cells, and duct cells (Fig. 1). A connective tissue matrix, including a basal lamina, surrounds the acinus, but does not insert itself between individual acinar cells. Nerve terminals in the exocrine pancreas differ among species, but in general they end near blood vessels, acinar cells, and duct cells. In mammals, they terminate near the acinar cell plasma membrane. In pancreatic duct cells, nerve terminals are usually on or near the basement membrane. The presence of nerve terminals so close to the basement membrane of these cells is critical because regulation of pancreatic acinar cell secretion is partially under the control of cholecystokinin (CCK) released from proximal intestinal cells in response to food intake. CCK has an indirect effect on pancreatic secretion by stimulating the release of acetylcholine (ACh) and other neurotransmitters from nerves. ACh, in turn, activates muscarinic receptors on the acinar cell to stimulate pancreatic secretion.

The glandular structure of the exocrine pancreas differs slightly from that of other digestive glands: the pancreas is composed of true glands with blind endings, similar to salivary gland structure, but also has other

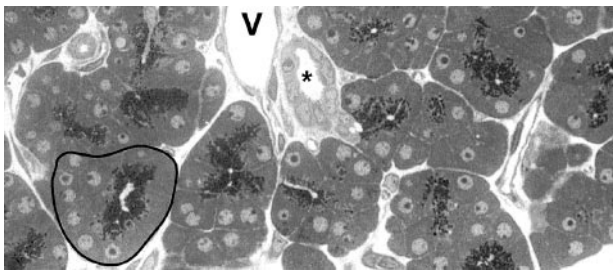

FIGURE 1 Exocrine pancreas structure. A portion of a rat pancreatic lobule containing individual acini is visible. An intralobular duct (asterisk) alongside a blood vessel (V) is visible at the top of the field. A single acinus (dark outline) is made up of several acinar cells. The polarized cells reveal large nuclei in the basolateral domains and zymogen granules near the apical surface. The clear area in the center of the acinus is the lumen.

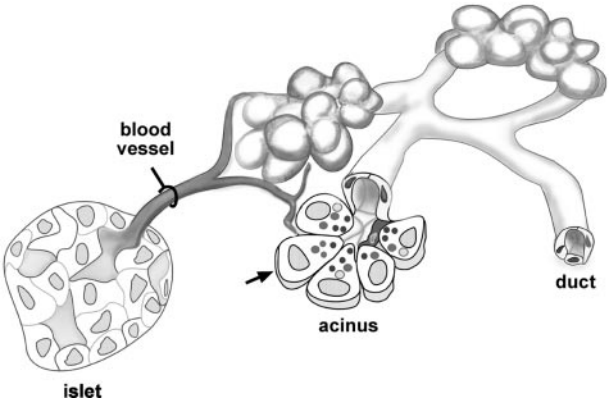

FIGURE 2 Acinar–islet portal system and duct structure. Note the blood vessel directly connecting the islet of Langerhans to the group of acini. Two duct structures (blind-ended and looped) are illustrated. The small gray shaded cell adjacent to an acinar cell at the beginning of the duct system represents a centroacinar cell. The arrow points to a single acinar cell in the acinus.

"looped" ducts seen going into, and emerging from, groups of acini (Fig. 2).

ACINAR PORTAL SYSTEM

The islet–acinar portal system is an arterial supply network that connects the islet cells with the exocrine cells (Fig. 2). The system surrounds and invades the islet cells (endocrine system), receives hormones and other peptides from islet cells, and then directly delivers its contents to the neighboring acinar cells (exocrine system). These endocrine hormones may modulate the function of the exocrine pancreas. For example, in the region adjacent to the pancreatic islet cells, the acinar cells contain more cytoplasm, a larger nucleus, and an increased amount of zymogen granules compared to those that are more distal to the islet. Islet hormones may also modulate both basal and stimulated pancreatic exocrine secretion.

THE ACINUS

The three-dimensional architecture of the acinus has been revealed using confocal analysis and scanning electron microscopy, which show the relationship of the connective tissue elements, vasculature, and excretory ducts to the acinar and centroacinar cells. Collagen and reticular fibers form a scaffold that surrounds the acini. The reticular fibers form a network with fenestrations, allowing for a continuous space between ducts, acini, vasculature, and lymph vessels. Techniques that use tissue disruption and scanning electron microscopy reveal that most pancreatic acini contain 30 to 40 large cells, but some smaller groups of acini of 10 to 20 cells are also present. However, electrical coupling experiments show that the functional coupled subunit is much larger and consists of about 500 cells. A possible advantage of an increased size of the functional acinus might be an enhanced secretory response when only a limited number of cells are stimulated.

Acinar Cells

Pancreatic acinar cells are pyramidal-shaped, polarized epithelial cells. The base of the cell rests on a basement membrane and the apex opens onto the lumen of the acinus. Junctional complexes are found between the cells, dividing each cell into an apical and a basolateral zone. The junctional complex is composed of four structures. The most apically located, the zonula occludens (tight junction), has two functions: it serves as a barrier to water and solutes and it restricts the molecular movement between apical and basolateral domains. The next three structures in order toward the basal portion of the cell are the zonula adherens, the macula adherens (desmosomes), and the macula communicantes (gap junctions). Gap junctions can selectively conduct small molecules (molecular weight <1000) between cells and may help to coordinate the response of an acinus to physiologic stimuli and to injury.

The pancreatic acinar cell is compartmentalized into distinct regions (Fig. 3). In the apical area, the cell contains zymogen granules and apical microvilli. Just deep to the apex, in the perinuclear region, there are condensing vacuoles and a Golgi apparatus. The basolateral zone contains the nucleus and a rich supply of rough endoplasmic reticulum (rER) (Fig. 4). This imparts the

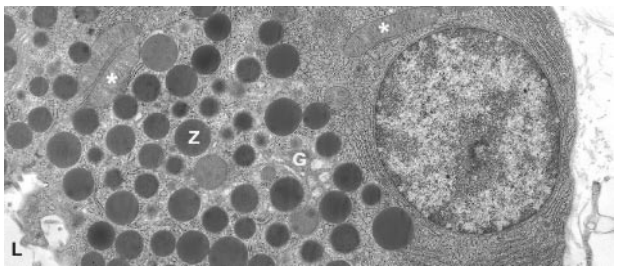

FIGURE 3 Pancreatic acinar cell. The apical surface of the cell lines the lumen (L). A small number of microvilli are evident at the lumen. Note the apical zone containing zymogen granules (Z) and a mitochondrion (asterisk). The Golgi apparatus (G) is in the perinuclear location. The nucleus and rough endoplasmic reticulum are in the basolateral zone. Some collagen fibrils are present in the connective tissue deep into the basal portion of the acinar cell (rat, $\times 5600$ original magnification).

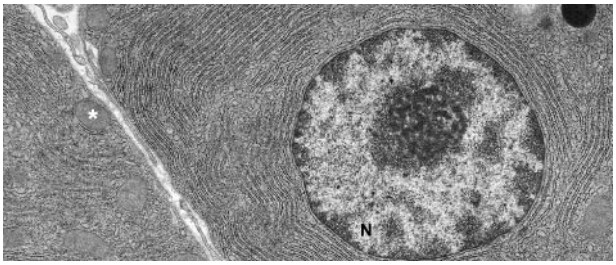

FIGURE 4 The basolateral region of the pancreatic acinar cell. Note the large nucleus (N) containing a small amount of heterochromatin, a great amount of euchromatin, and a prominent endoplasmatic reticulum and an elaborate nucleolus. Several mitochondria, one of which is labeled with an asterisk, are present (rat, ×5600 original magnification).

characteristic basophilia visible under light microscopy. Lysosomes, which are part of the late endosomal pathway, are scattered throughout the cytoplasm. Mitochondria are spatially organized as three distinct groups. One group is near the basolateral membrane, where active transport across the basement membrane is occurring. Another group of mitochondria is in the perinuclear region (Fig. 3). The third group resides in the apical region, separating zymogen granules from the basolateral area. The apically distributed mitochondria may have a role in generating calcium oscillations that are responsible for stimulated zymogen secretion.

The morphology of the acinar cell faithfully reveals its function in the synthesis, storage, and exocytosis of both active and inactive digestive enzymes. Pancreatic acinar cell enzymes are synthesized in the rER, traverse the late ER–Golgi compartment through vesicular transport, and enter the Golgi, where they are modified and sorted. In the Golgi, lysosomal enzymes, the ultimate destination of which are lysosomes, receive the mannose-6-phosphate (M6P) residue. Binding of the enzyme–M6P molecule to the M6P receptor (M6PR) results in targeting of the molecule to the late endosomal compartment. In late endosomes, a decline in pH initiates the release of lysosomal enzymes from the M6PR. The receptor is recycled to the Golgi or to the plasma membrane, and the lysosomal enzyme is transported to the lysosome. Additionally, M6PRs found on condensing vacuoles may retrieve lysosomal enzymes that have been sorted to the secretory pathway and return them to the Golgi complex.

In contrast to lysosomal proteins, secretory proteins are destined for exocytosis. On their exit from the Golgi, they enter membrane-bound, acidic condensing vacuoles, located near the nucleus (Fig. 5). Condensing vacuoles maintain the lowest pH compartment within the secretory pathway. As these vacuoles mature, their protein contents are condensed and the membrane is pinched off. The diameter of the resulting pancreatic zymogen granule is about two-thirds that of the condensing vacuole. Zymogen granules are stored in the apical one-third of the acinar, awaiting signals for exocytosis.

When the acinar cell is stimulated, contents of the zymogen granules are released into the acinar lumen. This process, called exocytosis, involves several steps:

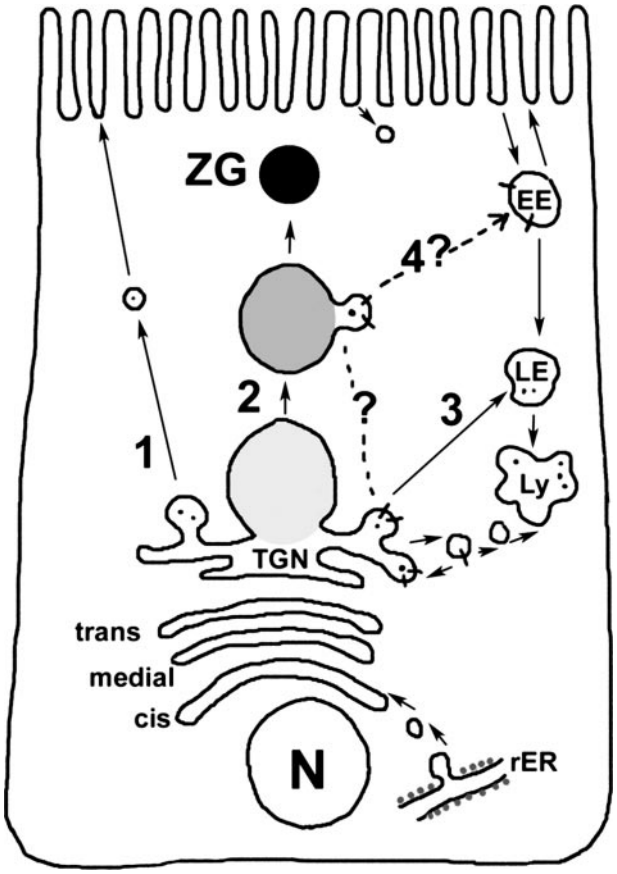

FIGURE 5 Vesicular trafficking pathways in the pancreatic acinar cell. Four main pathways are shown. (1) Constitutive secretion of proteins. A small fraction of newly synthesized proteins are secreted in an unregulated pathway in vesicles that bud off the trans-Golgi network (TGN). (2) Secretory pathway for zymogen granule release. The dark cores in vesicles budding from the TGN represent condensing vacuoles. As they mature, the membrane is pinched off and the content of the granule condenses to form zymogen granules (ZG). (3) Endocytic pathway for lysosomal enzyme delivery to lysosomes (short lines, mannose-6-phosphate receptors; EE, early endosome; LE, late endosome; Ly, lysosome). (4) A possible pathway for retrieval of lysosomal enzymes from the secretory pathway to the endocytic pathway. The open circles represent recycling membrane vesicles. Golgi domains are represented as trans, medial, and cis; rER, rough endoplasmic reticulum.

movement of granules to apical membrane, fusion of granules with the apical membrane, and the release of contents into the lumen. Actin is a major component of the apical cytoskeleton and plays a pivotal role in exocytosis. One study suggests that prior to fusion, zymogen granules become coated with actin, which might constrain their distribution to the apical part of the acinar cell and facilitate the movement of the zymogen granules across the subapical actin network toward the targeted site of fusion. A second actin network, located just below the apical membrane, may act as a barrier, blocking fusion of the zymogen granules with the apical plasma membrane. When the cell is stimulated, the actin barrier is reorganized and secretory granules can contact the apical plasma membrane. Fusion of the granules with the plasma membrane probably requires the interactions of the soluble *N*-ethylmaleimide-sensitive attachment protein receptor (SNARE) complex, a special group of proteins found on secretory granules and apical plasma membranes, along with other cytosolic factors.

Recent research, using atomic force microscopy, has identified a change in plasma membrane structure during exocytosis. In acinar cells, increases in the size of membrane depressions correlate with an increase in amylase secretion, and depression dynamics and amylase release are partly regulated by actin. This may indicate that there are predefined sites for fusion on the apical membrane. Following exocytosis, activation of the apical endocytic pathway leads to the subsequent retrieval of the secretory granule membrane via clathrin-coated retrieval vesicles. Therefore, an intact apical cytoskeleton may be a requirement for regulating normal exocytosis, maintaining organelle polarity, and membrane retrieval.

Calcium is the major secondary messenger for regulating protein secretion from pancreatic acinar cells. The major calcium storage compartments are in the ER and mitochondria. In acinar cells, polarized (apical to basal) waves of calcium are induced by the serial activation of two intracellular calcium channels that are principally responsible for calcium signaling: the apically located inositol 1,4,5-trisphosphate (IP_3) and the ryanodine receptor (RyR) located in the basolateral domain. Calcium waves begin in the apical domain of the cell, in the region of the type III IP_3 receptor (IP_3R), the most heavily expressed IP_3R isoform. Subcellular release of calcium coordinates the action of the IP_3R and RyR calcium channels. When acinar cells are stimulated with neurotransmitters, growth factors, or hormones, stored calcium is released from the ER by the action of IP_3. IP_3 binds to the IP_3R receptor, an ER calcium channel, to release calcium into the cytosol.

Centroacinar Cells

The location, morphology, and biochemistry of centroacinar cells reflect their role in electrolyte transport. Seen in cross-section, the centroacinar cells are centrally located within the acinus, and mark the beginning of ducts (Figs. 2 and 6). Centroacinar cells are small, pale-staining cells with microvilli on their apical surfaces. The pale-staining character reflects the sparse cytoplasm, small amount of rER, small size of the Golgi apparatus, and the lack of zymogen granules within the cell. Large, abundant, elongated mitochondria, suggesting an active role in ion secretion, are seen in the basal portion of these cells. The basal lamina staining characteristics of centroacinar cells differs from those of acinar cells. In centroacinar cells, the basal lamina contains more abundant, fixed anionic binding sites, suggestive of a role in ion transport. The luminal surface of the centroacinar cell is stained with silver, a marker of anions (in this case, bicarbonates). Unlike acinar cells, centroacinar cells contain carbonic anhydrase, which catalyzes the generation of HCO_3^- from CO_2. The cells also contain sialic-rich acid proteins, which work as cation filters, on their basolateral surfaces.

Pancreatic Duct Cells and Goblet Cells

Pancreatic duct cells exhibit morphologic heterogeneity along the length of the entire pancreatic duct; functional studies indicate that the types of solute-transport proteins within duct cells correlate to differences in duct cell location and morphology. For instance, duct cells most proximal to the acinus are squamous or low cuboidal in shape, having few cytoplasmic vesicles but a great many mitochondria (Fig. 6). These morphological features correspond to the function played by proximal duct cells in fluid and

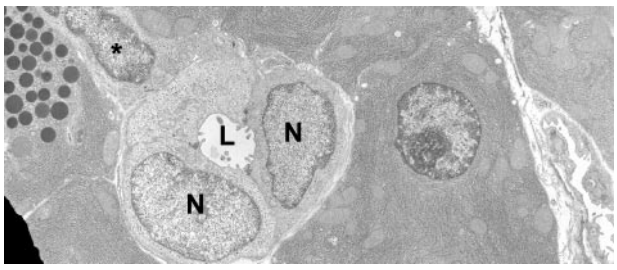

FIGURE 6 Pancreatic duct cells. In the center of the field, three low cuboidal duct cells surround a central lumen (L), forming a small intralobular duct. In two of the cells, nuclei (N) are visible. The duct is located close to the basolateral zones of five acinar cells. In the left upper field, a centroacinar cell with an elongated nucleus (asterisk) is visible. Note the pale-staining cytoplasm of the duct and centroacinar cells (rat, $\times 3300$ original magnification).

electrolyte transport. More distal duct cells are cuboidal to columnar in shape, and they contain more cytoplasmic vesicles and granules, which corresponds to the fact that more distal duct cells are capable not only of fluid and electrolyte transport, but also of protein secretion. Pancreatic duct cells express high levels of carbonic anhydrase and presumably play a role in HCO_3^- secretion. The duct and centroacinar cells secrete bicarbonate, which serves to neutralize gastric acid in the duodenum.

HCO_3^- secretion requires the activity of the cystic fibrosis transmembrane regulator (CFTR). The CFTR protein is concentrated on the apical membrane of proximal pancreatic duct cells. CFTR is a cAMP-regulated Cl^- conductance located in the luminal membrane and may be the major bicarbonate conductive pathway. In cystic fibrosis, a CFTR gene mutation results in the loss of CFTR expression at the plasmalemma and disrupts apical transport in pancreatic duct cells. There is a decrease in the secretion of bicarbonate and water, leading to duct obstruction, inflammation, and fibrosis.

Goblet cells are also found among the pancreatic duct cells. At the head of the main pancreatic duct (near the ampulla), goblet cells comprise about 25–30% of the duct epithelium. More proximally, the goblet cell population decreases to 5–10% of the duct cell population. Goblet cells secrete mucin (high-molecular-weight glycoproteins) production. When hydrated, mucins form mucus, which lubricates, hydrates, and mechanically protects surface epithelial cells. Mucins may also combat pancreatic infections by binding to pathogens and interacting with immune-competent cells.

Pancreatic Stellate Cells

Stellate cells have recently been isolated and characterized in the pancreas. They are similar to the stellate cells first identified in the liver. Hepatic stellate cells are known to play a major role in production of hepatic fibrosis and are the source of collagen and other extracellular matrix proteins in liver disease. Pancreatic stellate cells (PSCs) are located in the interlobular area, or the interacinar region, of the pancreas. The cells are triangular in shape and contain a prominent ER with cisternae containing flocculent materials (which reflect the presence of collagen and other extracellular matrix proteins), microfilaments, a large nucleus, few mitochondria, and cytoplasmic lipid droplets. In culture, PSCs have characteristics that are identical to those of hepatic stellate cells, with abundant vitamin A-containing lipid droplets in the cytoplasm. PSCs respond to cytokines (platelet-derived growth factor, transforming growth factor-β) by proliferating and synthesizing large amounts of extracellular matrix proteins (collagen, fibronectin, laminin). In addition, activated PSCs undergo a transformation into a myofibroblast-like phenotype, exhibiting positive staining for the cytoskeletal marker protein α-smooth muscle actin (α-SMA). PSCs are also activated by ethanol exposure and the ethanol effect is mediated by metabolism to acetaldehyde and generation of oxidant stress within the cells. The presence of PSCs in fibrotic areas is suggestive of their participation in pancreatic fibrosis development, a pathological feature of chronic pancreatitis.

In summary, the functional subunit of the exocrine pancreas is the acinus. It is composed of several major cell types (acinar, centroacinar, duct, goblet, and PSC), connective tissue, vasculature, and lymphatics. Although there are subspecializations among the cell types, in general, the acinus synthesizes and secretes active and inactive digestive enzymes that ultimately enter the descending duodenum, where they are activated and digest foodstuffs. The duct and centroacinar cells secrete bicarbonate, which serves to neutralize gastric acid in the duodenum.

Exocrine Pancreatic Insufficiency

EUGENE P. DIMAGNO
Mayo Clinic

chronic pancreatitis Continual inflammatory disease of the pancreas.

enteric-coated Oral medication that is coated or encapsulated to avoid acid damage in the stomach but dissolve in the intestine.

malabsorption The failure to digest and absorb dietary nutrients.

proton pump inhibitors Drugs that block gastric acid secretion by inhibiting the ATPase enzyme that transports protons.

steatorrhea Increased fat in stool due to malabsorption.

Exocrine pancreatic insufficiency is the reduced secretion of exocrine pancreatic digestive enzymes from the pancreas into the duodenum. It arises from the destruction of pancreatic acinar cells that synthesize and secrete enzymes (pancreatitis, cystic fibrosis), obstruction of the ducts leading from the pancreas to the duodenum (pancreatic cancer), or removal of part of or the entire pancreas (pancreatic surgery). Mild to moderate exocrine insufficiency may be asymptomatic, but severe exocrine insufficiency causes malabsorption and malnutrition, which impacts on morbidity and mortality. For example, treatment of exocrine insufficiency in cystic fibrosis slows the decline of pulmonary function and prevents growth retardation.

PATHOPHYSIOLOGY AND NATURAL HISTORY

Malabsorption of fat, protein, or carbohydrate does not occur until maximal secretion of enzymes is reduced by $>90\%$. Fat malabsorption is the greatest problem, because lipase secretion declines more rapidly than that of other enzymes, causing steatorrhea to occur before other forms of malabsorption. It is also more difficult to treat than carbohydrate or protein malabsorption. The time course to onset of steatorrhea varies among diseases. Exocrine insufficiency is usually present at the time of diagnosis in cystic fibrosis and pancreatic cancer and occurs in 75–80% of patients. However, in alcoholic chronic pancreatitis, early-onset and late-onset idiopathic chronic pancreatitis, it takes a mean of 13, 26, and 17 years, respectively, to develop severe exocrine insufficiency.

Carbohydrate malabsorption and protein malabsorption are easier to treat than steatorrhea because (1) they occur later and are less severe than steatorrhea; (2) salivary amylase, gastric proteases, and intestinal brush border enzymes that digest carbohydrate and peptides partially compensate for the lack of pancreatic amylase and proteases; and (3) amylase and proteases are

Exocrine Pancreatic Insufficiency

EUGENE P. DIMAGNO
Mayo Clinic

chronic pancreatitis Continual inflammatory disease of the pancreas.

enteric-coated Oral medication that is coated or encapsulated to avoid acid damage in the stomach but dissolve in the intestine.

malabsorption The failure to digest and absorb dietary nutrients.

proton pump inhibitors Drugs that block gastric acid secretion by inhibiting the ATPase enzyme that transports protons.

steatorrhea Increased fat in stool due to malabsorption.

Exocrine pancreatic insufficiency is the reduced secretion of exocrine pancreatic digestive enzymes from the pancreas into the duodenum. It arises from the destruction of pancreatic acinar cells that synthesize and secrete enzymes (pancreatitis, cystic fibrosis), obstruction of the ducts leading from the pancreas to the duodenum (pancreatic cancer), or removal of part of or the entire pancreas (pancreatic surgery). Mild to moderate exocrine insufficiency may be asymptomatic, but severe exocrine insufficiency causes malabsorption and malnutrition, which impacts on morbidity and mortality. For example, treatment of exocrine insufficiency in cystic fibrosis slows the decline of pulmonary function and prevents growth retardation.

PATHOPHYSIOLOGY AND NATURAL HISTORY

Malabsorption of fat, protein, or carbohydrate does not occur until maximal secretion of enzymes is reduced by $>90\%$. Fat malabsorption is the greatest problem, because lipase secretion declines more rapidly than that of other enzymes, causing steatorrhea to occur before other forms of malabsorption. It is also more difficult to treat than carbohydrate or protein malabsorption. The time course to onset of steatorrhea varies among diseases. Exocrine insufficiency is usually present at the time of diagnosis in cystic fibrosis and pancreatic cancer and occurs in 75–80% of patients. However, in alcoholic chronic pancreatitis, early-onset and late-onset idiopathic chronic pancreatitis, it takes a mean of 13, 26, and 17 years, respectively, to develop severe exocrine insufficiency.

Carbohydrate malabsorption and protein malabsorption are easier to treat than steatorrhea because (1) they occur later and are less severe than steatorrhea; (2) salivary amylase, gastric proteases, and intestinal brush border enzymes that digest carbohydrate and peptides partially compensate for the lack of pancreatic amylase and proteases; and (3) amylase and proteases are

 Copyright 2004, Elsevier (USA). All rights reserved.

more resistant to acid denaturation than lipase. In contrast, fat digestion depends mainly on the pancreatic lipase.

TREATMENT OF EXOCRINE PANCREATIC INSUFFICIENCY

The current clinical dictum is that oral pancreatic enzyme replacement should be started when malabsorption occurs and the principle is simple—replace inadequate secretion of pancreatic enzymes by giving enzymes by mouth. Unfortunately, although carbohydrate and protein malabsorption is mostly reversed by pancreatic enzymes, fat malabsorption rarely is, because inadequate amounts of pancreatic enzymes may be ingested and because improper timing and schedule of taking enzymes and lipase may be inactivated by intragastric and intraduodenal acidity (irreversible inactivation at pH ≤ 4). Up to 90% of the ingested enzymes are destroyed by acid in the stomach and by acid and proteolytic digestion by chymotrypsin and trypsin in the small intestine.

Dosage

To abolish malabsorption, ~10% of normal enzyme output needs to be delivered to the duodenum. Because of misinterpretation of the experimental data, most pharmaceutical companies recommend a dose of 30,000 USP (United States Pharmacopoeia) lipase units. However, a unit of lipolytic activity in the experimental studies of the authors is equivalent to 3 USP units. Therefore, at least 90,000 USP units of lipase is needed. Although this dose rarely abolishes steatorrhea, it usually decreases steatorrhea by 50%. Inadequate dosing may occur because the amounts of enzymes in preparations vary among lots.

Pancreatic enzymes should be given with meals (e.g., 25% of the dose after first few bites, 50% of the dose during the meal, and 25% of the dose immediately at the end of the meal). Although taking enzymes every hour for 18 h (same total dose as prandial administration) is as effective as taking enzymes with meals, the prandial schedule is more practical. The hourly schedule may be more effective when postprandial gastric pH is >4.0 for more than 1 h, which occurs in some chronic pancreatitis patients.

Choice of Pancreatic Enzymes: Non-Enteric-Coated or Enteric-Coated?

Enteric-coated preparations should traverse the stomach and duodenum without lipase inactivation. However, when adequate dosages of lipase are used, enteric-coated and non-enteric-coated enzymes reduce steatorrhea to a similar extent. Better delivery of lipase into the small intestine occurs with enteric-coated microspheres (ECMS), but reduced steatorrhea due to smaller pellets is unconfirmed. In addition, ECMS are expensive and may be associated with fibrosing colopathy because of release of the enzymes and the polymeric coating in the distal small intestine. ECMS may be appropriate if patients do not respond to conventional enzymes with or without acid suppression therapy, are unable to tolerate conventional preparations, are unable to swallow tablets, have undergone gastric surgery or bypass surgery that might impair mixing, or have documented persistent gastric and duodenal pH of <4.0 despite acid suppression therapy. ECMS should not be used if there is hypochlorhydria (e.g., total gastrectomy or long-term acid suppression therapy for other gastrointestinal diseases).

Adjunctive Acid Suppression Therapy

Acid inactivation of lipase can be prevented by neutralization or suppression of gastric acid secretion. However, magnesium-containing antacids and calcium carbonate are not of benefit. Aluminum hydroxide is slightly beneficial. Low doses (2.5 g) of sodium bicarbonate are ineffective and large doses (16.6 g/day given with meals) are minimally effective. In contrast, adjunctive treatments with histamine-2 (H2) receptor antagonists or proton pump inhibitors (PPIs) are very effective in reducing steatorrhea because they inhibit gastric acid secretion and also enhance lipase and bile acid concentrations by reducing duodenal volume flow. Effective preparations in at least 40% of patients include the H2 receptor antagonists cimetidine, ranitidine, and famotidine and the PPIs omeprazole and lansoprazole. Although adjunctive acid suppression therapy is beneficial, routine use may not be justified because of cost, drug interactions, and long-term safety. It should be used only when abolition of steatorrhea is not achieved with conventional enzymes.

DIET MODIFICATION

Currently it is recommended that low-fat diets (50−75 g/day) should be used if steatorrhea is symptomatic. This recommendation may undergo change as recent studies have demonstrated in pancreatic-insufficient dogs that fat absorption was greater when pancreatic enzymes were given with high-fat diets. However, the effect of high-fat diets with pancreatic enzymes on fat absorption has not been tested in patients with exocrine insufficiency.

SUMMARY

Treatment of exocrine pancreatic insufficiency is necessary if there are symptoms of malabsorption secondary to severe exocrine pancreatic insufficiency, steatorrhea, diarrhea, or weight loss. Initially, patients are treated with 90,000 USP units of non-enteric-coated enzymes with meals. If patients continue to have steatorrhea and are symptomatic, dietary fat should be reduced to 50–75 g/day. If steatorrhea does not decrease, adjuvant therapy with H2 receptor antagonists or a PPI should be added, which will abolish steatorrhea in approximately half of the patients. Adjuvant acid suppression therapy is preferred over enteric-coated enzymes because it increases intraduodenal concentrations of lipase and decreases bile acid malabsorption.

Reducing steatorrhea by 50% (but not abolishing it) improves bowel symptoms, nutritional status, the sense of well-being, and weight gain. However, the optimal goal of pancreatic enzyme replacement is the complete abolition of steatorrhea because this improves growth in children and because adults with exocrine insufficiency have a significantly shortened life span, partly due to an increase in atherosclerotic cardiovascular disease. The cause of cardiovascular disease is unknown, but malabsorption, malnutrition, and metabolic derangement might be involved.

Exocytosis

XUEQUN CHEN AND JOHN A. WILLIAMS
University of Michigan, Ann Arbor

exocytosis The process by which membrane-enclosed intracellular vesicles fuse with the plasma membrane and then open and release their contents to the extracellular space.
membrane fusion The process by which membrane lipid bilayers merge.
NSF A cytosolic protein required for vesicle fusion that is sensitive to *N*-ethylmaleimide.
Rab A family of small monomeric GTP-binding proteins with an overall structure similar to that of Ras and which regulate vesicle trafficking and fusion.
secretory granule Membrane-bound vesicle containing condensed secretory material.
SNAREs Membrane proteins that serve as receptors for soluble *N*-ethylmaleimide-sensitive factor attachment proteins and that participate in vesicular docking and fusion.

Exocytosis is the process by which membrane-enclosed intracellular vesicles fuse with the plasma membrane and then open and release their contents to the extracellular space. Many cellular processes involve exocytosis: for example, in the gastrointestinal tract, the release of neurotransmitters in synaptic vesicles from presynaptic enteric neurons, the secretion of digestive enzymes in zymogen granules from gastric chief cells and pancreatic and parotid acinar cells, the release of mediators from mast and enterochromaffin-like cells, and the release of peptide hormones from endocrine cells such as the pancreatic islets. The fusion of vesicles with the plasma membrane also mediates the translocation of proteins such as Na^+,K^+-ATPase and glucose transporters (Glut 4) to the plasma membrane. Exocytosis, especially when coupled with endocytosis, also contributes to the turnover of plasma membrane.

Some exocytotic processes occur continually in the cell and are termed constitutive, whereas other exocytotic processes are regulated. The two pathways diverge in the *trans*-Golgi network. Many soluble proteins are continually secreted from the cell by the constitutive secretory pathway, such as plasma proteins secreted by the liver and basement membrane components secreted by epithelial cells. All cells require this constitutive secretory pathway, which involves the movement of small vesicles to the plasma membrane. This pathway also supplies the plasma membrane with newly synthesized lipids and proteins. Specialized secretory cells, however, have a second pathway—the regulated exocytosis pathway, in which selected proteins are stored in secretory vesicles (frequently called secretory granules or dense core vesicles because they have dense cores when viewed in the electron microscope) for later release triggered by extracellular signals.

MORPHOLOGY OF EXOCYTOSIS

Secretory vesicles bud off from the Golgi network, undergo maturation, and translocate toward their destination plasma membrane. The sizes of mature secretory vesicles vary in different cell types, with their diameters ranging from ~ 100 nm in synaptic vesicles to ~ 1 μm in zymogen granules. The cytoskeleton, especially microtubules, contributes to the transport of newly synthesized secretory vesicles from the Golgi to the cell surface and also may direct them toward a specific plasma membrane domain.

As shown in Fig. 1, several stages have been recognized in exocytosis. After translocation from the Golgi network to the periphery of cell surface (step 1), the secretory vesicles are tethered in the vicinity of the cell surface (step 2). This is followed by docking, where the granules are in close apposition to the membrane (step 3), which is followed by the fusion process itself

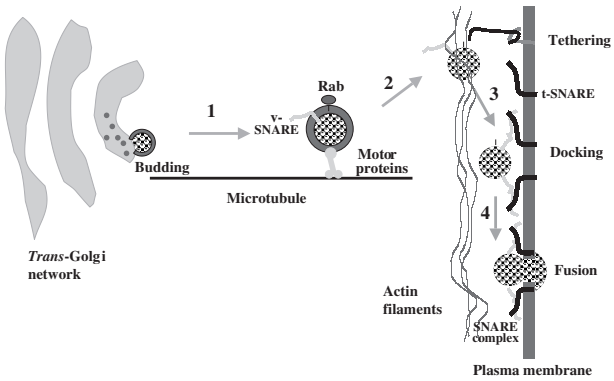

FIGURE 1 Tentative model of the steps in exocytosis of secretory granules including trafficking, docking, and fusion.

 Copyright 2004, Elsevier (USA). All rights reserved.

(step 4). Docking by itself is not a sufficient condition for fusion and some biochemical events, described as priming reactions, are likely to occur, rendering the granules competent for fusion. On fusion, the secretory vesicle membranes fuse with the plasma membrane, fusion pores open, and the contents of the vesicles are released through the fusion pores. Secretory vesicles fused with the plasma membrane maintain their Ω-shaped profile for a short period of time after releasing their soluble contents and this Ω-shaped profile becomes the morphological hallmark of membrane fusion.

In many types of secreting cells, such as chromaffin cells and pancreatic acinar cells, actin filaments form a cortical actin network under the membrane. This actin web serves as a barrier and regulates the access of granules to the docking sites. Recent evidence indicates that the cortical actin network may play multiple roles in regulating exocytosis.

MOLECULAR MECHANISM OF EXOCYTOSIS

Exocytosis is believed to share basic mechanisms with other vesicular trafficking events in the secretory pathway that are common in organisms ranging from yeast to human. To ensure the specificity of membrane fusion, transport vesicles must be highly selective in recognizing the correct target membrane with which to fuse. In the case of exocytosis, the secretory vesicles must recognize and fuse specifically with the target plasma membranes. Current models of membrane targeting and fusion have been dominated by consideration of two types of proteins, small G-proteins of the Rab family and SNARE [soluble *N*-ethylmaleimide (NEM)-sensitive factor attachment protein receptor] proteins. Early studies had shown that vesicular fusion events required a cytosolic protein sensitive to NEM, termed NSF for NEM-sensitive factor. Subsequent studies identified membrane proteins that interacted with NSF and were termed SNARE proteins. In the SNARE hypothesis, transport vesicles in the secretory pathway possess a set of vesicle v-SNAREs that interact with the complementary target membrane t-SNAREs and a stable v-SNARE/t-SNARE complex is assembled through coiled-coil interactions of α-helices between proteins inserted in opposing membranes. This pairing of a v-SNARE and a corresponding t-SNARE is thought to have a central role in vesicle docking and the fusion of the vesicle with the target membrane.

SNAREs have been best characterized in nerve cells, where they mediate the docking and fusion of synaptic vesicles at the nerve terminal plasma membrane. The principal v-SNARE in synaptic vesicles is VAMP (vesicle-associated membrane protein), also called synaptobrevin. The principal t-SNAREs in the plasma membrane of axon terminals are syntaxin and SNAP25 (soluble NSF attachment protein 25). Four long α-helices (two from SNAP25 and one each from VAMP and syntaxin) form a very stable SNARE complex between this pair of v- and t-SNAREs. The SNARE complexes at neuron terminals are the targets of powerful neurotoxins that are secreted by the bacteria that cause tetanus and botulism. These toxins are highly specific proteases that cleave SNARE proteins in the nerve terminals and thereby block synaptic transmissions.

In addition to SNAREs, several other cytosolic proteins are required for vesicle fusion. NSF is an ATPase that cycles between the membrane and the cytosol, and other proteins called α-, β-, and γ-SNAPs are required for NSF to bind to the vesicle membrane. SNAP in cooperation with NSF catalyzes the disassembly of *cis*-SNARE complexes (residing on the same membrane) using the energy of ATP. The requirement of NSF-mediated reactivation of SNAREs allows the cells to control when and where the membrane fusion events take place. In the case of synaptic vesicle exocytosis, which is regulated by calcium, another protein, synaptotagmin, is believed to serve as a calcium sensor. There are a large number of synaptotagmin analogues, some of which are calcium insensitive. Whether a synaptotagmin is required for all exocytotic events remains unclear. Another protein variously known as nSec1 or Munc 18 may serve as an inhibitory protein, preventing fusion until appropriate regulatory signals occur.

Once a transport vesicle has recognized its target membrane and docked, it unloads its cargo by membrane fusion. In regulated exocytosis, fusion is delayed until it is triggered by a specific extracellular signal. Docking and fusion are two distinct and separable processes. Docking requires only that the two membranes come close enough for proteins to interact. Fusion requires a much closer approach, bringing lipid bilayers to within 1.5 nm of each other so that they can join. For this close approach, water must be displaced from the hydrophilic surface of the membrane—a process that is energetically highly unfavorable. In one model, the formation of the SNARE complex may work like a winch, using energy that is freed when the interacting helices wrap around each other to pull the two membranes together, while simultaneously squeezing out water molecules from the interface.

Rab proteins, a family of monomeric GTP-binding proteins, participate in the control of the specificity of vesicular transport. All Rab proteins contain

approximately 200 amino acids and have an overall structure similar to that of Ras. Like the SNAREs, each Rab protein has a characteristic distribution on cell membranes and every organelle has at least one Rab protein on its cytosolic surface. For example, Rab5 is associated with the early endosome, Rab3A is associated with synaptic vesicles, and Rab3D is associated with secretory granules in exocrine glands. Rab proteins act as molecular switches that cycle between the inactive GDP-bound and active GTP-bound forms. The conversion to the GTP-bound form is stimulated by a Rab guanine nucleotide exchange factor and GTP hydrolysis is catalyzed by a Rab GTPase-activating protein. In their active form, Rab proteins interact with their effector proteins, which facilitate and regulate the rate of vesicle docking. Although the Rab proteins and their effectors use a range of different molecular mechanisms to influence vesicular transport at different sites in the secretory pathway, they have a common function. They help concentrate and tether vesicles near their target site and trigger the release of SNARE control proteins. In this way, Rab proteins speed the process by which appropriate SNARE proteins in two membrane find each other.

F

Familial Adenomatous Polyposis (FAP)

MARCIA CRUZ-CORREA AND FRANCIS M. GIARDIELLO
The Johns Hopkins University School of Medicine

autosomal dominant Mendelian gene that always manifests phenotypically; all affected individuals have at least one affected parent, and the phenotype affects males and females equally.

germ-line mutations Genetic alterations that occur in the cells that are of direct descent, from the zygote to gamete; are transmitted to progeny.

Osteomas Benign, slow-growing tumor composed of well-differentiated, densely sclerotic, compact bone, usually arising in the membrane bones, particularly the skull and fascial bones.

Penetrance Frequency of expression of a genotype; a trait has reduced penetrance if it is expressed less than 100%.

Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited syndrome that accounts for approximately 1% of the total colorectal cancer cases in the United States. FAP arises from germ-line mutations of the adenomatous polyposis coli (*APC*) gene located on chromosome 5q21. In 22–46% of cases, this disorder arises as spontaneous mutations, without an associated family history. It is estimated that FAP affects 1 in 10,000 individuals and is nearly 100% penetrant. This syndrome occurs worldwide and affects both sexes equally. The disease is characterized by the formation at early age of adenomatous polyps, primarily in the large intestine, and is associated with a virtual 100% risk of colorectal cancer. The mean age of adenoma development is 15 years. The average age of colorectal carcinoma in FAP ranges from 34.5 to 43 years. Colorectal cancer, primarily in the left colon, is inevitable in FAP patients if colectomy is not performed.

CLINICAL CHARACTERISTICS

FAP is an autosomal dominant disease clinically characterized by the occurrence of hundreds to thousands of adenomas throughout the colorectum at an early age (Fig. 1). The size of polyps in FAP is usually <1 cm; they may be pedunculated or sessile, with tubular, tubulovillous, or villous histology. Inevitably, colorectal cancer occurs usually by the fifth decade of life if colectomy is not performed. In addition, patients can acquire a variety of benign and malignant extracolonic manifestations (Table I).

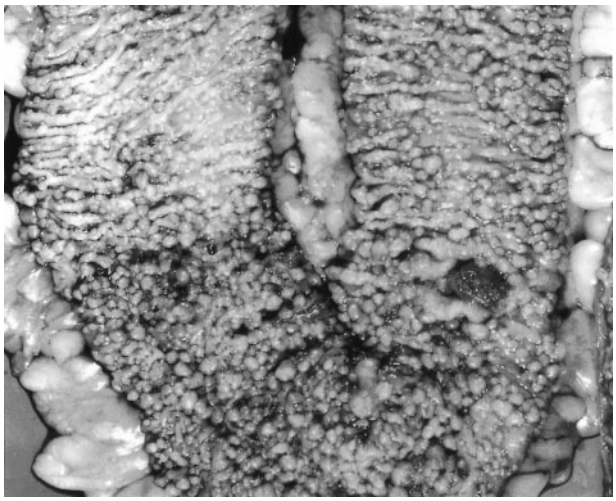

FIGURE 1 Photograph of a colectomy specimen in a patient with FAP, demonstrating hundreds of adenomatous polyps.

Benign Extracolonic Manifestations

Extracolonic Polyps

Adenomas of the small intestinal, primarily in the duodenum clustered around the papilla of vater, are found in 24–90% of FAP patients. Adenomas elsewhere in the small intestine occur occasionally. Two types of polyps are noted in the stomach: adenomas and fundic gland retention polyps. Adenomas, which can diffusely affect the stomach, are noted in up to 50% of FAP patients. Fundic gland retention polyps occur in 50% of FAP patients, usually localized in the fundus and body of the stomach while sparing the antrum. Fundic gland retention polyps are generally considered nonneoplastic, though dysplasia has been noted on histologic review in some individuals.

TABLE I Extracolonic Features in FAP

Cancers (lifetime risk)	Other lesions
Duodenal (5–11%)	CHRPE[b]
Pancreatic (2%)	Nasopharyngeal angiofibroma
Thyroid (2%)	Osteomas
Brain (medulloblastoma)[a] (<1%)	Radio-opaque jaw lesions
Hepatoblastoma (0.7% of children <5 years old)	Supernumerary teeth
	Lipomas, fibromas, epidermoid cysts
	Desmoid tumors
	Gastric adenomas/fundic gland polyps
	Duodenal, jejunal, and ileal adenomas

[a] Crail's syndrome is characterized by medulloblastoma associated with adenomatous polyposis.
[b] CHRPE, Congenital hypertrophy of the retinal pigment epithelium.

Desmoid Tumors

Benign desmoid tumors arise from the mesenchymal primordial germ cell layer and are usually slow growing. As fibromatous lesions occurring in extremities, the abdominal wall, and the mesentery of about 10% of FAP patients, desmoid tumors are the cause of death in about 1% of patients. About 80% of desmoid tumors are localized in the small bowel mesentery, whereas 20–30% develop within the abdominal wall or on the extremities. Desmoid tumors are flat or lobulated masses that often have intralesional hemorrhages and may undergo cystic degeneration. Desmoids, particularly of the mesentery, can grow locally, causing obstructive complications. Desmoid formation is associated with surgical trauma, familial aggregation, and specific *APC* gene mutations (see later).

Cutaneous Lesions

Epidermoid cysts, subcutaneous lesions typically located on the extremities, scalp, and face, develop in the teenage years. Fibromas, lipomas, and sebaceous cysts can also occur. Sebaceous cysts in association with FAP was previously called "Oldfield syndrome."

Osteomas are benign lesions that develop in the skull, long bones, and characteristically in the mandible at the angle of the jaw. These lesions, readily appreciated by physical examination, are usually asymptomatic but occasionally grow, causing complaints of local pain or discomfort. Occult radio-opaque jaw lesions (ORJLs) are osteosclerotic, asymptomatic lesions seen on panoramic jaw radiographs. These markers predict the development of adenomatous polyposis. Dental abnormalities are noted in 17% of FAP patients and include supranumerary and impacted teeth. Nasopharyngeal angiofibroma is a highly vascular, locally invasive tumor occurring almost exclusively in the nares or nasopharynx of male adolescents.

Malignant Manifestations

Adenocarcinoma of the duodenum and periampullary region is second only to the colorectum as a site of malignancy in patients with FAP. A high percentage of gastric cancer has also been reported in some polyposis registries worldwide. However, an analysis of American patients with FAP reveals a strikingly high relative risk of duodenal and ampullary adenocarcinoma but no increased risk of gastric or nonduodenal small intestinal cancer compared with the general population.

Hepatoblastoma is a rare, malignant, embryonal liver cancer occurring in the first 5 years of life in about 0.7% of the offspring of parents with FAP. This rapidly progressive tumor is potentially curable by removal, but carries a grave prognosis when malignancy has spread beyond surgical resection.

FAP has been associated with extracolonic malignancies of the thyroid gland, adrenal gland, biliary tree, pancreas, and brain. The relative risks of thyroid and pancreatic cancer are almost eight and five times that of the general population, respectively. Papillary thyroid carcinomas are associated with activation of the *RET* proto-oncogene and have a good prognosis.

Pigmented ocular fundus lesions (POFLs), also called congenital hypertrophy of the retinal pigment epithelium (CHRPE), are discrete, round to oval, darkly pigmented areas from 0.1 to 1.0 optic-disc diametersin size; they can be detected on the retina by indirect ophthalmoscopy. CHRPE consists of multiple hyperplastic layers of retinal pigment epithelium with hypertrophied cells filled with large spherical melanosomes, often in clusters. Although CHRPE causes no symptoms, it can

be a useful marker in identifying asymptomatic carriers in families with FAP. Also, the presence or absence of CHRPE lesions in an FAP patient correlates with the specific location of *APC* gene mutation.

FAP is also known by other terminology; the diagnosis of familial polyposis includes patients without extracolonic manifestations, and in Gardner syndrome, patients have various extracolonic manifestations (i.e., osteomas, epidermoid cysts, skin fibromas, desmoids, and jaw cysts). Other variants of FAP include Crail's syndrome, defined as typical FAP together with central nervous system malignancies (medulloblastoma), and attenuated familial adenomatous polyposis coli (AFAP). The clinical characteristics of AFAP include oligopolyposis (fewer than 100 colorectal adenomas at presentation) and a delayed onset of colorectal cancer, occurring on average 12 years later than in classic FAP.

GENETIC DEFECT

FAP is caused by germ-line mutations of the *APC* gene on chromosome 5q21. *APC* is a large gene, encompassing 15 exons, with an open reading frame of 8538 base pairs. The *APC* gene is a tumor suppressor gene encoding a 2843-amino-acid protein with a putative role in cell adhesion, signal transduction, and transcriptional activation. *APC* gene mutations can be found in 80–90% of families with FAP. More than 300 different disease-causing mutations of the *APC* gene have been identified. Most mutations are frameshifts that result from the insertion or deletion of one to eight base pairs. A higher frequency of mutations has been found in the 5′ region of exon 15 between codons 1000 and 1600; this is designated the mutation cluster region, comprising 20% of the entire gene. About 30% of *APC* mutations are at codon 1061, 1309, or 1465.

Several phenotypic characteristics in FAP patients correlate to the site of the *APC* gene mutation. Mutations between codons 169 and 1393 result in classic FAP, whereas more 5′ and 3′ mutations cause attenuated FAP. Alterations between codons 1250 and 1464 result in profuse colorectal polyposis (thousands rather than hundreds of colorectal adenomas), and retinal lesions occur only with mutations between codons 463 and 1444. *APC* mutations between codons 1445 and 1578 have been associated with severe desmoids, osteomas, epidermoid cysts, and upper gastrointestinal polyps. Nonetheless, considerable phenotypic variability may occur even among individuals and families with identical genotypic mutations.

The recently identified mutation in the *APC* gene, APC I1307K, was discovered as a cause for an unidentified proportion of familial colorectal cancer in individuals of Ashkenazi Jewish descent. Individuals with this mutation do not display the extracolonic manifestations of FAP but have an increased risk of development of colorectal cancer, with an estimated odds ratio of 1.4 : 1.9.

DIAGNOSIS

The diagnosis of FAP can be made clinically by the identification of hundreds to thousands of colorectal adenomatous polyps on colonoscopic examination. Individuals with attenuated FAP exhibit oligopolyposis (fewer than 100 colorectal adenomas). Histology is the key to differentiating FAP from the other known polyposis syndromes, such as lymphoid hyperplasia or hyperplastic polyposis, which may mimic FAP endoscopically. Also, the diagnosis of FAP can be confirmed by genetic testing. Additionally, in at-risk individuals, the presence of more than three pigmented ocular fundus lesions on ophthalmologic examination confirms the diagnosis of FAP.

MANAGEMENT

Screening

First-degree relatives of patients with FAP should undergo screening for FAP between ages 10 and 12 years old. The screening test of choice is genetic testing for the *APC* gene mutation. Indications for *APC* gene testing are found in Table II. The *APC* gene mutation responsible for the disorder in the pedigree can be identified in 80–90% of families with FAP. Genetic counseling is an essential part of genetic testing. Genetic counseling should include patient education, screening, management recommendations, possible consequences of genetic testing, and written, informed consent for genetic testing obtained from the patient and/or parents. Consequently, it may be prudent to refer relevant families to a regional high-risk colon cancer program for initial evaluation, where trained personnel are available to perform genetic testing and pedigree research.

TABLE II Indications for *APC* Gene Testing

≥100 colorectal adenomas
First-degree relatives of patients with FAP[a]
≥20 cumulative colorectal adenomas[b]
First-degree relatives of patients with attenuated FAP[a]

[a] Customarily, individuals older than 10 years are offered gene testing.

[b] Suspected attenuated FAP.

TABLE III Screening/Surveillance Guidelines in Patients with FAP

Patient group	Surveillance
At-risk individuals	Genotyping
	APC gene mutation (+), flexible sigmoidoscopy annually starting at age 12 years
	APC gene mutation (−), flexible sigmoidoscopy age 25 years
	If genotyping not available
	Flexible sigmoidoscopy annually starting age 12 years, then every 2 years starting at age 25, then every 3 years starting age 35, then as per the guidelines for average-risk individuals starting at age 50 years
Affected individuals	Upper gastrointestinal tract surveillance every 3−4 years, and annually if upper-tract polyps
	If retained rectum or J-pouch, flexible sigmoidoscopy every 6 months or 1−2 years, respectively
	Annual physical exam and routine blood tests

Once the disease-causing mutation is identified in an individual affected with FAP, other family members can be tested and endoscopic surveillance can be directed only at those who test positive for the mutation. If the pedigree mutation is not found or if informative genetic testing cannot be done, all first-degree family members should undergo endoscopic screening. Current screening recommendations include yearly sigmoidoscopy starting at 12 years old, reducing screening frequency with each subsequent decade up to age 50 years, after which screening should conform to the American Cancer Society guidelines for average-risk patients. Due to the increased risk of hepatoblastoma in patients with FAP, screening with α-fetoprotein levels and ultrasound imaging of the liver may be prudent in children of affected parents from infancy to 7 years of age (Table III).

Treatment

Surgical Treatment

All patients with FAP require surgical therapy. Colectomy is the recommended treatment to eliminate the risk of colorectal cancer. Prophylactic surgery should be performed shortly after the diagnosis of FAP is established clinically by endoscopy. There are several surgical options available, including subtotal colectomy with ileorectal anastomosis, total proctocolectomy with Brooke ileostomy, and total proctocolectomy with mucosal proctectomy and ileoanal pull-through (with pouch formation). Due to the risk of cancer in the retained rectal segment, surgical approaches that eliminate the rectum are advocated.

Patients with subtotal colectomy require routine endoscopic surveillance of the remaining rectum about every 6 months for recurrent adenomas and/or carcinomas. The cumulative incidence of rectal cancer in patients with FAP is approximately 25% at 25 years after colectomy with ileorectal anastomosis. Factors associated with increased risk of subsequent rectal cancer include high number of rectal polyps, long rectal segment (>10 to 15 cm), inadequate endoscopic surveillance, and colon cancer at the time of colectomy. About 16% of patients with an ileorectal anastomosis will eventually need proctocolectomy. Although the long-term risk of neoplastic transformation in the ileoanal pouch of patients with restorative proctocolectomies is low, adenomas in the pouch have been reported. In such cases, some experts have recommended that endoscopic biopsy surveillance should be considered.

Most authorities recommend upper endoscopic surveillance (with biopsy and brushing) of the stomach, duodenum, and periampullary region with front- and/or side-viewing endoscopes, every 6 months to 4 years, depending on polyp burden. Annual physical examination of the thyroid is warranted, along with consideration for ultrasonography.

Medical Treatment

Use of nonselective or selective cyclooxygenase-2 (COX-2) inhibitors (sulindac and celecoxib, respectively) to prevent or induce regression of polyps in the retained rectum of patients with FAP has been shown to be effective in short-term trials, and in long-term sulindac studies. Currently, celecoxib is approved by the Food and Drug Administration (FDA) for this indication. Administration of sulindac for primary chemoprevention of FAP has failed to prevent the development of adenomatous polyposis in gene mutation carriers. Moreover, use of sulindac has not shown to be effective in regression of duodenal adenomas.

The mechanisms by which nonsteroidal antiinflammatory agents (NSAIDs) mediate polyp regression are not completely understood. However, prostaglandins are believed to promote tumorigenesis by increasing cellular proliferation and inhibiting apoptosis, and NSAIDs (such as sulindac) reduce production of prostaglandins from arachidonic acid via cyclooxygenenase inhibition.

Familial Risk of Gastrointestinal Cancers

JASON C. WILLS AND RANDALL W. BURT
University of Utah Health Science Center, Salt Lake City

adenomatous polyp A polyp derived from the surface epithelium and exhibiting cellular and morphologic dysplasia.
attenuated A less intense form of a condition or disease.
extracolonic Pertaining to areas outside the colon itself.
familial A disorder or trait with excess familial occurrence.
genotype The genetic constitution of an individual.
hamartomatous polyp A benign polyp that arises from the overgrowth of some constituent of the lamina propria, submucosa, or muscular tissue. The surface mucosa or epithelium is normal and corresponds to the location of the polyp within the gastrointestinal tract. Some conditions with hamartomatous polyps have a malignant predisposition.
hereditary Transferred via genes from parent to child.
hyperplastic polyp A nonneoplastic epithelial polyp that is almost always found in the colon. These polyps are characterized by a saw-toothed appearance of surface epithelium thought to be secondary to inadequate sloughing of the cells. Endoscopically, they are usually one to several millimeters in diameter and appear to have little if any malignant potential. Only rarely do they grow larger. These tiny polyps account for approximately half of the polyps found in the colon and their primary importance is distinguishing them from adenomatous polyps. The syndrome of hyperplastic polyposis, on the other hand, does have some risk of malignancy.
inflammatory polyp A pseudo-polyp, consisting of normal tissue, often with increased inflammatory elements. These polyps are mostly associated with the chronic inflammatory conditions of the bowel including ulcerative colitis and Crohn's disease. They do not have malignancy risk, but the inflammatory conditions themselves do.
mismatch repair gene A gene responsible for repairing small DNA errors or mismatches that occur during DNA replication.
mutation A permanent transmissible change in the genetic material, usually in a single gene.
phenotype The physical characteristics of an individual as determined by the expression of that individual's genes.
polyp An abnormal growth of tissue. Polyps are defined histologically within two broad categories, epithelial or hamartomatous. Polyps may be pedunculated (having a stalk) or sessile (flat) and the surface if often described as either smooth or lobulated.
polyposis A condition in which numerous polyps develop in various areas of the gastrointestinal tract.

Gastrointestinal (GI) syndromes include those inherited diseases of the GI tract that predispose to cancer. This article will discuss the risk of gastrointestinal cancer in known inherited syndromes as well as the increased familial risk of colorectal cancer that is not yet genetically defined. Many inherited colon cancer syndromes belong to the category of "polyposis syndromes" in which multiple polyps of the GI tract form and precede colorectal cancer. The polyposis syndromes are categorized by polyp histology and are discussed in detail. More recently, elucidation of the underlying genetic etiology of these conditions has allowed further refinement of syndrome classification. Several polyposis syndromes that are not premalignant and others that are not inherited are also discussed, as they must be distinguished from the inherited, precancerous syndromes. In addition, several miscellaneous inherited conditions that lead to GI cancers but do not involve polyps will be discussed.

THE POLYPOSIS SYNDROMES

Conditions in Which Adenomatous Polyps Develop

Adenomatous polyps are derived from surface epithelium and are divided into three subtypes: tubular, tubulo-villous, and villous. Adenomas are precancerous growths in which the surface epithelium of the gastrointestinal (GI) tract shows features of dysplasia. The lamina propria, submucosa, and muscularis features of the tissue remain normal. Dysplasia is characterized by branching of the microscopic glands and loss of goblet cells and cellular features, including loss of basilar polarity of the nucleus, an increased nuclear : cytoplasmic ratio, increased basophilia of the cytoplasm, and loss of cytoplasmic glycogen. Villous changes are seen as the presence of elongated villi at the surface of the polyp. Each of the three subtypes of adenomatous polyps may also be subclassified by the degree of dysplasia: mild, moderate, and severe. The risk of an

 Copyright 2004, Elsevier (USA). All rights reserved.

adenoma containing malignant tissue or becoming malignant, especially in the colon, relates to several variables including polyp size, the amount of villous tissue in the polyp, and the degree of dysplasia.

Endoscopically, polyps become visible at 1 to 2 mm in diameter. As they enlarge to centimeter size, they usually become more pedunculated, although they may remain sessile. Approximately 5% of adenomas eventually become malignant in accordance with the polyp → cancer sequence. The change to malignancy takes, on average, 10 years, although the variation in duration is substantial. Thirty to 50% of adults eventually develop small adenomas of the colon. Approximately 5% of these colonic adenomas enlarge and become malignant. Approximately half of colonic polyps less than 5 mm in diameter are adenomas. Ninety-five percent of colonic polyps larger than 1 cm are adenomas, as hyperplastic polyps rarely grow larger and hamartomatous polyps are uncommon.

The inherited adenoma syndromes of colon cancer account for only a small fraction of persons with colon cancer overall (approximately 3 to 5%). Nonetheless, the inherited conditions remain a very important part of clinical medicine because of the high risk of colon cancer in affected persons and the inherited nature of the conditions in families. Additionally, the inherited syndromes have revealed important clues to understanding the molecular pathogenesis of all colon cancers.

Familial Adenomatous Polyposis

Disease phenotype Familial adenomatous polyposis (FAP) is characterized by the development of hundreds to thousands of colonic adenomatous polyps. It occurs in between 1 in 8000 and 1 in 10,000 births. The average patient age of adenoma development is 16 years, whereas the average patient age of colon cancer is 39 years. Colon cancer will inevitably develop in all FAP patients if the colon is not removed. If the affected colon is left intact, 87% of FAP patients will develop colon cancer by age 45 and 93% will develop colon cancer by the age of 50. Symptoms such as bloody bowel movements, change in bowel habits, diarrhea, abdominal pain, and weight loss will occur, on average, at age 36. Unfortunately, by the time symptoms occur, two-thirds of persons will already have colon cancer. This syndrome accounts for less than 0.5% of colon cancers in the United States.

Extracolonic gastrointestinal findings are common in FAP. Gastric polyps occur in up to 90% of patients but rarely cause symptoms. The polyps are fundic gland polyps histologically with very little malignant risk (0.5%).

Duodenal polyps occur in up to 90% of FAP cases. These are adenomatous polyps and do have malignant potential with 5−10% of persons with FAP developing duodenal cancer. The duodenal papilla is particularly prone to the development of adenomatous polyps and cancer. Small bowel adenomas also occur distal to the duodenum but the risk of malignancy appears to be very low.

Extraintestinal lesions are common and appear to correlate with the location of the mutation in the adenomatous polyposis coli (APC) gene. Osteomas occur in 20% of FAP patients, most frequently at the angle of the mandible and on the skull. They also may occur on any bone surface of the body, including the long bones. Epidermoid cysts occur in 20% of patients typically along the legs, face, scalp, and arms but potentially on any cutaneous site. The osteomas and epidermoid cysts are always benign but may cause cosmetic problems as they vary in size from millimeters to centimeters. Asymptomatic sclerotic bone lesions of the mandible or maxilla occur in over 90% of FAP patients. Supernumerary teeth and odontomas are unusual.

Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in some families but is always asymptomatic. Desmoids, benign fibroblastic tissue growths, occur in 10% of patients. Symptoms occur in half of these patients through local invasion or compression of other organs, particularly in the abdomen. Lesions in the mesentery are often referred to as mesenteric fibromatosis. Stimulated by surgery, trauma, and estrogens, these lesions can lead to significant morbidity and even some mortality. Extraintestinal cancers are sometimes observed in FAP. Pancreatic and thyroid cancers occur later in life in 2% of patients. Hepatoblastomas develop in 1.6% of children usually within the first 5 years of life. In the FAP variant Turcot syndrome, central nervous system (CNS) tumors occur. These are usually cerebellar medulloblastomas and may occur at any age but in $<1\%$ of patients.

Disease variants Gardner syndrome is a variant of FAP that involves the presence of prominent extracolonic manifestations together with typical colonic findings of FAP. These extracolonic manifestations include osteomas, odontomas, epidermoid cysts, fibromas, and desmoid tumors. This variant is mainly of historical significance, as it is now known to arise from mutations of the same gene, with extraintestinal manifestations determined to some extent by the location of the mutation on the APC gene.

Turcot syndrome is another variant of FAP, with the same colonic findings but coupled with CNS malignancies. Two-thirds of Turcot syndrome families are a subset of FAP and typically have cerebellar

medulloblastomas. The other one-third of Turcot families develop glioblastomas. The colonic lesions of this smaller subset arise not from mutations in the FAP gene, but from mutations in mismatch repair genes.

In attenuated adenomatous polyposis coli (AAPC), the average number of colonic adenomas is only 30. Although these polyps can form throughout the colon, they tend to develop in the proximal colon. The appearance of both colonic adenomas and cancer is delayed approximately 10 years compared with FAP. The risk of cancer is lower than in FAP, but still approaches 80% over a lifetime. The upper GI findings do not appear to be attenuated.

Genetics FAP is inherited as an autosomal dominant disease with near 100% penetrance in terms of colonic polyps and cancer. At least 95% of affected families arise from mutations in the APC gene on chromosome 5q21. The APC gene is a tumor suppressor gene whose normal function is to control cell proliferation and apoptosis. Most mutations reported give rise to a premature stop codon through either a single base-pair substitution or one or two base-pair deletions or additions. Some large chromosomal deletions have been reported. Approximately 30% of newly diagnosed cases, not belonging to families with known disease, appear to represent new mutations.

Normally, the APC gene functions as a negative regulator in the WNT signaling pathway. It binds to soluble β-catenin together with several other molecules and phosphorylates it, leading to cytosolic degradation of the β-catenin. The stimulation of the WNT signaling pathway gives rise to uncoupling of the β-catenin to the complex and therefore no phosphorylation occurs. β-Catenin then traverses the nuclear membrane and binds to Tcf-Lef transcription regulators, giving rise to the transcription of various proteins (c-Myc, cyclin D1, and others). The result is increased cell proliferation and decreased cell apoptosis. Therefore, aberrant function with the mutant APC gene results in a constant failure of β-catenin/phosphorylation and unregulated nuclear transcriptional stimulation, leading to unregulated cell proliferation and unregulated suppression of apoptosis.

Genetic testing Genetic testing is now considered part of the standard management of families with FAP. Testing is used in two settings: (1) to confirm the diagnosis of FAP in suspected cases and (2) to determine the gene carriers in families with FAP.

A person known to have the disease is tested first. Many methods are used for genetic testing in FAP. *In vitro* protein truncation assay detects the presence of truncated mutations *in vitro*. It detects a mutation in 80–90% of affected families known to have FAP. Once the mutation has been found in an affected person, testing is nearly 100% effective in detecting mutations in family members. A second method, gene sequencing, is often preceded by single-strand conformational polymorphism (SSCP) or denaturing gradient gel electrophoresis (DGGE) to narrow the area of the gene where sequencing is to be performed. Sequencing is up to 95% effective at finding a disease-causing mutation if one is present and, once a mutation is found, sequencing is nearly 100% effective at detecting the mutation in family members. If these two methods are unsuccessful, genetic linkage testing can be performed. Two or more affected persons from two generations must be living for DNA to be obtained and linkage to be performed. Linkage is effective in $>95\%$ of families with $>98\%$ accuracy.

Genotype–phenotype correlations have not yet been found to be of precise use in clinical settings. At this time, the following correlations have been made:

1. CHRPE is present in families with mutations distal to exon 9 of the APC gene;
2. Dense polyposis is present with mutations in the midportion of exon 15;
3. AAPC is found with mutations in the extreme proximal or distal end of the APC gene; and
4. Osteomas and desmoids are more commonly found with mutations in the distal portion of exon 15.

Clinical management Genetic testing should be considered between the ages of 10 and 12 years when it will first be clinically useful. There may be a role for earlier testing to determine who should be screened for hepatoblastoma.

Gastrointestinal tract screening Sigmoidoscopy should be performed every 1–2 years in gene carriers or in all at-risk persons if genetic testing is not performed or not informative. This should begin at age 10 to 12 years. Colonoscopy should be performed in families with AAPC every 2 years beginning by age 21 years, or earlier, depending on the age of polyp emergence in other family members.

Upper GI endoscopy should begin when colon polyps emerge or by age 25 years and repeated every 1–3 years depending on polyp size, number, and histology. Side viewing should be performed as part of the examination to carefully identify and examine the duodenal papilla. Small bowel X ray should be carried out if numerous or large adenomas are present in the duodenum as well as before planned colectomy. The number and size of polyps found determine follow-up. Overall cancer-screening recommendations for FAP are found in Table I.

Colon surgery Surgery should be considered once polyps emerge, although surgery can often be de-

TABLE I Cancer Risk and Screening Recommendations in Familial Adenomatous Polyposis

Cancer	Cancer risk	Screening recommendation
Colon	Nearly 100%	Sigmoidoscopy annually, beginning at age 10–12 years
Duodenal or peri-ampullary	5–10%	Upper GI endoscopy (including side-viewing exam) every 1–3 years, starting at age 20–25 years
Pancreatic	~2%	Possibly periodic abdominal ultrasound after age 20 years
Thyroid	~2%	Annual thyroid exam, starting at age 10–12 years
Gastric	~0.5%	Same as for duodenal cancer
CNS, usually cerebellar meduloblastoma (Turcot syndrome)	<1%	Annual physical exam, possibly periodic head CT scan in affected families
Hepatoblastoma	1.6% of children <5 years of age	Possible liver palpation, hepatic ultrasound, α-fetoprotein annually during first decade of life

CT, computed tomography.

layed until a patient finishes high school. Surgery should not be delayed if the number of polyps is near 100, if any polyps approach 1 cm in diameter, or if advanced histology is detected. If surgery is delayed, colonoscopy should be performed annually.

Surgical options include subtotal colectomy with ileorectal anastomosis or total colectomy with mucosal proctocolectomy, ileal pouch construction, and ileo-anal anastomosis. The former is single stage and much less complicated but the latter is a more definitive surgery that eliminates the risk of rectal cancer. The subtotal colectomy still requires surveillance of the remaining rectum every 6–12 months for polyp ablation. The total colectomy also requires surveillance of the ileal pouch every 2 years as polyps sometimes recur there. Because the total colectomy is more a complicated surgery, it should be performed only by specialized surgeons.

Chemoprevention Chemoprevention as primary therapy in the gut is still experimental. Nonsteroidal anti-inflammatory drugs are known to suppress rectal adenomas and possibly colonic adenomas. Sulindac, in particular, has a modest effect but the side effects in the upper GI are of concern. Other, more selective agents, such as the cyclooxygenase-2 inhibitors or sulindac metabolites, are currently being evaluated as they also decrease the size and number of polyps throughout the colon. At this time, only celecoxib is approved for preventive treatment of the remaining rectum in persons with a subtotal colectomy.

Hereditary Nonpolyposis Colorectal Cancer

Disease phenotype Hereditary nonpolyposis colorectal cancer (HNPCC), also termed Lynch syndrome, accounts for 2–3% of all colon cancer cases. It is characterized by multiple family members with colorectal and other cancers. This is not a polyposis syndrome in the strict sense, as multiple adenomatous polyps may form but most usually only a few will appear. It is inherited as an autosomal dominant disease of primarily colon and endometrial cancer. The colonic polyps that form are larger, occur earlier, and more often contain advanced histology when compared to age-matched controls. Although usually only one or several adenomatous polyps form, the average lifetime risk of developing colon cancer is 80% for those affected by HNPCC. The average age of cancer diagnosis is 44 years.

Diagnosis The clinical criteria for the diagnosis of HNPCC are called the Amsterdam criteria. They are as follows:

Classic or Amsterdam I Criteria There should be at least three relatives with colorectal cancer with the following criteria also met:

1. One should be a first-degree relative of the other two.
2. At least two successive generations should be affected.
3. At least one colorectal cancer should be diagnosed before the age of 50 years.
4. Familial adenomatous polyposis should be excluded.
5. Tumors should be verified by pathological examination.

Amsterdam II Criteria (a recent modification of the original criteria) There should be at least three relatives with an HNPCC-associated cancer (colorectal, endometrial, small bowel, ureteral, and renal pelvis).

The same additional criteria as stated for the Amsterdam I Criteria also need to be met.

Clinical Implications of Meeting the Criteria When the classic Amsterdam criteria are met, 50–70% of families will be found to have a mutation of one of the mismatch repair genes. Approximately 8% of families with multiple cases of colon cancer, but who do not meet the classic Amsterdam Criteria, will be found to have a mutation in one of the mismatch repair genes and, therefore, will have HNPCC. An elevated risk

for cancer at many other sites exists and screening is recommended (see Table II).

Disease variants Muire-Torre syndrome is typical HNPCC together with cutaneous tumors, such as sebaceous adenomas or epitheliomas, basal cell epitheliomas, keratoacanthomas, or sebaceous carcinomas (usually of the eyelid). This arises from mutations in the MSH2 mismatch repair gene.

Turcot syndrome is HNPCC together with CNS tumors, especially glioblastomas. This represents one-third of Turcot syndrome families.

Patients with MSH6 syndrome carry a 60% risk of developing endometrial cancer and a 40% risk of colon cancer. Some families reported have tumor onset later than typical HNPCC. The syndrome is associated with mutations in the MSH6 mismatch repair gene.

Genetics Hereditary nonpolyposis colorectal cancer is inherited in an autosomal dominant manner with at least 80% penetrance by age 70. HNPCC arises from mutations in any one of the mismatch repair (MMR) genes, of which six mutations are known. Two gene mutations, MLH1 and MSH2, are present in over 95% of those families in whom mutations have been found. Genetic errors that accumulate when the MMR genes are mutated and dysfunctional are quite specific and include genes such as TGF-β and BAX.

Mismatch repair genes These genes are responsible for the repair of errors that occur during DNA replication. When one of these genes is damaged, a certain type of DNA mutation, called a replication error, accumulates throughout the genome of the involved tumors. Replication errors are common during cell division but are usually repaired by the MMR system. When an MMR gene itself is damaged or inactivated, replication errors persist and accumulate through repeated cell divisions. Such mutations are most easily identified in segments of DNA called microsatellites, which are sequences of repeating DNA bases found throughout the human genome. When multiple microsatellite errors are present, the tumor tissue is said to exhibit microsatellite instability (MSI). Almost all (>90%) colon cancers in HNPCC exhibit microsatellite instability. MSI is found in only 15% of sporadic colon cancer and occurs by a different mechanism. Because MSI is easily detected in tumor tissue, it is used as a marker for HNPCC. It has been suggested that MSI testing on tumors should be performed when any of the "Bethesda Criteria" are met (Table III). The Bethesda criteria are a more complex and inclusive set of rules but it is hoped that a greater number of HNPCC families will be detected by the use of these criteria.

Genetic testing Testing for MSI instability is carried out on the tumor tissue. To find mutations in the mismatch repair genes, sequencing is most commonly used. Gene sequencing is often preceded by SSCP or DGGE to narrow the area of the gene where sequencing is to be performed. This is successful in 50 to 70% of families who meet the Amsterdam criteria. Once a disease-causing mutation is found in an index case, testing in other family members approaches 100% accuracy.

Genetic testing should be performed to confirm a diagnosis of HNPCC. It should also be offered to members of families in which there is a known mutation or that meet the Amsterdam criteria. In families not meeting the Amsterdam criteria, however, the issue is problematic. The phenotype is not distinct in a single individual as it is in other polyposis syndromes. Yet, a percentage of families with a family history of colon cancer but not meeting the Amsterdam criteria will,

TABLE II Cancer Risk and Screening Recommendations for Hereditary Nonpolyposis Colorectal Cancer

Cancer	Cancer risk	Screening recommendations
Colon	>80%	Colonoscopy every 1–2 years starting at age 20–25 years or 10 years younger than earliest case in the family, whichever is earlier
Endometrial	43–60%	Pelvic exam, transvaginal ultrasound and/or endometrial aspirate every 1–2 years starting at age 25–35 years
Ovarian	9–12%	Same as for endometrial cancer
Gastric	13–19%	Upper GI endoscopy every 1–2 years starting age 30–35 years
Urinary tract	4–10%	Ultrasound and urinalysis every 1–2 years starting age 30–35 years
Renal cell adenocarcinoma	3.3%	Same as for urinary tract cancer
Biliary tract and gallbladder	2.0–18%	Uncertain, possibly liver chemistries annually after age 30 years
Central nervous system, usually glioblastoma (Turcot syndrome)	3.7%	Uncertain, possibly annual physical exam and periodic head CT scan in affected families
Small bowel	1–4%	Uncertain, at least small bowel X ray if symptoms occur

Note. CT, computed tomography.

TABLE III The Modified Bethesda Criteria for Hereditary Nonpolyposis Colorectal Cancer

Individuals with cancer in families that meet the Amsterdam criteria
Individuals with two synchronous or metachronous HNPCC-related cancers[a]
Individuals with colorectal cancer *and*
—A first-degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer[a] and/or colorectal adenoma *and*
—A cancer diagnosed before age 50 years *or*
—An adenoma diagnosed before age 40 years
Individuals with colorectal and endometrial cancer diagnosed before age 45 years
Individuals with right-sided undifferentiated colon cancer diagnosed before age 45 years
Individuals with signet-ring cell type colorectal cancer diagnosed before age 45 years
Individuals with adenomas diagnosed before age 40 years

[a] Colon, rectum, stomach, small bowel, endometrium, ovary, ureter, and other cancers.

indeed, have HNPCC. Three approaches have been suggested to determine which families that do not meet the Amsterdam criteria should nonetheless have genetic testing for HNPCC.

1. Apply MSI testing to the colon cancer tissue in the following situations and when positive, perform testing on the DNA from peripheral blood to find MMR mutations:
   a. Colon cancer diagnosis < 50 years;
   b. Colon cancer plus one first-degree relative with colon or colorectal cancer;
   c. Colon cancer plus a previous colon or endometrial cancer.

   With this method, 24% of colon cancer cases will undergo MSI testing of the tumor tissue and 4% of colon cancer cases will have MMR mutations found.
2. Use a specific logistic model applied to an extended family that includes kindred structure and known cancer cases.
   a. If the model predicts $> 20\%$ chance of HNPCC, go directly to mutation finding.
   b. If the model predicts $< 20\%$ chance of HNPCC, do MSI first and go to mutation finding only if MSI is positive on tumor tissue.
3. Go directly to MMR mutation finding if one of the first three Bethesda criteria is positive, but use age < 50 years rather than 45 years.

   In one study, this approach had 94% sensitivity and 49% specificity.

Clinical management Colon screening should be performed in all at-risk persons within a family known to have HNPCC either by genetic testing or by the Amsterdam criteria, even if a disease-causing mutation cannot be found. Screening should be carried out by colonoscopy every 2 years starting at age 25, or 10 years earlier than the youngest colon cancer diagnosis in the family, whichever comes first.

Screening recommendations and cancer risk in other organs are listed in Table II.

Surgical management A subtotal colectomy is the procedure of choice to prevent colon cancer and should be performed if colon cancer is diagnosed or an advanced adenomatous polyp that cannot be adequately treated endoscopically is found. Prophylactic colectomy in persons known to have a disease-causing mutation in one of the MMR genes is currently being debated. Hysterectomy is indicated if any dysplasia is found with endometrial aspirate.

Conditions in Which Hamartomatous Polyps Develop

The most common hamartomas involved in inherited conditions include Peutz-Jeghers polyps (arborizing pattern of muscular tissue) and juvenile polyps (overgrowth of the lamina propria often with cysts). Other hamartomatous polyps that occasionally occur include lipomas, leiomyomas, neurofibromas, and ganglioneuromas. All of these polyps may be either sessile or pedunculated.

Although the hamartomatous polyps themselves are considered nonneoplastic and therefore benign lesions, most of the hamartomatous conditions exhibit substantial malignancy risk. Furthermore, adenomatous change has been noted to sometimes occur in both Peutz-Jeghers and juvenile polyps.

Hamartomatous polyps are much less common than adenomatous polyps but more commonly involve extracolonic sites of the GI tract. Hamartomas account for substantially less than 5% of colonic polyps overall. Two to 3% of children will develop sporadic juvenile polyps of the colon, whereas sporadic Peutz-Jeghers polyps are very unusual. The hamartoma syndromes are likewise much less common than adenoma syndromes.

Peutz-Jeghers Syndrome

Disease phenotype Peutz-Jeghers is characterized by melanin pigment spots, often in the perioral area, and distinctive polyps throughout the gastrointestinal tract but most commonly in the small bowel. Polyps are sessile or pedunculated, ranging in size from a few millimeters to centimeters. The small bowel is most commonly affected (78%), followed by the colon (42%), stomach (38%), and rectum 28%.

During the first three decades of life, benign complications of bleeding, obstruction, and intussusception occur but malignant transformation of the polyps is the main concern thereafter. GI and non-GI cancers are common, with a combined frequency of 93% by age 65 years. The characteristic pigmentation is seen in >95% of individuals, most commonly the perioral and buccal areas. They also occur around the eyes, palm, soles of the feet, and perineum. Pigmentation appears in infancy and begins fading at puberty except on the buccal mucosa, which provides a clinical feature for diagnosis throughout life.

Genetics Peutz-Jeghers is an autosomal dominantly inherited syndrome occurring in 1 in 200,000 births. It arises from mutations of the STK11 gene (also called LKB1). Only half of families with the disease have this mutation, suggesting that there is another responsible gene. Genetic testing for this specific mutation is commercially available.

Clinical management Management involves screening for cancer prevention and is reviewed in Table IV.

Juvenile Polyposis

Disease phenotype Juvenile polyps occur in 2% of children. The diagnosis of juvenile polyposis (JP) is made with the presence of 10 or more juvenile polyps, which occur most commonly in the colon but which can occur anywhere in the GI tract. The full-blown syndrome may be characterized by hundreds of polyps. These hamartomatous polyps involve overgrowth of the lamina propria, often with cysts. Endoscopically they appear smooth, sessile, or pedunculated and often are covered with exudate. They range in size from millimeters to centimeters. Polyps in JP differ from sporadic juvenile polyps in that new polyps almost always form after removal and polyps always occur in adults. Benign problems, particularly colonic bleeding or anemia, usually occur in the first decade of life. The risk of colon cancer is substantial, with the average age of diagnosis being 34 years. Cancer in the stomach, small bowel, and pancreas has been reported but the

TABLE IV Cancer Risk and Screening Recommendations for Peutz-Jeghers Syndrome

Cancer type	Cancer risk[a]	Screening recommendation
GI Cancer		
Colon	39%	Colonoscopy, beginning with symptoms or in late teens if no symptoms occur; interval determined by number of polyps but at least every 3 years once begun
Pancreatic	36%	Endoscopic or abdominal ultrasound every 1–2 years starting at age 30 years
Stomach	29%	Upper GI endoscopy every 2 years starting at age 10 years
Small bowel	13%	Annual hemoglobin, small bowel X ray every 2 years, both starting at age 10 years
Esophagus	0.5%	None given
Non-GI cancer		
Breast	54%	Annual breast exam and mammography every 2–3 years, both starting at age 25 years
Ovarian	21%	Annual pelvic exam with pap smear, and annual pelvic or vaginal ultrasound and/or uterine washings, all starting at age 20 years
Uterine	9%	
Adenoma malignum (cervix)	Rare	
Sex cord tumor with annular, tubules, in almost all women	20% become malignant	
Sertoli cell tumor (males), rare	10–20% become malignant	Annual testicular exam, starting at age 10 years, testicular ultrasound if feminizing features occur
Lung	15%	None given

[a] Cumulative cancer risks, ages 15–64 years.

TABLE V Screening Recommendations for Juvenile Polyposis

Cancer	Cancer risk	Screening recommendations
Colon	May be as high as 50%	Colonoscopy, beginning with symptoms or in early teens if no symptoms occur; interval determined by number of polyps but at least every 3 years once begun
Gastric and duodenum	Rare	Upper GI every 3 years, starting in early teens (mainly to avoid complications of benign polyps)

association is not certain. Congenital defects are seen with the nonfamilial form of the disease and include cardiac and cranial abnormalities, cleft palate, polydactyly, and bowel malrotations. Cancer risk and screening recommendations are outlined in Table V. Half of the affected families have a mutation of the SMAD4 gene (also called DPC4) on chromosome 18 or the BMPRA1 gene on chromosome 10. Other genes may be involved. Testing for the SMAD4 gene mutation is commercially available.

Clinical management Clinical management consists mainly of prevention of benign and malignant complications with empiric guidelines as described under the screening recommendations given in Table V.

Cowden Syndrome

Disease phenotype Multiple hamartomatous polyps occur in the colon and throughout the GI tract in Cowden syndrome (CS). A number of different types of hamartomas occur. Juvenile polyps are by far the most common but lipomas, inflammatory polyps, ganglioneuromas, and lymphoid hyperplasia are also seen.

Skin lesions commonly occur in CS. The hallmark is the presence of multiple facial trichilemmomas. They most commonly occur around the mouth, nose, and eyes. Café-au-lait spots, vitiligo, cysts, and squamous cell or basal cell carcinomas have less commonly been described.

Oral mucosal lesions similar to trichilemmomas develop a few years after skin growths in approximately 85% of individuals. They appear as pinpoint, red, flat-topped papules on the outer lips and small, flat, papillomatous or verrucous papules on the oral mucosa, gingiva, and tongue.

Thyroid abnormalities occur in two-thirds of patients. Goiter arising from nodular hyperplasia or follicular adenomas is seen histologically. The risk of thyroid carcinoma is 10%.

Breast lesions, including fibrocystic disease or fibroadenomas, occur in three-fourths of affected females. The reported incidence of breast cancer is 50% with frequent bilateral occurrence. Median age at diagnosis is just 41 years.

Additional benign soft tissue and visceral tumors, such as hemangiomas, lipomas, lymphangiomas, neurofibromas, uterine leiomyomas, and meningiomas, have been observed. Developmental and congenital abnormalities also occur. These include hypoplastic mandible, prominent forehead, and a high arched palate.

Diagnosis The International Cowden Consortium for the diagnosis of CS has suggested specific clinical diagnostic criteria, as shown in Table VI.

The diagnosis can be made in an individual based on mucocutaneous lesions alone if:

- there are $\geq$6 facial papules, of which $\geq$3 are trichilemmomas;
- **or** if there are $\geq$6 palmoplantar keratoses;
- **or** if oral mucosal papillomatosis and acral keratosis are found;
- **or** if there are cutaneous facial papules with oral mucosal papillomatosis.

If mucocutaneous lesions are absent, the diagnosis can be made under the following conditions:

1. two major criteria (one must be macrocephaly or LDD) are met; or
2. one major criterion and three minor criteria are met; or
3. four minor criteria are met.

Operational diagnosis in a family in which one person is diagnostic for Cowden syndrome is made with the presence of pathognomonic criteria: any one major criterion with or without minor criteria or any two minor criteria must be met.

A related syndrome, Bannayan-Riley-Ruvalcaba (BRR) syndrome, is believed to be allelic to Cowden syndrome, arising from mutations of the PTEN gene. It is characterized by macrocephaly, lipomas, pigmented macules of the glans penis, and other features of Cowden syndrome.

Genetics Cowden syndrome is inherited in an autosomal dominant manner and occurs in 1 in 200,000 individuals. The mutation of the PTEN gene, a tumor suppressor gene, is found in 80% of those who meet the diagnostic criteria for Cowden syndrome and

TABLE VI The *International Cowden Consortium's* Clinical Diagnostic Criteria for the Diagnosis of CS

Pathognomonic criteria—mucocutaneous lesions
a. Trichilemmomas, facial
b. Acral keratoses
c. Papillomatous papules
d. Mucosal lesion
Major criteria
a. Breast carcinoma
b. Thyroid carcinoma (nonmedullary), especially follicular thyroid carcinoma
c. Macrocephaly (megalencephaly $>$ 95th percentile)
d. Lhermitte-Duclos disease (cerebellar dysplastic gangliocytoma)
e. Endometrial carcinoma
Minor criteria
a. Other thyroid lesions (e.g., adenoma or multinodular goiter)
b. Mental retardation (IQ $\leq$ 75)
c. GI hamartomas
d. Fibrocystic breast disease
e. Lipomas
f. Fibromas
g. GU tumor (renal cell carcinoma, uterine fibroids) or malformation

approximately 50% of those who meet the criteria for BRR syndrome.

Management There is little if any risk of colon cancer and therefore no screening is needed. Thyroid cancer risk is 3−10% and it is recommended that patients have annual thyroid exams starting in the teenage years. Breast cancer risk is 25−50%. Annual breast exams starting at 25 years and annual mammography starting at 30 years are recommended. The uterine and ovarian cancer risks are possibly elevated but screening recommendations are uncertain.

Hereditary Mixed Polyposis Syndrome

There have been three families described with links to a locus on chromosome 6. Affected persons exhibit primarily juvenile polyps, but also adenomatous polyps, hyperplastic polyps, and sometimes polyps containing mixed histology.

Gorlin's Syndrome

Gorlin's syndrome is also called nevoid basal cell carcinoma syndrome. This is an autosomal dominant disorder with an estimated occurrence of 1 in 56,000. It primarily involves multiple basal cell carcinomas, odontogenic jaw cysts, broad facies, congenital skeletal anomalies, ectopic calcification of the falx cerebri, and characteristic pits in the skin of the palms and soles. Gastric hamartomatous polyps have been reported. It occurs secondary to mutation of the tumor suppressor gene PTCH on chromosome 9q22.3.

Cronkhite-Canada Syndrome

This is an acquired condition characterized by the rapid onset of generalized polyposis, cutaneous hyperpigmentation, hair loss, nail atrophy, diarrhea, weight loss, and hypogeusia (the dominant symptom in most patients).

It is extremely rare with a worldwide distribution. The average age of onset is 59 years with a range of 31 to 86 years. Males are affected 60% of the time but no familiar occurrences have been observed. It is rapidly progressive and can be fatal within a few months, although a protracted course is also observed. Diarrhea and protein-losing enteropathy may be severe, leading to malnutrition and its complications.

The polyps vary in size from millimeters to centimeters and are always sessile. The esophagus appears to be spared. The mucosa between visible polyps also shows changes typical of juvenile polyps. Adenomas and cancer have been reported in the hamartomatous polyps. The incidence of colon cancer is 12%.

The etiology is unclear but may have nutritional, infectious, and immunological associations as variable success has been seen with hyperalimentation, antibiotics, and corticosteroids. Surgery may be necessary for complications of polyps, cancer, and protein-losing enteropathy.

Neurofibromatosis Type I

Neurofibromatosis type I (NFI) is also called Von Recklinghausen disease. Clinical features include greater than five cutaneous café-au-lait spots and frequent neurofibromas of the skin. Approximately 25% will exhibit multiple intestinal polypoid neurofibromas and less commonly ganglioneuromas. The small bowel is most commonly affected, followed by the stomach and colon. It is autosomal dominant, arising from mutations of the NFI gene on chromosome 17q.

Multiple Endocrine Neoplasia Type I

Multiple endocrine neoplasia type I is also called multiple neuroma syndrome. In addition to the presence of medullary thyroid carcinoma, pheochromocytoma, and parathyroid disease, there are enlarged and nodular lips (from ganglioneuromas), marfanoid habitus, and ganglioneuromatosis of the entire GI tract from lip to anus, although most commonly in the colon and rectum. Dysmotility, as a result of the ganglioneuromatosis, causes diarrhea and/or constipation. The syndrome arises from mutations of the RET proto-oncogene on chromosome 10q11.2 but half of the

cases are considered to be new mutations. Diagnosis is made by biopsy.

Devon Polyposis

Devon polyposis is also known as Devon family syndrome. Three generations of females in a family were found to have multiple inflammatory fibroid polyps of the ileum. The polyps varied in size from 0.5 to 8.0 cm. Similar polyps were found in the gastric antrum in one patient. Each affected person experienced intussusception or small bowel obstruction. The polyps were a benign proliferation of histiocytes.

Miscellaneous Conditions with Multiple Polypoid Lesions of the Gastrointestinal Tract

Hyperplastic Polyposis Syndrome

Hyperplastic polyposis (HPP) is usually defined as one of three phenotypes:

1. ≥ 5 hyperplastic polyps proximal to the sigmoid colon with at least 2 that are > 10 mm in size; or
2. any number of hyperplastic polyps proximal to the sigmoid in an individual with a first-degree relative with HPP; or
3. > 30 hyperplastic polyps of any size distributed throughout the colon.

All these phenotypes appear to have an increased risk of colon cancer. Cancer appears in small and large polyps with or without dysplasia. Patients are encouraged to undergo colectomy and asymptomatic family members should probably undergo colonoscopy. Families with HPP have been reported but account for a small minority of cases. The underlying genetic etiology is unknown.

Inflammatory Polyps in Inflammatory Bowel Disease

Multiple inflammatory polyps are frequently found in ulcerative colitis (UC) and Crohn's disease. The polyps represent remaining normal tissue, with some inflammatory elements that persist during the healing phases of the diseases. The polyps themselves have no malignant potential, although both UC and Crohn's disease have a colon malignancy risk, which parallels the extent of colonic involvement and the duration of the disease.

Nodular Lymphoid Hyperplasia

Lymphoid nodules are a normal part of the GI tract, but are usually not visible during colonoscopy. Prominent lymphoid nodules may sometimes be observed in the following situations:

1. occurring in association with lymphoma;
2. occurring in association with common variable immunodeficiency;
3. occurring in younger children and due to an uncertain cause, particularly when occurring in the terminal ileum;
4. occurring in adults and due to an uncertain cause, particularly when occurring in the terminal ileum.

Lymphomatous Polyposis: Two Types

Multiple lymphomatous polyposis This is a non-Hodgkin's B-cell lymphoma, which is the GI counterpart of mantle cell lymphoma. It arises from lymphocytes that have homing receptors for the lymphoid tissue of the GI tract, thus giving rise to diffuse polyposis. Mucosa-associated lymphoid tissue lymphomas, follicular lymphomas, and primary T-cell lymphomas have now also been described and are morphologically similar to multiple lymphomatous polyposis (MLP) in that they exhibit a multiple polypoid appearance in the gastrointestinal tract and are thus considered types of MLP.

Immunoproliferative small intestinal disease Immunoproliferative small intestinal disease (IPSID), previously called both Mediterranean-type lymphoma and α-heavy chain disease, can also exhibit multiple nodular lesions of the small bowel. These lymphomatous lesions result from an intense proliferation of the plasma cells of the lamina propria of the GI tract. A paraprotein is usually present and it is usually classified as a plasma cell tumor or an immunoblastic sarcoma. The disease most often occurs in young people with predominance in the Mediterranean region and an association with malabsorption.

Leiomyomatosis and Lipomatosis

Leiomyomatosis and lipomatosis have been reported but usually only a single leiomyoma or lipoma occurs.

Pneumatosis Cystoides Intestinalis

Pneumatosis cystoides intestinalis is characterized by multiple air-filled cysts of the wall of the GI tract, usually from endoscopy, trauma, surgery, infection, or systemic disease, but sometimes the condition is idiopathic.

FAMILIAL RISK AND COLON CANCER

Risk of Colon Cancer in Relatives

The majority of colon cancer cases appear to be sporadic with no evidence of an inherited disorder.

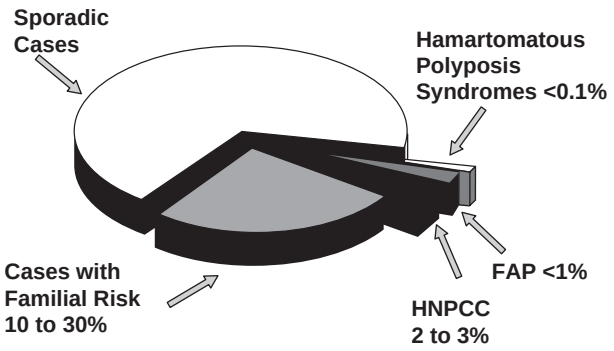

FIGURE 1 The fractions of colon cancer cases that arise in various family risk settings.

Roughly 20–30% of cases can be attributed to familial risk, with known inherited syndromes accounting for 1–3% (Fig. 1). The average American has an approximately 6% lifetime risk of developing colorectal cancer but first-degree relatives of persons with colon cancer have a two- to threefold increased risk of large bowel malignancy compared with controls or the general population. A high-risk family history is defined as a first-degree relative with colorectal cancer or adenoma diagnosed earlier than age 60 years or two first-degree relatives diagnosed with colorectal cancer at any age.

Many studies examining the familial risk of colon cancer also relate certain clinical findings to the severity of risk. The findings most consistently predictive of severity were the number of immediate relatives with colon cancer and the age of cancer diagnosis. If two or more first-degree relatives had colon cancer, the risk of large bowel malignancy for other family members is consistently higher than if only one first-degree relative was affected. The risk is higher if the first-degree relative is diagnosed at a younger age (Table VII). Colon cancer even in a second-degree relative (grandparent, aunt, uncle) or third-degree relative (great-grandparent, cousin) increases an individual's risk for colon cancer, but only approximately 50% above the average risk.

Some familial risk stratification findings related to adenomatous polyps in relatives have also been made. In the National Polyp Study, the risk of colorectal cancer in siblings and parents of persons with any adenomatous polyp was 1.78 (95% CI, 1.18–2.67). The risk of colon cancer, however, was 2.59 (95% CI, 1.64–4.58) in siblings of an adenoma patient diagnosed at an age <60 years compared with siblings of an adenoma patient diagnosed at an age ≥ 60 years. Therefore, first-degree relatives of patients with adenomatous polyps have an increased risk of colon cancer. Similarly, first-degree relatives of persons with colon cancer have an increased risk of adenomatous polyps. Given the current knowledge about the adenoma–carcinoma sequence, this would seem logical.

Genetics

The etiology of the commonly observed familial risk is generally unknown. It likely occurs from both inherited susceptibility and share environmental factors, with genetic determinants making one more susceptible to deleterious environmental agents. Spouses of persons with colon cancer do not exhibit the increased risk found in first-degree relatives, indicating the small contribution of shared environment. Kindred studies have further found that common familial risk probably arises from mildly to moderately penetrant inherited susceptibility factors. A number of genes and chromosomal loci that seem to be involved in this manner have been described. The I1307K APC mutation in the Ashkenazi Jewish population gives rise to a milder form of colon cancer predisposition than observed in FAP. The degree of predisposition is low to modest at most, with no difference in phenotype from sporadic colorectal cancer.

Disease-causing mutations of the MSH6 gene (a mismatch repair gene) are found in approximately 7% of patients with a positive family history of colon cancer. This mutation may be responsible for a substantial

TABLE VII Summary of Familial Risk of Colon Cancer

Familiar setting	Approximate lifetime risk of colon cancer
General population	6%
One first-degree relative with colon cancer	2- to 3-fold increase
Two first-degree relatives with colon cancer	3- to 4-fold increase
First-degree relative with colon cancer diagnosed at ≤ 50 years	3- to 4-fold increase
One second- or third-degree relative with colon cancer	$\sim$1.5-fold increase
Two second-degree relatives with colon cancer	$\sim$2- to 3-fold increase
One first-degree relative with an adenomatous polyp	$\sim$2-fold increase

Note. First-degree relatives include parents, siblings, and children. Second-degree relatives include grandparents, aunts, and uncles. Third-degree relatives include great-grandparents and cousins.

number of familial colon cancers that occur at somewhat older ages but do not fit into the syndrome of HNPCC.

A type I transforming growth factor receptor allele, TβR-1(6A), has been found in a higher fraction of colon cancer patients, both homozygotes and heterozygotes.

A family whose members exhibit frequent colonic adenomas, villous adenomas, serrated adenomas, and colon cancer was found to link to a locus on chromosome 15q. Finally, certain polymorphisms of genes involved in the metabolism of both protective and deleterious environmental agents have been associated with predisposition to colon cancer. Such genes include methylenetetrahydrofolate reductase and *N*-acetyltransferases 1 and 2 (NAT1 and NAT2).

Screening

The presence of strong familial risk dictates a more aggressive screening compared with average-risk individuals beginning at a younger age. The American Cancer Society recommends full colonoscopy for persons with first-degree relatives with colorectal cancer or adenoma diagnosed prior to age 60 years and for those with two or more first-degree relatives with colorectal cancer. This screening should start at age 40 years or 10 years earlier than the age of diagnosis of the youngest affected relative. Full colonoscopy is recommended every 5 years if no neoplasms are found. Patients with a less severe family history should have average risk screening, but starting at age 40 years, rather than 50 years. Current screening recommendations for persons with increased familial risks are outlined in Table VIII.

OTHER CANCERS OF THE GASTROINTESTINAL TRACT

Hereditary Diffuse Gastric Cancer

A small fraction of gastric cancers occur as part of inherited syndromes in which it is not the predominant feature. These include HNPCC, Peutz-Jeghers, FAP, juvenile polyposis, and possibly Cowden syndrome, as well as subsets of families with Li-Fraumeni Syndrome (LFS). However, hereditary diffuse gastric cancer (HDGC) is a rare syndrome, accounting for a substantial fraction of inherited gastric cancers. It is an autosomal dominant disease with approximately 70% penetrance arising from mutations of the DCH1 gene encoding the intracellular adhesion receptor molecule, E-cadherin. The average age of diagnosis is 38 years, with several cases reported to occur under the age of 18, but not younger than 15 years. A "*linitis plastica*" picture develops with mucosal abnormalities usually occurring late. The histology is always of the diffuse type.

Screening is recommended with endoscopy with biopsies every 6–12 months in gene carriers. Prophylactic surgery should be discussed with all gene carriers but the high morbidity and mortality of total gastrectomy should be weighed against the very high risk of developing this highly incurable cancer. Additional cancers of the breast, colon, and prostate have been reported in HDGC families but the association of these cancers is uncertain. Even so, screening for these other cancers is recommended in gene carriers.

Familial Pancreatic Cancer

A number of families with multiple cases of pancreatic cancer have now been identified. Risk factors for pancreatic cancer are typically environmental but genetic etiology relates to several syndromes in which pancreatic cancer is observed and also families in which a specific syndrome has not been identified. These include the following:

1. familial atypical multiple mole–melanoma (FAMM), with mutations of CDKN2A;
2. Breast–Ovarian Cancer Family syndrome (BRCA1/BRCA2);
3. hereditary pancreatitis;
4. Von Hippel-Lindau syndrome; and
5. isolated pancreatic cancer families.

TABLE VIII Colon Cancer Screening Recommendations for Persons with Familial Risk

Familial risk category	Screening recommendation
Two or more first-degree relatives with colon cancer **or** One first-degree relative with colon cancer or adenomatous polyps diagnosed at age <60 years	Colonoscopy every 5 years beginning at age 40 years or 10 years younger than earliest diagnosis in the family, whichever is earlier; double-contrast barium enema may be substituted but colonoscopy is preferred
Second- or third-degree relatives with colon cancer **or**	Same as for average-risk individual
First-degree relative with colon cancer or adenomatous polyp diagnosed ***after*** age 60 years	Same as for average-risk individual but begin at age 40 years

Hereditary Hemochromatosis

Disease Phenotype

Hereditary hemochromatosis (HH) is characterized by increased iron absorption with resultant tissue iron deposition. Liver cirrhosis along with a risk of hepatic cancer, hepatoma, occurs in advanced cases. Most persons are asymptomatic, with symptoms developing with advanced iron overload. Symptoms correlate to the organ involved and include abdominal pain (hepatomegaly), arthralgias (arthritis-chondrocalcinosis), loss of libido and impotence (pituitary, cirrhosis), cardiac arrhythmias and congestive heart failure (heart), amenorrhea (cirrhosis), and diabetes (pancreas). Nonspecific symptoms include weakness, fatigue, lethargy, apathy, and weight loss.

Findings on physical exam range from no findings or mild hepatomegaly in the asymptomatic patient to a broad range in the symptomatic patient including arthritis and joint swelling, increased skin pigmentation, edema, and other signs of congestive heart failure, testicular atrophy, hypogonadism, or findings of hypothyroidism. Typical stigmata of end-stage liver disease are found, such as hepatosplenomegaly, ascites, encephalopathy, and cutaneous stigmata-like angiomata and loss of hair on the extremities.

Genetics

This is a common autosomal recessively inherited disorder affecting between 1 in 200 and 1 in 400 persons of northern European descent. The disease arises from mutations of the HFE gene; two mutations have been identified, C282Y and H63D. Homozygosity for the C282Y mutation is found in 64–100% of hemochromatosis patients. Compound heterozygotes C282Y/H63D account for a very small percentage of patients. Other mutations yet to be defined are responsible for 10 to 15% of hemochromatosis patients. Genetic testing for these mutations should be performed in any individual with iron overload and family members once appropriate mutations are confirmed.

Pathophysiology

The HFE protein is found in the intestinal crypt cell of the duodenum and is associated with β2-microglobulin and the transferrin receptor. HFE protein facilitates transferrin receptor-dependent iron uptake into crypt cells. Mutant HFEs lose this ability, leading to iron deficiency within the duodenal crypt cells. This results in the increased expression of an iron transport protein called divalent metal ion transporter 1 (DMT-1, also called DCT-a or Nramp2). This is responsible for unregulated dietary iron absorption in the villous cells of the small intestine. Up-regulation of DMT-1 expression has been confirmed in the HFE knockout mouse and in humans with hereditary hemochromatosis.

Diagnosis

Any persons suspected of having hemochromatosis should first have iron studies performed that include serum total iron and iron-binding capacity, transferrin saturation, and ferritin. If transferrin saturation or ferritin is elevated, a liver biopsy should be performed to establish the diagnosis of hemochromatosis by histology using the hepatic iron concentration (HIC) and then calculating the hepatic iron index, which takes into account the progressive increase in HIC with age. Generally, a hepatic iron index >1.9 is diagnostic of hereditary hemochromatosis but heterozygotes can have a lower value (1.5–1.8). Liver biopsy is also helpful to establish the presence of cirrhosis although it is unlikely in those with a serum ferritin level <1000 ng/ml, normal liver enzymes, and no hepatomegaly and in those who are <40 years old.

It is very important to distinguish HH from other conditions of iron overload because the treatment varies. Acquired iron overload can result from ineffective erythropoiesis as in β-thalassemia, sideroblastic anemia, aplastic anemia, pyruvate kinase deficiency, and pyridoxine-responsive anemia. Liver diseases associated with alcohol, hepatitis B and C, nonalcoholic steatohepatitis, porphyria cutanea tarda, or postportocaval shunting all can result in iron overload. Transfusions of red blood cells or parenteral iron either from iron injections or with hemodialysis also may result in iron overload. In addition, miscellaneous conditions can be responsible: iron overload in individuals in sub-Saharan Africa, neonatal iron overload, aceruloplasminemia, and congenital atransferrinemia.

Treatment

When a patient with HH has been found to have iron overload, weekly phlebotomies of 500 ml of whole blood should be carried out (equivalent to 200–250 mg iron). This is continued until the hemoglobin levels do not recover before the next treatment. Monitoring serum transferrin saturation (TS) and ferritin levels every 3 months also is helpful with continued phlebotomy until TS is $<50\%$ and ferritin is <50 ng/ml. Patients diagnosed and treated before cirrhosis have a normal expected survival but not so in those with cirrhosis. In those persons with established cirrhosis, hepatoma screening with liver ultrasound and serum α-fetoprotein should be performed every 6–12 months.

Liver transplantation has been performed but because the abnormal gene is in the enterocyte and

not the hepatocyte, iron reaccumulates in the allograft. Undiagnosed cancer, infection, and coexisting cardiac disease contribute to postoperative morbidity and mortality.

Fast-Track Surgery

DOUGLAS W. WILMORE
Brigham and Women's Hospital and Harvard Medical School

epidural anesthesia Technique in which local anesthetics are placed in the space around the spinal cord and its protective membrane, blocking nerve transmission.
hypothermia Body temperature below normal.
ileus Situation in which the intestinal tract fails to propel food along its surface.
meta-analysis Statistical approach to reach a conclusion using combined data from multiple trials.
regional blocking procedure Method of injecting local anesthesia under the skin, but around the nerves that are supplied to a specific area.
spinal anesthesia Technique in which local anesthetics are placed within the fluid-filled sack around the spinal cord, blocking nerve impulses.

Fast-track surgery is the combined use of a variety of relatively new approaches in operative techniques and perioperative care to enhance the outcome of the elective surgical patient. These methods greatly reduce the stress of an operative procedure, controlling pain and reducing complications. As a result, the operation may be performed as outpatient surgery, or the patient may be required to stay in the hospital for only a day or two.

INTRODUCTION

The new operative and perioperative methods applied in fast-track surgery include epidural or regional anesthesia, minimally invasive operative techniques, optimal pain control, and aggressive postoperative rehabilitation, including early oral nutrition and enforced ambulation. These approaches, when combined, reduce the deleterious effects of the stress of an operation; treating the stress of surgery limits organ dysfunction and the potential for complications and allows shortened convalescence and an earlier recovery. The following measures are generally utilized in most rapid-recovery programs.

OPTIMIZING PREOPERATIVE PHYSIOLOGY FUNCTION AND PATIENT EDUCATION

Before any elective operation, a patient is assessed and comorbid conditions are treated. For example, the patient with diabetes mellitus has blood sugar control maximized and the patient with mild congestive heart failure receives medications (diuretics and cardiotonic drugs) to assure optimal cardiac function. In addition to these and other conditions, it has been shown that if pharmacological means can be used to enforce abstinence in alcohol misusers (even in those without signs of liver impairment), mortality rate will decrease and shortened recovery can be achieved. Prolonged smoking cessation (for 1–2 months) is necessary in the preoperative period to reduce postoperative pulmonary complications.

Classic studies have demonstrated that informed patients require less pain medication in the postoperative period and have shorter hospital stays. Nurses or physician assistants can help the patient understand various aspects of the hospital procedures and may aid by teaching techniques to reduce pain and anxiety following the operation.

ANESTHESIA

Even though a patient receives general anesthesia and is sleeping during surgery, the incision and surgical procedure are perceived by the central nervous system. This results in a variety of reflex responses transmitted via spinal nerves to other organs (liver and intestinal tract, for example), activates the autonomic nervous system (which activates heart rate and increases vascular resistance, for example), and stimulates the hypothalamic–pituitary–adrenal axis (to release glucocorticoids, a major "alarm" hormone). These responses, when combined, are termed the "stress response," and if uncontrolled or exaggerated, they contribute to debility following an operation.

How can the stress response be modified? Local anesthetics and other agents can be placed within the subarachnoid or epidural space (techniques that provide spinal or epidural anesthesia, respectively), thus blocking nerve transmission from the operative site and diminishing the stress response. The effects of blocking nervous impulses from the surgical site are greatest when procedures are performed in the

TABLE I Effect of Regional Anesthetic/Analgesic Techniques Compared with General Anesthesia and Systemic Analgesics on Postoperative Morbidity

Complications	Reduction in morbidity
Pulmonary infectious complications	~30%
Respiratory depression	~40%
Pulmonary embolism	~50%
Myocardial infarction	~30%
Other thromboembolic complications	~40%
Ileus	2 days
Blood loss and transfusion requirements	~20–30%
Cerebral complications	No effect
Renal failure	~30%
Other infectious complications (wound, etc.)	No effect

lower body (the lower abdomen, pelvis, and lower extremities), compared with upper abdominal and thoracic operations. This approach improves postoperative pulmonary function, decreases cardiac demands, reduces ileus, and improves pain relief. A recent meta-analysis comparing neural axial blockade (e.g., spinal or epidural anesthesia) with general anesthesia, involving 141 trials including 9559 patients, showed improved morbidity and mortality with the blocking techniques (Table I).

Not all procedures require spinal or epidural anesthesia, and regional blocking procedures have proved quite satisfactory for patients undergoing mastectomy or inguinal hernioraphy.

IN THE OPERATING ROOM

The use of minimally invasive surgical techniques, such as laparoscopic cholecystectomy, has greatly reduced the stress of an operation. When carefully studied, minimally invasive surgical techniques have been found to reduce the inflammatory responses following an operation, although they fail to attenuate early metabolic responses to surgery. Pulmonary function is improved and the postoperative ileus is reduced with the minimally invasive approach. These techniques are now being extended to a variety of procedures in the abdomen and are also used for cardiovascular, thoracic, cerebral, and major orthopedic procedures.

Operating rooms are cold (21°–24°C), and semiclad patients are further disadvantaged by the use of drugs or techniques that inhibit normal responses to cold exposure, such as shivering. This has traditionally resulted in mild hypothermia, which increases the patient's stress response following the procedure. Newer techniques of keeping patients warm in the operating room have resulted in a threefold decrease in the rates of wound infections, a reduction in operative blood loss, a decrease in untoward cardiac events (including ventricular tachycardia), and a reduction in protein loss and patient discomfort.

MODIFYING POSTOPERATIVE CARE

Little evidence supports the routine use of nasogastric tubes in the postoperative period, and, in fact, this approach may be detrimental by increasing the incidence of pneumonia. In addition, there is little scientific basis to the use of drains after cholecystectomy, joint replacements, colon resection, thyroidectomy, and radical hysterectomy.

Oral intake is commonly limited to the postoperative period, but with epidural anesthesia and minimally invasive surgical techniques, ileus is minimized and early feeding is possible. If postoperative nausea and vomiting occur, drugs are available for effective treatment.

Bed rest is frequently recommended following an operation, but with adequate pain control and the use of short-acting anesthetic agents, early ambulation is possible. Exercise also enhances early oral feedings, reduces venous stasis and the potential complications of thrombosis, and stimulates skeletal muscle protein synthesis.

Adequate pain control is essential following an operation and this may require special training of the hospital staff or organization of an acute-care pain service with expertise in the multifaceted aspects of pain control. After minor to moderate operations, patients should receive nonopioid analgesics such as nonsteroidal antiinflammatory agents. This avoids the potential side effects of narcotics, which prolong recovery. More complicated operations are associated with greater pain intensity; using epidural anesthesia for the next 2–3 days reduces the stress of the operation and enhances recovery.

After the second postoperative day, recovery depends on resolution of pain and fatigue. The latter may be related to sleep disturbances that occur in the hospital setting because of noise, drugs, and possibly inflammatory factors. Loss of strength is related to muscle weakness secondary to inactivity and reduced food intake. By attenuating surgical stress and emphasizing early mobility and food intake, this problem may be greatly reduced and convalescence shortened.

TABLE II Recent Data on Fast-Track Surgery from Single-Center Studies

Operation	Hospital stay
Laparoscopic cholecystectomy	Ambulatory procedure
Laparoscopic or vaginal hysterectomy	Ambulatory procedure, 1 day
Laparoscopic gastroesophageal reflux surgery	Ambulatory procedure, 1 day
Elective surgery for aortic aneurysm	3–4 days
Carotid endarterectomy	1–2 days
Mastectomy	Ambulatory procedure, 1 day
Lung lobectomy	1–2 days
Prostatectomy	1–2 days
Partial colectomy	2 days

THE FUTURE

Many medical units are now initiating some or all of the fast-track approaches in the surgical patient. Early results, usually from single-center trials, are encouraging (Table II). When patient satisfaction is studied, it has been high and exceeds that measured with the usual postoperative approach. Rather than emphasizing monitoring and high-technology interventions in the postoperative period, the fast-track approach emphasizes rehabilitative care, with emphasis on pain relief, mobilization, and nutrition.

The trend in the future will be to greatly reduce the length of the hospital stay following operations, because patients recover from their operations sooner. This will be related to less operative stress because of the use of fast-track and other techniques. In addition, morbidity and mortality will decrease because the stress response to a specific surgical procedure is diminished. Further work is needed to understand perioperative pathophysiology, to reduce hospital convalescence, and to improve operative outcome. Physician education is also needed to institute fast-track care.

Fat Digestion and Absorption

CHARLES M. MANSBACH
The University of Tennessee Health Science Center and Veteran's Affairs Medical Center, Memphis

apolipoprotein B-48 Product of translation of 48% of the total apoB-100 transcript.
chylomicron Lipoprotein uniquely made in the intestine; contains a central core of triglyceride, cholesterol ester, and phospholipid surrounded by a phospholipid coat and apolipoproteins.
enterocytes Mature absorptive cells that line the villi of the small intestine.
exocytosis Budding of membranes in which a selected particle is pushed out into the pericellular space by rupture of the bud.
lipase Enzyme that hydrolyzes glycerol esters of fatty acids.
micelles Association of amphiphilic compounds in which hydrophilic surfaces face outward into the aqueous medium and hydrophobic surfaces face the interior.
phospholipase Enzyme that hydrolyzes phospholipids at specific sites on the molecule.
triglyceride Fat in which fatty acids are esterified to each of the three alcoholic groups.
very low-density lipoprotein Triglyceride-carrying lipoprotein that is like a chylomicron except that it is made both in the intestine and the liver and is smaller.

Absorption of lipid by the intestine is a series of events complicated by the hydrophobic nature of dietary fat. Ingested fat must first be processed to water-interactive lipid products such as fatty acids, which can then be dispersed in the aqueous environment of the intestinal lumen. The lipid products are absorbed into the enterocytes of the small intestine and are resynthesized as triglyceride; if this process does not occur, the fatty acids act as soaps, which can dissolve cellular membranes. A process in which the triglyceride is packaged in chylomicrons enables the fat ultimately to be directed to its final destination, mostly muscle and adipose tissue.

FAT ABSORPTION

Humans can absorb and process large amounts of daily dietary fat in an extremely efficient manner. In the gastrointestinal tract, fat, which is water insoluble, can be made to interact with water, enabling absorption. Once absorbed, hydrolyzed lipids are resynthesized as triacylglycerol and participate in the formation of the chylomicron. The nascent chylomicron is moved from its site of formation in the endoplasmic reticulum to the Golgi for further processing and then is transported from the Golgi to the basolateral membrane of the enterocyte, where the mature chylomicron moves into the lamina propria by reverse exocytosis and into the lymph. The metabolism of chylomicrons is determined by lipoproteins that are present on the chylomicron surface.

FAT DIGESTION

The normal American daily diet contains 100–150 g of fat. This fat is absorbed with 95% efficiency, and even immense amounts of fat, up to 500 g/day, can be absorbed with the same efficiency. It is evident that large variations in fat intake can be handled easily. Although dietary fat has a bad connotation, both because of obesity and because of the relationship between blood cholesterol and the development of atherosclerosis, it should be remembered that fat makes most foods tastier and that some fatty acids are essential for normal body functioning. The so-called essential fatty acids are not synthesized by humans and therefore must be supplied in the diet and appropriately absorbed. Cholesterol, too, is a necessary constituent of biomembranes. In considering the complexities of fat digestion and absorption, it should be kept in mind that the body operates in an aqueous environment but that ingested lipids are most often in a water-insoluble state. If humans did not possess mechanisms for breaking down water-insoluble compounds, there would be no absorption of lipids, which are necessary for their caloric content and for their specific, essential fatty acids.

Gastric Lipase

Fat digestion begins in the stomach. The chief cells of the gastric mucosa produce gastric lipase (GL), the preduodenal lipase of humans. This lipase primarily hydrolyzes fatty acids esterified at the *sn*-3 position on the glycerol backbone of triacylglycerol (TAG). This is especially true if the fatty acid (FA) at the *sn*-3 position is of medium carbon chain length, an important factor in the digestion of milk, the TAG of which

 Copyright 2004, Elsevier (USA). All rights reserved.

is mainly composed of a medium-chain FA at the *sn*-3 position. In neonates, the pancreas is not well developed and pancreatic lipase is secreted in greatly reduced amounts compared to adult levels. As a result, GL is the primary enzyme that hydrolyzes fat in the intestine at this time of life. The major products of lipolysis by gastric lipase are one fatty acid and *sn*-1,2-diacylglycerol (DAG), although the enzyme can hydrolyze both of the primary alcoholic groups of TAG, resulting in *sn*-2-monoacylglycerol (MAG) and two fatty acids. The effect of GL is to provide FAs, which are surface active, and DAG, which dissolves into the interior of lipid droplets and awaits further hydrolysis. The surface-active FAs have the effect of reducing the diameter of the lipid droplets, greatly increasing their surface area with respect to their interaction with water (Fig. 1). This has been shown to increase the rate at which lipid is absorbed in the small intestine. In patients with pancreatic insufficiency, GL provides the majority of lipolytic activity in the intestine. In cases of atrophic gastritis, in which little if any GL should be produced, no defect in overall lipid absorption is found. This points to the lack of requirement of GL for lipid absorption.

Gastric lipase is about the same molecular weight as pancreatic triacylglycerol lipase (PTL) but differs from it in significant ways. The pH optimum for GL is, as would be expected, more acidic, 4–6 versus the pH optimum for PTL of 8.5. GL resists proteolysis by pepsin whereas PTL is susceptible. GL is 15–18% glycosylated whereas PTL is only minimally so. The purified enzyme is very active (1.2 mmol/mg protein/min) against an optimal substrate, tributyrin.

Pancreatic Lipase

Pancreatic triacylglycerol lipase is the single most important determinant of lipid absorption. In its absence, only 30% of an ingested lipid load is absorbed. The enzyme is secreted by the acinar glands of the pancreas into the pancreatic duct and then into the intestine in response to ingestion of a fatty meal. The hormonal signal that initiates the process is cholecystokinin (CCK). CCK originates in enteroendocrine cells in the duodenum. PTL, unlike all other pancreatic hydrolases, does not require activation prior to attaining maximal activity.

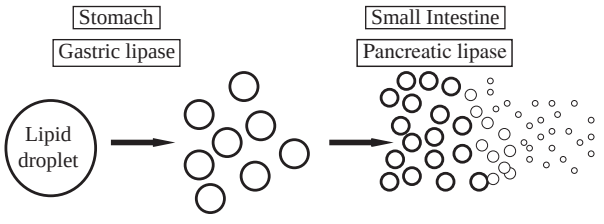

FIGURE 1 Gastric and pancreatic lipases, by producing surface-active fatty acids, progressively increase the surface area of the lipid droplets by decreasing their diameter.

The physiology of PTL has been extensively studied. The enzyme operates only at an oil/water interface; it does not hydrolyze TAG substrate that is soluble in water. An interfacial recognition site on PTL assures that it is correctly aligned with its substrate, TAG, at an oil/water interface. At this point, a hinge mechanism lifts a "lid," exposing a serine hydrolase within the hydrolytic site. Unfortunately, bile salts, which are present in the normal digestive tract after a meal, remove the lipase from the oil/water interface and render the PTL inactive. An associated protein, secreted by the pancreas in an inactive form as pro-colipase, is activated by trypsin, and the active protein, colipase, is able to hold PTL at the oil/water interface even in the presence of bile acids. The colipase activation peptide, called enterostatin, is absorbed intact and has been shown to be a satiety factor. The result of continued lipolysis is to further reduce the size of the lipid droplets, further increasing the surface area for additional lipolytic activity (Fig. 1).

PTL hydrolyzes TAG at primary ester groups, resulting in the release of two FAs and MAG. If the MAG isomerizes to the *sn*-1,3 position, then the MAG isomer becomes a target for further lipolysis, with the final products being three FAs and glycerol. The rate of isomerization is slow, however. These products are constantly being swept away from the oil/water interface, so there is no product inhibition of lipolytic activity. Against the ideal substrate tributyrin, the purified enzyme is even more active (4.5 mmol/mg protein/min) than GL.

Pancreatic Phospholipase A_2

Pancreatic phospholipase A_2 (PLA_2) is secreted by the pancreas from the pancreatic acinar glands in response to the hormonal signal, CCK. It is secreted as a proenzyme that must be activated by trypsin prior to achieving maximal activity. The proenzyme can hydrolyze its phospholipid substrates at a reduced rate but cannot recognize and be activated by an oil/water interface, as can the active enzyme. The specific hydrolytic site of the enzyme is the FA esterified at the *sn*-2 position, resulting in release of an *sn*-1-lysophospholipid and one FA, usually an unsaturated one because that is the commonest FA esterified at that location. The resultant products can be absorbed easily; unhydrolyzed phospholipid is not absorbed.

The effect of PLA_2 on lipid absorption is to remove phospholipids from the surface of fat emulsions, enabling PTL to more quickly penetrate the surface of the lipid droplet and begin hydrolysis. In the presence of phospholipids, PTL does not hydrolyze the neutral TAG until some of the phospholipid has been hydrolyzed, the so-called lag time. After the phospholipid is partially removed from the emulsion surface, PTL activity increases exponentially.

It is interesting to consider why PLA_2 does not hydrolyze the apical membrane phospholipids that it comes into contact with after its activation. Venom phospholipases A_2 are readily able to attack membrane phospholipids. Snake venom PLA_2 injected into the paw of a rabbit causes swelling and inflammation, whereas there is little effect if pancreatic PLA_2 is injected. Similarly, red cells are rapidly lysed when exposed to snake venom PLA_2 but not following exposure to pancreatic PLA_2. The reason for this is the relative abilities of the two PLA_2s to penetrate the membrane surface layer of phospholipids. The lateral surface pressure of the phospholipids in membranes is on the order of 30 dynes/cm^2, a pressure that venom PLA_2 can easily penetrate. This is far above the ability of pancreatic PLA_2, which has a maximal activity at 12 dynes/cm^2.

Cholesterol Esterase

Cholesterol esterase (CE) (bile salt-stimulated esterase or carboxyl ester lipase) primarily hydrolyzes cholesterol esters. It is synthesized in the pancreas and is released in response to CCK in a fully active form. Studies from CE knockout mice show that this enzyme has no effect on free cholesterol absorption but does dramatically lower cholesterol ester absorption, pointing to its key role in hydrolyzing cholesterol ester to free cholesterol and FA. Its nonspecific hydrolyzing ability means that it can hydrolyze TAG as well as MAG. It would appear that its effect on TAG is not clinically significant, whereas the hydrolysis of MAG would reduce the efficiency of the reesterification process to TAG that occurs in the enterocyte (see later).

INTRALUMINAL PROCESSES

After the emulsion lipid droplets are broken down into small-sized, stable emulsion particles, pancreatic lipase, in conjunction with colipase and PLA_2, attack their substrates at the oil/water interface. The released hydrolytic products are removed from the surface by their solubilization in bile salt micelles or in liquid crystals of MAG and FA (Fig. 2). Bile salts, by their self-associating qualities above a certain concentration, i.e., the critical micellar concentration, form a micelle, arranged such that the hydrophobic sides of the bile salts face each other and the hydrophilic sides face the aqueous solution. This forms a hydrophobic interior into which FA and MAG acyl chains and cholesterol penetrate, forming a bile salt mixed micelle. These micelles diffuse toward the apical surface of the enterocytes. FAs and MAG have a finite water solubility and these monomers diffuse as well toward the apical surface. Because diffusion rates are inversely proportional to the square of the radius of the diffusing moiety, the micelles diffuse much more slowly than the monomer species. However, the concentration of FAs and MAG in the micelles is so great that it more than makes up for the slower diffusion rate in terms of the ability of the micelles to deliver lipids efficiently to the apical enterocyte surface (Fig. 2). These micelles, the monomers, and the liquid crystals diffuse across the unstirred layer next to the apical surface of the intestine. The enterocytes secrete H^+, making the juxtaapical surface more acidic compared to the bulk luminal fluid, the so-called acidic microclimate. The effect of the reduction in juxtaapical pH to ≈ 6.0 is to partially protonize the FA, which has an effective pK_a of 4.5. The protonated FA then can passively traverse the apical membrane into the enterocyte. Once in the enterocyte, the more neutral pH causes the FA to again become ionized, effectively trapping the FA inside the cell. FA absorption may also be mediated in part by membrane fatty acid transporters. Several have been described: A plasma membrane-associated fatty acid binding protein (FABPpm) is present in the human colon carcinoma cell line, Caco-2 cells, which at confluence have many of the characteristics of intestinal absorptive cells. Antibodies to this transporter do not inhibit the uptake of FA. A fatty acid transporter protein (FATP) but not FAT/CD36 is expressed in Caco-2 cells. Treatment of these cells with trypsin to hydrolyze surface potential FA transporters reduces the uptake of FA into Caco-2 cells by $\approx 30\%$, suggesting that at least some FAs are absorbed by a FA transporter, presumably

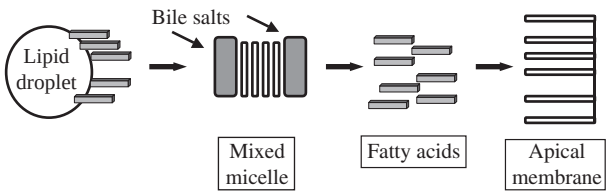

FIGURE 2 Lipase action produces fatty acids, which combine with bile salts to form mixed micelles. The micelles diffuse toward the cell surface; the fatty acids solubilize in the aqueous fluid and penetrate the apical surface membrane.

FATP. The role of the micelles and liquid crystals is to act as reservoirs for monomer FAs and MAG so that the monomer concentration of both lipids remains maximal in the unstirred layer.

RESYNTHESIS OF TRIACYLGLYCERIDES IN ENTEROCYTES

Interaction of Absorbed Split Lipids with Fatty Acid Binding Proteins

FAs and MAGs that desorb from the cytosolic face of the apical membrane are in part solubilized in the cytosol in monomer form. In addition, the intestine expresses two lipid-binding proteins, the intestine and liver fatty acid binding proteins (I-FABP and L-FABP). These proteins comprise a large amount of the total proteins in the cytosol, up to 2% each. Each I-FABP can bind only one FA, whereas each L-FABP can bind two FAs as well as MAG. The role of the FABPs in promoting TAG resynthesis is not clear, but it has been shown that FAs bound to FABP move more quickly in the cytosol than do FAs alone. It is postulated that L-FABP acts as a reservoir for intracellularly bound FA and MAG, delivering its cargo to the site of TAG resynthesis by diffusion across the apical membrane–endoplasmic reticulum (ER) space. By contrast, I-FABP delivers its FA cargo by actual contact with the ER membrane.

Synthesis of TAG in the ER

The products of intestinal luminal lipolysis are resynthesized to TAGs, phospholipids, and cholesterol esters by the ER of the enterocyte. The enterocyte, which has no effective control over the entry rate of FAs, performs this function very quickly or risks having toxic concentrations of FAs present in the cytosol. FA is a soap and as such greatly disturbs cellular membranes or solubilizes them completely, depending on the FA concentrations. The two ways that the enterocyte has to dispose of FAs is by binding them to FABP or by reforming TAGs, which are essentially physicochemically inert. The enterocyte can perform the resynthetic function very quickly. In 30 seconds, large amounts of FAs, of which 79% is already reesterified to TAGs, can be absorbed from the lumen of the intestine. Multiple enzymes perform this function. First the FA must be activated to form FA–coenzyme A (CoA) by the enzyme FA–CoA ligase. This enzyme is located on the cytosolic hemileaflet of the ER membrane. The activated FA can then be used by a series of two acyltransferases to form TAG. First DAG is formed from MAG by MAG acyltransferase (MGAT) and subsequently TAG is formed from the DAG by DAG acyltransferase (DGAT). If MAG is not available, then TAG can be resynthesized by the so-called *de novo*, or Kennedy, pathway. This begins with *sn*-3-glycerol phosphate, which is acylated by glycerol phosphate acyltransferase to lysophosphatidic acid (LPA). LPA, in turn, is acylated by LPA acyltransferase to phosphatidic acid (PA). PA phosphatase, the limiting enzyme on this pathway, then hydrolyzes the PA to DAG. This DAG, in contrast to the DAG synthesized from MAG, can be utilized for phospholipid synthesis. The DAG can then be converted to TAG by DGAT. In this reaction, another enzyme appears to be important, acyl-CoA acyltransferase (AAT). The role of AAT is not yet clear, but its removal from the TAG synthetic complex stops TAG synthesis, at least in liver.

Movement of TAG to the ER Lumen

It is not certain on what side of the ER membrane the lipid resynthesis occurs. Some resynthesis clearly occurs on the cytosolic face of the ER membrane. The TAG thus produced must cross the ER membrane to gain access to the ER lumen, where the forming chylomicron is situated. There is a finite solubility of TAG in membranes of 3%, thus, depending on the rapidity of TAG movement across the membrane; a variable proportion of cytosolically synthesized TAG could be made available for chylomicron formation. Alternatively, the TAG could be formed on the lumenal side of the ER membrane, which would do away with the requirement for TAG to traverse the ER membrane. If DGAT and possibly MGAT are located on the luminal side of the ER membrane, however, they must have access to their substrate FA-CoA. FA-CoA cannot cross the ER membrane and CoA concentrations in the ER lumen are very low. Therefore, a mechanism must exist for the FA-CoA to cross the ER lumen. Current data indicate that a majority of the TAG that is synthesized by the enterocyte for chylomicron formation is synthesized by DGAT on the luminal surface of the ER membrane.

CHYLOMICRON FORMATION AND MOVEMENT OF MATURE PARTICLES

Formation of the Chylomicron

Chylomicrons are formed in the ER lumen by a two-step process. In the first step, apolipoprotein B-48 (apoB-48), which is only 48% of the translated full-length apoB transcript, is pulled across the ER

membrane through its translocon by the microsomal triacylglycerol transport protein (MTP). MTP, acting as a chaperone, is made up of a large (97 kDa) and a small (55 kDa) component; the smaller component is protein disulfide isomerase (PDI). PDI is utilized for proper folding of proteins because its function is to link together intramolecular cysteines. ApoB-48, once inside the ER lumen, combines with phospholipid, mainly phosphatidylcholine (PC), and some TAG to form a dense, small, primordial chylomicron. The majority of the TAG that will eventually enter the chylomicron forms a lipid aggregate, mediated by MTP, more distally in the ER, mainly the smooth ER. How the dense chylomicron becomes lipidated by the TAG is unclear. However, the chylomicron is formed and results in a very large particle that is 100−500 nm in diameter. The forming chylomicron is composed of a TAG and CE core with a surrounding coat of phospholipid, mainly PC, cholesterol, apoB-48, apolipoprotein A-IV, and some C lipoproteins. This "mature" ER chylomicron is now ready to be transported to the Golgi (Fig. 3).

Movement of Chylomicrons from the ER to the Golgi

The movement of chylomicrons out of the ER has been postulated to be the rate-limiting step in the transit of TAG across the enterocyte. Consistent with this hypothesis, when the load of dietary TAG is increased, the amount of TAG remaining in the ER increases in direct proportion. In fact, if the dietary load is very great, at least in rats, some TAG never makes it across the ER membrane but remains on the cytosolic surface of the ER.

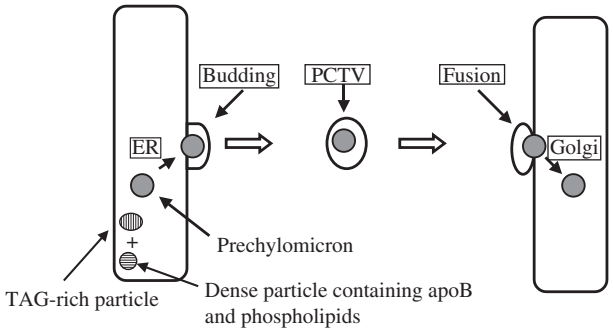

FIGURE 3 Prechylomicrons are cargo in the prechylomicron transport vesicle (PCTV), which buds from the endoplasmic reticulum (ER) membrane, traverses the intracellular space, and fuses with the Golgi, delivering its cargo to the Golgi lumen. TAG, Triacylglycerol; apoB, apolipoprotein B.

The movement of chylomicrons out of the ER is just beginning to be understood. It appears certain that the chylomicrons move from the ER to the Golgi in a prechylomicron transport vesicle (PCTV) (Fig. 3). The mechanism by which the prechylomicron is selected as cargo in the vesicle is not known. What is known is that the group of proteins known as the coatomer II proteins, or COPII proteins, which are crucial to the export of proteins from the ER to the Golgi, are not involved with the budding of the PCTV from the surface of the ER (Fig. 3). Indeed, inhibition of the protein vesicles causes an increase in PCTV formation by 6- to 10-fold. The actual proteins involved in budding from the ER are not known, but the COPII proteins appear to be present on the PCTV, not for the purpose of budding but rather to enable the PCTV to acquire the proteins requisite for targeting the PCTV to the cis-Golgi, tethering it to the Golgi, docking, and then fusion of the PCTV with the Golgi membrane. In this way, the very large chylomicron can be delivered across the Golgi membrane for the additional processing that takes place in the Golgi (Fig. 3). This process appears to be unique to the intestine in that PCTV cannot deliver its cargo to liver Golgi. In addition, the vesicle is sealed, which precludes entry of the cytosolic lipase (PTL) present in the cytosol of the intestine. This lipase, which is pancreatic PTL but expressed in the intestine, would hydrolyze the chylomicron TAG if it had access to the TAG present in chylomicrons. The proteins involved in targeting the PCTV to the Golgi and involved with its fusion with the cis-Golgi appear to be the typical fusion machinery used for protein vesicles, but the details are not yet worked out. In sum, the effect of this delivery mechanism is to move the very large prechylomicron out of the ER, across the cytosolic space, direct it to the Golgi, and to get it across the Golgi membrane to the Golgi lumen.

Apolipoprotein A-I (apoA-I), a constituent of the mature chylomicron particle, is not found in the PCTV but is found in both the ER and Golgi. It is well established that apoA-I secretion can be divorced from apoB-48 secretion as well as TAG secretion. Therefore, the lack of apoA-I in the PCTV offers a mechanism whereby apoA-I could get from the ER to the Golgi by an independent mechanism, presumably via the protein vesicles.

Movement of Chylomicrons from the Golgi to the Lymph

Once inside the Golgi lumen, the chylomicrons are destined to go into the lymph. The mechanism by which the prechylomicrons move across the Golgi stack to the

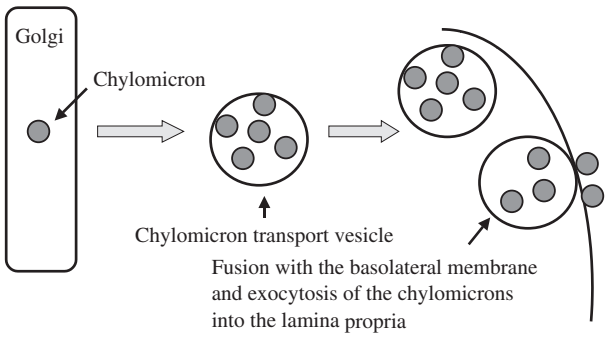

FIGURE 4 Chylomicron transport vesicles bud off the trans-Golgi network and go to the basolateral membrane, where they fuse and deliver their chylomicron cargo to the lamina propria.

trans-Golgi network is unknown. Also not clear is how the chylomicron is budded off the Golgi and enters a vesicle that transports several chylomicrons at a time from the Golgi to the basolateral membrane (Fig. 4). Once at the basolateral membrane (BLM), the vesicle fuses with the BLM and the chylomicrons are released into the intercellular space by reverse exocytosis. Once in the lamina propria, the rapidity of movement of the chylomicrons into the lymph is governed by the extent of tissue hydration. Under conditions in which hydration is poor, the chylomicron is slowed. By contrast, when the tissue is well hydrated, chylomicron movement is enhanced.

Effect of Phosphatidylcholine on Chylomicron Export

For many years it has been known that PC availability governs the rate at which chylomicrons are delivered to the lymph. For example, in rats infused intraduodenally with triolein (135 μmol/hour), the output rate varies from 50% in bile duct-intact rats to 85% of the input rate in rats in which PC was included in the triolein infusion. The output rate is even less in rats with a bile fistula; in these rats, if choline is infused into the duodenal lumen along with triolein, there is a modest increase in chylomicron output into the lymph. However, if lyso-PC is infused, then chylomicron output is restored to control (bile duct-intact) levels. These data suggest that *de novo* synthesis of PC cannot keep up with demand, but that when lyso-PC is provided, adequate amounts of PC for chylomicron export can be synthesized. At what step PC dependency occurs is not clear. It could be the utilization for PC for chylomicron membrane formation or it could be PC utilization for PCTV membranes. Bile PC appears to be favored over other forms of PC.

INTESTINAL PRODUCTION OF VLDL

The intestine also produces very low-density lipoproteins (VLDLs), which are operationally of greater density than chylomicrons. The vast majority of TAG that is exported from the intestine is as chylomicrons vs. VLDLs. If the dietary load of TAG is increased, the amount of TAG appearing in the chylomicrons and in the VLDLs progressively increases until a point is reached in which the amount in the VLDLs does not increase further, although additional output in chylomicrons continues. At least at low levels of dietary intake, the saturated FAs (palmitate) tend to be transported out of the intestine in VLDLs, whereas the unsaturated ones (oleate) appear in chylomicrons. Even under fasting conditions, TAG continues to be secreted by the intestine as both VLDLs and chylomicrons. Most of this TAG comes from acyl groups derived from the bile PC. In rats with a bile fistula, hardly any TAG is exported either in VLDLs or chylomicrons.

DIFFERENCES IN TRIGLYCERIDE TRANSPORT

The ileum is perfectly capable of absorbing lipid and resynthesizing TAG from it. The question is how it is transported from the gut. Interestingly, for reasons that are not clear, in the rat, lipid delivered to the distal intestine appears to be poorly transported by chylomicrons. Even if the distal intestine is perfused with lipid for a week to be certain that the lack of delivery of dietary lipid to the distal intestine as a causation of this effect is overcome, the lipid is still not well transported in chylomicrons. However, if the ileum is transposed to the proximal intestine and lipid is delivered to it, then the TAG is exported in chylomicrons. The reasons for these effects are not known nor is it known if these rat data are transferable to humans.

TWO POOLS OF INTESTINAL TRIGLYCERIDE

The TAG that is synthesized by the enterocytes can distribute into two different pools. The first pool, the prechylomicron pool, is composed mainly of dietary FAs and of TAGs synthesized predominantly from dietary MAGs. The result is a pool of TAG that closely reflects the acyl constituents of the diet. The data predict that chylomicrons, which utilize the TAGs from this pool, would consist of TAGs that mimic the diet. When tested, this prediction held true. It is also predicted that

this TAG would be sequestered in the lumen of either the ER and/or the Golgi. This prediction has also proved true.

The TAG in the second pool, the storage pool, has a completely different fate. Unlike the liver, in which TAG enters a storage pool prior to its secretion in very low-density lipoproteins (the major TAG transport vehicle of the liver), the intestine appears to transport absorbed dietary fat directly into chylomicrons, without passing through a storage pool. The storage pool acyl groups come predominantly from endogenous sources such as circulating FAs. If the circulating FAs are radiolabeled and traced to the intestine, it is found that at radiolabel steady state, most of the labeled FA is in TAG and that the mucosal TAG has a much higher radiolabel-specific activity compared to TAG that is being secreted into the lymph. In fact, the lymph TAG has a lower specific activity than does the mucosal TAG, the opposite of what occurs when dietary TAG is radiolabeled. These studies demonstrate that the TAG in the storage pool is not selected for export into the lymph. Studies show, however, that the TAG in this pool does leave the intestine. Because the TAG does not leave in the lymph, and it has been shown that endogenous TAG and especially FA appear in the portal vein, it is very likely that the TAG in this pool leaves via the portal vein, either as TAG or, if hydrolyzed by the intestinal lipase, as FA.

The two TAG pools likely split at the level of the ER. The rationale for this is that TAG within the ER lumen has a radiolabel-specific activity that is similar to that found in chylomicrons and approaches that of the dietary TAG. By contrast, the TAG on the cytosolic face of the ER has a very low radiolabel-specific activity when dietary TAG is radiolabeled. Because these two pools appear to be separated only by the ER membrane, it is clear that this is where the division between the two pools occurs.

DELIVERY OF FAT TO THE PORTAL VEIN SYSTEM

It has been established that 10–15% of absorbed FA enters the portal vein during normal lipid absorption, with the unsaturated FAs being favored. When studied in a more quantitative way, however, under conditions of large intake loads, the portal vein can transport up to 39% of the absorbed lipid as FA and some as TAG. Where do these FAs and TAGs come from? One potential is that these lipids are the ones that never cross the ER membrane but are sequestered on the cytosolic face of the ER. If ER in which this distribution of lipid occurs is incubated with cytosol containing lipase, the TAG on the outside of the ER is rapidly hydrolyzed, whereas the TAG in the ER lumen is not touched. The amount of FA and TAG delivered to the portal vein is inversely proportional to the amount of lipid appearing in the lymph. For example, in rats receiving PC in an intraduodenal triolein infusion, almost all the TAG infused comes out into the lymph. In this case, very little appears in the portal vein. Similarly, if the input load of triolein is greatly reduced, again, very little dietary lipid appears in the portal vein. It is not clear in what particle the dietary portal vein TAG is in. In snakes that lack a lymphatic system, portomicrons are generated. A similar situation may exist in humans, but this has not yet been demonstrated.

PHYSIOLOGICAL CONSEQUENCES OF LYMPHATIC/PORTAL VEIN DELIVERY

TAG that is synthesized in the intestine can be exported in either the portal vein or the lymph. Two factors that are known to influence this process are PC and dietary load, as discussed previously. The physiologically important question is the consequences of the TAG exiting the intestine by either path. If the TAGs exit in chylomicrons, their metabolism in the periphery, mostly by adipose tissue and muscle, results in a much smaller particle, the chylomicron remnant. Because of the greatly reduced surface area of the remnant versus the original chylomicron particle, the surface lipids bud off and become PC-rich disks containing predominantly apoA-I. When these disks become loaded with cholesterol, they become high-density lipoprotein (HDL) particles and initiate reverse cholesterol transport. The importance of this process to overall circulating HDL levels has recently become clearer. Mice who are mouse apoB knockouts have a lethal mutation. However, if they are made transgenic for the human apoB gene, they survive. The apoB gene is expressed only in the liver, however, and the intestine has no apoB. In this case, the mice do not mount a chylomicronemia after eating a lipid-loaded diet. These mice have only 36% of the levels of circulating HDL of normal mice. It is unclear if the same data would hold true in humans but it is clear that HDL does form after chylomicron metabolism. By contrast, if dietary lipids enter the portal vein, they go to the liver. Once in the liver, the lipids can either be stored or oxidized. If the lipids are stored, they eventually exit the hepatocyte in the liver's TAG-rich lipoprotein, VLDL. This lipoprotein circulates and, on its metabolism, it first becomes intermediate-density lipoprotein (IDL) and then low-density lipoprotein (LDL). LDL is the predominant cholesterol transporter and the recognized

lipoprotein particle associated with the development of atherosclerosis. Thus, forcing TAG to be exported in the lymph is likely to be beneficial to humans with respect to atherosclerosis.

Fecal Incontinence

WILLIAM E. WHITEHEAD
University of North Carolina at Chapel Hill

gluteal flap transposition When the external anal sphincter is damaged or denervated, an innervated and vascularized segment of the gluteus maximus muscle may be wrapped around the anal canal to substitute for the external anal sphincter.

gracilis muscle Located on the inner aspect of the thigh; may be cut at its distal end and transposed around the anal canal to substitute for a damaged or denervated external anal sphincter. The transposed muscle is often electrically stimulated to maintain a state of contraction.

levator ani muscle Part of the pelvic floor situated anterior to the anal canal; it can be voluntarily contracted to pinch off the rectum from the anal canal.

puborectalis muscle Sling muscle that forms part of the pelvic floor; it loops around the posterior aspect of the rectum and anchors anteriorly to the symphysis pubis. It maintains an angle between the rectum and anal canal and can be voluntarily contracted to further pinch off the rectum from the anal canal.

pudendal nerve motor latency Test for the integrity of the pudendal nerve; involves electrically stimulating the nerve with a finger-mounted electrode and measuring the time elapsed before the external anal sphincter contracts, as detected by electromyographic activity.

sampling reflex Internal and external anal sphincters spontaneously relax for brief periods, allowing the contents of the rectum to be exposed to the sensory receptors in the upper anal canal.

Fecal incontinence is defined as recurring, unintentional loss of fecal material in an individual with a developmental age of at least 4 years. Continence depends on rectal reservoir capacity, sensation of rectal filling, and sufficient strength in the striated pelvic floor muscles. Rectal or pelvic inflammation or injury and diseases that impair nerve conduction may cause fecal incontinence.

INTRODUCTION

In defining fecal incontinence, some clinicians believe that involuntary passage of flatus should be included, because this significantly impairs quality of life. However, involuntary passage of flatus may occur normally up to six times per day, making it difficult to distinguish health from disease. Therefore, patients whose only complaint is uncontrollable flatus should be distinguished from patients who involuntarily lose liquid or formed stool. The usual amount of incontinence should be noted: small-volume incontinence (less than two teaspoons) or only staining of underwear is five to seven times more common than large-volume incontinence and is likely to have a different etiology (e.g., hemorrhoids or irritable bowel syndrome versus sphincter muscle injury or pudendal nerve injury).

Several scales have been developed to measure the severity of fecal incontinence. Most of these scales ask patients to rate the frequency of gas, liquid, and solid stool incontinence; a summary score is calculated based on the frequency of gas incontinence plus the frequency of liquid incontinence plus the frequency of solid incontinence. Some severity scales also include questions on use of pads and impact on quality of life.

EPIDEMIOLOGY

The prevalence of fecal incontinence in community-dwelling people is 2.2–6.9%, but in nursing homes, 45–47% of residents are fecally incontinent. The total prevalence of fecal incontinence, when community-dwelling and institutionalized individuals are combined, is approximately 15% of the adult population. When surveys distinguish minor (small volume) from major (larger volume) fecal incontinence, minor incontinence is more common (6% minor incontinence vs. 1% major incontinence in one large survey). The etiologies for minor and major incontinence are believed to differ: approximately 50% of patients with hemorrhoids report minor incontinence and about 20% of patients with irritable bowel syndrome report occasional, minor incontinence. Major incontinence is more likely to involve obstetrical trauma, pudendal nerve injury, diabetes, dementia, or constipation with overflow.

The prevalence of fecal incontinence increases with age in both genders. This is partly explained by the association of incontinence with dementia and mobility impairment in older people. As a consequence, 97%

 Copyright 2004, Elsevier (USA). All rights reserved.

of patients with fecal incontinence in nursing homes also experience urinary incontinence whereas isolated fecal incontinence is more common in younger and community-living people.

Obstetrical trauma resulting in injuries to the external anal sphincter and/or its innervation during vaginal childbirth is a well-recognized etiology for fecal incontinence, and gynecologists report that fecal incontinence is eight times more prevalent in women than in men. However, surveys of representative community samples show approximately equal representation in men and women.

PATHOPHYSIOLOGY

Continence is preserved by a learned, voluntary behavior; in response to the perception of fecal material entering the rectum, voluntarily contraction of the external anal sphincter, puborectalis muscles, and perhaps other muscles of the pelvic floor is maintained for long enough to allow the rectum to relax to accommodate an increased volume. Thus, continence depends on three factors: the reservoir capacity of the rectum, sensation for rectal filling, and sufficient strength in the striated pelvic floor muscles to postpone stool passage. These functions and the muscles on which they depend are depicted in Fig. 1.

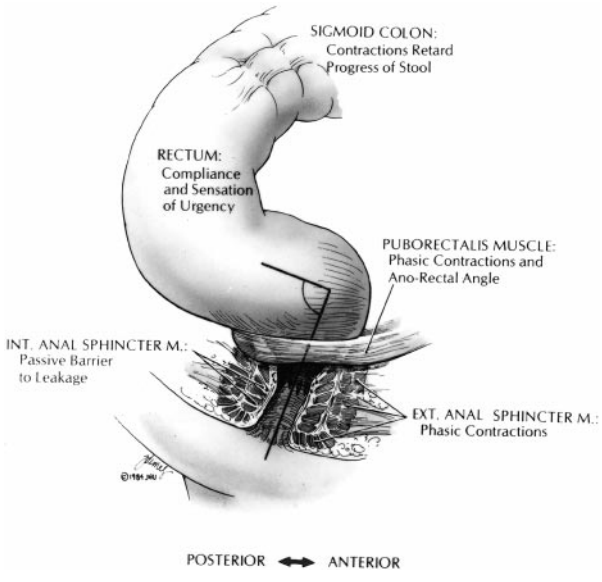

FIGURE 1 Continence depends on three factors: the reservoir capacity of the rectum, sensation for rectal filling, and sufficient strength in the striated pelvic floor muscles to postpone stool passage.

Rectal Compliance

As fecal material enters the rectum, the rectum is able to relax to accommodate increased volume, and there is little or no increase in intrarectal pressure. This accommodation continues up to a critical threshold at which the rectum reflexly contracts. Voluntary effort may also precipitate rectal contraction, but this is poorly studied. Noncompliance of the rectum due to inflammation (e.g., ulcerative proctitis) or scarring (e.g., radiation injury) is associated with an increased risk of incontinence.

Rectal Sensation

Relatively small distensions of the rectum are consciously perceived, allowing a choice to be made for voluntary contraction of the pelvic floor muscles and appropriate timing of defecation. Deficits in rectal sensation, which often occur in association with diabetes mellitus or spinal cord injury, may result in incontinence.

Anal Sensation and Sampling Reflex

The internal and external anal sphincters spontaneously relax for brief periods (sampling reflex), allowing the contents of the rectum to enter the upper anal canal. Afferent nerve endings there may contribute to continence by allowing an individual to discriminate whether the rectum contains gas, liquid, or formed stool. Anal sensation is less well studied than rectal sensation.

Pelvic Floor Muscles

The pelvic floor is composed of multiple muscles, including the puborectalis and levator ani muscles. The puborectalis is a sling muscle that anchors anteriorly to the symphysis pubis and loops around the rectum. Normal resting tone is responsible for preserving the approximately 90° angle between the rectum and anal canal. The puborectalis can be voluntarily contracted to further pinch off the rectum from the anal canal and prevent accidental passage of formed stool. The levator ani muscles can also be voluntarily contracted to pinch off the rectum from the anal canal. Injuries to the innervation of the puborectalis and levator ani are less common during childbirth than are injuries to the nerves supplying the external anal canal, and for this reason, surgeons often plicate these muscles to improve continence following obstetrical injuries to the external anal sphincter.

External Anal Sphincter

The external anal sphincter is a striated muscle surrounding the anal canal; it has no bony attachments and functions like a purse-string to close off the anal canal with voluntary effort. It is believed to be more effective than the puborectalis for preventing liquid and gas incontinence. Injuries to the external anal sphincter or its innervation are commonly associated with childbirth and increase the risk of incontinence.

Internal Anal Sphincter

The internal anal sphincter is a smooth muscle sphincter that normally stays closed to maintain anal canal pressure higher than rectal pressure. It is not under voluntary control and serves as a passive barrier to leakage of liquid and gas. The most common injury to the anal canal is an obstetrical tear, but decreases in internal anal sphincter tone may also occur for unknown reasons and may compromise continence.

DIAGNOSTIC ASSESSMENT

Medical History

A patient's medical history should include responses to questions about (1) typical bowel habits (diarrhea or constipation), (2) surgical and obstetrical history, (3) other medical conditions such as diabetes mellitus, inflammatory bowel disease, hemorrhoids, or irritable bowel syndrome, (4) volume and type of stool lost, and (5) circumstances in which incontinence occurs.

Necessary Tests

Anal canal ultrasound is the gold standard for assessing the structural integrity of the internal and external anal sphincters. In addition, anorectal manometry should be used to assess anal canal squeeze pressure, anal canal resting pressure, rectal sensation, and compliance of the rectum.

Optional Tests

Pudendal nerve motor latencies are a measure of the time elapsed between electrical stimulation of the pudendal nerve and contraction of the external anal sphincter. This is a relatively specific method of detecting pudendal nerve injuries, but it lacks sensitivity. Needle electromyographic (EMG) activity can detect subtle nerve injuries that may be missed by functional tests such as anorectal manometry. Surface EMG activity detected by perianal or intraanal electrodes may be useful for detecting nerve injuries and for biofeedback training.

TREATMENT

Medical Treatment

Antidiarrheal agents such as loperamide are used when incontinence is caused or exacerbated by diarrhea. Laxatives may be used in patients with overflow incontinence secondary to constipation with fecal impaction.

Biofeedback

This is a behavioral treatment in which patients are taught to improve anal canal squeeze pressures and/or rectal sensory thresholds with the help of electronic devices that amplify and display small contractions of pelvic floor muscles. This is often considered the second line of treatment (after medical therapy) because it involves minimal risk. Published reviews indicate that biofeedback benefits approximately 75% of patients, including approximately 50% who become completely continent and another 25% who have fewer accidents. However, randomized controlled trials are lacking.

Surgery

A variety of surgical techniques have been described for the repair of separated or damaged sphincters. The simplest is to identify the separated ends of the internal and/or external anal sphincter, juxtapose or overlap them, and suture them together. This may be combined with plication of the levator ani muscles or the puborectalis muscles. The success rate is approximately 68% at 1 year. When sphincteroplasty is not practical because the sphincter damage is too extensive or the sphincter is denervated, a flap of gracilis or gluteal muscle may be transposed to create a new sphincter. The transposed muscle may be electrically stimulated to maintain it in a contracted state until defecation is desired. In a multicenter randomized controlled trial of gracilis transfer surgery, 85% of patients reported initial improvement and 66% maintained this improvement for 2 years.

Less Commonly Employed Treatments

Artificial sphincters similar to those used for the treatment of urinary incontinence are reported to be successful in small series of patients. Electrical stimulation of the sacral nerve roots with implantable stimulators is also employed but is still regarded as experimental. Antegrade colonic enemas administered through a cecal conduit have been used successfully to

treat fecal incontinence in children with spina bifida, and may find application in older patients.

cytokine Nonantibody proteins secreted by multiple cell types that act as intercellular mediators.
extracellular matrix Array of macromolecules constituting the scaffolding for maintenance of liver architecture.
polymorphism Germ-line sequence alteration present in at least 1% of the population.

The fibrotic response, which underlies all the complications of end-stage liver disease, is deleterious both by its effects on cellular function (synthetic dysfunction, impaired metabolic activity, and encephalopathy) and by its mechanical contribution to increased portal resistance (ascites and variceal bleeding). Therefore, therapies that are able to retard and reverse the fibrotic response will have a dramatic impact on the treatment of patients with chronic liver disease. This article will review the current understanding of the cellular basis of hepatic fibrosis and how these insights are leading to advances in the diagnosis and treatment of chronic liver disease.

INTRODUCTION

Hepatic fibrosis is a reversible wound healing response characterized by the accumulation of extracellular matrix or "scar" that occurs in almost all patients with chronic liver injury. Ultimately, hepatic fibrosis leads to cirrhosis, characterized by nodule formation and organ contraction. The causes of cirrhosis are multiple and include congenital, metabolic, inflammatory, and toxic liver disease (Table I).

EXTRACELLULAR MATRIX COMPOSITION IN NORMAL LIVER AND HEPATIC SCAR

Extracellular matrix (ECM) refers to the array of macromolecules constituting the scaffolding of normal and fibrotic liver. The components of hepatic extracellular matrix include several families of structural and supporting molecules: collagens, noncollagen glycoproteins, matrix-bound growth factors, glycosaminoglycans, proteoglycans, and matricellular proteins.

In the normal liver, so-called "fibril-forming" collagens (types I, III, V, and XI) are largely confined to the capsule, around large vessels, and in the portal triad, with only scattered fibrils containing types I and III collagen in the subendothelial space. Smaller amounts of other collagens (including types VI, XIV, and XVIII), glycoproteins, matricellular proteins, and proteoglycans (consisting primarily of heparan sulfate) are also present.

With progressive fibrosis, there is both a quantitative and qualitative shift in the matrix composition compared to normals and these changes are similar regardless of the type of liver injury. Total collagen content increases 3- to 10-fold, although the collagen itself is not "abnormal" in sequence or structure. Overall, there is a marked increase in "interstitial matrix" typical of the healing wound, which includes fibril-forming collagens (types I, III, and V) and some non-fibril-forming collagens (types IV and VI), several glycoproteins, as well as a large number of proteoglycans and glycosaminoglycans. In particular, there is a shift from proteoglycans containing heparan sulfate to those containing chondroitin and dermatan sulfates. This shift in ECM in turn contributes to the loss of hepatocyte microvilli and sinusoidal endothelial fenestrae, which results in deterioration of hepatic function (Fig. 1).

STELLATE CELL ACTIVATION: THE CENTRAL EVENT IN HEPATIC FIBROSIS

The hepatic stellate cell (previously called lipocyte, Ito, fat-storing, or perisinusoidal cell) is the primary source of the extracellular matrix in normal and fibrotic liver. Hepatic stellate cells are resident perisinusoidal cells in the subendothelial space between hepatocytes and sinusoidal endothelial cells. They are the primary site for storing retinoids and therefore can be recognized by their vitamin A autofluorescence. In addition, their perisinusoidal orientation and expression of the cytoskeletal proteins desmin and glial acidic fibrillary protein allow for their *in situ* identification.

Studies in both animals and humans with progressive injury have defined a gradient of changes within stellate cells that collectively are termed "activation" (Fig. 2). Stellate cell activation refers to the transition from a quiescent vitamin A-rich cell to a highly fibrogenic cell characterized morphologically by enlargement of rough endoplasmic reticulum, diminution of vitamin A droplets, ruffled nuclear membrane, appearance of contractile filaments, and proliferation. Proliferation of stellate cells generally occurs in regions of greatest injury, which is typically preceded by an influx of inflammatory cells and is associated with subsequent extracellular matrix accumulation.

Stellate cell activation, the central event in hepatic fibrosis, is thought to occur in two stages: initiation and perpetuation. Initiation refers to early events encompassing rapid changes in gene expression and phenotype that render the cells responsive to cytokines and other stimuli. It results from paracrine stimulation due to rapid, disruptive effects of liver injury on the homeostasis of neighboring cells and from early changes in ECM composition. Perpetuation incorporates those cellular events that amplify the activated phenotype through enhanced cytokine expression and responsiveness and involves at least seven discrete changes in cell

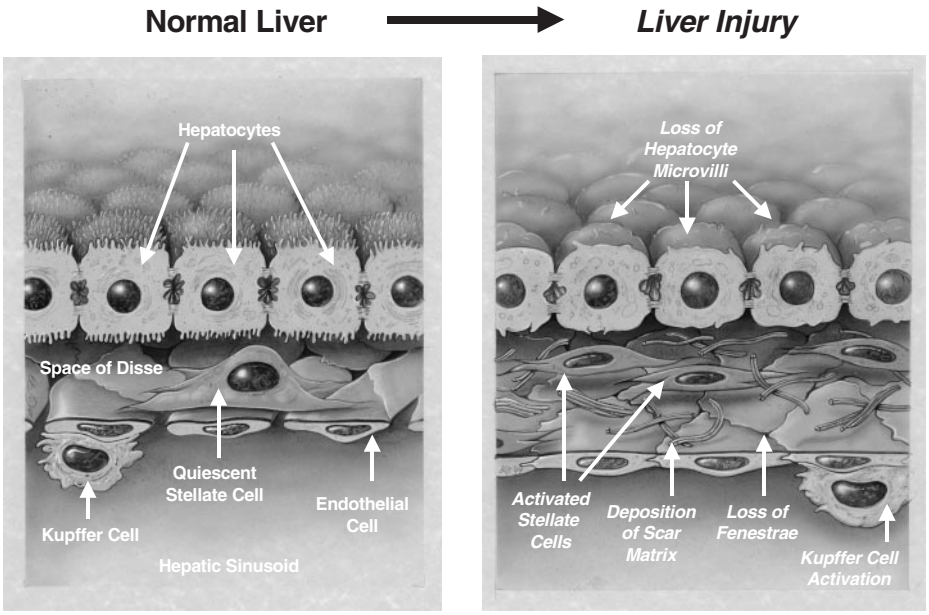

FIGURE 1 Matrix and cellular alterations in hepatic fibrosis. Changes in the subendothelial space of Disse and sinusoid as fibrosis develops in response to liver injury include alterations in both cellular responses and extracellular matrix composition. Stellate cell activation leads to the accumulation of scar (fibril-forming) matrix. This in turn contributes to the loss of hepatocyte microvilli and sinusoidal endothelial fenestrae, which result in the deterioration of hepatic function. Kupffer cell (macrophage) activation accompanies liver injury and contributes to paracrine activation of stellate cells. Reprinted from Friedman (2000), with permission of The American Society for Biochemistry and Molecular Biology.

behavior: (1) proliferation; (2) chemotaxis; (3) fibrogenesis; (4) contractility; (5) matrix degradation; (6) retinoid loss; and (7) white blood cell chemoattractant and cytokine release. Either directly or indirectly, the net effect of these changes is the accumulation of extracellular matrix.

CLINICAL ASPECTS OF HEPATIC FIBROSIS

Fibrosis Progression and Reversibility

The rate of progression of fibrosis in an individual patient with chronic liver disease cannot be predicted with certainty. However, some general rules apply:

1. Fibrosis usually requires at least several months to years of ongoing insult;
2. Severity of inflammation and injury usually correlate with rate of progression;
3. Concurrent hepatic insult by more than one agent is synergistic for the progression of fibrosis;
4. The exact moment at which fibrosis becomes irreversible is not known;
5. Host genotype is an intrinsic determinant of fibrosis.

Diagnosis and Assessment of Hepatic Fibrosis

Accurate assessment of the extent of fibrosis is essential to guide management and predict prognosis in patients with chronic liver injury. Histologic assessment of a liver biopsy specimen remains the "gold standard" for quantifying fibrosis, with increasing interest in the use of noninvasive markers to allow more frequent sampling and avoid the risks of percutaneous biopsy.

Histologic and Morphometric Methods

Several semiquantitative morphologic methods that evaluate extracellular matrix in biopsy specimens stained with either hematoxylin and eosin or connective tissue stains such as Masson's Trichrome, reticulin silver impregnation, or Van Gieson have been described. These methods can be prone to sampling error if the fibrosis is not uniformly distributed. Semiquantitative methods include the Knodell-Ishak score, the French Metavir system, and others. The systems correlate well with one another and employ a 4- to 6-point scale that grades fibrosis based on its distribution and amount. Standard methods may be complemented by more accurate morphometric approaches using image analysis,

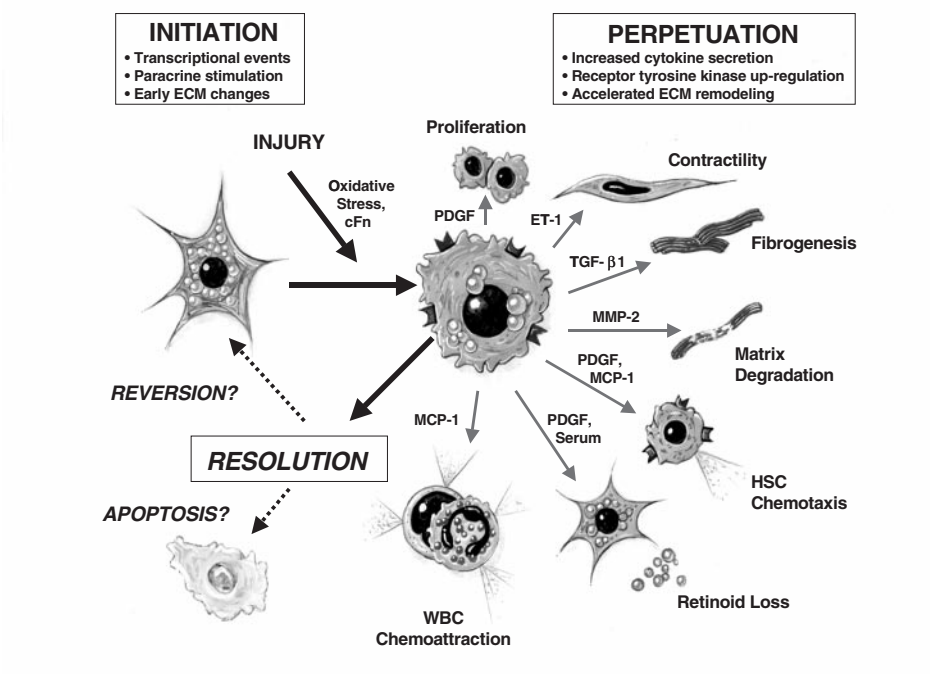

FIGURE 2 Phenotypic features of hepatic stellate cell activation during liver injury and resolution. Following liver injury, hepatic stellate cells undergo "activation," which connotes a transition from quiescent vitamin A-rich cells into proliferative, fibrogenic, and contractile myofibroblasts. The major phenotypic changes after activation include proliferation, contractility, fibrogenesis, matrix degradation, chemotaxis, retinoid loss, and white blood cell (WBC) chemoattraction. Key mediators underlying these effects are shown. The fate of activated stellate cells during resolution of liver injury is uncertain but may include reversion to a quiescent phenotype and/or selective clearance by apoptosis. PDGF, platelet-derived growth factor; MCP-1, monocyte chemoattractant protein-1. Reprinted from Friedman (2000), with permission of The American Society for Biochemistry and Molecular Biology.

in which tissue is stained with picrosirius red, which binds type I collagen.

Noninvasive Methods

There has been considerable effort to identify serum markers as noninvasive measures of hepatic fibrosis. Although their accuracy and predictive value are improving, they cannot yet supplant direct analysis of liver. Several classes of molecules can be measured in serum: (1) enzymes involved in extracellular matrix production or modification (lysyl oxidase or prolyl hydroxylase); (2) matrix molecules (hyaluronic acid, types IV and VI collagen, or laminin); (3) components of matrix molecules that are cleaved off before incorporation of the parent molecule into the fibrotic bundle (carboxy-terminal propeptide of type I collagen); (4) fibrogenic or proliferative cytokines (transforming growth factor-β1 or fibroblast growth factor); and (5) enzymes involved in matrix degradation (MMP-2, TIMP-1, and TIMP-2). Thus far, no single test has emerged as the perfect marker of fibrosis, although it remains possible that a battery of tests used together may prove useful.

Several caveats must be overcome for serum markers of fibrosis to become useful: (1) they typically reflect the rate of matrix turnover, not deposition, and thus tend to be more elevated when there is high inflammatory activity. Conversely, extensive matrix deposition can go undetected if there is minimal inflammation. (2) None of the molecules are liver-specific, so that concurrent sites of inflammation may contribute to serum levels. (3) Serum levels are affected by clearance rates that may be impaired due to either sinusoidal endothelial cell dysfunction or impaired biliary excretion.

In summary, there remains a compelling need for noninvasive markers that accurately reflect the matrix content of tissue and have better prognostic accuracy than standard clinical and laboratory indices such as the

Child-Pugh or MELD classification. Such markers will be invaluable as anti-fibrotic therapies undergo clinical trials in the coming years.

THERAPY OF HEPATIC FIBROSIS

The improved understanding of mechanisms underlying hepatic fibrosis makes effective anti-fibrotic therapy an emerging reality. Treatment will remain a challenging task, however, and thus far no drugs have been approved as anti-fibrotic agents in humans. Therapies will need to be well tolerated over decades, demonstrate liver-specific targeting, and have limited adverse effects on other tissues. Putative agents must have direct anti-fibrotic effects rather than indirect effects by abrogating the injury and must be effective in reversing already established liver disease, which more accurately mimics the clinical scenario in which they would be utilized. Given the long natural history of the fibrotic response and the fact that it is the scarring, not the injury, that usually leads to liver failure, anti-fibrotic therapies capable of even slowing the progression of the fibrotic response could lead to a dramatic improvement in morbidity and mortality from chronic liver disease. The paradigm of stellate cell activation provides an important framework to define sites of anti-fibrotic therapy. These include the following: (1) cure the primary disease to prevent injury; (2) reduce inflammation or the host response in order to avoid stimulating stellate cell activation; (3) directly down-regulate stellate cell activation; (4) neutralize proliferative, fibrogenic, contractile, and/or pro-inflammatory responses of stellate cells; (5) stimulate apoptosis of stellate cells; and (6) increase the degradation of scar matrix, by stimulating cells that produce matrix proteases, by down-regulating their inhibitors, or by directly administering matrix proteases.

FUTURE PROSPECTS

Continued progress can be anticipated in the molecular regulation of fibrosis and its treatment. Rapid advances in gene therapy, tissue-specific targeting, and high-throughput small-molecule screening of cytokine inhibitors are likely to benefit diagnosis and therapy of hepatic fibrosis. Methods have been developed for stellate cell-specific targeting in animal models, which could lead to successful targeting to minimize toxicity of anti-fibrotics, and for use as novel diagnostics. New insights into the regulation of growth and apoptosis could have direct implications for stellate cell behavior in liver injury. Sequencing of the human genome and use of microarrays may yield genetic polymorphisms that predict the rate of fibrosis prospectively and patterns of multigene expression that have clinical or therapeutic implications. Additionally, there is tremendous interest in herbal and natural anti-fibrotic remedies, particularly in the Far East, where many such compounds are undergoing clinical trials. Future therapies may emerge from these efforts as well.

Fistula

THOMAS E. CLANCY AND DAVID B. LAUTZ
Brigham and Women's Hospital, Boston

fistula An abnormal connection between two epithelialized surfaces, such as two hollow viscera or one hollow viscera and the skin ("enterocutaneous fistula").

A fistula is most accurately described as an abnormal connection between two epithelialized organs or between an epithelialized organ and the skin. This article will discuss gastrointestinal fistulas only—those involving some portion of the alimentary tract. Although congenital causes of fistula exist, the majority are acquired. Furthermore, the majority of acquired fistulae are a complication of some surgical or endoscopic manipulation of the stomach or intestine. Drainage of intestinal contents through the fistula tract typically leads to severe metabolic and nutritional abnormalities, as well as local and systemic sepsis. Historical reports from the 1960s cite a mortality of approximately 40% from gastrointestinal fistulas. With improved management of the multiple nutritional and metabolic derangements of these patients and with improved control of sepsis, mortality is significantly decreased but still remains substantial. Today mortality ranges from 5 to 20%, depending on anatomic location of the individual fistula studied and etiology. Management of patients with gastrointestinal fistulas has evolved to emphasize metabolic resuscitation, nutritional support, and control of infection. This supportive, nonoperative approach can be prolonged. In most cases, surgical intervention is reserved for control of overwhelming contamination or for the failure of a long period of conservative management. With this algorithm, the vast majority of fistulas will close without an operation. Notable exceptions include fistulas involving a malignancy or complete disruption of intestinal continuity.

CLASSIFICATION OF FISTULAS

Fistulae are most commonly classified according to their anatomic localization. The general term "enterocutaneous fistula" usually refers to a fistula between the small intestine and the skin. Less common are gastric and duodenal fistulas, colocutaneous fistulas, pancreatic fistulas, and colonic fistulas. Anatomic localization is usually derived from a combination of plain contrast films (fistulogram) and computed tomography (CT). Anatomic information is further combined with etiologic information to characterize fistulas as simple acquired postoperative fistulas or as spontaneous fistulas, such as those linked to radiation therapy, inflammation, or malignancy.

Enterocutaneous fistulae are typically described as "low-output" if daily output from the cutaneous fistula is less than <200 cc per 24 h. Similarly, "high-output" fistulas are those with >500 cc output per 24 h. The link between output and prognosis is not accepted by all clinicians, although many feel that site-for-site, high-output fistulas are associated with increased mortality and decreased chance of successful spontaneous closure.

Less common than the external fistulas described above are "internal" fistulas between two viscera, such as enteroenteric (i.e., between two portions of the intestine) or enterovesical (between the intestine and the bladder). Internal fistulas are more difficult to recognize and have a far lower rate of spontaneous closure.

GENERAL MANAGEMENT OF FISTULAS

Stabilization

Fluids and Electrolytes

The most important aspect of the initial management of the patient with a gastrointestinal (GI) fistula is the recognition and treatment of existing metabolic abnormalities. Loss of enteric contents through the fistula leads to dehydration, significant electrolyte abnormalities, and often acidosis (although patients with gastric fistulas can be alkalotic). Intravenous access and resuscitation with isotonic crystalloid solution is the mainstay, with invasive hemodynamic monitoring as indicated. Oral intake generally increases flow through the GI tract and thus output from an enterocutaneous fistula, so it is typically withheld. The endpoint for fluid resuscitation should be the correction of electrolyte and acid–base derangements.

Nutrition

A significant number of patients with gastrointestinal fistulas present with malnutrition. In malnourished

 Copyright 2004, Elsevier (USA). All rights reserved.

patients, it is well recognized that complications and mortality are increased and chances of spontaneous fistula closure are decreased. Malnutrition is particularly common in high-output small bowel fistulas. As noted above, oral intake must be withheld to avoid stimulating further fluid, electrolytes, and protein. Enteral nutrition is occasionally appropriate for low-output fistulas from the distal intestinal tract in which adequate absorption may be obtained or with proximal fistulas with distal feeding via a jejunostomy. Thus, most GI fistula patients require some form of parenteral nutrition.

All patients with GI fistulas must undergo early assessment of nutritional status. Common methods include determination of nitrogen balance, laboratory data including albumin and prealbumin, and sometimes indirect calorimetry. An estimation of baseline required kilocalories can be obtained using the Harris-Benedict equation. Of note, energy requirements are increased in the setting of stress, and fistula patients need to receive up to 1.5 times their basal estimated energy expenditure in order to achieve positive nitrogen balance. It is appropriate in the nonseptic patient to obtain a form of central intravenous access that will allow the patient to receive weeks to months of parenteral nutrition.

Control of Sepsis

Loss of intestinal continuity is followed by localized infection that involved adjacent structures and subsequently drainage of an infected focus in the form of a fistula. Infection may remain localized, but may also evolve into generalized infection with peritonitis or sepsis. Sepsis control involves evacuation and washout of grossly contaminated debris. Inability to control infection remains a major cause of morbidity and mortality from GI fistulas. Without control of infection, successful resolution of fistulas is very rare. Identification and localization of a septic focus are crucial and CT scan is the best way to visualize intra-abdominal collections. For stable patients, attempted percutaneous drainage of an abscess under radiographic guidance is a reasonable fist step in management. The purpose of these percutaneous drains is to create a controlled fistula whereby output can be quantified, skin can be protected, and infection can be drained.

Early operative drainage is typically reserved for worsening infection. Aggressive intervention is not without risks, due to significant intra-abdominal inflammation and associated early adhesions. Particular indications for early operative management include the presence of multiple collections, an open anastamosis, incompletely drained fluid collections, or extensive cellulitis. Drains should be placed next to the fistula whenever possible.

Skin Care

External leakage of enteric fluids can lead to significant breakdown in skin integrity. Multiple strategies exist to reduce skin exposure to toxic intestinal contents, including the use of ostomy appliances, liberal use of powders and creams, consultation with an enterostomal therapist or wound expert, and the use of histamine receptor blockers. High-output fistulas often require the use of ostomy appliances for adequate control of effluent. Skin breakdown will complicate abdominal wall closure and interferes significantly with patient satisfaction.

Investigation/Localization of Fistula

The most useful initial radiographic study is the CT scan. CT allows preliminary information on anatomic localization to be acquired, but more importantly allows an assessment of local gastrointestinal spillage in the abdominal cavity and the need for operative or percutaneous drainage. Water-soluble oral contrast is most helpful and barium should be avoided due to the severe peritoneal inflammation it causes.

Additional gastrointestinal contrast studies are useful for further management once the patient has been stabilized. A "fistulogram" can be obtained by directly injecting water-soluble contrast into the fistula orifice. Small bowel follow-through or contrast enemas may be indicated as well. Precise anatomic localization of the fistula should be performed prior to any operative intervention if at all possible.

Definitive Management

Nonoperative Management

Factors associated with successful nonoperative management With adequate control of infection, as well as nutritional and metabolic support, most (approximately 90%) of gastrointestinal fistulas will close without operative management. A number of factors are associated with high spontaneous closure rate. Colonic and pancreatic fistulas commonly heal without operation. Fistulas that are acute, have a long fistula tract, have no distal obstruction, and have low output are more likely to heal spontaneously. Well-nourished patients also have greater success with nonoperative management.

Factors associated with nonhealing fistulas Fistulas arising in an area of previously irradiated tissue

or in the presence of ongoing infection will rarely close. Those fistula involving actively diseased bowel, such as those involving a malignancy or inflammatory bowel disease are also less likely to close. Likewise, a fistulogram showing interruption of bowel continuity suggests that spontaneous closure is unlikely. Local mechanical factors such as a foreign body or distal obstruction also promote nonhealing. Finally, chronicity of a fistula and epithelialization of the fistula tract are associated with decreased spontaneous closure.

Operative Management

With infection controlled, most fistulas should close in 4–6 weeks, so surgical closure is generally not recommended until at least 6–8 weeks after the onset of the fistula. Earlier operative intervention should be limited to control of infection and fecal diversion, if indicated. Early operation is associated with iatrogenic bowel injury and it is best to wait until acute inflammation has decreased in the operative field. Delayed operative management should involve meticulous sharp dissection and resection of the involved segment of bowel with primary anastamosis.

SITE-SPECIFIC ISSUES FOR FISTULAS

Small Bowel

The small intestine is the source of most of what are commonly referred to as "enterocutaneous fistulas" and most of the above principles apply here. Most fistulas are iatrogenic and postoperative; of these, approximately one-half are due to anastamotic leak and one-half are due to unrecognized bowel injury at the time of laparotomy. Approximately one-fifth of small intestinal fistulas are spontaneous, involving inflammatory bowel disease, radiation, or malignancy. Those due to radiation or malignancy are particularly unlikely to heal with conservative management.

Stomach/Duodenum

These represent a small proportion of GI fistulas and the vast majority are postsurgical. Duodenal fistulas have a high rate of spontaneous closure. Gastric fistulae, however, are less likely to close spontaneously, possibly due to the high percentage associated with ongoing disease such as malignancy. Histamine receptor blockers are particularly helpful in decreasing output and promoting closure although somatostatin analogues have not had similar success.

Colon/Rectum

Postoperative colonic fistulas have a high rate of spontaneous closure. Low-output fistula often heal while the patient continues to tolerate enteral feeding. With local infection, proximal diversion of the fecal stream may be indicated. In such cases, ileostomy is preferred to transverse colostomy to avoid distal bowel ischemia.

Colovesical fistulas rarely heal without surgery and require resection of involved colon in a one-stage procedure. Diagnosis is most reliable with cystoscopy, although sigmoidoscopy is also required to rule out the presence of cancer, which would indicate an *en bloc* partial cystectomy at the time of colectomy.

Radiation-associated fistulas may present years after radiation treatment of pelvic malignancy. These are often complex and may involve multiple organs. Treatment is primarily by proximal bowel diversion, without attempts at fistula resection.

Esophagus

Postoperative esophageal fistulas after esophageal anastamoses are more common than those after anastamoses in other portions of the GI tract, with an up to 10% leak rate from these anastamoses. Esophagogram is best for diagnosis. Leaks in the mediastinum require thoracotomy and diversion to control sepsis, whereas a cervical anastamosis permits cervical drainage and nonoperative management.

Particularly troublesome are fistula between the esophagus and trachea due to malignancy. These involve persistent contamination of the respiratory tract, leading to pneumonia and sepsis. Palliation is the goal, although resection of the fistula is complicated by a high rate of morbidity and mortality. A new technique is esophageal intubation with endoscopic stents to allow swallowing while preventing aspiration.

Pancreatic

Pancreatic fistulas result from disruption of the main pancreatic duct or one of its branches after trauma, pancreatitis, pancreatic surgery, or splenectomy. Diagnosis is suspected with a peripancreatic fluid collection on CT scan and is confirmed in the external fistula with high amylase content in the effluent. Endoscopic retrograde cholagiopancreatography is useful to define ductal anatomy and to identify ductal obstruction. Bowel rest is critical to management and most of these fistulas will close with nonoperative management. Somatostatin analogues may decrease fistula output but do not affect the rate of spontaneous closure.

Flatulence

CHRISTOPHER J. MCNEILL
Veterans Affairs Medical Center, San Diego

aerophagia The swallowing of excessive amounts of air.
flatulence The passage of colonic gas from the rectum.

The discomfort and embarrassment of intestinal "gas" have been a concern of humans for thousands of years. Hippocrates authored a treatise entitled "The Winds," which reviewed various illnesses that he postulated to be related to this malady. Over 200 years ago, Benjamin Franklin, with his droll sense of humor, published the pamphlet "Fart Proudly," in which he suggested dietary changes as a cure to "escaped wind." To this day, patients continue to experience gastrointestinal symptoms that they attribute to excess intestinal gas and, although the physiology of flatulence has been better defined, medical knowledge has yet to describe a cure.

SOURCE OF COLONIC GAS

Flatulence is not by itself a marker for intestinal disease and is in fact a perfectly normal occurrence in healthy adults. Studies of gas passage by normal adults on a regular diet have shown great variability in the volume of gas passed during a 24 h period (476–1496 ml with a median of 705 ml) and similar variability in the frequency of passage (10 to 20 times per day). For the purposes of this discussion, aerophagia is not considered a significant source of flatulence and will not be considered further. There are five odorless gases that account for 99% of gas passed per rectum: nitrogen, oxygen, carbon dioxide, hydrogen, and methane. The percentage of each gas is highly variable from subject to subject: N_2 (11–92%); O_2 (0–11%); CO_2 (3–54%); H_2 (0–86%); and CH_4 (0–54%). Other gases, present only in trace amounts, are odoriferous and account for the noxious smell of flatus, which in the case of hydrogen sulfide (H_2S) can be detected by the human nose in concentrations as low as one-half part per billion! As above, the gas composition of flatus is highly variable from person to person and is the net result of bacterial fermentation of partially digested foodstuffs entering the colon and to a lesser extent the passive diffusion of gases between blood and the colonic lumen.

Many vegetables, especially legumes and most notably beans, contain nonabsorbable oligosaccharides that enter the colon and provide a tasty substrate for gas-producing bacteria. The lactose in milk and milk products likewise is inadequately absorbed in many adults due to a deficiency of the enzyme lactase (β-galactosidase), which splits this sugar into glucose and galactose in the small intestine. Of commonly ingested flours, only rice and gluten-free wheat flour are completely absorbed and thus noncontributory to gas production. Sorbitol and xylitol, found in many sugar-free gums and candies, are poorly absorbed and add to flatulence. Figure 1 shows the fate of

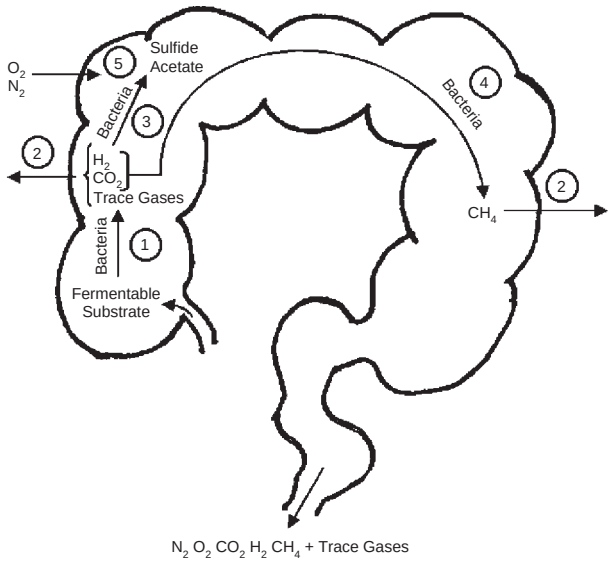

FIGURE 1 (1) In the colon, malabsorbed ingested material and mucus are fermented by bacteria that subsequently release trace gases (some of which are odoriferous), CO_2, and H_2. (2) A fraction of the bacterial gases are absorbed into the blood perfusing the colon. (3) In the right colon, H_2 is consumed by bacteria in the process of reducing sulfate to sulfide and converting CO_2 to acetate. (4) In addition, H_2 is consumed in the left colon by methanogens in the process of reducing CO_2 to CH_4. (5) N_2 and O_2 diffuse from the blood into the colonic lumen down a gradient created by the production of gas by bacteria. The net result of all of the aforementioned processes determines the composition and rate of excretion of gas per rectum. Adapted from Strocchi and Levitt, with permission.

these nonabsorbable fermentable substrates when they meet up with billions of hungry anaerobic bacteria in the colon. It is noteworthy that production of odorless methane gas seems limited to only one-third of adults and, when present in sufficient quantities, leads to stools that float. The combustibility of both methane and hydrogen can have explosive consequences for the immature individual who attempts to ignite his flatus.

THERAPEUTIC INTERVENTIONS

Treatable gastrointestinal pathology such as bacterial overgrowth, chronic exocrine pancreatic insufficiency, celiac disease, parasitic infestations, especially *Giardia lamblia*, or other causes of maldigestion and malabsorption should be identified and managed first. In general, pharmacological interventions with anticholinergics, activated charcoal, simethicone, probiotics, and antibiotics have proved ineffective. The mainstay of therapy has been the elimination of common offending flatugenic foods such as milk or milk products, beans, and sugar-free gums and candies. Commercially available β-D-galactosidase (LactAid drops) may be used to prophylactically treat milk or be ingested at mealtimes in lactase-deficient individuals to normalize lactose absorption. Soaking beans for up to 12 h and discarding the water before cooking or the use of α-D-galactosidase (Beano) at mealtime will enhance digestion and reduce the flatulence associated with the ingestion of beans. The selective avoidance of many other fruits and vegetables that are cited as problematic such as apricots, bananas, bell peppers, broccoli, Brussels sprouts, cabbage, carrots, celery, corn, onions, prunes, and raisins may also be helpful. Sulfur-rich foods such as eggs and cauliflower are notorious for promoting bacterial H_2S production and malodorous flatulence. Cooking or consuming products with rice or gluten-free wheat flour, which are well absorbed, will lessen gas production in the colon. In the end, if all else fails, walking briskly around will disperse the sounds and smells of flatulence and avoid the embarrassment of detection.

Folate Deficiency

JUDITH K. SHABERT
Harvard Medical School

meningocele/meningomelocele Failure of closure of the spinal cord in the lower back that results in a protrusion of skin containing spinal tissue.
neural tube defect Congenital defect of the neural tissue affecting the spinal cord, spine, brain, and skull, resulting in miscarriage, fetal or neonatal death, or disability.
vitamer Active analogue and isomer of a vitamin.
vitamin Organic substances necessary in minute quantities to maintain normal metabolism, usually working as cofactors by regulating biochemical processes.

Folate, or pteroylglutamate, is a member of a family of naturally occurring compounds that serve as essential vitamins in the normal metabolism of animals and humans. Folic acid, or pteroylglutamic acid, is the synthetically derived form of folate that is included in nutritional supplements and enriched foods; its absorption is about 50% more efficient than the 100 or so vitamers (e.g., folate compounds) that occur naturally in foods, particularly in leafy vegetables such as spinach.

BIOCHEMICAL PHYSIOLOGY

Absorption

Naturally occurring folate in food is present in the polyglutamate forms and its absorption is dependent on enzymatic deconjugation on the brush border of the jejunum to produce folyl monoglutamate. Folate-binding proteins sequester folate and it is transported across the membrane through an active transport process. When intake of the vitamin exceeds active transport mechanisms, it passively diffuses across the cell membrane.

The 5-methyltetrahydromonoglutamyl form of folate is the most abundant folate in the blood. However, it must be demethylated to tetrahydromonoglutamate for cellular assimilation. It undergoes polyglutamation in a series of steps that require one molecule of ATP for the addition of each glutamate. The polyglutamyl form represents both the functional and the storage forms of folate, with over one-half of the vitamin stores found in the liver.

Biochemical Role in Methylation

The primary function of folate is to serve as a cofactor for enzymatic reactions involving the transfer of single carbons. Folic acid is essential as a one-carbon donor (a methyl donor) and is required for the *de novo* synthesis of DNA and RNA by transferring a one-carbon unit for purine and thymidylate synthesis. Folate is also required for the *de novo* synthesis of the amino acids choline, serine, and methionine.

Folate and vitamins B_6 and B_{12} are necessary for one-carbon metabolism that synthesizes methionine from homocysteine and produce *S*-adenosylmethionine (SAM), the universal methyl donor. A deficiency of B_{12} produces an excess of 5-methyltetrahydrofolate, creating a functional folate deficiency known as the "methylfolate trap."

GENETICS

Several hereditary enzymatic defects have been reported related to the regeneration of methionine from homocysteine, which can result in elevated blood and urine concentrations of homocysteine. The homozygous state for defects in cystathionine synthase and methionine synthase results in a characteristic syndrome of mental retardation, detached lens of the eyes, osteoporosis, and severe atherosclerotic and/or thromboembolic events, resulting in premature death.

A more common defect substitutes a thymidine for cytosine on the gene that produces 5,10-methylenetetrahydrofolate reductase (MTHFR), an enzyme essential for the activation of folate. This defect (C677T mutation) results in the substitution of the amino acid valine for alanine in the protein, which greatly reduces the activity of the enzyme, resulting in a folic acid-deficient state. The homozygotic form occurs in approximately 12% of the North American population. Approximately 25% of the population is heterozygous for this gene mutation. In general, this enzymatic defect can be overcome by the administration of increased quantities of folic acid (see Fig. 1).

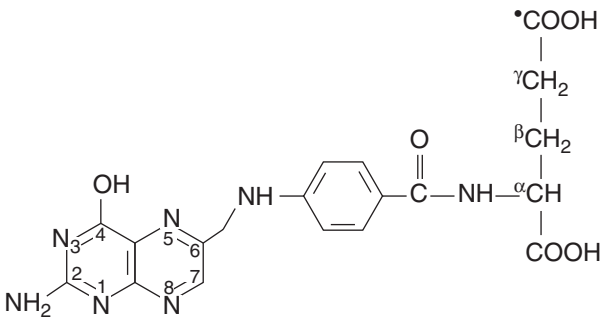

FIGURE 1 Folic acid.

REQUIREMENTS

The Dietary Reference Intake (DRI) established in 1998 for folate for children and adults recommends nearly double the recommendations established for folate in 1989. The recommendation for infants ranges from 65 to 80 μg/day. Children aged 1 to 13 years old require 150−300 μg/day, depending on their age. The folate recommendation for adult men and women is 400 μg/day; for pregnant women, the recommended intake is 600 μg/day, decreasing during lactation to 500 μg/day. This recommendation for an increased intake of folate was a result of extensive research that established the role of folate in the prevention of neural tube defects. Thus, it is recommended that all females who could become pregnant consume 400 μg/day of synthetic folic acid in addition to the amount of folate obtained in a well-balanced diet.

Folate requirements are increased during times of rapid cell turnover and increased metabolism,such as with tissue growth, infection, and recovery from catabolic states. Alcohol consumption increases folate requirements because alcohol interferes with folate utilization. As previously noted, folate exerts it effects in conjunction with other vitamins, specifically B_6 and B_{12}. Thus, the requirement for folate is predicated on satisfying requirements for these other nutritional factors.

SOURCES

Spinach and other green leafy vegetables are rich sources of folate along with other vegetables, fruit, Brewer's yeast, legumes, and especially liver. In the American diet, the most common food from which people obtain natural folate is orange juice. Some but not all breakfast cereals are fortified with folic acid to supply the total daily value of folate (400 μg/day) per serving. Folate is heat labile and up to 90% can be destroyed during cooking.

In 1996, the United States Food and Drug Administration mandated that, beginning in January of 1998, enriched cereal grain products, including wheat flour, pasta, breads, corn meal, and rice, be fortified with folic acid. Each 100 g of cereal grain is supplemented with 140 μg of folic acid. This mandate was instituted to increase folate consumption in women of childbearing age and thereby reduce the risk of having a pregnancy affected by neural tube birth defect.

DEFICIENCIES

It is estimated that at least 10% of the United States population has low folate stores, and this estimate may increase to 50% in disadvantaged populations. Deficiency can result from increased requirements, from decreased intake, from poor utilization, and from a functional folate deficiency associated with a deficiency of vitamin B_{12}.

Some anticonvulsant medication (dilantin, phenytoin, carbamazepine, and diphenylhydantoin), oral contraceptives, some antibiotics (trimethoprim, and triamterene), and excessive alcohol intake may also cause folate insufficiency. Due to the increased requirements of DNA and RNA for cell division, states of folate deficiency are most obvious in tissues with rapid cell turnover: hematopoietic cells, the gastrointestinal tract, the dermis, and germinal cells.

Hematopoietic System

Folate deficiency causes anemia, and stages of folate inadequacy are most evident in the hematopoietic system. Stage I (negative folate balance) is manifest with lowered plasma or serum folate <3ng/ml. In stage II folate deficiency, the red blood cell level is <160 ng/ml. Hypersegmented granulocytes (>3.5 lobes/cell) are seen with stage III folate deficiency. Stage IV deficiency is manifest by a full-blown anemia, with a hemoglobin level of <10 g/dl and macrocytic red blood cells.

Pregnancy

Approximately 4000 pregnancies are affected by neural tube defects (NTDs) annually in the United States. The major types of NTDs are anencephaly and spinal bifida. Half of all cases of NTDs produce anencephaly, which results in spontaneous abortion, fetal demise, or newborn death. Spina bifida affects cases of NTDs, with 10% of infants born with meningocele and 90% born with myelomeningocele.

Adequate folate intake in early pregnancy could prevent 40−70% of NTDs. The neural tube is formed between 17 and 30 days postconception (4−6 weeks

after the last menstrual period). Because approximately one-half of all pregnancies in the United States are unplanned, the U.S. Public Health Service recommended in 1992 that all women of childbearing age consume 400 μg/day of folic acid, even if pregnancy is not planned. The Food and Nutrition Board of the Institute of Medicine recognized that synthetic folic acid is more easily absorbed than folate from food, and in 1989 they recommended that 400 μg/day of synthetic folic acid be consumed by all women capable of becoming pregnant.

Despite the recommendation that women of childbearing age consume 400 μg/day of folic acid, a 1998 Gallop poll survey of women of childbearing age demonstrated that only 13% knew that folic acid reduces the risk for NTDs and only 7% knew that folic acid should be taken before conception; less than one-third of the women in this survey took folic acid on a regular basis.

The prevalence of NTDs in the United States has declined by 19% since mandatory fortification of cereal grain products was implemented in 1998.

Cardiovascular Disease

The association of hyperhomocysteinemia and atherosclerotic vascular disease was proposed in 1969. It is now accepted that hyperhomocysteinemia is a modifiable, independent risk factor for coronary artery disease (CAD) and peripheral vascular disease.

Adults with elevated blood homocysteine are 30% more likely to have premature vascular disease, compared to individuals with concentrations of <10 μmol/liter. In the Framingham Study, CAD and hyperhomocysteinemia showed an inverse correlation with serum folate concentration. Hyperhomocysteinemia has both genetic and nongenetic influences. Individuals who are homozygous for MTHFR and have low serum folate concentrations are at highest risk for elevated blood homocysteine. In experimental animals, elevated homocysteine levels cause an increase in coagulation of the blood and may produce a deleterious effect on the vascular endothelium.

The adverse effect of homocysteine on vessels appears to be a graded response. In patients with CAD, the risk of death 4–5 years after diagnosis is proportional to plasma homocysteine levels. Research has demonstrated a reduction of serum homocysteine in populations who receive folate and vitamins B_{12} and B_6. Despite these associations, no double-blind placebo controlled trial has demonstrated that the provision of folate, B_6, and B_{12} reduces the risk of atherosclerotic vascular disease, and the American Heart Association does not endorse the use of these vitamin supplements to treat elevated homocysteine.

Colon Cancer

Folate inadequacy has been implicated in the development of cancer, especially cancer of the colon. Folate supplementation above what is presently considered to be the basal requirement may have a protective effect. A 20-year epidemiological followup study of folate status and colon cancer risk was determined from the first National Health and Nutrition Evaluation Study (NHANES I). It was demonstrated that the risk for colon cancer in men decreases in a dose–response manner as folate intake increases, especially for men who do not drink alcohol and who eat a high-methionine diet. This association was not found in women. In the Nurses Health Study, 15 years of synthetic folic acid supplementation was associated with a decreased risk of colon cancer.

Inflammatory Bowel and Celiac Disease

Patients with both types of inflammatory bowel disease (IBD)—ulcerative colitis and Crohn's disease—are at risk for nutrient deficiencies, including folic acid. Reasons for this include increased folate requirements secondary to inflammation and catabolism, decreased absorption from malabsorption and inflammation of the gastrointestinal mucosa, and the effect of drugs on folate metabolism. Both methotrexate and sulfasalazine, used to treat IBD, are folate antagonists. There are numerous case reports of anemia and macrocytosis secondary to folate deficiency in patients on these medications. It appears that there may be an increased prevalence of a MTHFR variant in patients diagnosed with IBD compared to the general population. This may also explain the increased incidence of thrombosis in patients with IBD.

Individuals with celiac disease who have not been diagnosed or those who do not follow a gluten-free diet may develop folate deficiency secondary to malabsorption.

Seizure Disorders

The majority of antiseizure drugs are folate antagonists. Hyperhomocysteinemia with depressed folate concentrations can be seen in patients on antiseizure medications and it is associated with the MTHFR polymorphism. It is recommended that folic acid be prescribed along with antiseizure medications to prevent folate deficiency, although the provision of excessive folic acid may lower the seizure threshold. For some patients, individual titration of medication and folic acid may be necessary.

Cognitive Changes

Vitamin B_{12} and to a lesser extent folic acid have been associated with dementia and impairment of cognitive function in the elderly. Elevations in plasma homocysteine with normal serum folate have been demonstrated in patients with Alzheimer's disease. Cerebral spinal fluid folate concentrations are significantly lower in patients with late-onset Alzheimer's disease compared to age-matched controls. Improvement of cognitive function has been demonstrated in elderly patients with elevated homocysteine treated with folate and B_{12}. Folate is critical in brain metabolic pathways due to its role in the synthesis of choline and in the metabolism of neurotransmitters. The prevalence of borderline low or deficient serum or red blood cell folate levels in individuals diagnosed with depression is 15–38%. There is evidence that individuals refractory to antidepressant medication have inadequate folate status as well.

Food Allergy

M. CECILIA BERIN
Mount Sinai School of Medicine, New York

anaphylaxis The term is used here specifically as systemic anaphylactic shock, affecting the cardiovascular system.

atopic A hereditary predisposition to immunoglobulin E-mediated allergic reactions against innocuous antigens (allergens).

RAST (radioallergosorbent test) Test that measures allergen-specific immunoglobulin E in the serum of patients.

skin-prick test A small needle or lancet is pressed through a commercial extract of a food into the epidermis. The presence of immunoglobulin E against the food tested results in a measurable wheal and flare reaction.

Food allergy is defined as an adverse immunologically mediated reaction to a food protein that not only can result in gastrointestinal symptoms but also can affect the skin, respiratory tract, and cardiovascular system. Food allergy can occur via different mechanisms, leading to very diverse clinical outcomes, from anaphylactic shock to enterocolitis. A limited number of foods are responsible for the majority of allergic reactions. The clinical spectrum and immune mechanisms of food allergy are discussed in this article.

INTRODUCTION

Adverse food reactions, of which food allergy is one category, can occur by toxic or nontoxic mechanisms. Toxic reactions are those that can occur in anyone, given a sufficient dose. Nontoxic reactions occur due to host factors, either by mounting an inappropriate immune response to a food protein (food allergy) or by nonimmune mechanisms, such as lactase deficiency resulting in intolerance to foods containing lactose. Thus, food allergy is only one mechanism by which adverse reactions to food can occur and refers only to those that are immunologically mediated.

Food allergies can be broadly grouped into two categories: immunoglobulin E (IgE)-mediated and

Food allergy is defined as an adverse immunologically mediated reaction to a food protein that not only can result in gastrointestinal symptoms but also can affect the skin, respiratory tract, and cardiovascular system. Food allergy can occur via different mechanisms, leading to very diverse clinical outcomes, from anaphylactic shock to enterocolitis. A limited number of foods are responsible for the majority of allergic reactions. The clinical spectrum and immune mechanisms of food allergy are discussed in this article.

INTRODUCTION

Adverse food reactions, of which food allergy is one category, can occur by toxic or nontoxic mechanisms. Toxic reactions are those that can occur in anyone, given a sufficient dose. Nontoxic reactions occur due to host factors, either by mounting an inappropriate immune response to a food protein (food allergy) or by nonimmune mechanisms, such as lactase deficiency resulting in intolerance to foods containing lactose. Thus, food allergy is only one mechanism by which adverse reactions to food can occur and refers only to those that are immunologically mediated.

Food allergies can be broadly grouped into two categories: immunoglobulin E (IgE)-mediated and

Copyright 2004, Elsevier (USA). All rights reserved.

non-IgE-mediated hypersensitivity, also referred to as cell-mediated or delayed hypersensitivity. Symptoms can affect the gastrointestinal tract (nausea, vomiting, abdominal pain, malabsorption), the skin (urticaria, atopic dermatitis), the respiratory tract (bronchospasm, rhinitis), and the systemic circulation (anaphylactic shock). Although most rapid reactions that occur within minutes to 1–2 h after ingestion of the allergen are mediated by IgE, chronic disorders affecting the gastrointestinal tract include both IgE- and non-IgE-mediated mechanisms.

EPIDEMIOLOGY

Food allergy is most common in children and in atopic individuals. Although it is common for children to outgrow their hypersensitivity to food proteins, food allergies remain a significant problem in the adult population, with an estimated prevalence of 2%. In children under 3 years of age, 8% were found to have food allergy confirmed by oral allergen challenge. Food allergens affecting the pediatric and adult populations differ, with cow's milk, egg, wheat, peanut, and soy being dominant in early childhood and peanut, tree nuts, and shellfish constituting the main allergens of concern in the adult population. Peanut and tree nut allergies in particular are not frequently outgrown, providing an explanation for their dominance as allergens in the adult population. A strong genetic component has been observed in food allergy, as with other atopic disorders.

CLINICAL SPECTRUM

The first category of food allergic syndromes includes those that are IgE-mediated and immediate in onset. These include immediate gastrointestinal hypersensitivity reactions, with nausea, diarrhea, abdominal pain, or vomiting within minutes up to 1–2 h after ingestion of the allergen. This disorder is often associated with involvement of other organ systems, including the respiratory tract, skin, or cardiovascular system. IgE-mediated immediate reactions also include oral allergy syndrome, characterized as edema and pruritis limited to the oral cavity. These latter reactions usually occur in individuals allergic to pollens and who cross-react to proteins found in certain fresh fruits and vegetables.

The second group of food allergic disorders includes those that are IgE-associated, cell-mediated, and delayed in onset. These include the eosinophilic gastroenteropathies, characterized by eosinophilic infiltration of the gastrointestinal mucosa. Symptoms include postprandial nausea, diarrhea, vomiting, and protein-losing enteropathy. Atopic dermatitis in children is another disorder frequently associated with food allergy. Oral challenge exacerbates skin symptoms and allergen elimination can improve clinical symptoms. Food-specific T lymphocytes in eczematous lesions are thought to mediate this link between food allergens and skin symptoms. IgE can play a role by facilitating antigen uptake for presentation to T cells by keratinocytes.

Non-IgE-mediated disorders affecting the gastrointestinal tract include dietary protein-induced proctitis or proctocolitis, enteropathy, and enterocolitis. These disorders affect infants and are most often associated with reactivity to cow's milk or soy in the absence of detectable IgE by skin-prick test or RAST (radioallergosorbent test). Symptoms, depending on the site of involvement, include vomiting, diarrhea, rectal bleeding, growth failure, and hypoproteinemia. Histological findings reveal eosinophilia and eosinophilic abscesses in the colon or villous atrophy in the small intestine. A switch to hydrolysate formula in formula-fed infants or maternal dietary restriction in exclusively breast-fed infants is associated with clinical improvement. Celiac disease can also be regarded as a non-IgE-mediated food protein-induced enteropathy.

DIAGNOSIS

The gold standard for diagnosis of food allergy is the double-blind, placebo-controlled, food challenge, which eliminates the bias inherent in self-reporting of adverse reactions to food. The diagnostic approach begins with a detailed history that may suggest an IgE- or non-IgE-mediated reaction based on the suspected food, timing of reactions, and organ involvement. IgE against particular allergens can be measured by skin-prick testing or RAST, which measures allergen-specific IgE in serum. An elimination diet excluding potential allergens identified by laboratory tests should abolish symptoms and a follow-up oral challenge using individual allergens is used to identify those allergens that are responsible for clinical reactivity. This is important as the presence of allergen-specific IgE does not necessarily indicate clinical reactivity. There are currently no well-validated laboratory tests available for assessing non-IgE-mediated food allergies. Endoscopy can be used to support a diagnosis of food allergy in non-IgE-mediated allergic disorders, but does not identify the allergen. A diagnostic allergen elimination diet is required to identify potential allergens in non-IgE-mediated disorders and a follow-up oral challenge is used to confirm the diagnosis.

MANAGEMENT

Currently, allergen avoidance is the only effective strategy for management of food allergy. However,

accidental ingestion is common in patients with food allergy due to inadequate ingredient labeling, contamination during the manufacturing process of foods, or the lack of appropriate ingredient information in restaurants. Food allergies are the leading cause of generalized anaphylaxis seen in hospital emergency rooms and acute severe reactions require immediate management of respiratory and cardiovascular symptoms. There are no established preventative therapies, but emerging therapies under investigation include the use of anti-IgE antibodies, immunotherapy with mutated peptides or proteins, immunostimulatory oligonucleotide sequences, probiotics, and complementary medicines such as Chinese herbs.

ALLERGENS

A small number of allergens account for the majority of food-induced allergic reactions. Typically these allergens are 10–70 kDa in size and are heat-stable glycoproteins, which may make them resistant to digestion. Many food allergens have been identified, sequenced, and cloned. These have then been used to identify IgE-binding sites on the protein. One of the goals of this area of research is the development of mutated peptides or proteins that lack IgE-binding activity, but retain T-cell immunogenicity. These could therefore be used for immunotherapy without the high risk of anaphylaxis observed in food allergic patients.

MECHANISMS OF FOOD ALLERGY

A schematic illustrating the mechanisms involved in allergen-induced gastrointestinal dysfunction is shown in Fig. 1.

Immediate IgE-Mediated Gastrointestinal Hypersensitivity

Animal models of food allergy have typically relied on a model food allergen, such as ovalbumin (OVA) from chicken egg, which when administered systemically together with adjuvants such as alum or pertussis toxin induces the production of OVA-specific IgE antibodies in mice or rats. Antigen challenge leads to increased epithelial permeability and ion secretion (a driving force for water secretion and thus diarrhea) and changes in smooth muscle function, underlying motility changes. Antigen crosses the intestinal epithelium and cross-links IgE bound to the surface of mast cells in the lamina propria, inducing the release of mast cell mediators including histamine, serotonin, and prostaglandins. These mediators can then act directly on epithelial cells and smooth muscle cells to induce the immediate

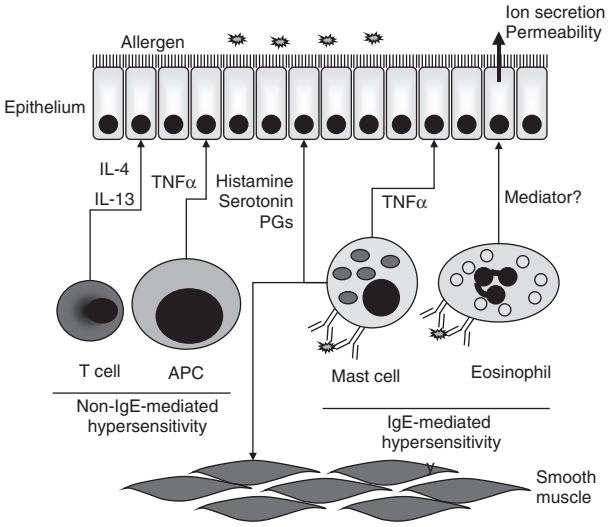

FIGURE 1 Schematic illustrating the mechanisms of allergen-induced gastrointestinal dysfunction in food allergy. Allergen present in the lumen must first cross the epithelial barrier. Interaction with IgE bound to the surface of mast cells or eosinophils can activate these cells to release mediators [histamine, serotonin, prostaglandins (PGs)] that can have an immediate action on intestinal epithelial or smooth muscle function. In addition, the release of cytokines such as TNFα from mast cells, or as yet unidentified mediators from eosinophils, can induce a late-phase reaction characterized by mucosal injury and cellular infiltration into the mucosa. Non-IgE-mediated reactions are believed to be mediated by presentation of antigen to T cells within the intestinal mucosa by antigen-presenting cells (APCs). Cytokines released by this interaction can induce chronic changes in mucosal architecture and epithelial function.

gastrointestinal symptoms observed after allergen challenge. Mast cell activation has been shown to occur in the intestine of patients with food allergy after administration of allergen directly in the duodenum.

It has been suggested that barrier function is reduced in patients with food allergy. In sensitized mice and rats, epithelial cells transport antigen from the lumen to the lamina propria by a mechanism involving IgE and its low-affinity receptor, CD23. This results in uptake of antigen in greater quantities and at a faster rate than in nonallergic animals, potentially explaining the rapid nature of intestinal hypersensitivity reactions. CD23 has also been demonstrated on human intestinal epithelial cells obtained from children with cow's milk enteropathy, suggesting that this mechanism may also play a role in human disease.

Chronic (or Late-Phase) IgE-Associated Allergic Reactions

IgE-mediated mast cell activation in animal models is associated with a late-phase reaction occurring days

after challenge, characterized by infiltration of mononuclear cells into the gastric or intestinal mucosa and mucosal damage. This infiltration of leukocytes is also commonly observed in the mucosa of patients with food allergy. Mast cells release tumor necrosis factor α (TNFα) after activation by IgE cross-linking and this has been shown to contribute to the pathological changes observed in the gastric tissue of mice after allergen challenge. TNFα is up-regulated in the mucosa of patients with food allergy, but its role in clinical symptoms has not been directly investigated in patients.

Eosinophils have also been shown to contribute to gastrointestinal pathology observed after allergen challenge in sensitized mice. Eosinophilia alone is not sufficient for gastrointestinal damage, however, suggesting that an activation step must occur. This, like mast cell activation, probably occurs via allergen/IgE triggering. The eosinophil mediators responsible for gastrointestinal damage have not yet been identified.

Non-IgE-Mediated Food Allergy

The mechanism of non-IgE-mediated reactions to food are the least understood of the gastrointestinal allergic reactions. Peripheral blood mononuclear cells isolated from milk allergic children release TNFα after stimulation with milk proteins and this has been shown to reduce epithelial barrier function *in vitro*. In addition, in children with food protein-induced enterocolitis, increased mucosal TNFα is associated with villous atrophy. TNFα is well known to play a crucial role in other inflammatory diseases such as inflammatory bowel disease or rheumatoid arthritis and it is conceivable that it plays a role in chronic gastrointestinal dysfunction in food allergy, whether from IgE-triggered mast cells or IgE-independent release from monocytes or macrophages.

T lymphocytes are thought to orchestrate allergic diseases through the production of cytokines such as interleukin-4 (IL-4) and IL-13, which contribute to IgE production, or IL-5, which influences eosinophil survival. T cells may also contribute to food allergic reactions by direct modulation of gastrointestinal physiology. Cow's milk-specific T-cell lines grown from the gastrointestinal mucosa of patients with milk-induced enteropathy or eosinophilic gastroenteritis are predominantly of the Th2 subtype, releasing elevated levels of IL-5 and IL-13 but not interferon-γ. In mice, the transfer of T cells from a sensitized mouse to a naive mouse is sufficient to induce diarrhea in response to an allergen challenge. This may be due to the release of IL-4 and IL-13, which have been shown to have direct effects on intestinal epithelial ion secretion and barrier function *in vivo*.

The possibility that IgE-mediated reactions could occur in the absence of detectable serum IgE or positive skin-prick test reactions should also be considered. IgE-bearing cells and activated eosinophils have been shown to be elevated in the lamina propria of patients with active hypersensitivity symptoms in the gastrointestinal tract, despite the lack of allergen-specific IgE or positive skin-prick tests. Therefore, the inability to detect IgE in serum or skin does not rule out the possibility of IgE-mediated reactions occurring in the intestinal mucosa, especially as IgE is produced locally in the mucosal tissue.

Food Intolerance

M. Cecilia Berin
Mount Sinai School of Medicine, New York

adverse food reaction Abnormal physiologic response to food ingestion, due to either food intolerance or food allergy.
food allergy (hypersensitivity) Immune-mediated reaction to food.
food intolerance Abnormal physiologic response to an ingested food or food additive; intolerance has not been proved to be immunologic in nature and falls under the umbrella term, adverse food reaction.

Food intolerance refers to nonimmunologic adverse reactions to ingested foods; the physiologic reactions resolve after dietary elimination of the food substances and reoccur on subsequent challenges with the foods. This category of adverse food reactions includes well-defined disorders such as enzyme deficiencies (i.e., lactose intolerance) and responses to pharmacological agents in food (i.e., tyramine in cheese or wine). In addition, intolerance includes non-immune-mediated reactions to food additives. Symptoms of food intolerance can appear identical to those arising from immune-mediated food allergy, despite the difference in underlying mechanisms. Therefore, the two categories of disorders are often confused.

ENZYME DEFICIENCY

The most commonly reported food intolerance is due to a deficiency in the brush border enzyme lactase, resulting in intolerance to lactose, the common sugar found in milk (see Table I). The inability to digest and absorb lactose leaves an osmotic load in the small intestine that draws water into the intestinal lumen and causes diarrhea. Patients with lactose intolerance can typically tolerate small amounts of lactose, whereas those with cow's milk allergy (caused by an immune reaction to proteins in milk) must practice complete avoidance of products containing milk proteins. Food intolerance can also occur due to nonspecific loss of brush border enzymes secondary to inflammatory events in the small intestine, where epithelial cells are damaged (such as in celiac or Crohn's disease).

Food-induced symptoms that do not involve the gastrointestinal tract can also occur because of enzyme deficiencies, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD deficiency results in hemolytic anemia after ingestion of fava beans ("favism"). Fava beans contain two potent oxidants that damage erythrocyte membranes in the absence of the G6PD enzyme. This genetic enzyme deficiency is not common in the Caucasian North American population, but is common in the Middle East and Africa.

FOOD ADDITIVES AND PRESERVATIVES

Intolerance to a number of food additives has been reported, but only a few cases have been verified by appropriately controlled studies, including an elimination diet and placebo-controlled challenge. The list of causative agents includes flavorings and preservatives (sulfites, monosodium glutamate, benzoic acid) and dyes

Copyright 2004, Elsevier (USA). All rights reserved.

TABLE I Causes of Food Intolerance

Cause	Food	Symptom
Enzyme deficiency		
Disaccharidase deficiency		
Lactase deficiency	Lactose or milk-containing foods	Diarrhea, abdominal pain, flatulence
Sucrose–isomaltase deficiency	Sucrose-containing foods	Diarrhea
Trehalase deficiency	Mushrooms	Diarrhea, flatulence
Glucose-6-phosphate dehydrogenase	Fava beans	Hemolytic anemia
Pharmacologic agents		
Histamine	Cheese, wine, fermented foods (sauerkraut)	Urticaria, abdominal pain, diarrhea, nausea
Tyramine	Fermented cheeses, chocolate	Migraine
Phenylethylamine	Chocolate, cheese, red wine	Migraine
Additives		
Tartrazine (FD & C Yellow No. 5)	Various foods	Exacerbation of urticaria
Sulfites	Various foods	Bronchospasm, anaphylaxis
Monosodium glutamate	Various foods	Headache, nausea, abdominal pain
Gastrointestinal disease		
Cystic fibrosis (pancreatic insufficiency), gallbladder disease, enteropathy (celiac disease, Crohn's disease)	Various foods	Diarrhea due to malabsorption/maldigestion

(tartrazine). Sulfites, which are antimicrobial and prevent oxidation or browning of food, have been shown to induce bronchospasm in a subset of patients with severe steroid-dependent asthma. The prevalence of sulfite intolerance has been estimated at between 2 and 8% of the adult asthmatic population. Tartrazine, also known as FD & C Yellow No. 5, is one of a family of azo dyes. Tartrazine has been shown to exacerbate skin symptoms after ingestion in a subset of patients with chronic urticaria. Monosodium glutamate, a flavoring agent, has also been reported to induce symptoms, including headache, nausea, flushing, and abdominal pain.

PHARMACOLOGICAL AGENTS

Vasoactive amines compose the largest class of substances responsible for pharmacological reactions to foods. These include histamine, phenylethylamine, and tyramine. This category of food intolerance includes agents that, given in a sufficient dose, induce effects in individuals regardless of host status. Individual variation in sensitivity to histamine may be related to expression levels of the enzyme diamine oxidase, which degrades histamine. Histamine-rich foods include cheese, wine, fish, sausages, and fermented food products such as sauerkraut. These foods can induce food allergy-like symptoms, including nausea and diarrhea, in susceptible individuals. Tyramine (found in chocolate, fermented cheeses, and pickled herring) and phenylethylamine (found in chocolate, cheese, and red wine) can also induce symptoms, including migraines, in susceptible individuals. Susceptibility to tyramine is enhanced in patients taking monoamine oxidase (MAO) inhibitors.

FOOD INTOLERANCE IN INFLAMMATORY BOWEL DISEASE AND IRRITABLE BOWEL SYNDROME

Patients with inflammatory bowel disease (IBD) and irritable bowel syndrome (IBS) self-report food intolerance at a much higher rate than do normal controls, and many restrict their diet accordingly. There is currently no conclusive evidence demonstrating that food-induced immunological mechanisms play a role in the pathophysiology of these diseases. Food intolerance may exacerbate symptoms, but there is conflicting evidence on the usefulness of elimination diets in the management of IBD and IBS. Certain intolerances, such as to lactose, may occur secondary to inflammatory damage of the small intestine. The high rate of self-report of food intolerance indicates the awareness of food as a possible trigger of symptoms, and this is an area of research that requires further investigation.

enteritis necroticans Severe necrotizing disease of the small intestine, associated with high mortality, caused by *Clostridium perfringens* type C; see also pigbel.

enterotoxin Bacterial toxin that exerts its effect by stimulating net fluid secretion by intestinal epithelial cells, without damaging the cells; contrast with other types of bacterial toxins, such as cytoskeletal-altering toxins, cytotoxins, and toxins with immune- or nerve-stimulating activity.

food-borne disease outbreak Two or more cases of a similar illness that occurs after eating a common food.

norovirus Recently adopted name to designate the genus of the viral family *Caliciviridae*; the viruses in this genus were previously called Norwalk-like viruses or small round structured viruses.

pigbel Severe necrotizing disease of the small intestine, associated with high mortality, caused by *Clostridium perfringens* type C, and named after an illness that developed in New Guinea natives after large feasts of inadequately cooked pork.

Food poisoning is an acute illness that develops from less than 1 h to 15 or more hours after the ingestion of food contaminated with bacterial, viral, or parasitic pathogens or toxins (biological or chemical). Although the clinical manifestations of food poisoning are generally gastrointestinal, neurological symptoms may occur with certain types of ingestion. The spectrum of food-borne illness in the United States has changed over time, in association with globalization of food production and broadening of consumer tastes, which have led to greater exposure to food-borne pathogens and chemicals.

INTRODUCTION

In the United States, the morbidity and mortality of food-borne illness have been estimated to be in the range of 76 million illnesses and 5000 deaths, respectively. Food-borne diseases are tracked by the Centers for Disease Control and Prevention through the Food-borne-Disease Outbreak Surveillance System, which has been in place since 1966. During the period 1993–1997, 2751 outbreaks of food-borne illness involving 86,058 persons were documented. For the outbreaks in which a pathogen could be identified (32%), 75% of the outbreaks and 86% of the cases were attributable to bacterial pathogens. In contrast, no etiologic agent could be identified in the majority of outbreaks (68%) and the longer incubation period ($\geq$15 h) associated with these outbreaks suggests a viral cause. These data do not include outbreaks that occurred on cruise ships, those in which the suspect food was consumed outside the United States, and those transmitted through contaminated drinking water (separately tracked). Despite these limitations and the fact that these data represent only a fraction of all outbreaks, the medical and economic impact of food-borne disease cannot be underestimated.

BACTERIAL FOOD POISONING

Bacterial food poisoning is generally attributable to 12 bacteria: *Clostridium perfringens, Staphylococcus aureus,*

BACTERIAL FOOD POISONING

Bacterial food poisoning is generally attributable to 12 bacteria: *Clostridium perfringens, Staphylococcus aureus,*

Copyright 2004, Elsevier (USA). All rights reserved.

Bacillus cereus, Vibrio cholerae /Vibrio parahaemolyticus, Salmonella, Clostridium botulinum, Shigella, toxigenic Escherichia coli, and certain species of Campylobacter, Yersinia, Listeria, and Aeromonas. In addition, group A *Streptococcus* has been implicated in a few outbreaks. Toxin-mediated illness, with short incubation times, as exemplified by the first three pathogens listed, is discussed below.

Clostridium perfringens

C. perfringens is a gram-positive, spore-forming, obligate anaerobe that is normally found in the intestinal flora of humans and animals and in the soil.

The typical episode of food poisoning by *C. perfringens* is characterized by watery diarrhea and severe crampy abdominal pain that develop 8 to 24 h after the suspect meal. Vomiting is usually not a prominent symptom. The illness usually resolves within 24 to 36 h after onset, with no sequelae. Although fatalities are rare, they may occur in debilitated and/or hospitalized patients.

This form of food poisoning is caused by a heat-labile, 35 kDa enterotoxin produced by *C. perfringens* type A. The enterotoxin is a structural protein of the spore coat and is produced during sporulation. Unlike cholera toxin, the *C. perfringens* enterotoxin has greatest activity in the ileum and can inhibit glucose transport, damage intestinal epithelial cells, and induce protein loss.

High attack rates (40 to 50 persons per outbreak) are common. Outbreaks usually are associated with large group gatherings and institutional settings in which precooked meat (beef, chicken, or turkey) that requires reheating is served. When food is cooked in large batches for these gatherings, spores of *C. perfringens* may survive and germinate as the food is cooled. If the food is not reheated to a temperature sufficiently high to kill the organisms, food poisoning may develop among individuals who ingest a large number of organisms and a large amount of toxin.

In contrast, *C. perfringens* type C causes a more severe illness called enteritis necroticans (Darmbrand) or pigbel, which has a high mortality rate ($\sim$40%). Historically, eating rancid meat (post-World War II Germany) and large amounts of poorly cooked pork (New Guinea) has been associated with this illness. Although rare in the United States, outbreaks have been associated with eating chitterlings (hog intestines).

Although the enterotoxin elaborated by *C. perfringens* type C is similar to that produced by type A, it induces a much more severe clinical course that includes bloody diarrhea, necrotizing intestinal damage, and intestinal perforation.

Staphylococcus aureus

S. aureus was the leading cause of food poisoning in the United States until $\sim$1973, but now ranks third. The illness is associated with coagulase-positive strains that elaborate heat-resistant enterotoxins A, B, C1, C2, C3, D, and/or E (28 to 34 kDa). Most outbreaks are caused by strains that produce enterotoxin A alone or together with enterotoxin D. An immunoassay that detects toxin in food and *in vitro* is useful for diagnosis in cases where the organism has been killed, but the preformed, heat-stable toxin remains in the sample. Phage typing has also been useful in outbreak investigations where the organism may be cultured from clinical specimens (emesis or feces). Phage type III alone, or in combination with phage type I, is the most common type found in outbreaks. Matching the phage type between the suspect food and affected individuals, or food handler(s), helps to establish the diagnosis and lines of transmission.

Staphylococci grow well in foods that have a high salt (e.g., canned meats) or sugar/protein (e.g., custards and creams) content and can be passed to prepared food by food handlers who carry toxin-producing *S. aureus*. It is estimated that 20 to 50% of healthy persons carry *S. aureus* on their skin, in their nose, or in their intestinal tract.

After a short incubation period (1 to 6 h), affected individuals develop nausea, vomiting, abdominal cramping, and later, diarrhea. Profuse vomiting may result in dehydration and metabolic alkalosis, which may require medical attention. Despite a stormy acute course, the illness resolves completely in 24 to 48 h and fatalities are rare. Many patients do not seek care because the symptoms resolve relatively quickly.

Bacillus cereus

B. cereus, an aerobic, spore-forming, gram-positive rod is found in soil and water globally, in most raw foods, and in human carriers (10 to 40%). The spores are heat-resistant. *B. cereus* is not a common cause of food poisoning in the United States.

B. cereus is associated with two distinct toxin-mediated types of food poisoning: the emetic syndrome, which has a short incubation period (range 1 to 6 h), and the diarrheal syndrome, which has a longer incubation period (range 8 to 16 h). The type of toxin elaborated depends on the type of food contaminated with *B. cereus*, rather than the strain of the organism.

The emetic toxin is produced in foods such as fried rice left at room temperature, whereas proteinaceous foods are usually associated with the diarrheal syndrome. Typically within 2 h of ingestion of the

preformed emetic toxin (5 to 10 kDa), affected individuals experience vomiting and abdominal cramping. Approximately one-third of them go on to develop diarrhea, but in general, the illness is mild, with prompt resolution in 8 to 10 h. *B. cereus* infection can be proven by isolating 10^5 organisms per gram of suspect food. However, if the food was reheated before consumption, the heat-stable emetic toxin may persist and cause illness in the absence of viable bacteria.

The longer incubation period and large inoculum (10^6 organisms per gram of food) required to induce the diarrheal syndrome suggest intestinal colonization, rather than preformed toxin alone, as the likely mechanism of disease. The diarrheal enterotoxin is a 38 to 46 kDa heat-labile protein. The majority of the patients have diarrhea and cramps. Less than 25% experience vomiting. The illness lasts 20 to 36 h.

DIFFERENTIAL DIAGNOSIS

The onset of gastrointestinal symptoms within 1 to 6 h after eating suggests an illness caused by the ingestion of a preformed toxin or a chemical irritant. If the incubation period is less than 1 h, heavy metal poisoning should be suspected and urine samples collected to screen for toxic chemicals.

Symptoms of zinc poisoning (nausea, abdominal cramps, metallic taste, headache, dizziness, and chills) have been reported to occur from 5 min to 2 h after consuming a beverage containing emetic doses of zinc (225 to 450 mg for adults). The beverage was acidic and had been stored in a galvanized container. The zinc in the galvanized metal was converted to easily absorbable zinc salts by contact with the acidic beverage. The symptoms resolved after vomiting of the zinc salts. The amount of vomiting was generally less than with food poisoning due to a preformed toxin.

Vomiting after drinking accidentally overfluoridated water has been reported to occur within 7 min (median). In the stomach, fluoride combines with hydrogen ions to form the gastric irritant hydrofluoric acid. Other symptoms include nausea, abdominal pain, and diarrhea. Fluoride poisoning also causes significant hyperkalemia and hypocalcemia, which can potentially trigger cardiac dysrhythmias and result in death.

In benign mushroom poisoning, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal cramping) begin from a few minutes to 2 to 3 h after consumption. In contrast, the onset of gastrointestinal symptoms is 6 to 12 h from ingestion in the more serious types of mushroom poisoning that involve amatoxins or monomethylhydrazine and the symptoms resolve before progression to life-threatening hepatic or renal disease. Incubation period alone, however, is not a reliable predictor of benign disease, since more than one type of mushroom is usually consumed in these situations.

If a patient develops acute, severe epigastric pain, nausea, and vomiting between 1 and 12 h after eating raw fish, gastric anisakiasis should be suspected. Symptoms usually subside after the nematode larvae are expelled from the stomach by regurgitation. In some cases, the worm may invade the gastric mucosa and cause perforation or cause a local granulomatous response and chronic symptoms. The worm can be seen and removed by upper endoscopy.

Viral gastroenteritis, such as that caused by noroviruses, also should be considered in the differential diagnosis, because it shares a similar constellation of symptoms with food poisoning, including the abrupt and prominent development of acute vomiting and/or diarrhea and it may be related to the ingestion of contaminated seafood. The incubation period for norovirus infection is longer (ranges from 10 to 51 h), the secondary infection rate is significantly higher, and symptoms last longer (1 to 5 days).

Finally, food additives, such as monosodium glutamate (MSG), and natural toxins associated with fish and shellfish consumption should be considered if extragastrointestinal and neurological symptoms are reported. The effect of MSG has a quick onset (<2 h following ingestion) and is characterized by a burning sensation in the chest or chest pressure, diaphoresis, and lacrimation.

Syndromes associated with fish and shellfish include ciguatera fish poisoning (most common; associated with toxins produced by the dinoflagellate *Gambierdiscus toxicus* and other benthic algae), neurotoxic shellfish poisoning (associated with red tides caused by *Gymnodinium breve*, which produces brevotoxin), diarrhetic shellfish poisoning (okadaic acid and dinophysistoxin-1 toxins produced by *Dinophysis fortii* or *D. acuminata*; cases mostly from Japan, some from Europe, and none from the United States), amnesic shellfish poisoning (domoic acid produced by *Pseudonitzschia pungen*, a diatom), and scromboid fish poisoning (high levels of free histamine due to bacterial decomposition of fish tissues after capture; may occur without overt evidence of spoilage).

TREATMENT AND PREVENTION

Most food-borne illnesses resolve without specific therapy. General supportive measures are aimed at maintaining adequate hydration and avoiding the use of anti-motility drugs in cases of inflammatory diarrhea.

Food poisoning is preventable. First, proper preparation of food is essential. For example, a common practice is to cook or steam shellfish until the shells just begin to part (usually less than 1 min of cooking time). If cooking is terminated at that time, the internal temperature of the shellfish meat will likely not have reached the 85 to 90°C maintained for 1.5 min that is required to inactivate hepatitis A virus and noroviruses that may be concentrated in the shellfish.

Second, storage of food at proper holding temperatures will help to prevent many cases of staphylococcal, *B. cereus*, and *C. perfringens* outbreaks. Prompt and adequate refrigeration (<40°F) for cold foods and maintenance of temperature (>140°F) for foods served hot are recommended to prevent the growth of bacterial pathogens.

Third, pathogens such as noroviruses, hepatitis A virus, *Salmonella typhi*, *Shigella* species, *S. aureus*, and *Streptococcus pyogenes* are more likely than other pathogens to be transmitted by an infected food worker who handles the food before it is served. It is, therefore, important for food handlers to practice good handwashing and maintain good personal hygiene, work with food on appropriately disinfected surfaces with clean implements, and abide by workplace policies that prevent symptomatic (or recently symptomatic) employees from working in food preparation.

In conjunction with these practical guidelines, laws have been enacted to promote the safety of domestic and imported food. The application of sound practices at every level of food production will help to prevent incidents such as the contamination of meat products during slaughter or processing or the contamination of fruits and vegetables by polluted water for washing.

food-borne illnesses Diseases, usually either infectious or toxic in nature, caused by agents that enter the body through the ingestion of food.

food-borne pathogens Microorganisms that contaminate food destined for human consumption; *Campylobacter*, *Salmonella*, and *Shigella* are the most frequently implicated bacteria involved in food-borne illnesses.

polychlorinated biphenyls Colorless and odorless chemicals, once widely used in electrical equipment; now banned from use, remain in the environment and contaminate the food chain, primarily through waterways.

Food-borne diseases are a growing public health problem. In industrialized countries, the percentage of people suffering from food-borne diseases each year has been reported to be as high as 30%. In the United States, estimates of 6.5 to 76 million cases of food-borne diseases occur annually, resulting in 325,000 hospitalizations and 5000–9000 deaths. The costs from these diseases and lost productivity are estimated to be $6.5–35 billion annually.

OVERVIEW

The United States has one of the safest food supplies in the world, with an interlocking system for monitoring production, importation, and distribution of food. Food and water safety in the United States is regulated by a number of local, state, and national governmental agencies. Within the Department of Health and Human Services, the Food and Drug Administration (FDA) is the primary regulator for the safety of all domestic and imported food and bottled water sold through interstate commerce. Meat, poultry, and frozen, dried, and liquid eggs are under the authority of the U.S. Department of Agriculture; the labeling and safety of alcoholic beverages (above 7% alcohol) are regulated by the Department of the Treasury's Bureau of Alcohol, Tobacco, and Firearms, and the safety of drinking water, except bottled water, is regulated by the Environmental Protection Agency. In addition, the National Wildlife and Fisheries Agency provides a fee-for-service inspection of fishery production.

Local and state public health departments and the Centers for Disease Control and Prevention (CDC) investigate sources of food-borne disease outbreaks. Food produced and consumed within a state is regulated by state agencies. This becomes particularly important in the regulation and safety of animal foods for human consumption, such as livestock and fish.

The World Health Organization indicates that cases of food-borne diseases may be 300–350 times more frequent than reported cases. Although toxic metals and other environmental hazards play a role in food-borne diseases, pathologic microbes pose the greatest risk to the nation's food supply. Estimates of the incidence of microbial causes of food-borne illness are complicated by newly emerging pathogens, which may not be tested for when suspected outbreaks occur. There is also increased antibiotic resistance in known pathogens.

Persons at greatest risk for food-borne illness are the elderly, infants, and preschool-age children, persons on immunosuppressive medications, those undergoing radiation therapy, and persons infected with the human immunodeficiency virus.

INFECTIOUS CAUSES OF FOOD- AND WATER-BORNE ILLNESS

In the United States, the most common infectious causes of food-borne illness, in order of prevalence, are *Campylobacter*, *Salmonella*, and *Shigella*; poultry is the food most often contaminated with disease-producing organisms. It has been estimated that 60% or more of raw poultry sold in retail stores carries some disease-producing bacteria.

Antimicrobial resistance is emerging as a major public health concern and this is primarily due to the overprescription of antibiotics in clinical medicine. However, the most likely cause of antibiotic resistance in food pathogens is the use of antibiotics in food-producing animals. Antibiotic resistance is present in the microflora of farm animals and of farm animal food products. In the United States, an estimated 50% of all antibiotics manufactured is provided to animals. Antibiotics are prescribed for specific infectious diseases in food animals as they are in humans, but they are also given in subtherapeutic doses as growth promoters and to prevent widespread infection in herds and flocks.

 Copyright 2004, Elsevier (USA). All rights reserved.

In 1995, fluoroquinolones were licensed for therapeutic use in poultry. The use of fluoroquinolones in food animals has led to the emergence of reduced-susceptibility and fluoroquinolone-resistant *Campylobacter* and *Salmonella*. Prior to their use in poultry, no resistant strains of *Campylobacter* were reported in individuals except in those with previous exposure to quinolones. A 1997 study by the Minnesota Health Department documented that 79% of chickens sampled from supermarkets were infected with *Campylobacter* and 20% of those samples carried the antibiotic-resistant strain.

Salmonella spp. colonize and cause disease in both humans and animals. *Salmonella enteritidis* is the most common *Salmonella* infection in human. In 1994, the largest single outbreak of *Salmonella* infection occurred in the United States. An outbreak of *S. enteritidis* affected an estimated 224,000 persons across the country due to contaminated ice cream from one creamery that had nation-wide distribution. The company manufacturing the ice cream was using good manufacturing practices but the vehicles used to transport the pasteurized ice cream premix were transporting unpasteurized eggs as well. Between transports, the vehicles were not adequately sterilized. An estimated six microbes per half-cup serving of ice cream caused symptoms in those affected. This example illustrates how rapidly an infectious agent can penetrate the country because of the great extent to which the United States has consolidated the production of food.

Salmonella typhimurium resistance is another increasing concern. *Salmonella typhimurium* resistance to tetracyclines has increased from 0% in 1948 to 98% in 1998. Since fluoroquinolones have been licensed for use in animals, emerging strains of fluoroquinolone-resistant *S. typhimurium* DT104 have emerged that are also resistant to ampicillin, streptomycin, chloramphenicol, and sulfonamides. Transmission of this strain from animal-derived food (unpasteurized cheese) to humans has now been confirmed.

Escherichia coli O157 produces a potent verotoxin that has been traced to contaminated meat. Subsequent outbreaks have been confirmed in raw sprouts, unpasteurized orange juice, mangoes, and lettuce. Sources of *E. coli* O157 may come from imported produce that is washed in rivers prior to shipment, rather than in potable water. *Listeria monocytogenes*, although not a common cause of food-borne disease, has a fatality rate of up to 30% and is a known cause of miscarriage or of meningitis of the fetus and newborn. The source has been confirmed in soft cheeses.

A number of government programs have been instituted to combat the spread of food-borne diseases from infectious causes. In 1996, the CDC developed a surveillance network to monitor food-borne illnesses. The CDC's Emerging Infections Program Foodborne Diseases Active Surveillance Network (FoodNet) covers 10.8% of the United States population in a number of states throughout the country. This program monitors the outbreak, incidence, and laboratory-confirmed cases of *Campylobacter*, *E. coli* O157, *L. monocytogenes*, *Salmonella*, *Shigella, Vibrio*, *Yersinia enterocolitica, Cryptosporidium*, and *Cyclospora cayetanensis* in an effort to design interventions to reduce infections.

The FDA Center for Veterinary Medicine, together with the CDC and the U.S. Department of Agriculture, has established the National Antimicrobial Resistance Monitoring System (NARMS) to monitor prospectively changes in antimicrobial susceptibilities of enteric pathogens from human and animal clinical specimens, from healthy farm animals, and from carcasses of food-producing animals at slaughter plants. The FDA has also moved to impose regulations to help curb the development of antibiotic-resistant bacteria in animals. The FDA is also enforcing the Hazard Analysis and Critical Control Point (HACCP) system. This system is meant to control microbial hazards as well as chemical and physical hazards. Although HACCP has been in effect for over 20 years for many sectors of the food industry, it now includes seafood processors and importers and meat and poultry producers. Food handlers in the food service industry are an important component of HACCP.

HEAVY METALS AND ENVIRONMENTAL CONTAMINANTS

A variety of heavy metals and environmental contaminants can affect the food supply, but the two substances of greatest concern currently are methylmercury and polychlorinated biphenyls.

Methylmercury

Mercury is released into the atmosphere by degassing from the Earth's crust and from environmental wastes, which are the source of 2700–6000 and 2000–3000 tons, respectively, each year. The first recorded episode of human mercury poisoning occurred in Minimata, Japan, where people who lived downstream from a local industrial plant were exposed to extremely high concentrations of mercury in their drinking water. Their mercury blood levels ranged from 9 to 24 ppm.

Mercury released into the environment undergoes bacterial transformation to methylmercury, and in this

form is absorbed by fish as it crosses their gills. It is then concentrated in large predatory fish as it moves up the food chain. Traces of methylmercury are found in most fish, but concentrations may be higher in areas of industrial mercury pollution. The usual concentration in most fish ranges from < 0.01 to 0.5 ppm. Except for shark, swordfish, large tuna (the type used to make sushi or fresh steaks), tilefish, and king mackerel, few species of fish reach the FDA limit for human consumption of 1 ppm. Freshwater predatory species such as pike and walleye sometimes have methylmercury levels in the 1-ppm range.

In January 2001, the FDA issued a warning for pregnant women and women of childbearing age to limit consumption of shark and swordfish to no more than once a month. For persons other than pregnant women and women of childbearing age, consumption of shark and swordfish should be limited to no more than 7 ounces per week. For fish with concentrations of mercury averaging 0.5 ppm, consumption should be limited to about 14 ounces per week. The types of seafood that make up 80% of the market—canned tuna, shrimp, pollack, salmon, cod, catfish, clams, flatfish, crabs, and scallops—all have methylmercury levels < 0.2 ppm, and restrictions do not apply unless people eat more than 2.2 pounds of these types of seafood per week.

The Canadian government has established guidelines with tighter restrictions than those in the United States. An acceptable level of methylmercury in fish is 0.5 ppm. In addition to the fish that are restricted in the United States, the Canadian government advises that fresh and frozen tuna also be restricted in the diet of pregnant women and women of childbearing age.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) represent over 200 individual colorless and odorless chemicals that were once widely used in electrical equipment such as transformers and capacitors; the production and use of PCBs were banned in 1976. PCBs are stable and nonflammable, making them ideal for industrial application. These same characteristics have also enabled them to persist in the environment for long periods of time. Of the over 1.2 billion pounds of PCBs produced in the United States prior to 1976, an estimated 0.6 billion pounds still remain in the environment and have primarily been taken up through water systems. PCBs concentrate in fatty flesh of larger fish, such as salmon, lake trout, and carp, as they move up the food chain. Although PCBs can be absorbed through the skin and lungs, they primarily enter the body when ingested in contaminated fatty fish. They readily pass through the placenta and breast milk, so pregnant and nursing women and women of childbearing age should avoid eating fish from water known to be contaminated with PCBs.

FOOD IRRADIATION

The history of food irradiation in the United States is extensive. Patents to use ionizing radiation to kill bacteria in food were issued in 1905, but the first use of food irradiation by the U.S. government was in 1963 to control insects in wheat when the shipment arrived in Russia. To achieve the goal of controlling bacteria and extending shelf life, the U.S. government has approved irradiation of spices, dry vegetable seasonings, fruit and vegetables, poultry, meat, meat by-products (sausage, etc.), fresh shelled eggs, and packaged foods. Food irradiation is widely supported by governmental agencies including the CDC, and industry. However, irradiated food has not met with success in the market place because there is extensive opposition to its use by consumers.

There are three different technologies used to irradiate food: gamma rays (using radioactive cobalt or cesium salt), an electron beam, and X rays. Gamma rays can penetrate food to a depth of several feet; an electron beam penetrates to 3 cm and X rays penetrate to several feet. Doses of irradiation that have been approved vary from 0.05 kGy, to inhibit sprouting in white potatoes, to 30 kGy, to sterilize herbs and spices.

With the exception of thiamin, the nutritional value of food is relatively unaffected by irradiation. Irradiation effectively eliminates pathogenic bacteria, molds, parasites, and insects from food that has been handled in a clean and safe manner. Irradiation does not mitigate the need for good sanitation practices on the farm or in production plants.

Individuals have raised concerns that there is lack of extensive testing on the long-term effects in humans of irradiated food. Food irradiation has been likened to the introduction of a new antibiotic, and opponents to its use suggest that further research is required prior to the large-scale introduction of this technology into food production.

FOOD HANDLING

Although the FDA and other agencies set standards for commercial food handling, the consumer must be aware of basic rules that apply when purchasing and preparing food. Susceptible foods should be refrigerated, meats should be adequately cooked, dishes and kitchen counters should be sanitized periodically

(and especially after preparing raw meat and fish), and only a reliable dealer should supply fresh raw seafood. Other advice is available on the FDA web site (http://www.fda.gov/fdac/features/895_kitchen.html).

Foreign Bodies

CYNTHIA D. DOWNARD, SNOW PENA-PETERSON, AND TOM JAKSIC
Children's Hospital Boston

achalasia Abnormal relaxation of the sphincter at the bottom of the esophagus, causing difficulty swallowing.

bougie A flexible tube used to calibrate or gradually open a narrowed cylindrical passage.

esophagoscopy Inspection of the interior of the digestive tract connecting the mouth and stomach with an endoscope.

mastication The process of chewing food in preparation for swallowing and digestion.

Foreign body ingestion is a common diagnosis in the pediatric emergency department; it is usually due to accidental swallowing of nondigestible objects. Foreign body aspiration is the leading cause of unintentional mortality in children under 1 year of age and accounts for 7% of deaths in children under 4 years of age. Infants and toddlers are at risk for aspiration of food items, especially small hard objects such as peanuts, due to their limited experience with chewing prior to swallowing. Small household objects, such as coins, pins, batteries, and small toys such as Legos and tiddly winks, pose a problem for older children. Although most foreign body ingestions usually result in little morbidity, prompt recognition and treatment are important.

Ingested foreign bodies may move asymptomatically through the esophagus and intestinal tract. If the object does not pass easily, children may develop abdominal pain, vomiting, choking, coughing, cyanosis, refusal to eat or drink, and wheezing. Treatment for foreign body ingestion is not standardized. The size, shape, and nature of the foreign body play an intricate role in the determination of appropriate management.

Foodborne Diseases

CHRISTOPHER J. GILL* AND DAVIDSON H. HAMER†
*Boston University School of Public Health and †Tufts University School of Medicine

hemolytic uremic syndrome A syndrome defined as the triad of acute renal failure, microangiopathic hemolytic anemia, and thrombocytopenia that follows infection with certain strains of enterohemorrhagic *Escherichia coli*, particularly serotype O157:H7. The syndrome appears to be mediated by bacteriophage-encoded Shiga toxin expressed during infection.

nontyphoidal *Salmonella* (NTS) The most important agents of foodborne illness, second only to campylobacteriosis in incidence. More than 2400 serotypes of NTS have been identified; all are now considered members of a single species, *Salmonella enterica*, and are commonly designated by their capitalized, nonitalicized serotype name. Most NTS are named for the place where they were first isolated. For example, "*Salmonella* Newport" refers to *S. enterica* serotype Newport.

secondary spread Transmission of infection from an index case to close contacts. In foodborne diseases, this usually is via fecal–oral contamination of foodstuffs.

typhoid fever Often called "enteric" fever. This is a syndrome characterized by high fevers, chills, abdominal pain, bacteremia, and metastatic seeding of organs, bones, and other structures with bacteria. Diarrhea may or may not be present. The principal agent is *Salmonella enterica*, serotypes Typhi and Paratyphi; several rarer NTS serotypes have been occasionally implicated as well. Prior to the availability of antibiotics, this disease was frequently fatal.

Foodborne illness includes all diseases that may be infectious or toxin-mediated that are passively introduced into patients by means of a food vehicle. A disease is generally considered foodborne if it meets the following two criteria: (1) two or more persons experience a similar illness, usually gastrointestinal, after ingestion of a common food and (2) epidemiologic analysis implicates food as the source of the illness. The Centers for Disease Control estimate that 76 million new domestic cases of food poisoning occur annually, making them among the most common diseases afflicting modern society. They also incur great human and financial costs, with 4000 to 5000 deaths annually and between 4 and 23 billion dollars per year in direct patient care costs.

CHANGING EPIDEMIOLOGY OF FOODBORNE DISEASES

The epidemiology of foodborne illnesses in the developed world has undergone significant changes during the past half century. Significantly, improvements in sanitation and hygiene have almost eliminated some of the "classical" gastrointestinal diseases, such as cholera and typhoid fever (see Fig. 1). However, these pathogens have been replaced by other pathogens more uniquely adapted to the conditions established by our modern food production and distribution systems. This evolution is typified by the nontyphoidal *Salmonella* (NTS), *Campylobacter jejuni*, and strains of enterohemorrhagic *Escherichia coli* (EHEC), all of which have "emerged" over the past century as significant threats to public health. Remarkably, *Ca. jejuni*, the most common bacterial cause of gastroenteritis in the United States—causing between 2 and 4 million cases of acute diarrhea per year—was not even recognized as a cause of diarrhea until the late 1970s.

The current pattern of infectious foodborne disease outbreaks differs substantially from the pattern 50 years ago. Prior to the Second World War, outbreaks usually occurred in tight clusters and could be more easily attributed to a single locally produced point-source food exposure. Secondary spread from cases to close contacts was relatively common.

In the 21st century, the average U. S. consumer has ~60,000 food items readily available for consumption, most of which can be found in a typical modern supermarket. Very few of these items will have been produced within 500 miles of the consumer, but are instead mass

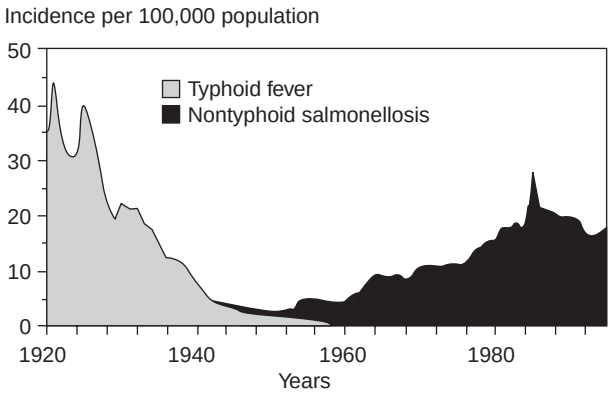

FIGURE 1 Reported incidence of typhoid fever and nontyphoidal salmonellosis, 1920–2000. Adapted from Tauxe *et al.* (1997), *Emerg. Infect. Dis.* **3**(4), 425–434.

 Copyright 2004, Elsevier (USA). All rights reserved.

produced centrally and then widely distributed via an increasingly complex network of distribution channels. Contamination of food items at the point of production thus has the potential for causing widespread outbreaks on an unprecedented scale. This potential was amply demonstrated in 1994 when a contaminated milk truck transporting ice cream premix resulted in over 224,000 cases of intestinal salmonellosis across 41 states.

Another consequence of this widespread distribution of food items is that it presents unique challenges to public health officials since the true scope of an outbreak may easily go unrecognized. This feature also complicates efforts to coordinate strategies to interrupt the chain of transmission. Moreover, for pathogens with low attack rates, it may be difficult to recognize that an outbreak is even occurring. Produce items have increasingly been identified in the context of large-scale outbreaks due to such organisms as NTS, EHEC, and *Cyclospora cayetanensis* (see Table I). Alfalfa and other seed sprouts appear to be particularly efficient vehicles and have caused at least 1500 culture-confirmed cases of disease over the past 10 years (see Table II). Due to the inevitable underreporting of infections, these culture-confirmed cases likely represent closer to 50,000 actual infections in the community.

CAUSES OF FOODBORNE DISEASES

Overview

Numerous infectious and noninfectious agents can cause foodborne illnesses. Table III summarizes the etiologic breakdown and predicted pathogen-specific mortality for the estimated 38 million yearly cases for which a particular agent has been directly implicated; an additional 38 million unexplained, though probably infectious, cases are believed to occur annually. Numerically, viruses are the most frequent agents of diarrheal disease though only approximately 30% of cases of viral gastroenteritis occur via foodborne transmission as opposed to person-to-person transmission.

However, most of the severe morbidity and death is due to bacterial pathogens, particularly NTS, *Ca. jejuni*, and *Listeria monocytogenes*. Unusual sporadic causes of foodborne illness include intoxications due to inorganic poisons, such as heavy metals and agricultural pesticides, and organic toxins, such as pufferfish poisoning and the hepatotoxic death cap mushroom, *Amanita phalloides*. Table IV summarizes some of the less commonly encountered agents of foodborne diseases and their syndromes.

Bacterial Causes of Foodborne Illness

In the developed world, *Ca. jejuni* and NTS account for the majority of foodborne bacterial gastroenteritis, with enteric fever due to *Salmonella typhi* now causing less than 0.1% of all U.S. foodborne disease. Although *Ca. jejuni* is usually associated with small, self-limited point-source outbreaks, usually traced to poultry, raw milk, or contaminated surface water, NTS are hardy and may continue to replicate outside the host animal. These biological features may underlie the propensity of NTS to cause widespread outbreaks involving multiple states or countries.

TABLE I Recent Foodborne Outbreaks Traced to Contaminated Fresh Produce

Year	Pathogen	Vehicle	Cases (No.)	States (No.)	Source
1990	*Salmonella* Chester	Cantaloupe	245	30	Central America
1990	*Salmonella* Javiana	Tomatoes	174	4	U.S.
1990	Hepatitis A	Strawberries	18	2	U.S.
1991	*Salmonella* Poona	Cantaloupe	>400	23	? U.S. vs Central America
1993	*Escherichia coli* O157:H7	Apple cider	23	1	U.S.
1993	*Salmonella* Montevideo	Tomatoes	84	3	U.S.
1994	*Shigella flexneri*	Scallions	72	2	Central America
1995	*Salmonella* Hartford	Orange juice	63	21	U.S.
1995	*E. coli* O157:H7	Leaf lettuce	70	1	U.S.
1996	*E. coli* O157:H7	Leaf lettuce	49	2	U.S.
1996	*Cyclospora cayetanensis*	Raspberries	978	20	Central America
1996	*E. coli* O157:H7	Apple juice	71	3	U.S.
1997	*Cy. cayetanensis*	Raspberries	80	5	Central America
1999	*Cy. cayetanensis*	Basil	64	1	U.S./Mexico
1999	*Salmonella* Thompson	Cilantro	76	1	U.S.
1999	*Salmonella* Baildon	Tomatoes	86	8	U.S.

TABLE II Recent Outbreaks Associated with Seed Sprouts

Year	Pathogen	No. of culture-confirmed cases	Location	Type of sprout	Likely source of contamination
1973	*Bacillus cereus*	4	1 U.S. state	Soy, cress, mustard	Seed
1988	*Salmonella* Saint-Paul	143	United Kingdom	Mung	Seed
1989	*Salmonella* Gold Coast	31	United Kingdom	Cress	Seed and/or sprouter
1994	*Salmonella bovismorbificans*	595	Sweden, Finland	Alfalfa	Seed
1995	*Salmonella* Stanley	242	17 U.S. states, Finland	Alfalfa	Seed
1995–1996	*Salmonella* Newport	133	>7 U.S. states, Canada, Denmark	Alfalfa	Seed
1996	*Salmonella* Montevideo and *S. meleagridis*	~500	2 U.S. states	Alfalfa	Seed and/or sprouter
1996	*Escherichia coli* O157:H7	~6000	Japan	Radish	Seed
1997	*E. coli* O157:H7	126	Japan	Radish	Seed
1997	*S. meleagridis*	78	Canada	Alfalfa	Seed
1997	*Salmonella infantis* and *S. anatum*	109	2 U.S. states	Alfalfa, mung, other	Seed
1997	*E. coli* O157:H7	85	4 U.S. states	Alfalfa	Seed
1997–1998	*Salmonella* Senftenberg	52	2 U.S. states	Clover	Seed and/or sprouter
1998	*E. coli* O157:NM	8	2 U.S. states	Clover, alfalfa	Seed and/or sprouter
1998	*Salmonella* Havana, *S.* Cubana, and *S.* Tennessee	34	5 U.S. states	Alfalfa	Seed and/or sprouter
1999	*Salmonella* Mbandaka	81	4 U.S. states	Alfalfa	Seed

Note. Adapted from Taormina *et al.* (1999). *Emerg. Infect. Dis.* 5(5), 626–634.

Other important bacterial causes of gastroenteritis include *Shigella* spp., highly contagious pathogens that readily spread from person to person and which are the predominant cause of bacillary dysentery worldwide; *Yersinia enterocolitica*, common zoonotic organisms epidemiologically linked to swine herds; and *Vibrio parahaemolyticus*, a sporadic agent of gastroenteritis frequently associated with shellfish consumption in coastal areas of the United States during periods of warmer ocean temperatures.

Recently, Shiga toxin-producing strains of EHEC have emerged as important foodborne pathogens. EHEC share epidemiologic features similar to those of NTS in that they continue to replicate outside of a host animal/patient and thus are capable of causing widely disseminated point-source outbreaks of disease, but share with *Shigella* the ability to cause secondary infections. EHEC are strongly associated with causing the hemolytic uremic syndrome and are now understood to be the most common cause of pediatric end-stage renal disease.

Although *L. monocytogenes* infrequently causes febrile gastroenteritis, controlling foodborne listeriosis remains an important public health priority. This is due to the organism's disproportionate lethality, its tendency to cause permanent neurologic sequelae in its survivors, its innate tolerance to antimicrobials, and its association with both neonatal sepsis and prenatal fetal demise.

Viral Causes of Foodborne Illness

Viral infections are the most common agents of acute, watery, gastroenteritis in adults and children, though mortality is low. Although it is not a cause of gastroenteritis, hepatitis A virus is of particular public health concern. Hepatitis A is highly infectious, is pathogenic, and may cause fatal fulminant hepatitis in 0.5–2% of patients, with risk increasing with age. A highly efficacious vaccine was introduced in 1995. It is used mainly for primary prophylaxis of high-risk populations and international travelers, but has also been used to terminate outbreaks and appears to prevent or attenuate symptomatic disease if given up to 2 weeks following exposure to hepatitis A.

Parasitic Causes of Foodborne Illness

Parasitic infections are comparatively rare but include several important pathogens. *Cryptosporidium parvum* recently achieved notoriety in 1993 after a contaminated municipal water supply caused illness in approximately 400,000 individuals. *Cryptosporidium*

TABLE III Foodborne Illnesses Due to Known Pathogens

Pathogen	Estimated cases[a]	Total cases (%)	Foodborne (%)	Deaths (No.)	Fatality rate
Bacterial					
Campylobacter spp.	2,453,926	14.2	80	124	0.001
Salmonella, nontyphoidal	1,412,498	9.7	95	582	0.0078
Shigella spp.	448,240	0.6	20	70	0.0016
Yersinia enterocolitica	96,368	0.6	90	3	0.0005
Toxigenic *Escherichia coli* (ETEC)	79,420	0.2	70	0	<0.001
E. coli O157:H7 (EHEC)	73,480	0.5	85	61	0.0083
E. coli non-O157:H7 (EHEC)	36,740	0.2	85	7	0.0083
Noncholera *Vibrio* spp.	7,880	<0.1	65	20	0.025
Listeria monocytogenes	2,518	<0.1	99	504	0.2
Brucella spp.	1,554	<0.1	50	11	0.05
Salmonella Typhi[b]	824	<0.1	80	3	0.004
Vibrio vulnificus	94	<0.1	50	37	0.39
Toxin-mediated illnesses					
Clostridium perfringens	248,520	1.8	100	7	<0.001
Staphylococcal food poisoning	185,060	1.3	100	2	<0.001
Streptococcal food poisoning	50,920	0.4	100	0	<0.001
B. cereus	27,360	0.2	100	0	<0.001
Clostridium botulinum	58	<0.1	100	4	0.08
Parasitic					
Giardia lamblia	2,000,000	1.4	10	10	<0.001
Cryptosporidium parvum	300,000	0.2	10	66	0.005
Toxoplasma gondii	225,000	0.8	50	750	<0.001
Cyclospora cayetanensis	16,264	0.1	90	0	<0.001
Trichinella spiralis	52	<0.1	100	0	0.003

Caliciviruses (includes Norwalk)	23,000,000	66.6	40	310	<0.001
Rotavirus	3,900,000	0.3	1	30	<0.001
Astrovirus	3,900,000	0.3	1	10	<0.001
Hepatitis A virus	83,391	< 0.1	5	83	0.003
Total cases of diarrheal illness	38,629,641[a]	Bacterial 30%	Parasitic 3%	Viral 67%	

Note. Data from Mead *et al.* (1999). *Emerg. Infect. Dis.* 5(5). EHEC, Enterohemorrhagic *E. coli*; ETEC, enterotoxigenic *E. coli*.

[a] Case numbers are estimates derived from active and passive surveillance data, hospital discharge diagnoses, historical case ratios, and individual outbreaks.

[b] Greater than 70% of typhoid cases were imported from outside of the United States.

infections are frequently chronic and potentially fatal in patients with impaired cell-mediated immunity. At present, no effective antimicrobial agents are available for treatment of cryptosporidiosis; despite showing initial promise in uncontrolled trials, more recent randomized/placebo-controlled trials have shown no benefit to paromoycin for the treatment of autoimmune deficiency syndrome patients with cryptosporidiosis. *Cyclospora cayetanensis* recently achieved notoriety after causing back-to-back outbreaks in 1996 and 1997 linked to contaminated Guatemalan raspberries. *Cryptosporidium parvum, Cy. cayetanenesis, Isospora belli*, and other intestinal coccidian protozoans pathogenic to humans produce a subacute to chronic diarrhea, often complicated by malabsorption and wasting, particularly in immunosuppressed patients.

Giardia lamblia is a common zoonotic protozoan cause of acute self-limited gastroenteritis that generally responds well to antimicrobials. Serious sequelae of giardiasis are rare and usually a consequence of dehydration. Although it is usually a waterborne infection, $\sim$10% of giardiasis may be foodborne.

Bacterial Toxin-Induced Foodborne Illness

Ingestion of preformed bacterial toxins is a frequent cause of foodborne disease outbreaks. The most dangerous of these is the botulinum toxin, for which prompt administration of antitoxin (provided free on request from the Centers for Disease Control and Prevention) may prevent or attenuate the development of a potentially fatal paralysis if administered early in the course of

TABLE IV Uncommon Agents of Food Poisoning and Their Syndromes

Syndrome categories	Nature of disease/comments
Meat-borne	
Gastrointestinal anthrax	Usually caused by consumption of animals killed by anthrax; abdominal pain, nausea, vomiting, hematemesis, bloody diarrhea, and bacteremia progressing to death from septic shock
Trichinosis	Ingestion of larvae of *Trichinella spiralis* in undercooked pork or beef may result in a syndrome of diarrhea, abdominal pain, and vomiting followed by fever, painful myositis, weakness, eosinophilia, and periorbital edema
Fish/shellfish borne	
Anisakiasis	Syndrome of acute epigastric or abdominal pain, nausea, and vomiting after ingesting parasitic larvae in herring, squid, mackerel, salmon, and other white fishes
Ciguatera fish poisoning	Follows ingestion of barracuda, red snapper, amberjack, and grouper; dinoflaggelate neurotoxin concentrated in the fish leads to nausea, vomiting, diarrhea, cramps, hot–cold reversal, myalgias, blurred vision, and paralysis
Scombroid poisoning	A pseudo-allergenic, ingested histamine-mediated syndrome of wheezing, flushing, dizziness, nausea, vomiting, and diarrhea; colonizing gram-negative bacilli convert fish histadine to histamine within the flesh of the fish
Pufferfish poisoning	Sodium channel-blocking tetrodotoxin is concentrated in the fish's liver and ovaries; ingestion leads to respiratory failure and paralysis
Shellfish poisoning (red tide)	Each syndrome results from dinoflaggellate toxins that are concentrated within the tissues of filter-feeding shellfish
Paralytic	Symptoms include paraesthesias, dyspnea, and paralysis
Neurotoxic	Milder than paralytic shellfish poisoning; symptoms include nausea, vomiting, diarrhea, reversal of hot–cold sensation, paraesthesias, and confusion
Diuretic	Dinophysotoxins from the genera *Dinophysis* and *Prorocentrum* mediate this acute, self-limited syndrome of diarrhea and vomiting
Amnestic	Symptoms include gastrointestinal distress, diarrhea, confusion, and temporary or persistent loss of short-term memory formation
Haff syndrome	Epidemic rhabdomyolysis due to an unidentified toxin in bottom-dwelling freshwater fish; originally described near the Black Sea; now reported in California also
Fungal	
Mushroom poisoning	The classic example is the lethal hepatotoxin of *Amanita phalloides*
Mycotoxins	
Ergotism	Epidemic gangrenism and/or psychosis due to rye products contaminated by ergots of the fungus *Claviceps purpurea*
Aflatoxin	*Aspergillus flavus* and *A. parasiticus* produce aflatoxin, a potent carcinogen and putative human carcinogen; presents acutely as fever and fulminant hepatitis
Vegetable	
Neurolathyrism	Chronic consumption of the seeds of the grass pea, *Lathyrus sativus*, causes spasticity and hypermicturation
Hemagglutinin poisoning	Consumption of unsoaked and boiled red kidney beans, *Phaseolus vulgaris*, results in nausea, vomiting, and diarrhea
Ackee fruit (Jamaican vomiting sickness)	Underripe fruits contain high concentrations of hypoglycin, a naturally occurring insulin-like substance; symptoms include nausea, vomiting, confusion, and coma

Note. Reprinted from Gill, C.J. (2001). Foodborne illness. *Curr. Treat. Options Gastroenterol.* 4(1), 23–38, with permission. Copyright Current Medicine Inc.

the disease. Botulinum intoxications most commonly follow ingestion of foods that were contaminated with *Cl. botulinum* spores and then were allowed to incubate under strictly anaerobic conditions, though inoculation of spores into wounds can occasionally cause botulism also. By contrast, the rare syndrome of infant botulism signifies an actual infectious process. This occurs when honey contaminated with *Cl. botulinum* spores is fed to young infants whose intestinal flora has not yet matured to the point where it would naturally suppress the growth of these bacteria.

Strains of *Bacillus cereus*, *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Clostridium perfringens* all can colonize poorly preserved foods or undercooked foods. Although none of these organisms will invade the mammalian gut and lead to a replicative infectious

gastroenteritis, they secrete enteric toxins that do traverse the acid barrier and can lead to an abrupt self-limited syndrome of nausea, vomiting, and diarrhea that is not easily distinguishable from infectious forms of gastroenteritis.

MANAGEMENT OF FOODBORNE DISEASES

The response to foodborne illness has two essential components: the clinical management of acutely ill patients and the accompanying public health investigation as to the etiology, route, vehicle, and extent of community exposure of the agent in question. The public health intervention may be limited to counseling consumers about the risks posed by certain food items or strategies to reduce these risks or issuing health advisories. Other interventions include mandating voluntary or involuntary product recalls and embargos and in rare cases enforcing quarantines. As opposed to failure to prescribe the appropriate antibiotic, complications due to hypovolemia—chiefly metabolic acidosis and electrolyte imbalances—are the major cause of death due to foodborne illness. Oral rehydration salts offer a convenient, cheap, and highly effective mechanism for managing most patients with mild to moderate dehydration, whereas intravenous therapy may be required for seriously ill patients.

The indications for antibiotics are ill-defined and frequently debated by experts in the field. Although most of the bacterial pathogens show *in vitro* sensitivity to commonly used antibiotics, clinical evidence supporting their use for non-travel-associated diarrhea is lacking in most cases, with the notable exceptions of shigellosis and typhoid fever, where therapy is clearly beneficial. Empiric trials of antibiotics for acute gastroenteritis show that antibiotic therapy shortens the average duration of illness by 1−3 days. Caution is raised, however, by other studies indicating that antibiotics may worsen outcomes in the case of infection with certain pathogens. In the case of uncomplicated NTS infections, the indication for antibiotics is hotly disputed, given earlier studies showing that antibiotic therapy prolongs the duration of bacterial shedding, increases relapse rates and has no discernible impact on shortening the duration of illness. Exceptions include bloodstream or disseminated infections or infections in severely immunocompromised patients who are at high risk of developing disseminated disease.

EHEC infections may be of greater concern: epidemiologic and laboratory data indicate that certain DNA-active antibiotics, notably sulfonamides and fluoroquinolones, may increase the risk of developing hemolytic uremic syndrome (HUS) for patients with EHEC infections. Despite several reports supporting the use of fosfomycin in this disease, the evidence proving that this drug reduces the risk of HUS is inconclusive. For these reasons, most authorities recommend that antibiotics be used with great caution when EHEC infections are suspected. As with NTS infections, antibiotics are indicated if patients appear to have disseminated disease or bacteremia.

Food Intolerance

M. Cecilia Berin

Mount Sinai School of Medicine, New York

adverse food reaction Abnormal physiologic response to food ingestion, due to either food intolerance or food allergy.

food allergy (hypersensitivity) Immune-mediated reaction to food.

food intolerance Abnormal physiologic response to an ingested food or food additive; intolerance has not been proved to be immunologic in nature and falls under the umbrella term, adverse food reaction.

Food intolerance refers to nonimmunologic adverse reactions to ingested foods; the physiologic reactions resolve after dietary elimination of the food substances and reoccur on subsequent challenges with the foods. This category of adverse food reactions includes well-defined disorders such as enzyme deficiencies (i.e., lactose intolerance) and responses to pharmacological agents in food (i.e., tyramine in cheese or wine). In addition, intolerance includes non-immune-mediated reactions to food additives. Symptoms of food intolerance can appear identical to those arising from immune-mediated food allergy, despite the difference in underlying mechanisms. Therefore, the two categories of disorders are often confused.

ENZYME DEFICIENCY

The most commonly reported food intolerance is due to a deficiency in the brush border enzyme lactase, resulting in intolerance to lactose, the common sugar found in milk (see Table I). The inability to digest and absorb lactose leaves an osmotic load in the small intestine that draws water into the intestinal lumen and causes diarrhea. Patients with lactose intolerance can typically tolerate small amounts of lactose, whereas those with cow's milk allergy (caused by an immune reaction to proteins in milk) must practice complete avoidance of products containing milk proteins. Food intolerance can also occur due to nonspecific loss of brush border enzymes secondary to inflammatory events in the small intestine, where epithelial cells are damaged (such as in celiac or Crohn's disease).

Food-induced symptoms that do not involve the gastrointestinal tract can also occur because of enzyme deficiencies, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD deficiency results in hemolytic anemia after ingestion of fava beans ("favism"). Fava beans contain two potent oxidants that damage erythrocyte membranes in the absence of the G6PD enzyme. This genetic enzyme deficiency is not common in the Caucasian North American population, but is common in the Middle East and Africa.

FOOD ADDITIVES AND PRESERVATIVES

Intolerance to a number of food additives has been reported, but only a few cases have been verified by appropriately controlled studies, including an elimination diet and placebo-controlled challenge. The list of causative agents includes flavorings and preservatives (sulfites, monosodium glutamate, benzoic acid) and dyes

Foreign Bodies

CYNTHIA D. DOWNARD, SNOW PENA-PETERSON, AND TOM JAKSIC
Children's Hospital Boston

achalasia Abnormal relaxation of the sphincter at the bottom of the esophagus, causing difficulty swallowing.

bougie A flexible tube used to calibrate or gradually open a narrowed cylindrical passage.

esophagoscopy Inspection of the interior of the digestive tract connecting the mouth and stomach with an endoscope.

mastication The process of chewing food in preparation for swallowing and digestion.

Foreign body ingestion is a common diagnosis in the pediatric emergency department; it is usually due to accidental swallowing of nondigestible objects. Foreign body aspiration is the leading cause of unintentional mortality in children under 1 year of age and accounts for 7% of deaths in children under 4 years of age. Infants and toddlers are at risk for aspiration of food items, especially small hard objects such as peanuts, due to their limited experience with chewing prior to swallowing. Small household objects, such as coins, pins, batteries, and small toys such as Legos and tiddly winks, pose a problem for older children. Although most foreign body ingestions usually result in little morbidity, prompt recognition and treatment are important.

Ingested foreign bodies may move asymptomatically through the esophagus and intestinal tract. If the object does not pass easily, children may develop abdominal pain, vomiting, choking, coughing, cyanosis, refusal to eat or drink, and wheezing. Treatment for foreign body ingestion is not standardized. The size, shape, and nature of the foreign body play an intricate role in the determination of appropriate management.

COINS

Coins are the most frequently ingested foreign body in the pediatric population. Treatment following coin ingestion depends on the position of coin at the time of diagnosis. A coin that has passed unaided through the esophagus to the stomach will most likely pass uneventfully through the remaining gastrointestinal tract. However, coins frequently become lodged in the esophagus and may require medical intervention for removal.

Diagnosis

Once foreign body ingestion is suspected, plain radiographs are useful in localizing radioopaque substances such as coins (Fig. 1). The most common site of obstruction is relatively high in the esophagus, at the level of the cricopharyngeus. Contrast studies can be used to identify nonradioopaque foreign bodies. Ultrasound may also demonstrate the location of foreign body with visualization of a hyperechoic substance within the alimentary tract.

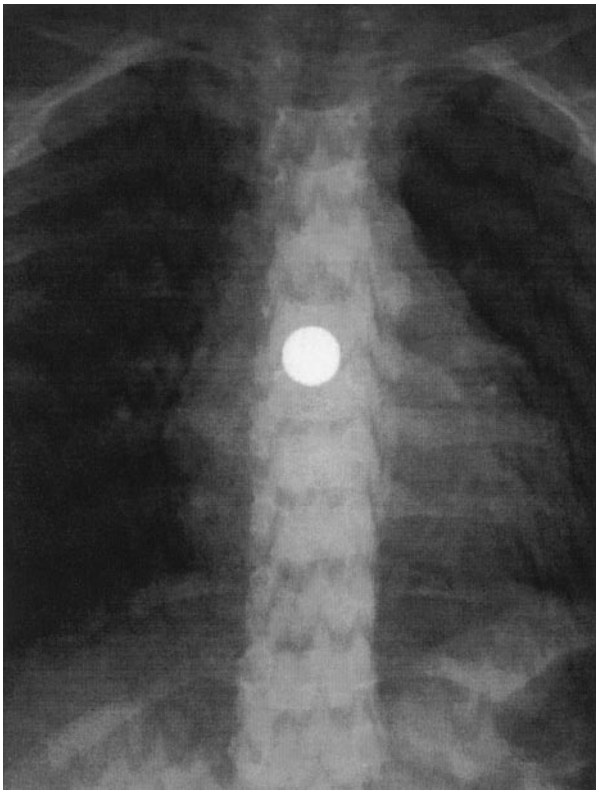

FIGURE 1 Plain chest radiograph showing a coin lodged in the esophagus. This object was removed by esophagoscopy.

Treatment

Coins that become lodged in the esophagus may pass to the stomach spontaneously. If a coin has been in the esophagus for less than 24 h, it is acceptable to monitor a child for an additional 12–24 h for spontaneous passage prior to removing the coin in an invasive manner.

Coins lodged in the esophagus are reliably removed by esophagoscopy. Perforation is rare when removing a rounded object, such as a coin, in an operating room under general endotracheal anesthesia.

Alternatively, a Foley catheter, passed distal to the coin and then inflated, may be used to withdraw esophageal foreign bodies under radiographic guidance. This technique does not require general anesthesia, but does require a cooperative patient. The risk of using this method of foreign body extraction is that the coin, when being withdrawn from the esophagus, could easily pass into the trachea from the oropharynx and cause airway compromise. Series have reported up to 96% success with removal of coins using this technique, but the possibility of aspiration has resulted in relatively few centers adopting this approach.

A third method being utilized for the removal of esophageal coins is the penny pincher technique, which involves the use of grasping forceps covered by a soft rubber catheter. After this device is directed into the esophagus fluoroscopically, the forceps are advanced from the shield and aligned with the foreign body. The forceps are used to grasp the coin, which is then withdrawn under radiographic guidance. Like the Foley catheter technique, no anesthesia or sedation is needed; however, with forceps control of the foreign body, the risk of aspiration during removal is theoretically decreased. Experience with this technique is limited and this special catheter is not widely available.

Outcome

Both esophagoscopy and the Foley catheter techniques have approximately 90% success rates as methods for foreign body removal. When a coin is unable to be removed by either method, it can simply be pushed through to the stomach, with the expectation that it will pass through the remaining gastrointestinal tract. The expulsion of the foreign body should be ensured with careful examination of the stool. If obstructive symptoms develop, repeat radiographs can visualize the position of the foreign body and treatment can be appropriately determined. In the rare event that a coin becomes lodged at the ileocecal valve, operative removal may be necessary.

PINS

Diagnosis

The ingestion of pins (and other sharp metal objects such as screws) is dangerous due to the potential for perforation of the alimentary tract. When pin ingestion is suspected, plain radiographs can usually identify the position of the foreign body.

Treatment

Ingested pins should be removed immediately after failure of advancement is established because of the risk of perforation. In addition to direct perforation, longer foreign bodies, such as hair pins, may become lodged transversely in the esophagus and produce pressure necrosis and fistula formation. Once pin ingestion is diagnosed, endoscopic removal of the foreign body is undertaken immediately to minimize the potential for perforation or fistula formation. Pins should be endoscopically removed even if they pass spontaneously to the stomach. A magnet may also be used to remove metallic foreign bodies such as pins, provided that precautions are taken to minimize the likelihood of perforation on withdrawal.

Outcome

Pin ingestion is worrisome due to the risk of alimentary tract perforation. Every effort should be directed toward removing the object while it is within the upper gastrointestinal tract. Should the child present after an ingested pin has passed through the stomach, the stool must be carefully examined to ensure enteral elimination of the object. If symptoms suggesting perforation or fistula formation develop, repeat radiographs should be obtained. These complications require operative intervention for correction.

BATTERIES

Diagnosis

Button-style batteries are frequently ingested because of their small size and household availability in daily items such as hearing aids, hand-held games, and cameras. Ingested batteries require immediate attention due to the possible leakage of alkaline fluid and discharge of electric current, which can cause severe necrosis and perforation when lodged in the esophagus. An initial radiograph should be performed on patients who have ingested a battery in order to confirm the diagnosis and determine the location of the battery.

Treatment

Immediate endoscopic removal is mandatory when a battery is lodged in the esophagus. Batteries lodged in the esophagus for as little as 4 h have been associated with significant mucosal burns. Esophagoscopy, in preference to other extraction methods, should be used to remove impacted esophageal batteries to allow for direct visualization of the adjacent mucosa. If mucosal damage is present, scarring and subsequent narrowing of the esophagus may occur.

Batteries that have passed the esophagus can be left to navigate the remaining gastrointestinal tract, although intestinal damage from the leakage of contained fluid may still occur. The diameter and chemical type of battery should be determined by examining a similar battery or the device with which the ingested battery is associated. Larger batteries (>15 mm) may not readily pass through the pylorus and ileocecal valves in young children. If the battery is retained in the stomach, it can be removed endoscopically. If it is lodged further in the intestinal tract, operative removal may be necessary.

If a battery is determined to contain mercuric oxide (approximately 25% of ingestions) and the battery splits in the intestinal tract, serum and urine mercury levels should be monitored for toxicity. Serial radiographs are not necessary unless the patient develops obstructive symptoms or passage of the battery in the stool has not been noted. Emetics are not useful for battery expulsion after ingestion.

Outcome

Over 90% of batteries located in the esophagus at the time of diagnosis are successfully removed. However, in one large series, 40% of patients with batteries removed from the esophagus experienced serious adverse outcomes, including esophageal perforation, scarring requiring dilations, and death. If batteries pass unaided through the esophagus, there is a very small likelihood that operative intervention will be required for removal and outcome is generally excellent. The stool should be carefully inspected to document successful evacuation of ingested batteries.

Food

As solid foods are introduced into the diet, inadequate mastication can lead to food becoming lodged in the alimentary tract. This is a particular problem for children who have undergone prior repair of esophageal atresia early in life, with the food becoming lodged in the hypomotile distal esophagus. Severe acid reflux causing esophageal stricture may also cause food to lodge in the

esophagus. Additionally, esophageal dysmotility, as seen in achalasia, may come to clinical attention after food becomes stuck in the esophagus. Small bones in foods such as chicken and fish are also easily swallowed by children.

Diagnosis

Detection of radiolucent foreign bodies such as food products is difficult. A negative plain radiograph in this situation does not indicate the absence of a foreign body. Gastrointestinal contrast studies may be used in this situation to identify radiolucent foreign bodies. A history of foreign body ingestion and symptomatic presentation with difficulty swallowing and excess saliva production should guide treatment.

Treatment

Food that becomes lodged in the esophagus can be removed by esophagoscopy. Alternatively, digestible food products can be pushed through to the stomach using a bougie and allowed to pass through the remaining alimentary tract. Bones from chicken and fish should be treated as sharp objects and removed if at all possible due to the risk of intestinal perforation. Removal of a lodged food product should be followed with contrast evaluation to search for underlying esophageal stricture or dysmotility.

Outcome

Unless the ingestion involves sharp bones, obstruction of the alimentary tract with inadequately chewed food is usually well tolerated. Eventual outcome depends on the underlying problem predisposing the patient to swallowing difficulty. All children should be reminded to chew food well before swallowing.

BEZOARS

Bezoars are caused by repeated swallowing of an indigestible foreign body. Most frequently, this material is from an excessively fiber-rich diet (phytobezoar) or hair (trichobezoar). Bezoars present with symptoms of intestinal obstruction and are sometimes diagnosed by plain radiographs or endoscopy. If the bezoar is in the stomach, endoscopic removal of the material may be attempted. Operative intervention with a possible gastrotomy or enterotomy is often required to relieve the intestinal obstruction. Psychological evaluation, as well as an evaluation for anemia, should accompany surgical therapy for this condition.

CONCLUSION

A variety of household objects and foods can be accidentally ingested in the pediatric population. Treatment following foreign body ingestion is determined by the size, shape, and nature of the swallowed material, with sharp objects and batteries lodged in the esophagus requiring urgent removal. If a foreign body has passed through the upper intestinal tract, the stool should be monitored to ensure successful transit of the foreign body. Few serious problems are associated with most foreign body ingestions, but timely recognition and treatment are important in minimizing adverse outcomes.

Fulminant Hepatic Failure

JOHN J. POTERUCHA
Mayo Clinic

aminotransferases Usually two types, alanine aminotransferase and aspartate aminotransferase; these hepatocellular enzymes are released into the bloodstream with injury of hepatocytes, thus elevated levels serve as markers of liver cell injury.
cerebral edema Increased extracellular water in the brain, leading to increased intracranial pressure.
coagulopathy Alteration in the normal clotting mechanisms of blood.
hepatic encephalopathy Changes in mental status due to liver dysfunction.

Fulminant hepatic failure is a clinical syndrome of severe acute liver failure with hepatic encephalopathy in a patient without a prior history of liver disease. The most common causes are medications, especially acetaminophen, and viral hepatitis A and B. Clinical manifestations include the cardinal features of liver failure and encephalopathy but also coagulopathy, hypoglycemia, infections, and various abnormalities of other organ systems. Models have been developed to help predict patient outcome to assist in management, including the timing of liver transplantation.

INTRODUCTION

Fulminant hepatic failure (FHF) has traditionally been defined as the presence of acute liver failure including the development of hepatic encephalopathy within 8 weeks after the onset of jaundice in a patient without a prior history of liver disease. Because not all patients with severe acute liver disease meet this definition, some have proposed to use the term "acute liver failure," which encompasses other clinical scenarios, including FHF. Various classifications are shown in Table I. Different classification schemes are proposed because of diagnostic and prognostic differences between groups. For example, hyperacute liver failure is most often due to ischemia or acetaminophen and may often be reversible, assuming the offending agent is removed. On the other hand, late-onset hepatic failure, often due to viruses or idiopathic causes, may lead to manifestations of portal hypertension, is seldom complicated by cerebral edema, and yet has a poor prognosis. Because most studies have used the traditional definition of FHF, that will be the nomenclature used herein.

There are about 2000 cases of FHF in the United States each year. The overall mortality of FHF without liver transplantation is up to 90%. Because many of these patients are young and previously healthy, the outcomes of this relatively unusual condition are particularly tragic. Specific management, including liver transplantation, is available for this group of patients and therefore knowledge of management strategies is important.

ETIOLOGY

Determining the etiology of FHF is important for two reasons: first, specific therapy may be available, such as with acetaminophen hepatotoxicity or herpes hepatitis, and second, prognosis will differ depending on etiology. For instance, spontaneous recovery rate with FHF due to acetaminophen or hepatitis A is $>50\%$ and therefore a more cautious approach before proceeding with liver transplantation would be advised. On the other hand, spontaneous recovery from FHF due to Wilson's disease is very unusual and therefore early liver transplantation would be recommended. In addition, determination of a specific etiology may have implications for other patients. Identification of a hepatotoxic agent is certainly helpful in monitoring other patients on the same drug. Identification of a viral cause of FHF has implications for other patients that have been exposed to the transmissible agent. Patients and family members need to be asked about risk factors for liver disease, medications, and a family history of liver disease that may give clues to the etiology of the acute hepatitis.

The etiology of FHF varies according to region, with hepatitis B being a more common cause in areas such as Asia, where hepatitis B is endemic, whereas studies from Great Britain generally report a high number of acetaminophen hepatotoxicity cases. The U.S. Acute Liver Failure Study Group has put together a coordinated effort from a number of centers attempting to better define the causes and outcome of acute liver failure in the United States. The most common identifiable

TABLE I Classification of Acute Liver Failure

Classification	Source
Acute hepatic failure (rapidly developing impairment of liver function)	Bernuau *et al.* (1986)
Severe acute hepatic failure (prothrombin time or factor V concentration <50% of normal, with or without encephalopathy)	
Fulminant hepatic failure (encephalopathy within 2 weeks of onset of jaundice)	
Subfulminant hepatic failure (encephalopathy between 3 and 12 weeks after onset of jaundice)	
Acute liver failure (requires encephalopathy)	O'Grady *et al.* (1993)
Hyperacute liver failure (0–7 days between onset of jaundice and encephalopathy)	
Acute liver failure (8–28 days)	
Subacute liver failure (29–72 days)	
Late-onset acute liver failure (56–182 days)	
Acute liver failure (encephalopathy within 4 weeks after symptom onset)	Tandon *et al.* (1999)
Hyperacute liver failure (within 10 days)	
Fulminant liver failure (10–30 days)	
Acute liver failure not otherwise specified	
Subacute liver failure (development of ascites and/or encephalopathy from 5 to 24 weeks after symptom onset; may be subclassified based on etiology)	

cause is acetaminophen hepatotoxicity followed by hepatitis B and hepatitis A (see Fig. 1).

FHF is usually evident from the time of presentation based on the cardinal features of liver failure and encephalopathy. It can sometimes be difficult to distinguish FHF from an acute presentation of chronic liver disease. Clues to the presence of a more chronic liver condition include spider angiomata and manifestations of portal hypertension, although portal hypertension may be seen in patients with late-onset acute hepatic failure. Also in the differential diagnosis of FHF is multisystem organ failure associated with sepsis, which can occasionally be accompanied by nonspecific mental status changes that mimic hepatic encephalopathy.

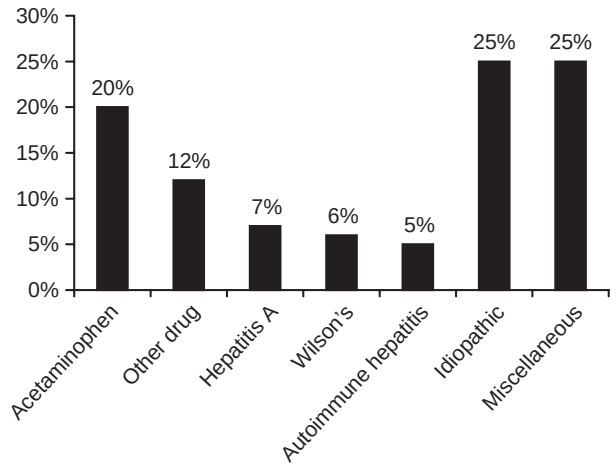

FIGURE 1 Etiology of acute liver failure in the United States Miscellaneous causes include Budd–Chiari syndrome, herpes, Epstein–Barr virus, paramyoxovirus, *Amanita* poisoning, ischemia, malignancy, acute fatty liver of pregnancy, and others. Data from Schiodt *et al.* (2003).

CLINICAL MANIFESTATIONS

The presenting symptoms of FHF are usually those of acute hepatitis, including malaise, nausea, and jaundice. Portal systemic encephalopathy is a required feature of the syndrome and can be staged as noted in Table II. Manifestations may range from subtle mental status changes, such as difficulty with concentration, to coma. The presence of encephalopathy in a patient with acute liver disease is an ominous sign and therefore mental status of patients with acute hepatitis should be frequently assessed.

Laboratory features of FHF are consistent with severe liver dysfunction. Aminotransferases are variably elevated, although usually quite high. The highest levels of aminotransferases, occasionally as high as 10,000 U/liter, are seen with acetaminophen hepatotoxicity or unusual viruses such as herpes. Viral hepatitis and other drug-induced liver diseases usually result in aminotransferase levels of 1000–5000 U/liter. Fulminant Wilson's disease is characterized by only modest aminotransferase elevations and a normal or only minimally elevated alkaline phosphatase, despite other more typical laboratory evidence of liver failure. Evidence of hepatocellular dysfunction includes a prolonged prothrombin time due to poor hepatic synthesis of clotting factors, high bilirubin secondary to decreased ability of the liver to excrete bilirubin, and sometimes a low albumin level, which may be due to cytokine-induced

TABLE II Stages of Hepatic Encephalopathy

Stage	Feature
I	Changes in behavior with minimal change in level of consciousness
II	Gross disorientation, gross slowness of mentation, drowsiness, asterixis, inappropriate behavior, able to maintain sphincter tone
III	Sleeping most of the time, arousable to vocal stimuli, marked confusion, incoherent speech
IV	Comatose, unresponsive to pain, includes decorticate or decerebrate posturing

increases in degradation or poor liver synthetic function.

Encephalopathy

The encephalopathy associated with FHF is likely different than that seen in chronic liver disease. The major difference is the propensity of encephalopathy of acute liver disease to progress to cerebral edema. Clinically, the encephalopathy is often associated with elevations in serum ammonia, although it is likely that alterations in other neurotransmitters are involved in causing the mental status changes. Marked elevations in serum ammonia are associated with a higher likelihood of subsequent cerebral edema and a poorer outcome of FHF. The exact mechanisms for the development of cerebral edema have not been clarified but may involve disruptions in blood–brain barrier and interference with mechanisms of cellular osmolarity.

Cerebral edema is estimated to cause of about 20% of deaths in patients with FHF; however, in autopsy studies of patients having died from FHF, cerebral edema is present in 50% of cases. Cerebral edema leads to death by causing brain ischemia and cerebral herniation. Symptoms and signs of cerebral edema are not specific and therefore intracranial pressure monitoring is often necessary. Computed tomography (CT) scans of the brain are relatively insensitive for detecting cerebral edema, although they are useful to exclude other causes of mental status changes, particularly intracerebral bleeding.

Coagulopathy

The liver is the site of synthesis of many clotting factors, including factors II, V, VII, IX, and X. Poor hepatocellular function leads to decreased synthesis of these factors, which can be measured directly or by determination of prothrombin time. Consumption of clotting factors due to intravascular coagulation and fibrinolysis (disseminated intravascular coagulation) can also contribute to the coagulopathy of FHF. Because factor V has the shortest half-life of the clotting factors synthesized in the liver, it is often used as a marker of residual liver function and has been utilized to help determine prognosis of FHF.

Hypoglycemia

Hypoglycemia is a frequent manifestation of FHF and glucose should be carefully monitored in all patients. The hypoglycemia is likely due to both inadequate degradation of insulin and diminished production of glucose by the diseased liver.

Infections

Infections are another common cause of death in patients with FHF. Reasons for the infections are multiple, but likely reflect severe illness and need for multiple interventions and monitoring. Typical clinical features of infection such as fever and leukocytosis are not reliable in patients with FHF. A high index of suspicion needs to be maintained and any clinical deterioration should mandate a search for infection. The presence of infection and progression of encephalopathy have been correlated in patients with FHF.

Cardiovascular System

A hyperdynamic circulation and reduction in systemic vascular resistance frequently accompany FHF. Although these features may be well tolerated, occasionally patients can develop hemodynamic compromise. Monitoring parameters may mimic septic shock. Fluid resuscitation is often necessary, although caution is advised because excessive fluid administration may worsen intracranial pressure; vasopressors are often necessary.

Other Organ Systems

Hypoxemia is due to multiple factors, including pneumonia or noncardiogenic pulmonary edema associated with adult respiratory distress syndrome. Renal and electrolyte abnormalities occur due to underlying disease such as Wilson's disease, functional renal failure due to sepsis or hepatorenal syndrome, or acute tubular necrosis. Renal dysfunction may be more common when FHF is due to acetaminophen hepatotoxicity. Monitoring of electrolytes, including sodium, potassium, bicarbonate, magnesium, and phosphorus, is important. Lactic acidosis is also common in FHF, likely due to hypoperfusion and inability of the diseased liver to clear lactate. The presence of acidosis is a risk factor

TABLE III Criteria for Liver Transplantation in Fulminant Hepatic Failure

King's College Hospital recommendations (any one of the three)
1. Fulminant hepatic failure due to Wilson's disease or Budd–Chiari syndrome
2. Acetaminophen-induced if either of the following criteria are met
a. pH < 7.3 24 hours after overdose
b. Creatinine >3.4 mg/dl and prothrombin time <100 seconds and grades 3 and 4 encephalopathy
3. Nonacetaminophen if either
a. International normalized ratio (INR) >6.5 or
b. Any three of the following: INR >3.5, more than 7 days from jaundice to encephalopathy, indeterminate or drug-induced cause, age <10 years, age >40 years, bilirubin >17.5 mg/dl
France recommendations
1. Grades 3 and 4 encephalopathy and
2. Factor V >20% of normal if age <30 years or <30% of normal if age >30 years

for poor outcome in FHF and has been incorporated into prognostic models.

PREDICTIVE MODELS AND MANAGEMENT

There have been several proposed models attempting to predict outcome of FHF. These have been developed to facilitate optimal timing of liver transplantation before the patient becomes so ill that there are contraindications to transplantation. Some of these models are summarized in Table III. The most well known and widely used are the King's College criteria. Liver transplantation likely improves mortality, although this has never been assessed except by comparison with historical controls.

All patients with FHF should be hospitalized. Patients who have no contraindications to liver transplantation should be transferred to a center where transplantation is available. Tests to establish an etiology are advised; history from the patients or family members should include a careful medication history, exam, serologic tests for viral hepatitis, autoantibodies, ceruloplasmin in appropriate patients, and liver ultrasound. Sedatives are avoided unless intubation or intracranial pressure monitoring is necessary.

Encephalopathy and Cerebral Edema

The appearance of encephalopathy precedes cerebral edema and therefore patients with acute hepatitis and evidence of liver failure need to be carefully monitored for mental status changes. Patients with encephalopathy should receive lactulose, although this agent is not as effective in acute liver failure as it is in chronic liver disease and may not prevent later cerebral edema. Patients with encephalopathy should be carefully monitored because rapid deterioration can occur. Patients with stage II encephalopathy are generally admitted to the intensive care unit for close monitoring of mental status and vital signs. It is especially important to avoid sedatives at this point to allow close monitoring of mental status. Most centers will also perform CT of the head to exclude an alternative cause for mental status changes.

Patients who reach stage III encephalopathy are at significant risk of progression to cerebral edema. Because clinical signs and head CT scans are insensitive for detecting increased intracranial pressure (ICP), many centers will institute ICP monitoring when patients reach stage III encephalopathy. This is usually preceded by endotracheal intubation and mechanical ventilation. A variety of ICP monitors are used, all of which can be complicated by infection and bleeding. The goal of ICP monitoring is to allow treatment of high pressures but also to identify which patients become too ill for liver transplantation because of excessively high ICP for a prolonged period of time. In general, the goal is to keep ICP less than 40 mmHg and cerebral perfusion pressure (the difference between mean arterial pressure and ICP) between 60 and 100 mmHg. Excessively high cerebral perfusion pressures (above 120 mmHg) can result in worsening cerebral edema.

Maneuvers that cause straining, including tracheal suctioning, should be avoided or limited. Paralyzing agents and sedatives may be necessary, although they limit further assessment of neurologic status. For ICP >20 mmHg or cerebral perfusion pressure below 60 mmHg, head elevation to 20°, hyperventilation to a P_aCO_2 of 25 mmHg, and mannitol (if renal function is intact) are advised. Barbiturate-induced coma or hypothermia can be used for refractory cases. A prolonged increase in ICP above mean arterial pressure may signify brain death and generally is a contraindication to liver transplantation. Sudden decreases in ICP may indicate brain herniation.

Management of Other Specific Complications

The prolonged prothrombin time seen in patients with FHF is a simple noninvasive parameter to follow and coagulopathy is generally not corrected unless there is bleeding or planned interventions such as monitoring devices. If bleeding occurs or invasive procedures are necessary, than fresh frozen plasma is generally used

first. Administration of platelets and fibrinogen may be necessary in certain circumstances. Continuous infusion of 5 or 10% dextrose is administered to keep the plasma glucose between 100 and 200 mg/dl. Plasma glucose should be carefully monitored, at least twice daily. Both bacteremia and fungemia are frequent enough that periodic blood cultures are advised and prophylaxis with antimicrobials may be used, although this has not been shown to impact survival.

Liver Transplantation

Liver transplantation has revolutionized the management of FHF. FHF is the indication for 6% of liver transplants in the United States. Even though survival with transplantation for FHF is lower than that for transplantation for other indications, outcomes are an improvement over the dismal survival rates seen in FHF when poor prognostic criteria (such as the King's College criteria) are met. Transplantation should be performed when a poor outcome is anticipated yet before the patient has uncontrolled sepsis or prolonged periods of increased ICP, such that recovery even with a functioning transplanted liver is not possible.

Contraindications to liver transplantation are advanced age, multisystem organ failure, uncontrolled sepsis, and prolonged increases in ICP. In the United States, patients with FHF are given highest priority for organs and therefore are often transplanted within 1 week. The 1-year survival after transplantation is about 60–75%.

Liver-Assist Devices

Artificial liver-assist devices have been in development for over a decade. Charcoal hemoperfusion and plasmapheresis have not been demonstrated to be beneficial. The newest system is the molecular adsorbent recycling system, which is based on dialysis of blood with a membrane that is coated with albumin to allow removal of both water-soluble and albumin-bound toxins. This promising system has yet to be formally studied.

Bioartificial livers use cultured porcine or hepatoma cell line hepatocytes in hollow fiber cartridges to provide metabolic functions. Such devices are able to achieve certain metabolic functions of the liver but have not yet been shown to improve survival compared to standard care, including liver transplantation. The ideal device would allow time for recovery of the diseased liver. Currently, the devices are used as a bridge to transplantation, keeping the patient stable until a liver becomes available.

Functional (Non-Ulcer) Dyspepsia

HENRY P. PARKMAN
Temple University School of Medicine

dyspepsia Refers to symptoms originating in the upper gastrointestinal tract; symptoms include upper abdominal pain/discomfort, early satiety, postprandial abdominal bloating/distension, and nausea without vomiting.
functional dyspepsia Refers to dyspeptic symptoms with no definable organic cause; diagnosis is based on negative findings after evaluation of medical history, physical examination, blood tests, and upper endoscopy.
gastroparesis Delayed gastric emptying in the absence of obstruction.

Dyspepsia refers to symptoms originating in the upper gastrointestinal tract, including upper abdominal pain/discomfort, early satiety, postprandial abdominal bloating/distension, and nausea with or without vomiting. Dyspepsia is a common condition with an estimated prevalence of approximately 20% of the population. Only about 25% of people with dyspeptic symptoms actually seek medical care. Dyspepsia accounts for 2–5% of patient visits to primary care physicians and 8% of patient visits to gastroenterologists. In approximately 60% of patients with dyspepsia, there is no apparent cause for the condition, and the diagnosis is "functional (nonulcer)" dyspepsia.

INTRODUCTION

Patients with functional (nonulcer) dyspepsia present with upper abdominal pain or discomfort with or without symptoms of early satiety, nausea, and/or vomiting with no definable organic cause. The Rome II criteria (Table I) help to diagnose functional dyspepsia. An upper endoscopy is suggested for evaluation of persistent or alarming dyspeptic symptoms. In young patients with uninvestigated dyspepsia, testing for *Helicobacter pylori* and treating if tests are positive will improve symptoms from underlying ulcer disease and will help prevent future development of ulcers. However, in patients with functional dyspepsia who have a negative endoscopy but a positive *H. pylori* test, the symptom response to *H. pylori* therapy is marginal. Lifestyle and dietary modifications are often suggested in the initial treatment. Antacids and over-the-counter histamine-2 (H2) receptor antagonists may be helpful as an "on-demand" therapy for intermittent symptoms. If the predominant symptom is epigastric pain (ulcerlike functional dyspepsia), H2 receptor antagonists or proton pump inhibitors are the initial treatment of choice. If fullness, bloating, early satiety, or nausea is the predominant complaint (dysmotility-like functional dyspepsia), a prokinetic agent may help. Metoclopramide is the only available effective prokinetic agent at present. If these treatments fail, patient reevaluation for other disorders (including other functional bowel disorders) is advised. Low-dose tricyclic antidepressant agents may be helpful for treatment of refractory dyspeptic symptoms.

TABLE I Rome II Criteria (1999) for Functional Dyspepsia

Persistent or recurrent abdominal pain or discomfort centered in the upper abdomen; discomfort is defined as an unpleasant sensation and may include fullness, bloating, early satiety, and nausea
Symptom duration of at least 12 weeks, which need not be consecutive, within the preceding 12 months
No evidence of organic disease (including at upper endoscopy) that is likely to explain the symptoms
No evidence that dyspepsia is exclusively relieved by defecation or is associated with the onset of a change in stool frequency or stool form (i.e., not irritable bowel syndrome)

The 1999 Rome II criteria for the diagnosis of functional dyspepsia listed in Table I have been useful in standardizing the diagnosis of functional dyspepsia in clinical studies. The Rome group has also suggested subcategorizing patient diagnoses, based on the predominant symptom, as ulcerlike, dysmotility-like, and nonspecific dyspepsias (Table II). Refluxlike dyspepsia in the Rome I criteria, with emphasis on predominant heartburn/regurgitation, is now categorized as primary gastroesophageal reflux disease (GERD). Specific symptoms, however, do not always correlate with pathophysiological abnormalities and response to treatment.

A variety of abnormalities have been implicated in functional dyspepsia (Table III). These include

TABLE II Rome II Subgroups for Functional Dyspepsia (Based on Predominant or Most Bothersome Symptom)[a]

Subgroup	Symptom
Ulcer like	Pain in upper abdomen
Dysmotility-like	Discomfort, fullness, early satiety, bloating, nausea
Nonspecific	No predominant symptom

[a] Overlap syndromes (not primarily dyspepsia, if main symptom): gastroesophageal reflux disease, with heartburn and acid regurgitation; irritable bowel syndrome, with pain relief following defecation; and biliary tract disease, with right upper quadrant abdominal pain.

inflammation, motility disturbances, visceral hypersensitivity, and psychological factors. Delayed gastric emptying, impaired gastric accommodation to a meal, gastric dysrhythmias, and visceral hypersensitivity are important pathophysiological factors. Delayed gastric emptying is present in approximately 35% of patients. As measured by electrogastrography (EGG), gastric myoelectrical abnormalities such as tachygastria, bradygastria, and a decreased postprandial : fasting power ratio are found in about 40% of patients with functional dyspepsia. Specific dyspeptic symptoms and their severity have generally correlated poorly with the degree of gastric stasis. However, in a large series of patients with functional dyspepsia, the severity of postprandial fullness and vomiting correlated with delayed gastric emptying. Regional gastric function abnormalities may be present in many dyspeptic patients and appear to correlate with symptoms. Reduced postprandial fundic relaxation and impaired accommodation are found in 40% of patients with functional dyspepsia. Transit from the proximal stomach into the antrum is rapid, leading to early antral distension, which correlates with symptoms. Hypersensitivity to gastric distension occurs in 35% of patients. Specific symptoms in dyspeptic patients may be related to the underlying pathophysiological abnormality. Early satiety is associated with impaired fundic accommodation, pain and belching are associated with hypersensitivity to gastric distension, and vomiting appears to be associated with delayed gastric emptying.

TABLE III Pathophysiological Mechanisms Linked to Functional Dyspepsia

Inflammation	*Visceral hypersensitivity*
Gastric acid sensitivity	Gastric
Helicobacter pylori gastritis	Duodenal
Enterogastric (bile) reflux	
Motility disturbances	*Psychologic factors*
Delayed gastric emptying/antral hypomotility	
Impaired fundic relaxation/antral distension to meal	

EVALUATION

Many patients seeking medical attention for dyspeptic symptoms are concerned about the possibility of other serious diseases, rather than the symptoms of dyspepsia. Definitive diagnosis of functional dyspepsia requires a normal esophagogastroduodenoscopy (upper endoscopy) during a symptomatic period when patients are not taking agents that suppress gastric acid. Upper endoscopy is not usually required in young patients (<50 years old) unless there are "alarm symptoms" such as dysphagia, weight loss, or anemia. Endoscopy rules out the presence of serious disease and helps to reassure the patient. This reassurance may be a useful initial step in management; some studies have shown that the endoscopic procedure alone may reduce symptoms.

Further noninvasive tests, such as gastric emptying scintigraphy and electrogastrography, can be performed to identify delayed gastric emptying and gastric dysrhythmias. These tests can demonstrate abnormalities in approximately 30–45% of patients with functional dyspepsia. As compared to patients with normal emptying, patients with delayed gastric emptying or an abnormal EGG may respond better to prokinetic agents, thus these tests may have prognostic importance. However, the link between prokinetic agent treatment and improved gastric emptying and relief from symptoms has not been proved.

Satiety testing with water or a nutrient drink may be used to evaluate impaired accommodation and sensation. Satiety tests offer the potential to evaluate gastric accommodation in a noninvasive way.

TREATMENT

Treatment of functional dyspepsia is influenced by several factors, including the episodic nature of symptoms, the occurrence of spontaneous remission, the heterogeneity of abnormalities, and the high placebo response rate, all of which have made it difficult to evaluate the actual response to drugs in many clinical studies. At the present time, there are several approaches to treatment, due in part to the proposed multiple causes of functional dyspepsia (Table IV). The treatment modalities that have been tested extensively are gastric acid suppressants, promotility agents, and *H. pylori* eradication. The aim of therapy in functional dyspepsia is to provide adequate symptom control and, if possible, to abolish symptoms. Another important aspect of drug therapy is

TABLE IV Multiple Causes and Therapies Proposed for Functional Dyspepsia

Multiple causes	Multiple therapies
Gastric acid	Antisecretory agents
Helicobacter pylori	Antibiotics
Dysmotility	Prokinetic agents
Hypersensitivity	Sensory modulators
Psychogenic	Psychotropic agents

to improve patient functioning and quality of life while minimizing the side effects.

Lifestyle and Dietary Changes

At present there is little evidence to implicate dietary habits in causing dyspeptic symptoms or to suggest that dietary modifications help relieve symptoms. Small, frequent meals rather than large meals should help relieve symptoms, assuming that the etiology involves receptive fundic relaxation and antral distension. Eating a low-fat diet, decreasing coffee intake, cessation of smoking, and limiting alcohol intake might be helpful in some patients. Patients should be advised to stop taking nonsteroidal antiinflammatory drugs (NSAIDs) and any other medication likely to cause dyspeptic symptoms, including digoxin, potassium supplements, and erythromycin. A lactose-free diet may be helpful in some patients. A high-fiber diet may delay gastric emptying and make the symptoms, especially bloating, worse.

Gastric Acid Suppressants

Gastric acid suppressants have been tested for several decades for their potential to treat functional dyspepsia. In general, improvement in dyspeptic symptoms with acid-suppressing agents has been moderate, averaging only 25% greater than with placebo. Antacids provide little help for chronic symptoms. Fourteen of the 24 studies that used prescription doses of acid-suppressing agents to treat nonulcer dyspepsia have reported a positive effect on symptoms in 35–80% of patients, compared to improvement in 30–60% of patients using placebo.

Histamine type 2 receptor antagonists (H2RAs) have a therapeutic effect of approximately 20% over placebo as reported in meta-analyses. However, a number of well-designed trials showed no benefit. The best response is seen in patients with endoscopy-negative GERD overlapping with functional dyspepsia.

Proton pump inhibitors (PPIs) are superior to placebo in promoting the complete relief of symptoms in ulcerlike dyspepsia with predominant epigastric pain. Complete relief of symptoms was obtained in 38% of patients treated with omeprazole (20 mg/day), compared to 28% with placebo. Omeprazole was not effective in dysmotility-like dyspepsia. In the near future, omeprazole will become generic as well as an over-the-counter medication, and the costs of PPI therapy will be dramatically reduced.

Promotility Agents

Promotility compounds, including metoclopramide, cisapride, and domperidone, have improved dyspeptic symptoms in patients with functional dyspepsia more effectively than placebo in the majority of reported studies. On average, the improvement was 40–50% greater than with placebo. The few studies comparing the effects of acid-suppressing and promotility agents on dyspeptic symptoms have favored promotility agents. In a recent meta-analysis, both cisapride and domperidone seemed to be effective in treating functional dyspepsia. One meta-analysis, however, suggested the possibility of publication bias with prokinetic agents. Cisapride was taken off the market due to its adverse cardiac effects and domperidone is not available in the United States. This limits the current choice of available agents to metoclopramide.

Metoclopramide is presently approved for short-term treatment of gastroparesis. Although a limited number of studies have directly tested use of this agent in functional dyspepsia, metoclopramide appears to be superior to placebo in the treatment of dysmotility-like dyspepsia. The main side effects are antidopaminergic and include sedation, diarrhea, and extrapyramidal symptoms, which occur in up to 25% of patients. These adverse reactions are most common in younger patients. Tardive dyskinesia, which may be irreversible even after stopping the medication, occurs rarely in elderly patients.

Erythromycin and other motilin receptor agonists have not demonstrated efficacy in treating functional dyspepsia. The motilin receptor agonist ABT-229 is ineffective in dyspeptic patients with delayed gastric emptying. Erythromycin and other motilin receptor agonists increase proximal gastric tone, which possibly aggravates the impaired fundic accommodation and worsens symptoms in functional dyspepsia.

Newer prokinetic agents under evaluation for treatment of functional dyspepsia include 5-hydroxytryptamine isotype 4 (5-HT4) agonists (tegaserod), dopamine antagonists (levosulpiride analogues), cholecystokinin antagonists (loxiglumide), and several motilin agonists. Tegaserod has been shown to improve symptoms and

gastric emptying in some studies. Fundic relaxing agents may improve the fundic accommodation response and may be helpful in patients with early satiety. 5-HT1 agonists (sumatriptan, buspirone), α-adrenergic receptor agonists (clonidine), and nitric oxide donors (glyceryl trinitrate) have been tried in a small number of series. Sumatriptan induces fundic relaxation through a nitric oxide-mediated pathway and improves meal-induced satiety in patients with functional dyspepsia. It has to be administered subcutaneously and can cause headaches. The α-adrenergic agonist clonidine reduces proximal gastric tone and pain perception during gastric distension in normal subjects. Thus, clonidine has the potential to reduce gastric sensation and increase gastric compliance. Clonidine, however, can delay gastric emptying and cause significant hypotension. Sildenafil (Viagra) has been shown to increase gastric accommodation. In animal models, it also relaxes the pylorus and improves gastric emptying, but in humans it can slow gastric emptying.

Eradication of *H. pylori*

Helicobacter pylori eradication is often suggested as first-line therapy for uninvestigated dyspepsia; patients with dyspeptic symptoms caused by ulcers will often be cured with this approach. The overall benefit of *H. pylori* eradication in uninvestigated dyspepsia depends on the underlying ulcer rate and the proportion of cases of ulcers that are associated with *H. pylori*. The latter has declined from a 90% association of *H. pylori* with duodenal ulcers in the 1980s to 60–65% at the present time. Although *H. pylori* is detected slightly more frequently in functional dyspeptic patients than in normal controls, only three of eight studies found that eradication of the bacteria improved patient symptoms. The 1994 National Institutes of Health (NIH) consensus conference on *H. pylori* did not support *H. pylori* eradication for treatment of functional dyspepsia: only 1 patient in 15 is likely to have improved symptoms. However, *H. pylori* eradication may decrease ulcer diathesis and may reduce the need for endoscopy, potentially reducing treatment costs. On a global scale, it may also reduce the eventual development of intestinal mucosa-associated lymphoid tissue (MALT) lymphoma and gastric adenocarcinoma. The potential drawbacks are treatment costs, side effects of antibiotic therapy, and antibiotic resistance. Moreover, *H. pylori* eradication may increase the chance of development of GERD/reflux esophagitis. Two recent large randomized studies on the effect *H. pylori* eradication in functional dyspepsia showed different results. One study suggested that symptomatic benefit from eradication may occur in a few patients whereas the other study suggested no benefit at all. The 1997 American Digestive Health Foundation (ADHF) panel on *H. pylori* and functional dyspepsia suggested that testing for *H. pylori* should be undertaken only if treatment is intended for a positive test. Testing should be considered in patients younger than age 45 years presenting with dyspepsia for the first time and in whom an ulcer is likely.

Psychotropic Medications

Psychotropic medications, including tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), are being used in the treatment of functional dyspepsia based on the evidence that augmented visceral sensitivity may be an important pathophysiological factor. Low-dose tricyclic antidepressants have analgesic effects that are independent of their psychological effects. The mechanism of action in treatment of functional dyspepsia is not clear, but may include reduction in visceral sensitivity. Two studies using tricyclic antidepressants reported a decrease in dyspeptic symptoms. In clinical practice, psychotropic medications have been recommended for patients with severe or intractable symptoms that interfere with their daily activities and are unresponsive to other treatment regimes. Major side effects are related to the anticholinergic action, causing dry mouth, blurred vision, and urinary retention. Orthostatic hypotension and reflex tachycardia can occur in the elderly. Sedation may be prominent, especially during the first few weeks of therapy; nighttime dosing is used to prevent this. In patients with poor sleep habits, the sedation effect can sometimes be advantageous. Agents with strong anticholinergic properties, such as amitriptyline, may adversely affect gastric motility. However, compared to amitriptyline, nortriptyline (Pamelor) and desipramine (Norpramin) have fewer side effects. Amitriptyline is the most commonly used and most thoroughly studied drug in this class for the treatment of functional dyspepsia. Dosages required for symptomatic improvement and complete remission are usually much lower than those conventionally used to treat depression. SSRIs may also be helpful but have not been studied in large-scale clinical trials.

Alternative Medicine

Complementary and alternative medicines are used frequently by patients with functional dyspepsia. Alternative medicine regimes, including special diets with herbal teas, yoga, and acupuncture, are used in Germany. Some commercially available herbal preparations, including Iberogast, which has extracts from

bitter candy tuft, and Enteroplant, which contains peppermint oil and caraway oil, have been shown in placebo-controlled trials to improve symptoms. Psychodynamic interpersonal psychotherapy and hypnotherapy have been reported effective in treating functional dyspepsia.

pseudomembrane False membrane. A layer of exudate on surface of skin or mucous membrane.

The increasing tide of fungal infections reflects the upsurge in the immunocompromised population. *Candida* spp. now rank fourth among bloodstream pathogens causing fungemia. The pulmonary tract, sinus tract, and skin are common target organs whereas the gastrointestinal tract rarely is involved apart from the oropharyngo-esophageal tract, the peritoneal cavity, and the hepatobiliary system. Compared to bacteria, fungi are distinctly unusual pathogens in the etiology of gastrointestinal mucosal–luminal infectious disease. Nevertheless, they cause substantial morbidity and mortality, pose problems for precision diagnosis, and can be challenging to treat. Fungal colonization in the gut serves as an important reservoir for bloodstream dissemination when the mucosal barrier is compromised for example, during chemotherapy-induced mucositis.

CANDIDAL OROPHARYNGO-ESOPHAGITIS AND NONESOPHAGEAL GUT SITES

Candida spp., mainly *Candida albicans*, colonize the gastrointestinal tract in up to 55% of normal individuals, depending on diet, age, and other factors. Hospitalization, broad-spectrum antibiotic use, steroids, and other immunosuppressive agents, e.g., in

pseudomembrane False membrane. A layer of exudate on surface of skin or mucous membrane.

The increasing tide of fungal infections reflects the upsurge in the immunocompromised population. *Candida* spp. now rank fourth among bloodstream pathogens causing fungemia. The pulmonary tract, sinus tract, and skin are common target organs whereas the gastrointestinal tract rarely is involved apart from the oropharyngo-esophageal tract, the peritoneal cavity, and the hepatobiliary system. Compared to bacteria, fungi are distinctly unusual pathogens in the etiology of gastrointestinal mucosal–luminal infectious disease. Nevertheless, they cause substantial morbidity and mortality, pose problems for precision diagnosis, and can be challenging to treat. Fungal colonization in the gut serves as an important reservoir for bloodstream dissemination when the mucosal barrier is compromised for example, during chemotherapy-induced mucositis.

CANDIDAL OROPHARYNGO-ESOPHAGITIS AND NONESOPHAGEAL GUT SITES

Candida spp., mainly *Candida albicans*, colonize the gastrointestinal tract in up to 55% of normal individuals, depending on diet, age, and other factors. Hospitalization, broad-spectrum antibiotic use, steroids, and other immunosuppressive agents, e.g., in

 Copyright 2004, Elsevier (USA). All rights reserved.

organ transplantation, increase fecal carriage rate and intensity. Widespread azole antifungal usage has been significantly associated with increased colonization of non-*albicans* spp., which may be resistant to azoles and other antifungal drugs. However, colonization does not equate with clinical infection and claims that the presence of gut *Candida* per se in an otherwise normal individual produces a symptom complex of diarrhea, debility, and weight loss has not been substantiated by vigorous clinical studies. On the other hand, there is little dispute that mucosal plaque formation and ulceration occur in patients with cancer and primary or acquired immunodeficiency states, particularly HIV infection. Oropharyngeal candidiasis presents clinically in four aspects: (1) pseudomembrane formation (Fig. 1), in which the plaques that constitute the pseudomembranes are composed of superficial hyperplastic, hyperkeratotic squamous epithelium with inflammatory cells, infiltrating fungal elements, and superinfecting bacteria; (2) acute erythematous epithelial atrophy, thinning, and papillary loss, which may be secondary to the pseudomembranous form; (3) chronic atrophy typified by mucosal edema and erythema (particularly in the elderly patients who have dentures), which may lead to hyperplasia (*Candida* leukoplakia), possibly premalignant; and (4) angular fissuring cheilitis.

Most cases present in the setting of HIV infection in which the key immunologic defect is a low CD4 T cell count. In non-HIV situations, steroid use, poor dental care, smoking, and antibiotic use are important predisposing factors. Increasingly recognized are other severe immunosuppressive states, including renal transplant patients receiving immunosuppressive therapy. Apart from the chronic atrophic form, oral discomfort is the commonest symptom and may result in poor food intake. Extension of the infection to the esophagus

FIGURE 1 Pseudomembranous candidiasis of the buccal cavity in an HIV-infected individual.

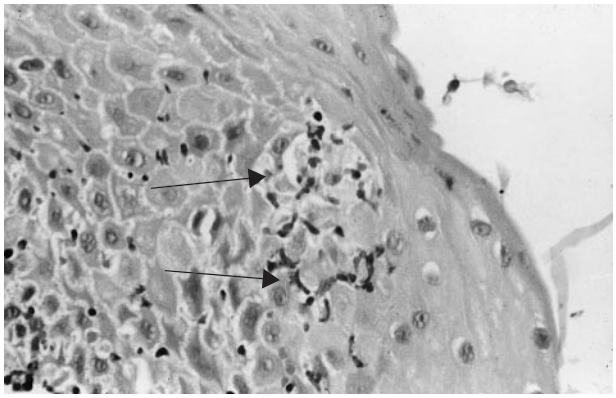

FIGURE 2 Esophageal biopsy showing infiltrating fungal elements from an HIV-infected patient with esophageal candidiasis.

(Fig. 2) results in painful and difficult swallowing due to the erosions and ulcerations (Fig. 3a). More severe esophageal disease is associated with coalescence of the plaques, leading to circumferential disease and luminal impingement. The combination of oral candidiasis and retrosternal pain on swallowing is reliably predictive of esophageal candidiasis, without recourse to endoscopy or barium swallow imaging examinations. Systemic candidiasis arising from this source is rare.

Oroesophageal candidiasis is best treated with systemically administered antifungals. Oral fluconazole (200–400 mg/day) or itraconazole, with the cyclodextrin vehicle to optimize absorption (100–200 mg/day), given for 2 weeks, is effective, with a rapid response seen in many patients (Fig. 3b). The relapses that occur in more than 30% of HIV patients are preferably managed by treating each episode rather than placing the patient on prophylactic antifungals, a course that fuels the emergence of drug resistance. Nevertheless, around 10% of all patients with advanced HIV infection (CD4 T cell count $< 100/\mu l$) have fluconazole-resistant infection associated with high minimum inhibitory concentrations (MICs) to the drug. Such cases can be managed either with high dosages of fluconazole (up to 1600 mg/day) or with liposomal amphotericin B or caspofungin. An integral part of the management of these patients is correction of the underlying immunodeficiency; for example, treating with highly active antiretroviral therapy (HAART) in HIV patients raises the CD4 T cell count.

After the esophagus, the stomach is the next most frequently involved site, followed by the small and large bowels. Underlying malignancy is often the setting in these patients. The etiologic role of histamine-2 (H2) blockers in increasing fungal disease susceptability remains a moot point. Plaques, fold thickening, superficial

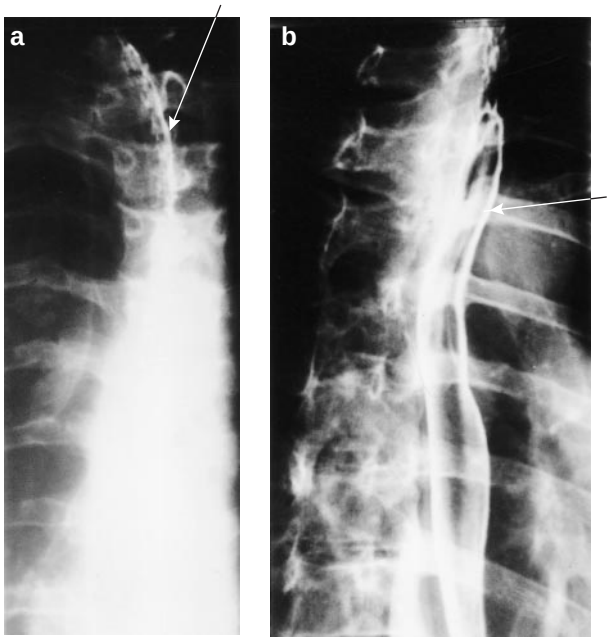

FIGURE 3 (a) Barium swallow, showing extensive ulceration and narrowing of the lumen. (b) The same patient after 3 days or oral fluconazole: normal swallow.

and penetrating ulcers, and perforation have all been described.

HEPATOSPLENIC CANDIDIASIS

Hepatosplenic candidiasis is a distinct form of disseminated candidiasis that occurs in the setting of leukemia. The classic scenario is of a patient with neutropenic fever and negative bacterial cultures, absent clinical foci, who subsequently resolves the neutropenia but has persistent fever for up to several weeks. Other cardinal features include weight loss, vague general unwell being and upper abdominal pain. There is hepatomegaly or splenomegaly or both in one-half of the patients. The hallmark biochemical abnormality is an elevated serum alkaline phosphatase. Upper abdominal imaging reveals multiple translucent lesions in the liver and spleen (Fig. 4). Liver biopsy may show fungal elements but tissue culture and blood culture are usually negative. Serological examination with *Candida* mannan antigen and antibody can be helpful in that situation (Fig. 5). Management with either liposomal amphotericin B (3–5 mg/kg/day) or fluconazole ($\geq$400 mg/day) continuing for 4 weeks after symptoms settle achieves success in 80% of cases. Widespread fluconazole prophylaxis use in leukemia patients has decreased the incidence of hepatosplenic candidiasis dramatically in recent years.

FUNGAL PERITONITIS

Fungal infections of the peritoneal cavity are usually due to *Candida* spp. They have become increasingly recognized, paralleling the increased numbers of patients undergoing continuous ambulatory peritoneal dialysis (infection incidence up to 20%) and gastrointestinal surgery (often associated with bacterial peritonitis and insidious in onset, but especially with anastomotic breakdown situations). Broad-spectrum antibiotic usage, parenteral nutrition, and immunosuppression are other important predisposing factors. Dissemination in patients who have candidal peritonitis in general is uncommon but occurs in up to 25% of cases of peritonitis secondary to intestinal perforation and following gastrointestinal surgery, with mortality as high as 80%. The presence of *Candida* in intraoperative specimens recovered from patients with intraabdominal perforations significantly relates to the risk of death. Fungal peritonitis is best managed with systemic antifungals and removal of the dialysis catheter if appropriate.

EMERGING AND UNUSUAL FUNGAL INFECTIONS

Several new fungal pathogens have emerged in recent years as important but rare causes of gastrointestinal disease. Increased treatment involving immunosuppression, selective antifungal drug pressure, and changing hospital environmental conditions drive this emergence. Dematiaceous fungi, including *Cladophialophora*, which causes esophagitis in small intestinal transplantation, and *Penicillium*, which causes peritonitis in chronic ambulatory peritoneal dialysis, have been described. Basidiobolomycosis, caused by a member of the Entomophthoraceae family, can mimic

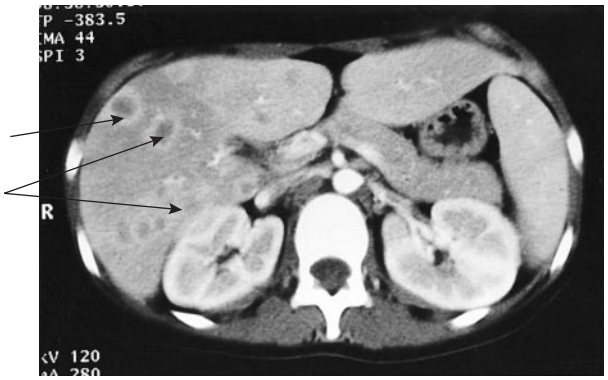

FIGURE 4 Computed tomography scan of a patient with acute myeloid leukemia and fever unresponsive to antibiotics, showing multiple hypolucent liver densities with enhanced rims.

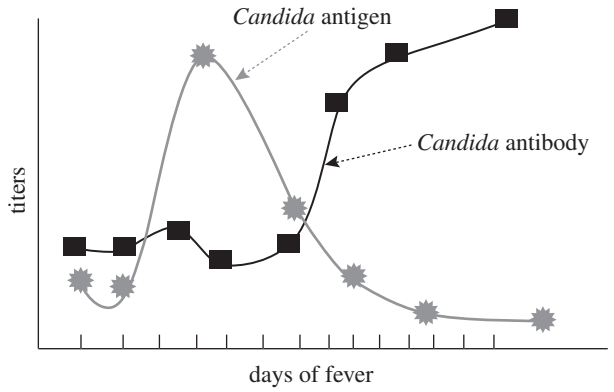

FIGURE 5 Serial *Candida* antigen (mannan) and antibody (antimannan) measurements in a patient with hepatosplenic candidiasis.

inflammatory bowel disease. Other members of the Zygomycetes, known gut wall invaders, include *Absidia*, *Rhizopus*, and *Mucor*, which producing nonspecific abdominal pain and hematemesis. Perforation can occur and is usually fatal. Another feature of the changing fungal profile is the increasing incidence of non-*albicans Candida* spp.

Several well-known invasive fungi have expanded their target organs to include the gastro-hepatobiliary system. Among these are *Aspergillus* spp., now documented in esophagitis and cecal deep wall involvement with ulceration and hemorrhage. Recent autopsy studies have indicated that in patients with hematological malignancy, *Aspergillus* infection occurred in 11% and the gastrointestinal tract was involved in 20%, which is an extraordinarily high figure. Most of these infections are not diagnosed postmortem.

Candida spp. are also known to involve the gallbladder, where they can present as a fungal ball, and bile ducts. *Cryptococcus* spp. are known to produce esophagitis and peritonitis. All of these new and unusual fungal infections, although uncommon, present considerable challenges for diagnosis and successful treatment.

Galactosemia

DOROTHY K. GRANGE
Washington University, St. Louis, Missouri

allele Alternate form of the DNA sequence of a gene at a given locus (position of a gene on a chromosome).
carrier A person who is a heterozygote for a mutant allele.
heterozygote An individual with two different alleles at a specific locus.
hypergonadotropic hypogonadism Reduced function of the gonads (ovaries or testes) due to congenital failure of development or postnatal damage or destruction, associated with elevation of gonadotropin (pituitary hormone) levels.
missense mutation A mutation that changes a codon for a specific amino acid to a different amino acid and results in a change in the amino acid sequence of a protein.
point mutation A mutation that involves a single nucleotide base-pair change in the DNA sequence of a gene.
verbal dyspraxia Expressive speech problem that results from the inability to properly program the muscles needed for speech, manifested by articulation problems, incorrect usage of words, or errors in word ordering.

Galactosemia is an autosomal recessive inborn error of carbohydrate metabolism that results in the inability to metabolize galactose to glucose. It occurs in approximately 1 in 60,000 newborns. Mason and Turner originally described the condition in 1935, when galactose was found in the urine of an affected patient. Individuals with galactosemia are intolerant of dietary lactose and galactose, primarily found in milk and milk products. If untreated, the disorder can cause liver failure, kidney dysfunction, sepsis, and death. If it is diagnosed soon after birth and treated by removal of lactose and galactose from the diet, the symptoms will resolve and many of the long-term complications, including cataracts and mental retardation, can be prevented.

BIOCHEMICAL PATHWAY

Dietary lactose is hydrolyzed to glucose and galactose by lactase in the intestine. Galactose is then further metabolized to uridyl diphosphate (UDP)-glucose by a series of reactions involving three enzymes, galactokinase (GALK), galactose-1-phosphate (PO_4) uridyl transferase (GALT), and UDP galactose-4-epimerase (GALE). Although galactosemia and galactosuria can be caused by a deficiency of any one of these enzymes, classic galactosemia, the condition of greatest clinical importance, is caused by a defect in GALT. Galactokinase catalyzes the conversion of galactose to galactose-1-PO_4 (Fig. 1). Galactose-1-PO_4 is then converted to glucose-1-PO_4 by a two-step reaction involving GALT and UDP galactose-4-epimerase. GALT catalyzes the transfer of UDP to galactose-1-PO_4 to form UDP galactose. UDP-galactose is then converted to UDP-glucose by UDP galactose-4-epimerase. Galactose is incorporated into glycoproteins and glycolipids, using UDP-galactose as the substrate for galactosylation reactions. In individuals with GALT deficiency, galactose and galactose-1-PO_4 accumulate in tissues, as well as the reduction product, galactitol, and the oxidation product, galactonate, which are derived from alternate metabolic pathways for galactose.

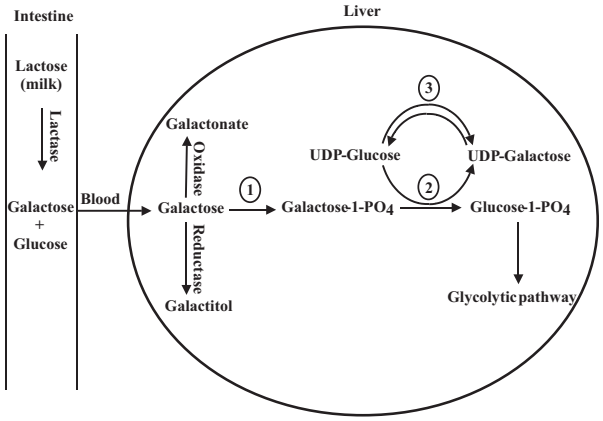

FIGURE 1 Lactose is metabolized by lactase in the intestine to galactose and glucose. Galactose is metabolized in the liver via the pathway shown in the figure. The enzymes required include (1) galactokinase, (2) galactose-1-PO_4 uridyltransferase (GALT), and (3) UDP galactose-4-epimerase. The defective enzyme in classic galactosemia is GALT (2). Galactose-1-PO_4 and galactose, as well as galactitol and galactonate, are elevated in patients with classic galactosemia.

CLINICAL PRESENTATION

A newborn infant with GALT deficiency appears normal at birth. However, if the baby is fed breast milk or a

 Copyright 2004, Elsevier (USA). All rights reserved.

lactose-based infant formula, symptoms will usually begin to develop within the first few days of life. Symptoms include vomiting, diarrhea, poor weight gain or weight loss, jaundice, and lethargy (see Table I). The baby will develop hepatomegaly and sometimes encephalopathy. If lactose-containing feedings are continued, the condition can be rapidly fatal.

Laboratory testing reveals liver dysfunction with elevated liver transaminases (alanine aminotransferase and aspartate aminotransferase), prolonged prothrombin time (PT) and partial thromboplastin time (PTT), and elevated bilirubin and ammonia. Hypoglycemia occasionally occurs during acute neonatal illness. The hyperbilirubinemia is primarily unconjugated initially, but there may be a conjugated component as the liver disease worsens over several days. The coagulopathy may be severe and can lead to significant bleeding. Vitreal hemorrhage and intracranial hemorrhage have been reported as complications. Kidney dysfunction, with development of renal Fanconi syndrome, is also a frequent complication. There is evidence of renal tubular disease, with hyperchloremic metabolic acidosis, glycosuria, aminoaciduria, and albuminuria. Urinalysis may reveal a positive test for reducing substances, indicating galactosuria. It is important to note that galactosuria can clear rapidly if the infant is placed on intravenous fluids, and thus, the absence of reducing substances in the urine does not rule out galactosemia. Other sugars in the urine besides galactose, such as fructose or pentose, can cause the test to be positive. Laboratory testing in suspected cases of galactosemia should include quantitative red blood cell (RBC) GALT activity and galactose-1-PO_4 measurements. RBC levels of galactose-1-PO_4 are markedly elevated in affected infants. RBC GALT activity is extremely low or absent in classic galactosemia.

In the untreated infant, cataracts can develop shortly after birth, although they most commonly develop after 3–4 weeks of lactose feedings. All infants with galactosemia should have an ophthalmology evaluation, which should include a slit lamp examination, since the cataracts may be missed on routine ophthalmoscopy. The cataracts in galactosemia are thought to be caused by injury to the lens from osmotic swelling due to the accumulation of galactitol. Cataracts usually regress spontaneously after treatment is initiated. The presence of such cataracts may aid in diagnosis while awaiting the results of laboratory testing.

Encephalopathy may occur in affected newborns, resulting in hypotonia, lethargy, and a reduced level of consciousness. Occasionally, pseudotumor cerebri may develop due to increased intracranial pressure; there may be increasing head circumference with bulging of the anterior fontanel and evidence of brain edema on computed tomography or magnetic resonance imaging scan. The encephalopathy is believed to be related to elevated galactitol in the brain, in some cases in combination with hyperammonemia. If galactosemia is untreated or diagnosed late, patients may have irreversible neurologic injury, with variable degrees of mental retardation.

Infants with galactosemia have an increased susceptibility to sepsis, particularly due to *Escherichia coli* and other gram-negative bacteria. Granulocyte function has been shown to be impaired by galactose and its metabolites. Thus, all ill newborns with galactosemia

TABLE I Clinical Findings in Symptomatic Neonates with Galactosemia

Abnormality	Percentage of patients affected	Additional findings
Hepatocellular damage	89	Jaundice (74%) Hepatomegaly (43%) Abnormal liver function tests (10%) Coagulation disorders (9%) Ascites (4%)

should be evaluated for possible sepsis and, until culture results are assessed, should receive broad-spectrum antibiotic coverage.

Because of widespread newborn screening for galactosemia, many newborns with mild variant forms of galactosemia are now being detected (see below). The most common of these is Duarte-classic galactosemia (DG) heterozygosity. In the vast majority of cases, there are no serious signs or symptoms of illness. Liver dysfunction and kidney dysfunction are not seen in affected newborns. Some infants with DG galactosemia have a mild increase in RBC galactose-1-PO_4 levels and GALT activity is approximately 20% of normal. There may be an increased risk for presenile cataracts in adulthood.

MOLECULAR GENETICS

All forms of galactosemia are inherited in an autosomal recessive fashion. Thus, parents who have had one affected child are both obligate carriers (heterozygotes) and have a 25% risk of having an affected child in each subsequent pregnancy. Approximately 1 in 120 individuals is a heterozygote for classic galactosemia. Over 170 different mutations have been identified in the GALT gene, which is located on chromosome 9p13. The most common mutation in classic galactosemia is the Q188R point mutation, found primarily in northern European populations and in patients of European descent. This mutation accounts for approximately 55% of mutant alleles in the Caucasian population. Another common mutation is the K285N point mutation, originating in eastern and central Europe. In some parts of Europe, this mutation is found on 25–40% of mutant alleles, but in North America, it accounts for approximately 5% of mutant alleles. Both of these mutations result in essentially total loss of GALT enzyme activity. The S135L mutation is almost always found in patients of African descent. In African Americans, it accounts for approximately 50% of the mutant alleles. Although the red blood cell GALT activity associated with the S135L mutation is very low, blood levels of galactose metabolites are lower and are easier to control than with other classic galactosemia mutations, reflecting higher GALT activity in other cells, with up to 5% of normal activity in the leukocytes and 10% activity in other tissues. Other common classic galactosemia alleles, also missense mutations, include L195P, Y209C, and F171S. Approximately 70% of affected individuals have two of these six common alleles, whereas 10% have one common allele and one "private" or rare allele, and approximately 20% have two rare alleles.

The Duarte allele (N314D point mutation) is very common and is present in 6–13% of the general population. Thus, approximately 1 in 3000 individuals is a compound heterozygote for the Duarte allele and a classic galactosemia allele. Compound heterozygotes have GALT activity between 5 and 20% of control values. Other mutations are sometimes detected via newborn screening, such as the Los Angeles allele, which is a gain-of-function mutation and results in increased GALT activity to approximately 140% of normal. Individuals who are compound heterozygotes for the classic galactosemia allele and the Los Angeles allele (LA/G) may be detected by newborn screening because the overall GALT enzyme activity is reduced. However, this genotype does not cause clinical disease.

NEWBORN SCREENING

Most states in the United States (48 of 50) and many developed countries of the world perform newborn screening for galactosemia. Although in many cases a newborn with classic galactosemia is beginning to show signs of illness before the results of the newborn screen are available, the goal of screening is early detection and prevention of both acute and long-term complications. Newborn screening methods vary among states, but usually involve fluorescent GALT enzyme assay and/or microbiologic or fluorescence measurement of galactose metabolites on red blood cells obtained from a filter paper blood spot. States that screen only by using GALT enzyme activity measurement would not detect cases of GALK and GALE deficiency, whereas those disorders would be detected by elevated galactose metabolites if both tests are performed. The enzyme activity on the screen can be falsely low if the filter paper is exposed to heat, a problem often encountered during transport of the filter papers to a centralized state laboratory in the summer months. The galactose metabolite measurements could be falsely low in an affected infant who has not yet consumed adequate lactose-containing milk at the time the blood sample is obtained, because the sample is collected too soon after birth or because of illness, poor feeding, or use of a soy-based or elemental formula. Therefore, it is critical that the laboratory be notified of the infant's feeding status to ensure accurate screening results.

Infants who are compound heterozygotes for the Duarte allele and a classic galactosemia allele (DG genotype) are often detected by newborn screening due to low GALT activity and, sometimes, mildly elevated galactose metabolites. GALT activity in these cases is approximately 20% of normal. Other GALT variants,

such as the Los Angeles allele, may be detected as a result of newborn screening.

TREATMENT

Dietary therapy for galactosemia has been used for nearly 50 years and involves removal of lactose- and galactose-containing foods and beverages from the diet. This means that breast-feeding or feeding with a cow's milk-based infant formula must be discontinued as soon as the diagnosis is made. Soy formula is used in infancy. As the baby gets older, galactose-free foods or foods that are extremely low in galactose, such as cereals, fruits, vegetables, and meats, are introduced. Some fruits and vegetables that contain galactose must be avoided and all milk and milk products (cheese, ice cream, etc.) must be removed from the diet. Parents must learn to read food labels and are provided with instructional materials about foods and medications that contain lactose. Treatment centers for children with galactosemia employ dieticians trained in metabolic disease treatment to assist patients and families and to monitor their progress. The diet must be maintained for the lifetime of the individual. Because of the lack of milk products in a galactose-free diet, calcium supplements must be provided to older individuals who are no longer consuming infant formula.

Long-term monitoring of compliance with dietary therapy is required for galactosemia patients. Growth and development are followed closely. After initiation of treatment, the galactose-1-PO_4 level will decrease, usually over a period of weeks to months. Regular clinic visits and galactose-1-PO_4 measurements on red blood cells can determine whether the patient is adhering to the prescribed diet. Urinary galactitol measurement is another way to monitor treatment. Patients with classic galactosemia are usually unable to lower their galactose-1-PO_4 levels to the normal range, despite good compliance with the diet, presumably because of the endogenous conversion of glucose to galactose via GALE, which has bidirectional activity. Galactose-1-PO_4 levels less than 3.5 mg/dl are considered adequate for galactosemics on diet, whereas the normal level is less than 0.5 mg/dl.

Although long-term complications are thought to be unlikely in DG galactosemia, many infants are placed on a galactose-restricted diet for some period of time after birth, ranging from 6 months to 2 years, depending on the treatment center. Some centers do not treat DG galactosemia. There have been no well-controlled studies to determine whether there are significant developmental or other long-term health risks in patients with DG galactosemia.

LONG-TERM COMPLICATIONS

Ovarian Dysfunction

Among women with galactosemia, there is a high risk for ovarian dysfunction and infertility. Hypergonadotropic hypogonadism occurs in 75% of affected females, manifested as primary amenorrhea and lack of secondary sexual development, delayed or abnormal puberty, or secondary amenorrhea due to premature ovarian failure in the 20s or 30s. Streak ovaries have been described pathologically. Risk factors for the development of ovarian dysfunction include homozygosity for the Q188R mutation, poor control of galactose-1-PO_4 levels (>3.5 mg/dl), and little ability to metabolize galactose (<5% galactose oxidation). These problems occur despite early diagnosis and treatment. The height of the galactose level at birth does not correlate with the degree of ovarian dysfunction, but there is some evidence that tight control of galactose-1-PO_4 levels throughout childhood may decrease the risk for ovarian failure. The cause of the ovarian dysfunction is poorly understood. It may be related to the effects of potentially toxic metabolites of galactose, such as galactitol, on the oocytes. Some women with galactosemia have been able to become pregnant and some have had children via ovum donation and *in vitro* fertilization techniques. Preteen girls with galactosemia should be evaluated by an endocrinologist and supplemental hormone therapy should be provided as needed to ensure pubertal development. Males with galactosemia do not have testicular dysfunction and have normal pubertal development and fertility.

Speech and Language Disorders

Despite good dietary control of the disorder, many children with classic galactosemia will exhibit speech and language problems, specifically verbal dyspraxia. Sixty-five percent of patients have been found to have these deficits. Most problems are in expressive language skills, speech articulation, word retrieval, and short-term memory. Receptive language skills are normal. Sibling pairs are similarly affected, even if the second child never received lactose or became ill as a newborn, suggesting a prenatal effect during brain morphogenesis.

Neurological Abnormalities

Some individuals with galactosemia may have later onset neurological abnormalities, again despite good dietary control. Patients have developed mild to severe

ataxia and a coarse intention tremor, beginning at 9–14 years of age. One study has shown a decline in IQ with age. The cause of these problems is not well understood. It has been postulated that there may be a deficiency of galactose-containing glycolipids or glycoproteins in the brain.

In summary, long-term follow-up of patients with galactosemia indicates that, although the outcomes have greatly improved with early diagnosis and treatment, certain health problems occur despite compliance with therapy. The cause of these problems is unclear, but may be related to prenatal elevation of galactose, galactose-1-PO_4, and galactitol, chronic postnatal intoxication by galactose metabolites as well as endogenous production of galactose, deficiency of UDP-galactose, or deficiency of galactose-containing glycolipids or glycoproteins in the brain.

OTHER FORMS OF GALACTOSEMIA: GALACTOKINASE AND UDP GALACTOSE 4-EPIMERASE DEFICIENCIES

GALK deficiency results in the development of cataracts. It does not cause systemic illness as seen in GALT deficiency, although pseudotumor cerebri has been reported occasionally as a complication in untreated individuals. This enzyme defect can be detected by newborn screening in those states that measure RBC galactose and/or galactose-1-PO_4 levels, which are elevated in affected individuals. It is treated with dietary restriction of galactose. The cataracts resolve with treatment.

GALE deficiency can also be detected through newborn screening, again if the state laboratory measures galactose metabolites. In North America, the most common form of GALE deficiency is limited to the red blood cells only and is most often seen in African Americans. Although RBC galactose-1-PO_4 levels are elevated and RBC GALE activity is absent or very low, GALE activity is 60–70% of normal in other tissues, including liver and fibroblasts. No treatment is required and patients are clinically well with normal growth and development. There have been rare patients reported in inbred populations with generalized GALE deficiency and, in those cases, the disorder presents in a manner similar to classic GALT deficiency.

choledochal cyst An often saccular dilation or other abnormal widening of a portion of the biliary tree.
cholelithiasis The presence of gallstones in the gallbladder.
common bile duct The duct formed by the juncture of the cystic duct and common hepatic duct, permitting the flow of bile from the liver and gallbladder to the small intestine.
mutagenic Of or pertaining to any chemical or physical environmental agent capable of inducing genetic mutations or increasing the mutation rate.
pancreatic duct (duct of Wirsung) The primary secretory channel of the pancreas.

Gallbladder carcinoma is an uncommon cancer with two distinct risk factors: cholesterol gallstones and anomalous pancreaticobiliary ductal junction. Few symptoms herald its presence, as late clinical presentations are the rule. Although surgery offers the opportunity for cure, other treatment options are limited in efficacy.

EPIDEMIOLOGY

Gallbladder carcinoma (GBCa) is an infrequent cancer, with an incidence ranging from 2.5 cases/100,000 population in the United States to 7.5 cases/100,000 population in parts of South America. A genetic predisposition to GBCa is undoubtedly important as women are affected three times as often as men, whereas people of Native American, Mexican, Japanese, Chilean, and Bolivian descent have the highest incidence worldwide. Most patients with this disease are age 65 or older.

ETIOLOGY/RISK FACTORS

Several disease processes are strongly associated with the development of GBCa. Cholesterol gallstones are the most commonly associated condition. Present in 70–90% of GBCa cases, they yield a threefold increase in risk for GBCa. The presence of cholelithiasis for a duration >40 years seems to increase the risk of GBCa as well. In its most chronic form, cholelithiasis leads to a "porcelain" gallbladder with partial or complete calcification of the gallbladder wall and imparts a significant risk of cancer.

Anomalous pancreaticobiliary ductal junction (APBDJ) occurs when the pancreatic duct and common bile duct join abnormally outside of the duodenal wall, yielding a longer common channel. Often associated with choledochal cysts, it is estimated that 11–18% of GBCa cases have an associated APBDJ. It is more common for GBCa to occur at younger ages in patients with this anomaly.

Gallbladder polyps are known to harbor cancer and represent another risk for GBCa. Gallbladder polyps in excess of 10 mm require that the gallbladder be removed surgically as the prevalence of GBCa increases significantly beyond this size (Table I).

Other etiologic factors with debatable roles in the development of GBCa include chronic *Salmonella typhi* carriage, various environmentally toxic compounds used in the automobile, textile, rubber, and metal industries, and previous gastrointestinal surgery.

PATHOGENESIS

The pathogenesis of GBCa depends on the etiologic factor implicated in its genesis. Cholelithiasis may lead to a vicious cycle of chronic gallbladder mucosal irritation with perpetual epithelial repair, resulting in carcinogenic mutations. Bile contains a multiplicity of

TABLE I Prevalence of Gallbladder Carcinoma According to Polyp Size

Polyp size	Prevalence of cancer
<10 mm	≤ 5%
10–15 mm	11–23%
>15 mm	50–70%

 Copyright 2004, Elsevier (USA). All rights reserved.

compounds that are potentially mutagenic, but the exact constituent(s) that may lead to cancer is yet to be defined.

Anomalous pancreaticobiliary ductal junction promotes free reflux of pancreatic juice into the biliary tree and, by altering the gallbladder milieu, promotes inflammation and proliferative activity of the gallbladder epithelium. This may facilitate mutagenesis at the cellular and nuclear levels. It is well known that up-regulation of the K-*ras* oncogene and mutations in the *p53* tumor suppressor gene exist more frequently in patients with APBDJ.

CLINICAL CONSIDERATIONS

Gallbladder carcinoma is a slowly progressive tumor, taking at least 15 years to develop. At presentation, symptoms are very nonspecific and their presence usually heralds a late presentation of this cancer. Nausea, vomiting, anorexia, and weight loss are typical. A fortunate patient will have the tumor located in the neck of the gallbladder intermittently occluding the cystic duct, causing symptoms mimicking cholecystitis. This may lead to an earlier diagnosis and increased chance for curative resection. Jaundice yields a particularly poor prognosis in that 85% of these tumors are surgically unresectable due to extensive local invasion into the adjacent hepatic parenchyma.

DIAGNOSIS

Most early-stage cancers are diagnosed incidentally at the time of cholecystectomy for unrelated reasons. If constitutional symptoms predominate, workup usually includes abdominal ultrasonography. Findings at ultrasound suggestive of GBCa include a thick gallbladder wall and/or lumenal mass, gallbladder calcifications, or obvious hepatic infiltration. Abdominal computed tomography defines more clearly the extent of disease, whereas ERCP with brushings may ultimately be diagnostic. Endoscopic ultrasound's role in staging these tumors is evolving.

STAGING/PROGNOSIS

The staging of GBCa follows that set forth by the American Joint Commission on Cancer and groups cancers into stages 0 through IV, with stage IV being the most advanced. For the less advanced stages 0 through II, prognosis is encouraging, as curative resection is possible. Stage III and IV cancers, however, have 1-year survivals of 25 and 10%, respectively, which reflect significant lymph node involvement and metastatic disease.

TREATMENT

Surgical resection of GBCa is the only potentially curative treatment modality. Chemotherapy using 5-FU (5-fluorouracil) based regimens has been explored, but the small number of patients treated limits interpretability. Combination therapy with surgery and either neoadjuvant or adjuvant chemotherapy may impart a trend toward improved survival in a heterogeneous group of case series and reports. Most centers treating GBCa would offer chemotherapy as an option. Radiation therapy has yet to be shown as a significant adjunct in the treatment of GBCa.

acalculous Lacking a gallstone.
adenoma (adenomatous) Benign epithelial tumor in which there are recognizable glands or in which cells are clearly derived from glandular epithelium.
agenesis Absence of an organ.
calculous Abnormal concretion, usually containing mineral salts; here, specifically a gallstone.
cholecystitis Inflammation of the gallbladder.
choledocholithiasis Stone in the common bile duct.
cholelithiasis Presence or formation of gallstones.
cystic duct Gallbladder duct that connects to the common bile duct.
empyema Accumulation of pus in a cavity of the body; can refer to accumulation external to or in the gallbladder.
functional Affecting function but not structure; in some cases, refers to absence of a specific disease entity although there is a symptom.
neoplasm Abnormal tissue growth that is uncontrolled and progressive but can be either benign or malignant.
peritonitis Inflammation of the peritoneum; in the case of cholecystitis, secondary to perforation, and extension of infection to involve the peritoneum and abdominal cavity.
Peutz–Jeghers Hereditary syndrome characterized primarily by gastrointestinal polyps (usually hamartomas).
polyp Protruding growth from a mucous membrane.

Gallbladder disease in children runs the gamut, from gallstones to neoplasms. In children, all gallbladder disorders appear to occur much less commonly than they do in adults. However, any estimate of prevalence or incidence is very difficult in children. In certain populations, there may be an increased incidence of diseases such as gallstones, but prospective data for these disorders are almost uniformly lacking.

ACALCULOUS DISORDERS OF THE GALLBLADDER

Acalculous Cholecystitis

Acalculous cholecystitis results from acute inflammation of the gallbladder. Reports of children with cholecystitis suggest that up to half may have acalculous cholecystitis. This inflammatory condition is generally categorized as either primary or secondary.

Primary inflammation has no identifiable cause, whereas secondary inflammation is seen in association with a variety of conditions, some similar to those associated with hydrops of the gallbladder. Conditions reported in association with acute inflammation of the gallbladder include septic infections with a variety of bacterial organisms, bacterial enteric infections, and streptococcal infections; pneumonias; viral infections such as gastroenteritis; opportunistic infections (e.g., cryptosporidium, cytomegalovirus, and fungal organisms) in immunocompromised patients, in patients following surgery, in severe illnesses such as burns, and in chronic inflammatory conditions such as Crohn's disease; congenital anomalies of the biliary tree causing cystic duct obstruction; and infections such as leptospirosis, Rocky Mountain spotted fever, and typhoid fever.

Patients usually present with biliary complaints, which include right upper quadrant pain, nausea, vomiting, and fever. On examination, they can have a mass, although this is unusual, and can have either localized right upper quadrant discomfort or generalized abdominal pain. Findings can be obscured by the abnormalities of the underlying associated disease process or the difficulty of examining some patients, e.g., patients with severe burns.

Recognition of the condition is important because of the complications of perforation, gangrene, and empyema that can result when the condition remains unrecognized. Because the symptoms can be consistent with a variety of other entities, such as peritonitis, intussusception, hepatitis, appendicitis, and choledochal cyst with cholangitis, distinguishing on clinical grounds alone can be difficult. Ultrasonography can show thickening of the gallbladder wall, absence of gallstones, edema around the gallbladder, and distension, but provides only supportive evidence of the clinical suspicion. Failure to fill the gallbladder on cholescintigraphy in the presence of good hepatic uptake is consistent with cholecystitis. However, a strong clinical suspicion is often the best clue to

 Copyright 2004, Elsevier (USA). All rights reserved.

the diagnosis. In most cases, cholecystectomy is recommended to avoid complications in a patient who is often already ill.

Hydrops of the Gallbladder

Acute hydrops is defined as gallbladder distension in the absence of evidence of obstruction (e.g., gallstones), inflammation, or congenital anomalies. The precise cause is unknown, but hydrops is seen only in association with other conditions, including Kawasaki syndrome, mesenteric adenitis, viral hepatitis, streptococcal or staphylococcal infection, Henoch–Schönlein purpura, hypokalemia, Sjogren syndrome, nephrotic syndrome, sepsis, parenteral nutrition, fasting, α1-antitrypsin deficiency, leukemia, familial Mediterranean fever, and systemic sclerosis. The unifying factor in all of these illness is unclear, but may relate to inflammation of the cystic duct secondary to a systemic illness, adenopathy compressing on the cystic duct leading to extrinsic obstruction, or possibly circulating factors (e.g., cytokines) that affect function of the gallbladder.

In general, patients with this disorder present with acute, crampy abdominal pain, nausea, and vomiting. Because the symptoms are nonspecific and not specifically biliary, a careful examination, looking for upper abdominal tenderness or mass in the right upper quadrant, is essential. Generally, there is neither fever nor jaundice. Ultrasonography is the most useful diagnostic test for verifying the diagnosis and will reveal a markedly distended gallbladder.

Once the diagnosis has been established, treatment is symptomatic and conservative, with spontaneous resolution occurring within days to weeks in the vast majority of patients. There is no evidence in these patients of chronic biliary dysfunction following resolution.

Neoplasms

Neoplasms of the gallbladder are extremely uncommon in childhood. Benign tumors (adenomatous polyps) have been described in patients with Peutz–Jeghers syndrome. Isolated adenomatous polyps have also been described in the absence of systemic illness. In each case, surgical removal is recommended because there is at least theoretical risk of progression to malignancy. Primary malignancies of the gallbladder are exceedingly rare in children. However, embryonal rhabdomyosarcoma has been described in the gallbladder and biliary tract in childhood. Thankfully, these are rarely found, because prognosis is extremely poor.

Congenital Abnormalities

Isolated congenital anomalies of the gallbladder are uncommon. Both gallbladder agenesis and torsion of the gallbladder secondary to a congenitally long mesentery have been described. This latter problem presents with clinical features essentially indistinguishable from cholecystitis (see later). Cholecystectomy is the treatment of choice.

Functional Disorders

Biliary dyskinesia is thought to be a motor dysfunction of the gallbladder and the sphincter of Oddi. Patient complaints are generally described as a recurrent, continuous biliary type of pain. Decreased gallbladder emptying on a quantitative cholescintigraphy is used as the standard for assessing this dysfunction in adults. However, there are no data to support the presence of such dysfunction in children or what would be normal values for such a functional study in children. At present, neither recommendations for identification nor treatment of such dysfunction can be made. It is more likely that many children thought to have this disorder have functional recurrent abdominal pain.

CHOLELITHIASIS

Gallstones

Gallstones in children can form *in utero* and be diagnosed in the fetus with prenatal ultrasounds or can be found with abdominal ultrasonography in otherwise asymptomatic infants or children. It is not clear what factors contribute to the formation of gallstones or what the incidence or prevalence is in children. In younger children, genetic predisposition is a likely important contributor to their formation.

Recent work by Paigen and colleagues in mouse models has suggested that genes that may contribute to the formation of these gallstones fall into several general categories. The processes suggested to be involved include cholesterol secretory rate, increased cholesterol delivery to the liver, up-regulation of cholesterol synthesis, development of type 2 diabetes and obesity, biliary hypersecretion of cholesterol, inhibition of bile salt synthesis, and coupling of biliary cholesterol to other biliary lipids. Further work in both mouse models and high-risk human populations should help elucidate how various genetic mutations or polymorphisms influence the process of gallstone formation (cholesterol stones).

Such genetic predisposition appears to underlie the increased incidence or prevalence observed in certain human populations. Some populations appear to be at much higher risk than others are, including some Native Americans (Amerindians), Swedes, and Czechs, whereas very low incidences are reported in Canadian Eskimos and in people in certain areas of Africa. In the few studies available in (Italian and Swedish) children, there is an increased incidence and prevalence in girls, with a rapid divergence of the incidence curves for boys and girls after 11 years of age. From these studies, Italian children between 6 and 19 years of age had an overall prevalence of 0.13%, with girls having a prevalence of 0.27%. In Swedish children, gallstones were very infrequent prior to 11 years of age. In studies of Amerindians, girls had an overall prevalence of around 10% during their teenage years, but this rose to 70% by their fourth decade. Amerindian men are also at increased risk, with reported prevalences of less than 2% during their teen years but rising to 25% during their forties and increasing to 70% by age 60. Variations noted in various human populations suggest that genetic differences may underlie the noted differences in prevalence. The fact that in the United States there can be vastly different incidences on diets that are roughly equivalent (Amerindians $\gg$ Caucasians $\gg$ African Americans) again points to the influence of genetic susceptibilities as important contributors to the burden of gallstone disease. Further support for genetic susceptibility to gallstone formation is found in the differences among Hispanics in the United States. Mexican Americans are at a much higher risk for gallstone formation and gallbladder cancer when compared to Puerto Ricans and Cubans. Such differences may relate to the higher prevalence of Amerindian genes in the Mexican American population. However, even among North American Amerindians, there is considerable variation in the prevalence from population to population. In individuals with 100% Amerindian heritage, those in the Dakotas had a prevalence of around 45%, those in Oklahoma had a prevalence of around 73%, and those in Arizona had a prevalence of approximately 93%. Prevalences observed were similar in both males and females. Thus, the contribution of genetic background can be inferred from such data, but remains to be better established on an experimental basis before specific recommendations can be made for screening or treatment based on genetic susceptibility.

In children, most gallstones are either pigment stones or cholesterol stones. Pigment stones are categorized as brown or black. Black pigment stones are primarily made of calcium carbonate and phosphate, whereas brown stones have large amounts of calcium soaps (fatty acid salts). In both, the underlying framework consists of mucin glycoproteins secreted by the biliary epithelium. Brown pigment stones form in the presence of both stasis and infection. Black pigment stones form most commonly in the presence of chronic hemolytic disease (e.g., hereditary spherocytosis, sickle cell anemia, or glucose-6-phosphate dehydrogenase deficiency), during fasting while on total parenteral nutrition, and because of cirrhosis or chronic cholestasis [including conditions such as Wilson's disease and progressive familial intrahepatic cholestasis type 1 (Byler's disease)]. The use of certain drugs, such as ceftriaxone, causes development of sludge (called pseudolithiasis) and may also contribute to stone formation.

There are some differences in etiology at different ages. Gallstones in infants are seen in association with total parenteral nutrition, sepsis, chronic lung disease, hemolytic anemia, malabsorption, abdominal surgery, hepatobiliary problems, and necrotizing enterocolitis. However, in many of these disorders, the children will be receiving intravenous nutrition or will be very limited in their oral intake, which may in and of itself be a major contributor to stone formation. In older children and adolescents, there is an increased association with both obesity and pregnancy.

Although it is estimated that up to 80% of gallstones in adults are silent, they can cause significant clinical symptoms. The most consistent symptoms relate to obstruction of the cystic or biliary duct. It is not known how many children without symptoms actually have gallstones, nor if those who do have "silent" gallstones ever develop symptoms during the course of their life. Those who develop symptomatic cholelithiasis have been described at all ages in childhood. The frequency of symptomatic patients at any age appears to be related to the risk for developing gallstones. For all symptomatic cases of cholelithiasis, cholecystectomy is the treatment of choice. With asymptomatic gallstones, most clinicians would recommend no treatment unless symptoms arise.

Complications of Cholelithiasis

Both chronic and acute cholecystitis can result from cholelithiasis. Gallstone obstruction of the cystic duct of the gallbladder appears to be the cause of acute cholecystitis. The symptoms that characterize acute cholecystitis are similar to those of symptomatic cholelithiasis without cholecystitis. They include "biliary colic," which is severe persistent abdominal pain that may localize to the right upper quadrant, with anorexia and vomiting. High fever is unusual. Physical examination may reveal right upper quadrant tenderness and a Murphy's sign

(inspiratory arrest secondary to pain in this area). In adults, a palpably enlarged gallbladder is found in up to a third of patients.

Laboratory abnormalities can include hyperbilirubinemia and elevated liver enzymes (alkaline phosphatase and aminotransferases). Leukocytosis is commonly observed. If there is choledocholithiasis, then amlyase and lipase may also be elevated. A suspected diagnosis of acute cholecystitis is best confirmed by ultrasonography, with the visualization of gallstones in the gallbladder. Failure to visualize the gallbladder following cholescintigraphy is also consistent with the diagnosis of cholecystitis. Management is initially conservative, with supportive care as needed and antibiotics. Cholecystectomy is the treatment of choice. All patients with acute cholecystitis should be carefully monitored for signs of potential complications, which include perforation and empyema.

Chronic cholecystitis undoubtedly occurs in children but is poorly characterized as an entity. This may in part be related to the standard of surgical removal of the gallbladder following an episode of acute cholecystitis in children. Because many patients with chronic cholecystitis have an antecedent history of an episode of acute cholecystitis, children may be less likely to present with this particular entity. Those who do have the disorder can have essentially asymptomatic disease or symptoms consistent with biliary colic. Treatment is a cholecystectomy.

Choledocholithiasis is not thought to be a common problem in children but is usually symptomatic, in marked contrast to studies in adults, who can be symptom free in this condition. In children, choledocholithiasis can cause pancreatitis, which can be the presenting problem for these children. Almost all children with duct obstruction secondary to gallstones have biliary colic and severe abdominal pain. If they have cholangitis as well, they will have fever and tenderness on exam. Most commonly, patients with obstruction will have a leukocytosis and elevated liver enzymes. An elevated conjugated bilirubin is also consistent with the diagnosis.

Initial diagnostic studies include ultrasonography. Dilatation of the common bile duct suggests an impacted stone or a congenital anomaly of the bile duct. Because biliary stones, especially those near the ampulla, can be missed on ultrasonography, the absence of a visualized stone does not exclude the diagnosis. Magnetic resonance cholangiopancreatography or computed tomography are both useful tools in the visualization of the common bile duct and pancreatic ducts and can detect stones in both the common bile duct and in some cases stones near the ampulla. In most cases, endoscopic retrograde cholangiopancreatography is necessary both for diagnosis and for treatment. Following treatment, if there are still gallstones in the gallbladder, a cholecystectomy is recommended.

antinucleating proteins Biliary proteins that can inhibit nucleation of cholesterol crystals *in vitro*. Examples include apolipoprotein A-I, apolipoprotein A-II, and immunoglobulin A.

biliary sludge Microscopic precipitates in bile that can be visualized with ultrasonography or bile microscopy. Can produce symptoms and complications similar to those of gallstones. Also known as microlithiasis or pseudolithiasis.

cholesterol saturation index In a given bile sample, the ratio of the actual amount of cholesterol to the maximum cholesterol-carrying capacity of that sample, determined *in vitro*. Bile with a cholesterol saturation index greater than 1 is considered supersaturated.

cholesterol supersaturation State in which the amount of cholesterol in bile exceeds the cholesterol-carrying capacity of the biliary lipids. A prerequisite for cholesterol gallstone formation.

nucleation Initial precipitation of solid cholesterol crystals from supersaturated bile. An initial step in gallstone formation.

pronucleating proteins Biliary proteins that can promote nucleation of cholesterol crystals. Examples include mucin, anionic peptide fraction, and phospholipase C.

Gallstones are extremely common in Western societies. Over 20 million Americans are believed to have gallstones, and approximately 700,000 cholecystectomies are performed every year. Symptoms and complications related to gallstones are among the most costly gastroenterologic disorders, at an estimated annual cost of almost $6.5 billion. In Western societies, gallstones are composed primarily of cholesterol. The formation of cholesterol gallstones requires three fundamental pathophysiological factors: hepatic secretion of cholesterol-supersaturated bile, nucleation of biliary cholesterol to form crystals, and gallbladder stasis.

SYNTHESIS OF BILIARY LIPIDS

Bile is a complex substance composed of lipids, proteins, electrolytes, and water. There are three principal biliary lipids: cholesterol, bile acids, and phospholipids (primarily phosphatidylcholine). Many species of proteins are present in bile, and they are derived from serum proteins as well as from hepatocyte, bile duct, and gallbladder epithelial secretion. Gallstone formation is determined by the physical–chemical interactions of biliary lipids, as well as interactions with biliary proteins.

Cholesterol

The total body pool of cholesterol is derived from dietary absorption and *de novo* synthesis. The liver is the primary site of cholesterol synthesis in the body. Free cholesterol is synthesized in the hepatocyte endoplasmic reticulum via the rate-limiting enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Cholesterol derived from lipoproteins is also taken up by the liver. Cholesterol enters the liver in esterified form and is transported to the lysosomes, where it is converted into its free form. It is then transported to the endoplasmic reticulum and is reesterified for storage. Cholesterol esters in the endoplasmic reticulum are continually undergoing hydrolysis, providing a constant supply of free cholesterol. This free pool in the endoplasmic reticulum is the source of cholesterol for bile acid and lipoprotein synthesis and for secretion into bile. Approximately 80% of biliary cholesterol originates from an existing pool in the liver. The remaining 20% of biliary cholesterol is derived from new hepatic synthesis. Total hepatic cholesterol is tightly regulated within a narrow range.

Bile Acids

Bile acids are synthesized from cholesterol through the rate-limiting microsomal enzyme cholesterol 7α-hydroxylase. Bile acids, which are amphiphilic, can solubilize and transport hydrophobic cholesterol in aqueous solutions such as bile. Two primary bile acids, chenodeoxycholic acid (CDCA) and cholic acid (CA), are synthesized *in vivo*. The relative proportions of these are regulated by the activity of the enzyme 12α-hydroxylase, which converts CDCA to CA. The cholesterol-carrying capacity of bile is influenced by the relative proportions of these two bile acids, because less cholesterol is solubilized by CA than by CDCA. 12α-Hydroxylase can be induced by estrogens, resulting

 Copyright 2004, Elsevier (USA). All rights reserved.

in higher proportions of CA and more lithogenic bile. This effect of estrogen may explain some of the female propensity for gallstone formation.

After synthesis, carrier proteins bind bile acids to transport them through the hepatocyte. Bile acids are then conjugated with glycine and taurine, which increases their water solubility. They are then actively secreted by bile acid transporters located in the bile canalicular membrane of the hepatocyte. Bile acids are initially excreted as individual molecules. However, at a critical micellar concentration, they can aggregate to form micelles that are capable of solubilizing cholesterol and phospholipids. When bile acids enter the intestine, they are metabolized by intestinal bacteria, deconjugated, and dehydroxylated. In this process, CDCA is converted to lithocholic acid and CA is converted to deoxycholic acid. Bile acids are reabsorbed in the terminal ileum and circulate via the portal vein to the liver. In the liver, they are reabsorbed, reconjugated, and resecreted into bile via the enterohepatic circulation.

Phospholipids

It is believed that phospholipids in bile are derived from the hepatocyte canalicular membrane or from membranous structures within the hepatocyte, such as the endoplasmic reticulum or lysosomes. Phosphatidylcholines comprise over 95% of the phospholipids in bile. Phospholipids are amphiphilic molecules, similar to bile acids, and can solubilize and transport cholesterol. Phospholipids are believed to be translocated across the canalicular lipid bilayer by a protein similar to the multidrug resistance gene protein. Cholesterol and phospholipids then aggregate and are secreted from the outer leaflet of the canalicular membrane into bile as vesicles.

CHOLESTEROL SECRETION AND SOLUBILIZATION

The primary route for elimination of cholesterol from the body is biliary secretion. As a hydrophobic molecule, cholesterol is relatively insoluble in aqueous solutions such as bile. Thus, in bile, cholesterol must be solubilized by amphipathic biliary lipids such as bile salts and phospholipids. Free cholesterol is virtually insoluble in aqueous solution. Bile acids, because of their unique amphipathic properties, are able to solubilize cholesterol and phospholipids in mixed micelles.

The major driving force behind the biliary secretion of cholesterol and phospholipid is bile acid secretion. Bile acids are actively secreted against a gradient into the bile canaliculus, inducing subsequent secretion of cholesterol–phospholipid vesicles. Hydrophobic bile acids are more effective than other bile acids as stimulators of lipid secretion, although the maximum rate of biliary lipid secretion is similar for all bile acids. In the bile canaliculus, cholesterol can be solubilized with phospholipids (such as phosphatidylcholine) as unilamellar vesicles ranging in size from 40 to 100 nm. These vesicles consist of a bilayer of phospholipid interdigitated with cholesterol, without associated bile acids. These vesicles are believed to be derived from the outer membrane leaflet of the canalicular membrane. Vesicles comprise a separate and distinct carriage system that probably represents the major mode of cholesterol transport from the hepatocyte.

Within the bile canaliculus, the bile acid concentration gradually increases, eventually reaching a critical micellar concentration. At this concentration, cholesterol–phospholipid vesicles can be converted into mixed micellar carriers containing cholesterol, phospholipids, and bile salts. This dynamic interchange between vesicular and micellar forms of cholesterol carriage continues within the bile ductules, ducts, and gallbladder. Bile salts are more efficient at solubilizing phospholipids than cholesterol. As lipid carriers are converted from vesicles into micelles, the remaining vesicles become progressively enriched with cholesterol.

The proportion of cholesterol transported in the micellar form can vary dramatically, depending on bile acid concentrations. For example, at low bile acid secretion rates, as with fasting, cholesterol hepatic bile is carried primarily in vesicles. Conversely, in the gallbladder, the higher bile acid concentrations favor a shift of cholesterol into the micellar forms. Thus, the degree of bile cholesterol saturation varies depending on physiologic conditions and the relative concentrations of the various biliary lipids.
