Phase equilibrium diagrams have been constructed to characterize cholesterol solubility at various concentrations of biliary lipids. Using these diagrams, the cholesterol saturation index (CSI) can be calculated. The CSI is the ratio of the actual amount of cholesterol in a given bile sample to the maximum cholesterol carrying capacity of that sample determined *in vitro*. Bile with a CSI greater than 1 is considered supersaturated. Supersaturated bile that does not form cholesterol crystals is called "metastable."

CHOLESTEROL SUPERSATURATION

The amount of cholesterol secreted by the liver can sometimes exceed the carrying capacity of the biliary lipids, resulting in bile that is supersaturated and

metastable. Various pathogenic conditions can disrupt the tight balance of biliary lipid secretion, resulting in absolute biliary cholesterol hypersecretion or relative bile acid hyposecretion.

Biliary cholesterol hypersecretion may occur by several different mechanisms. For example, nonobese gallstone patients may have higher intracellular levels of total and free cholesterol, suggesting enhanced intracellular cholesterol transport. Clinical situations associated with excessive secretion of biliary cholesterol include obesity, rapid weight loss, aging, drug effects, and hormonal therapy. In obesity, it is believed that activity of HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis, is increased, leading to higher total body cholesterol. Paradoxically, with rapid weight loss, cholesterol is rapidly mobilized from adipose tissue, with resultant increases in biliary secretion. With aging, there may be a decrease in activity of the 7α-hydroxylase enzyme, a key enzyme in the metabolism of cholesterol to bile salts. Various medications, including clofibrate, estrogens, and progesterone, affect cholesterol secretion by altering hepatic cholesterol uptake or metabolism.

Alternatively, biliary cholesterol supersaturation may occur with relative bile acid hyposecretion. In patients with ileal disease or who have undergone ileal bypass or resection, bile acid absorption is decreased, leading to a diminished bile acid pool. In patients with primary biliary cirrhosis or other chronic cholestatic diseases, bile acid secretion may be decreased. Recent attention has focused on the role of deoxycholic acid. In nonobese patients with cholesterol gallstones, cholic acid and chenodeoxycholic acid pools are reduced, and deoxycholic acid is often increased in bile. Deoxycholic acid may influence the amount of cholesterol and mucin secreted into bile. Prolonged intestinal transit seems to be the underlying reason for the increased percentage of deoxycholic acid in gallstone patients. Associated with these differences in intestinal transit, gallstone patients have higher concentrations of anaerobic and gram-positive aerobic bacteria in the colon, as well as significantly higher activity of the 7α-dehydroxylase enzyme, which is critical in the synthesis of deoxycholic acid formation. In the future, altering the metabolism of deoxycholic acid or accelerating intestinal transit may prove to be a mechanism to prevent gallstone formation.

Recent animal studies have indicated that specific genes determine the incidence of cholesterol stone formation in mice fed a lithogenic diet. Some of these genes may act through their role in regulation of biliary cholesterol or bile acid secretion. For example, apolipoprotein E (apoE), an important component of very-low-density and high-density lipoproteins and chylomicrons, has been the subject of many studies. It has a central role in hepatic lipoprotein catabolism and regulates the plasma cholesterol response to dietary cholesterol. Some, but not all, previous studies have associated the E4 allele of apoE with a higher risk of cholesterol gallstones. The E4 genotype of apolipoprotein E is reported to be associated with gallstone formation, and patients with the E4 genotype have higher gallstone cholesterol content. In apoE-deficient mice, the increase in plasma cholesterol in response to dietary cholesterol is attenuated. The apoE-deficient mice also have an attenuated increase in biliary or hepatic cholesterol concentration and cholesterol saturation index in response to a lithogenic diet. These mice form markedly fewer cholesterol crystals or stones compared to wild-type mice when fed a lithogenic diet. Thus, apoE may play a role in regulating biliary cholesterol secretion, while also playing a role in gene–diet interactions in gallstone formation.

Other ongoing work is characterizing the roles of various genes in mouse models of gallstone formation. For example, the murine *Lith1* gene is associated with gallstone disease in a dominant fashion. The bile salt export pump has been identified as a candidate protein for this *Lith1* gene. Other candidate genes for gallstones in mice include those for HMG CoA reductase, for the canalicular multispecific organic anion transporter (CMOAT), for the intracellular lipid transporters (Pctp and Fabp6), for lipoprotein lipase, and for lecithin–cholesterol acyltransferase. Further work will characterize these genes and hopefully identify their human homologues.

NUCLEATION OF CHOLESTEROL CRYSTALS

An early and indispensable step in cholesterol gallstone formation (Fig. 1) is nucleation, the precipitation of solid cholesterol crystals in saturated bile. Aggregation and fusion of cholesterol–phospholipid vesicles is a crucial step in this process, and cholesterol in stones appears to be derived preferentially from these vesicles. Thus, vesicular cholesterol may be more unstable and prone to precipitate than that in mixed micelles.

Vesicles in bile do not behave homogeneously. Vesicles in gallbladder bile are likely to participate in nucleation; vesicles in hepatic bile are much more resistant to nucleation. These differences are caused partly by the difference in their relative cholesterol-to-phospholipid ratio. Vesicles with increased ratios of cholesterol to phospholipid are more prone to aggregate, fuse, and nucleate. Vesicles with lower

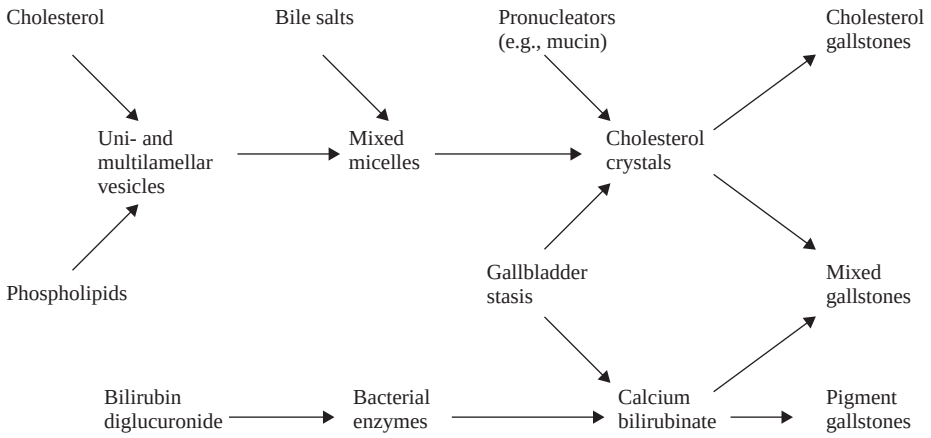

FIGURE 1 Cholesterol gallstone formation. Cholesterol and phospholipids are initially secreted into bile as uni- and multilamellar vesicles. With the addition of bile salts, mixed micelles can form. Further addition of pronucleating agents, such as mucin, in combination with gallbladder stasis can lead to nucleation of cholesterol crystals from supersaturated bile. These crystals may aggregate and grow, eventually forming gallstones.

cholesterol-to-phospholipid ratios, as seen in hepatic bile, are more stable and less prone to nucleation. Conversely, higher concentrations of bile acids, as seen in the gallbladder, favor preferential removal of phospholipids over cholesterol from vesicles during the transition to micellar carriage. The residual vesicles are relatively cholesterol enriched and prone to nucleate.

In humans, secretion of cholesterol-supersaturated bile is common, but not all people with supersaturated bile develop stones. Thus, factors in addition to supersaturated bile must be present for gallstones to form. Factors influencing the rate of crystal nucleation have been a subject of intense study. Biliary proteins have generated the most attention, because total biliary protein content is increased in bile with cholesterol crystals compared with samples without crystals. Several studies have suggested that protein–lipid interactions in bile might be important in promoting or inhibiting crystal formation.

Several pronucleating and antinucleating proteins have been identified in bile. Some putative pronucleating and antinucleating proteins are listed in Table I. All of the postulated pronucleating proteins can bind lipid microaggregates in bile. It is postulated that specific hydrophobic peptide segments of these proteins bind to cholesterol-enriched microdomains in biliary vesicles, eventually leading to their aggregation and fusion. This, in turn, facilitates precipitation of microscopic cholesterol crystals. Nevertheless, the experiments on pro- and antinucleators have often been performed *in vitro* or in animal models, and the significance of many of these proteins *in vivo* or in humans has not been fully established.

The most widely studied pronucleating agent is mucin, a high-molecular-weight glycoprotein secreted by the gallbladder epithelium that is the major organic constituent of gallbladder mucus. Mucin consists of a polypeptide core with multiple oligosaccharide side chains. The polypeptide cores contain hydrophobic domains that can bind cholesterol and phospholipid, thereby bringing vesicles and micelles into close contact. After this binding has occurred, the lipid membranes can fuse and mix, forming multilamellar vesicles. In this way, mucin can act as a pronucleator. Addition of mucin to supersaturated bile will greatly

TABLE I Postulated Pronucleating and Antinucleating Proteins

Pronucleating proteins	Antinucleating proteins

Haptoglobin	
Fibronectin	
Phospholipase A_2	
α1-Antichymotrypsin	

facilitate cholesterol crystal nucleation. Mucin may also be incorporated into the core of growing crystals, providing an architectural nidus for further crystal growth into stones. Mucin hypersecretion is a necessary antecedent to stone formation in a number of animal models of lithogenesis. The stimulus for mucin hypersecretion is not clear, although prostaglandins may play a role. For example, the hypersecretory response can be inhibited by aspirin. In some animal models, aspirin ingestion can inhibit formation of cholesterol crystals and gallstones. Although prostaglandins may play a role in mucin hypersecretion, the role of other factors, such as hydrophobic bile salts or lithogenic bile, has not been clarified. More recently, oxysterols have been identified in bile of patients with pigment gallstones, and their presence may also affect mucin secretion.

Calcium is another important factor influencing crystal nucleation. Calcium salts of bilirubin, phosphate, or carbonate are present in the center of many, if not all, cholesterol gallstones, and may serve as nidi for cholesterol crystallization. Calcium has been shown to bind to mixed micelles, simple micelles, and simple vesicles *in vitro*, potentially explaining its role in cholesterol crystal nucleation. Calcium may also regulate gallbladder secretion of electrolytes and glycoproteins such as mucin. However, studies of biliary calcium levels in gallstone patients are conflicting.

ROLE OF THE GALLBLADDER

The gallbladder is an essential organ in the pathogenesis of cholesterol gallstones. Cholecystectomy essentially prevents *de novo* formation of cholesterol stones. Both gallbladder motility and mucosal function are believed to be important. The gallbladder serves as more than a storage organ. The gallbladder can concentrate and acidify bile, substantially altering the solubility of cholesterol, calcium, and bilirubin in the process. Compared to hepatic ductal bile, gallbladder bile is more concentrated and prone to nucleation. Mucin gels accumulate with prolonged bile storage in gallbladder stasis. The viscosity of these gels may interfere with mechanical emptying. Increased cholesterol nucleation and crystal growth as well as enzymatic and nonenzymatic hydrolysis of bilirubin conjugates could occur with prolonged stasis. The resulting unconjugated bilirubin may precipitate with calcium. Thus, in the presence of gallbladder stasis, bile becomes more concentrated and lithogenic. In this setting, cholesterol crystals are more likely to form. Furthermore, after the initial nucleation step, cholesterol crystals will remain in a static gallbladder. Thus, with gallbladder stasis, cholesterol crystals are more likely to form, remain in the biliary system, and grow into stones. If gallbladder motility is adequate, nascent cholesterol crystals can be emptied, and further growth of these crystals into stones cannot occur.

Altered gallbladder contractility before cholesterol stone formation has been shown in a lithogenic animal model. Many clinical situations associated with gallbladder stasis are also associated with higher risk of gallstones. For example, prolonged total parenteral nutrition (TPN) induces profound gallbladder hypomotility and stasis, predisposing to subsequent biliary sludge and possible stone development. High spinal cord injury is linked to gallbladder stasis and gallstone formation. Pregnancy, oral contraceptives, obesity, diabetes mellitus, and octreotide therapy are also associated with impaired emptying and cholelithiasis.

Gallbladder mucosal function plays a vital role in lithogenesis, but the role of mucosal function is not as well studied compared to gallbladder motility. The gallbladder mucosa absorbs excess water and electrolytes, concentrating bile. The mucosa also normally secretes hydrogen ions and mucin. Transport of sodium and chloride ions across the mucosa is altered in animal models of lithogenesis. The role of the gallbladder in concentrating bile is magnified with gallbladder stasis.

In addition to concentrating bile, the gallbladder mucosa can secrete proteins, such as mucin, which might serve as sites for cholesterol crystal precipitation. Alterations of lipid metabolism in the gallbladder epithelium that might increase cholesterol content have also been studied. Hydroxymethylglutaryl-CoA reductase activity, governing cholesterol synthesis, is lower in the gallbladder mucosa than in hepatic tissue, and acylcoenzyme A : cholesterol acyltransferase (ACAT) activity catalyzing the esterification of cholesterol is several times higher than in the liver. A recent study also suggests that normal human gallbladders can absorb phospholipids and cholesterol from bile *in vitro*, resulting in bile becoming less lithogenic. In contrast, gallbladders from patients with cholesterol stones were less able to absorb cholesterol and phospholipids, resulting in potentially more lithogenic bile. This impaired ability to absorb biliary lipids may be an additional pathogenetic factor for gallstones.

MIXED CHOLESTEROL STONES, PIGMENT STONES, AND THE ROLE OF BACTERIA

Cholesterol gallstones commonly contain other constituents, including proteins and calcium salts of bilirubin or carbonate. Although sometimes called mixed stones,

they are still classified as cholesterol stones, because cholesterol compromises more than 70% of the stone by weight. Pigment gallstones can be subclassified into brown and black types, which differ in morphology, pathogenesis, and clinical associations. In contrast to cholesterol gallstones, ethnic origin is not an important risk factor for pigment gallstones. Black pigment stones can occur in persons with no predisposing conditions, but important risk factors associated with the formation of this type of stone include chronic hemolysis (e.g., sickle cell disease), thalassemia, prosthetic cardiac valves, advancing age, and cirrhosis. Black pigment stones seldom coexist with cholesterol stones in the same gallbladder.

In Asia, brown pigment stones are often found in the bile ducts and are strongly associated with bacterial infection. There is a high incidence of infection with *Escherichia coli* and other intestinal organisms such as *Enterococcus, Enterobacter, Pseudomonas,* and *Proteus.* Infection with anaerobic organisms such as *Clostridium* and *Bacteroides* species can also be documented. Infected bile exhibits high bacterial β-glucuronidase activity, believed to be an important enzymatic process in bilirubin deconjugation. Bilirubin, like cholesterol, is insoluble in water. After glucuronidation in the liver, bilirubin is secreted into bile, mostly as the diglucuronide (75–80%) or the monoglucuronide (20%), but with a small amount of the unconjugated form (3%). Because mixed cholesterol and pigment stones contain salts of calcium and bilirubin, deconjugation and precipitation of bilirubin is essential in the pathogenesis of these stones.

The role of biliary β-glucuronidase in the pathogenesis of pigment gallstones has been controversial. It has been hypothesized that bacterial β-glucuronidase facilitates the hydrolysis of conjugated bilirubin into insoluble bilirubin, providing the substrate for formation of infection-related brown pigment stones. However, this hypothesis does not seem to explain the pathogenesis of black pigment gallstones. β-Glucuronidase activity in uninfected bile has been demonstrated, suggesting that this enzyme may also originate in the biliary tract epithelium. In support of this, gallbladder bile from patients with pigment, cholesterol, or mixed gallstones has been shown to have a higher proportion of bilirubin monoglucuronide compared to bile from controls. However, another pathogenic factor, gallbladder stasis, must be present for precipitates of calcium bilirubinate to form. In a scenario similar to cholesterol gallstone formation, gallbladder stasis can provide an opportunity for nonenzymatic hydrolysis of conjugated bilirubin and its subsequent precipitation. For example, prolonged total parenteral nutrition, with the subsequent gallbladder stasis, can result in the formation of gallbladder sludge and black pigment stones.

The gallbladder may promote pigment gallstone formation in other ways. Calcium solubility is vitally linked to black and brown pigment gallstones, because both kinds of stones contain predominantly calcium bilirubinate. Hepatic bile is supersaturated with calcium carbonate. Normal gallbladder epithelium can acidify bile, which increases the solubility of calcium carbonate. An inflamed gallbladder may be unable to acidify bile, promoting pigment gallstone formation. The gallbladder epithelium secretes mucin into bile, which can bind to bilirubin and other hydrophobic lipids and is contained in black and brown pigment gallstones.

The role of biliary tract infection in gallstone pathogenesis is receiving renewed interest. It has traditionally been believed that bacterial infection is involved only in the pathogenesis of mixed pigment ("brown") stones, in which bacteria are believed to facilitate hydrolysis of conjugated bilirubin to its less soluble, unconjugated form. More recently, using molecular genetic techniques, it has been possible to identify bacteria in both mixed and pure (>90%) cholesterol stones. It has recently been hypothesized that the inciting factor in brown pigment stone formation is bacterial infection and bilirubin deconjugation. However, after initiation of the stone-forming process, bile may evolve in its composition, leading to formation of mixed or even pure cholesterol stones. Similarly, stones may act as foreign bodies and enhance bacterial colonization, resulting in precipitation of bilirubinate salts or remodeling of the existing stones. Thus, it is likely that significant overlaps exist in the pathogenesis of cholesterol and pigment stones. Study in this area has been hampered by the fact that it is often difficult, if not impossible, to determine whether bacterial infection or stone formation was the initial event. The development of gallstones likely includes the interaction of bacterial and physical–chemical mechanisms over a period of years, leading to diverse types, shapes, and numbers of stones.

BILIARY SLUDGE

Once sufficient numbers of crystals have formed, they may be visible by ultrasonography and produce the same range of clinical symptoms as gallstones. These precipitates in bile have been called by many names, including biliary sludge, microlithiasis, and pseudolithiasis. Sludge is best diagnosed by microscopic examination of a fresh sample of gallbladder bile. Sludge also appears ultrasonographically as low-amplitude echoes (without postacoustic shadow) that layer with gravity.

Biochemically, sludge is composed of cholesterol monohydrate crystals, calcium bilirubinate granules, or other calcium salts embedded in a mucus gel. Calcium bilirubinate granules are present in almost all cases, with bilirubin usually in its unconjugated and least soluble form. Proteins and other substances such as ceftriaxone are also important components. Sludge also contains a large proportion of mucin, protein–lipid complexes, and undefined residue. The calcium precipitates, with cholesterol crystals 50 μm or more in diameter, produce the characteristic ultrasonographic echoes in sludge. The deformable mucin gel accounts for its unique layering and flow characteristics.

In certain clinical conditions, sludge may evolve into cholelithiasis, and it has been hypothesized that the crystals in sludge aggregate and grow to form gallstones. Thus, sludge is believed by many to be a necessary precursor to stones. For example, in a prospective study of patients receiving prolonged TPN, 6% of the patients developed sludge during the initial 3 weeks. By 4–6 weeks, 50% of the patients had sludge, and after 6 weeks, sludge was seen universally. Stones developed in 43% of patients during followup. At this time, the risk factors for evolution of sludge into stones are unknown.

Gallbladder sludge may also appear spontaneously in selected individuals. For example, in the previous study of patients receiving prolonged TPN, sludge resolved with reinstitution of oral feedings in all the patients by the end of 4 weeks. Another study documented the clinical outcome of a group of patients presenting with upper abdominal pain and sludge documented on initial ultrasound examination. In approximately 18% of patients, the sludge resolved over a 2-year period. It had a disappearing and reappearing course in about 60% of patients. Gallstones also developed in 14% of patients. Other retrospective studies have demonstrated similar findings.

SUMMARY

The pathogenesis of cholesterol gallstones is complex and not completely understood. It is believed that a primary factor is altered secretion of biliary cholesterol, phospholipid, and bile acids from the liver, resulting in cholesterol supersaturation of bile. As the bile is progressively concentrated during its passage through the bile ducts and during storage in the gallbladder, the vesicular fraction of biliary lipids becomes relatively cholesterol enriched. These lipid vesicles aggregate and fuse. Gallbladder mucin hypersecretion and stasis develop, perhaps through the action of chemical mediators such as prostaglandins. With the addition of pronucleating proteins such as mucin, nucleation of cholesterol crystals can occur. The cholesterol crystals formed can be retained within the gallbladder, where they grow and conglomerate with mucin glycoprotein and other constituents, such as calcium and bilirubin. As these crystals aggregate and enlarge, they may become visible on ultrasonography as biliary sludge. Continued gallbladder stasis and impaired emptying of sludge eventually lead to macroscopic stone formation.

The pathogenesis of pigment stones has recently been revisited with the documentation of bacteria and bacterial biofilms in gallstones. Bacterial enzymatic deconjugation of bilirubin is a key factor in formation of bilirubinate stones, and may be an initiating factor for cholesterol gallstone formation as well. Ongoing work is focused on the role of pronucleating and antinucleating proteins, as well as further clarification of the role and timing of bacterial infection in gallstone pathogenesis.

antrectomy Type of partial gastrectomy in which the stomach's antrum is removed.
Billroth I and II Reconstructive surgical procedures used after partial gastrectomy in which the remaining part of the stomach is connected to the duodenum or jejunum, respectively.
endoscope Medical instrument used to examine the inside of the stomach and duodenum; consists of a thin, long, flexible tube that contains a light and camera, which can be easily passed through the mouth and into the stomach and duodenum. A small, flexible wirelike instrument can be inserted through the endoscope and out its end to sample or remove stomach masses such as polyps.
esophagojejunostomy Surgical creation of an artificial passage between the esophagus and jejunum; the passage is used to reconstruct the intestinal tract following a total gastrectomy.
gastrectomy Surgical procedure in which part (i.e., a "partial" gastrectomy) or all (i.e., a "total" gastrectomy) of the stomach is removed.
gastroduodenostomy Type of gastroenterostomy in which a portion of the stomach is connected to the duodenum.
gastroenterostomy Surgical creation of an artificial passage between the stomach and any part of the small intestine (e.g., the duodenum or jejunum).
gastrojejunostomy Type of gastroenterostomy in which a portion of the stomach is connected to the jejunum.
gastrostomy Artificial opening in the stomach wall, usually created by surgical means. Not to be confused with gastrectomy.
palliation Treatment designed to improve a patient's symptoms without curing the disease causing the symptoms.
sphincter Ringlike band of muscle fibers that can intermittently contract to constrict an opening, thereby controlling flow of substances out of a structure. For example, the pyloric sphincter controls flow of contents between the stomach and duodenum.
stomach polyp Raised mass of the inner lining of the stomach; protrudes into the lumen of the stomach.
tumor Abnormal collection of cells that form a mass or polyp; in the lay community, at times mistakenly assumed to be equivalent to "cancer," although tumors can be either malignant (i.e., cancerous) or benign (noncancerous). Malignant and benign tumors are distinguished by their appearance under the microscope and/or their propensity to spread throughout the body.
ulcer (stomach or duodenum) Local defect or erosion of the inner lining of the stomach or duodenum.

The word "gastrectomy" comes from the Greek *gaster*, meaning stomach, and the root word *ectomia*, meaning to surgically excise or remove. Christian Theodur Billroth, a well-known surgeon from Vienna, first described partial gastrectomy procedures in 1881. In recognition of his efforts, Billroth's name defines two important and well-known reconstructive surgical procedures—the Billroth I and Billroth II. Total or partial gastrectomies are usually performed to remove benign and cancerous tumors of the stomach and for treatment stomach or duodenal ulcers.

fundus is the uppermost portion of the stomach, the body is the middle and largest portion, and the antrum is the bottom portion, which is in continuity with the small intestine. The pylorus, a muscular sphincter located at the stomach's exit, regulates passage of partially digested food from the stomach into the first part of the small intestine or duodenum (see Fig. 1).

The cells of the stomach produce juices such as hydrochloric acid and enzymes (e.g., pepsin), which reduce food to a liquid form ready to enter the small intestine. The stomach rhythmically contracts to mix swallowed food with stomach juices, which aids in the digestive process over a few hours. Once reduced to liquid form, the stomach contracts and the pyloric sphincter relaxes, allowing the now liquefied contents of the stomach to flow into the small intestine. The small intestine then continues the digestion process and begins absorbing nutrients into the bloodstream for use by the body.

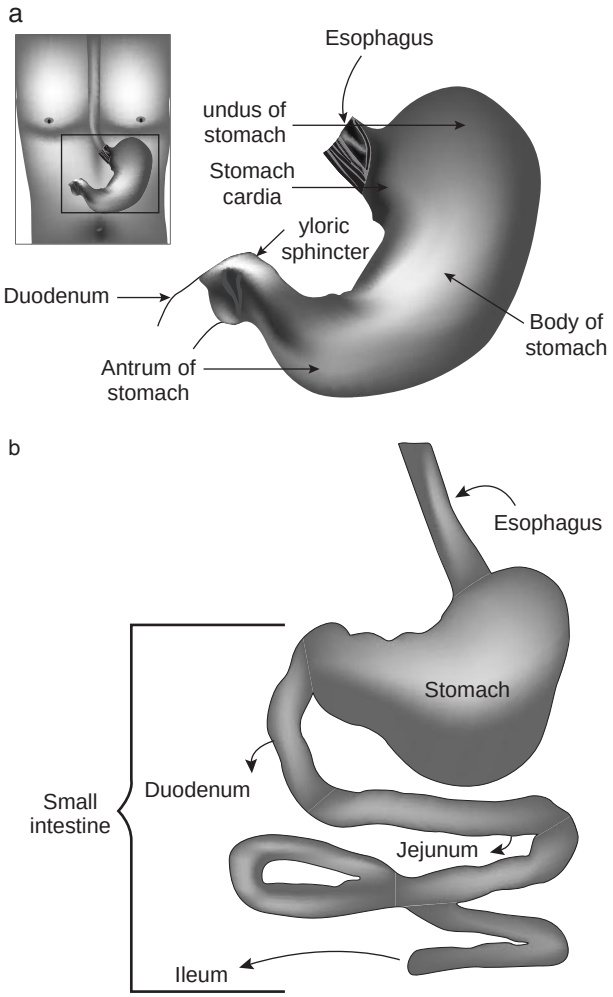

FIGURE 1 (a) Parts of the stomach. (b) Relationship between the stomach, esophagus, and small intestine.

BENIGN AND CANCEROUS STOMACH TUMORS

When treating diseases related to the stomach, the two main reasons to perform a gastrectomy are treatment of stomach tumors and ulcers. Partial gastrectomy may also be used as part of the treatment of other conditions, such as cancer of the pancreas and esophagus and treatment of obesity. Although these latter conditions are not the focus here, the principles of gastrectomy are similar regardless of the indication for performing such surgery.

The stomach can develop a variety of benign and malignant tumors. Benign (i.e., noncancerous) tumors are usually cohesive and have well-demarcated borders. They do not invade or infiltrate the surrounding normal tissues and do not spread to different areas of the body. Malignant (i.e., cancerous) tumors usually invade the surrounding normal tissues and have the potential to spread to distant sites in the body if they are allowed to continue to grow. The spread of malignant tumor cells to areas of the body that are distant from their site of origin is referred to as metastasis. Once metastasis has occurred, the chance of cure by surgery alone is highly unlikely. Hope for cure under such circumstances requires surgery to be combined with other cancer treatment modalities, such as chemotherapy or radiation therapy.

Stomach cancer, also known as gastric cancer, is a common cancer of the gastrointestinal tract. It occurs most frequently in men over age 50 years. Every year in the United States, 25,000 people develop gastric cancer. There are a variety of malignant stomach tumors, and the vast majority of stomach cancers require gastrectomy for potential cure. Although there have been many advances in the treatment of stomach cancer, the likelihood of survival depends on whether the cancer can be treated by gastrectomy while the tumor is still confined to the stomach. The proportion of all individuals diagnosed with stomach cancer who will survive for 5 years is approximately 5–15%. The survival rate for a particular individual, however, depends on the type of cancer, if it has invaded nearby structures, or if it is has metastasized to distant sites of the body, such as the liver. Hence, a person with a "favorable" stomach cancer may have a survival chance of greater than 90% whereas patients with "unfavorable" tumors may have no chance of survival.

Gastrectomy may also be used for palliation of patients who have advanced stomach cancer. Patients

whose stomach cancer blocks the passage of food or secretions, or causes significant bleeding and pain, may be treated by total or partial gastrectomy. Although there may be no hope of cure, the quality of these patients' lives may be significantly improved by performing a gastrectomy in such circumstances.

There are also a variety of benign tumors of the stomach, including benign stomach polyps. Polyps of small to medium size can be removed by an endoscope. However, polyps that are too large to be removed by the endoscope are usually treated by partial gastrectomy. In addition, patients whose polyps who have been removed by the endoscope and are found to be cancerous on microscopic analysis may require further treatment with gastrectomy.

STOMACH AND DUODENAL ULCERS

Another major reason to perform a gastrectomy is for treatment of stomach and duodenal ulcers. The ulcers may form as a result of acid and pepsin produced by the stomach eroding through the inner lining of the stomach and/or duodenum. Alternatively, nonsteroidal antiinflammatory drugs such as aspirin or ibuprofen may lead to ulcer formation. Finally, certain types of bacteria, such as *Helicobacter pylori*, may lead to ulceration of the stomach and duodenum. In the past, stomach and duodenal ulcers were routinely treated by partial, and in some cases total, gastrectomy. However, advances in medical treatments with a variety of drugs have made surgery unnecessary in most cases. These drugs include antacids and certain antibiotics.

Occasionally, stomach or duodenal ulcers do not heal with medical therapy. This not only causes persistent pain for the patient but also raises the possibility that cancer cells may be contained in the ulcer. In addition, complications from stomach and duodenal ulcers may develop due to failed drug therapy or progression of the ulcer disease before medical therapy is initiated. These complications include perforation, in which the ulcer erodes through all layers of the stomach or duodenum, leading to leakage of intestinal fluid into the abdomen and a life-threatening infection. Alternatively, there may be severe bleeding because the ulcer has eroded into a nearby blood vessel. Finally, swelling related to the ulcer may prevent passage of stomach contents into the small intestine. Total or partial gastrectomy may be necessary if a stomach or duodenal ulcer fails to heal with medical therapy, if there is any concern that an ulcer contains cancer, or if an ulcer complication occurs. The ulcer is removed as part of the gastrectomy in the case of a stomach ulcer. A gastrectomy alone does not remove a duodenal ulcer. However, gastrectomy decreases or eliminates the flow of acid and pepsin produced by the stomach into the duodenum, thereby allowing the duodenal ulcer to heal on its own.

GASTRECTOMY

There are two major steps involved in performing a gastrectomy: stomach resection and reconstruction of the intestinal tract. Resection involves determining the portion of the stomach to be removed or "resected." This determination is based on the location of the diseased portion of the stomach. When the entire stomach is removed, it is referred to as a "total" gastrectomy (Fig. 2). When part of the stomach is removed, it can be referred to as a "partial" gastrectomy. Often a partial gastrectomy is more precisely defined by the segment or amount of the stomach that is removed. Hence, an "antrectomy" is a partial gastrectomy in which the stomach antrum alone is removed. This is roughly 35% of the stomach (Fig. 3). A "distal" gastrectomy is a partial gastrectomy in which the distal 50% of the stomach (i.e., the part of the stomach closest to the duodenum) is removed. In a distal gastrectomy, all of the antrum and part of the body of the stomach are removed. Finally, a "subtotal" gastrectomy is a partial gastrectomy in which 80% of the distal stomach is removed. A subtotal gastrectomy is essentially just a more extensive form of a distal gastrectomy (Fig. 4).

Once a total or partial gastrectomy is performed, the remaining segments of the gastrointestinal tract must be reconnected to allow uninterrupted flow of food from the esophagus into the small intestine. This is referred to as reconstruction of the gastrointestinal tract. There are a wide variety of reconstruction procedures that can be done using sutures, surgical staples, or a combination of the two. Exactly, what reconstructive procedure is done and how it is performed largely depends on a surgeon's preference. Following an antrectomy, the surgeon may

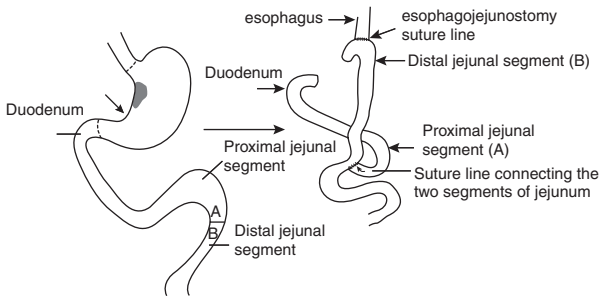

FIGURE 2 Total gastrectomy with esophagojejunostomy reconstruction.

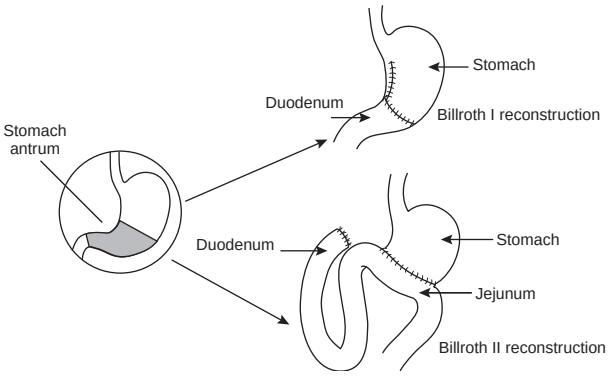

FIGURE 3 Antrectomy with Billroth I and II reconstructions.

choose to use a Billroth I reconstruction, in which a gastroduodenostomy is performed. Alternatively, the surgeon may use a Billroth II reconstruction, in which a type of gastrojejunostomy is performed (Fig. 3). For a distal or subtotal gastrectomy, another type of gastrojejunostomy may be used (Fig. 4).

A much more complex reconstruction is required following a total gastrectomy for the following reasons (see Fig. 2). The esophagus has very limited mobility and cannot be pulled down into the abdomen very far. In addition, the duodenum is fixed in position by its attachments to various other structures in the abdomen. Hence, the duodenum can not be pulled up to the esophagus. Thus, it is not possible to connect the esophagus to the duodenum after a total gastrectomy. In contrast, the jejunum is much more mobile than either the esophagus or the duodenum and is therefore used for reconstructive purposes following total gastrectomy. Although it may be possible to pull a segment of jejunum up to the esophagus without special surgical techniques, the connection between the esophagus and the jejunum may be under marked tension and may tend to tear or pull a part. Thus, the mobility of the jejunum is frequently optimized to allow safe connection to the esophagus in a two-step process. First, the jejunum is divided,

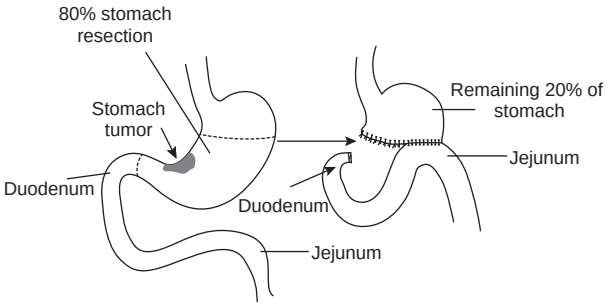

FIGURE 4 Subtotal gastrectomy with gastrojejunostomy reconstruction.

which allows the segment farthest from the duodenum (i.e., the distal segment) to easily be pulled up to the esophagus without tension. The reason this increases jejunal mobility is beyond the scope of this discussion, but has to do with certain anatomical properties of the jejunum and the blood vessels to which the jejunum is attached. This distal segment of jejunum is either sewn or stapled to the esophagus to form an esophagojejunostomy. The second step involves stapling or sewing the proximal segment of jejunum (i.e., the segment in continuity with the duodenum) to the side of the distal jejunum (see Fig. 2).

COMPLICATIONS FOLLOWING GASTRECTOMY

Unfortunately, removal of all or part of the stomach also decreases the stomach's reservoir and digestive capacity. Therefore, almost all patients have to alter their eating habits postgastrectomy. In addition, they may have nausea, vomiting, and diarrhea for several days or weeks after surgery. Changing to small and frequent meals with low sugar and high protein content helps many of these symptoms. Most people successfully adapt to the surgery and lead normal lives, assuming no other complications develop.

Unfortunately, 20% of patients have significant complications, with 5% of patients having lifelong complications and 1% with disabling complications. Early complications following surgery may include bleeding or injury to organs or structures in the area of the surgery. The connections made as part of the reconstruction procedure may leak intestinal fluids and lead to a mild, moderate, or life-threatening infection in the abdomen. Alternatively, the connections may swell or become constricted, resulting in partial or complete obstruction of the flow of food from the mouth into the distal small intestines. Finally, a superficial infection of the surgical skin incision may develop. Most of these complications are treatable without additional surgery. Occasionally, surgery is needed to correct long-term problems or fix problems that are identified immediately after surgery. In general, however, a gastrectomy results in high survival rates with low complications when performed for benign diseases or for early forms of cancer.

Gastric glands and surface epithelial cells in the stomach produce 1–2 liters/day of gastric juice, the major components of which are water, hydrochloric acid (HCl), salts (Na^+, K^+, and Cl^-), pepsins, intrinsic factor, and mucus. The gastric mucosal glands in the fundus and body of the stomach contain parietal (oxyntic) cells that secrete the HCl, a process regulated by neural, endocrine, and paracrine mechanisms. There are approximately 1 billion parietal cells in the human gastric mucosa, and these metabolically active cells have the ability to generate more than 3×10^6 hydrogen ions/second. The result of this intense acid secretory activity is that the pH of gastric juice is quite acidic, dropping below pH 1 at high rates of secretion. HCl is necessary for the conversion of inactive pepsinogen to pepsin, which initiates the digestion of collagen; HCl also aids in the destruction of ingested bacteria, although some bacteria, such as *Helicobacter pylori*, which has been implicated in the development of peptic ulcer disease, manage to survive despite the hostile environment. The maximal rate of acid output is gender and age related. In human males, maximally stimulated acid secretion initially generates 10–30 mmol of HCl/hour. In females, the rate is 25–40% lower. In both males and females, maximal acid output declines with age.

INTRODUCTION

The recognition that gastric juice contains HCl and that the secretion of HCl is controlled by multiple factors has gradually evolved from observations made over the past 200 years or so. As early as 1802, the French physiologist, Pierre Jean Georges Cabanis, recognized the link between gastric function and emotion. It was not until 1833, however, that the physician William Beaumont

INTRODUCTION

The recognition that gastric juice contains HCl and that the secretion of HCl is controlled by multiple factors has gradually evolved from observations made over the past 200 years or so. As early as 1802, the French physiologist, Pierre Jean Georges Cabanis, recognized the link between gastric function and emotion. It was not until 1833, however, that the physician William Beaumont

Copyright 2004, Elsevier (USA). All rights reserved.

provided the first scientific evidence, based on his observations of a fistulous patient, Alexis St. Martin, that emotional states influence gastric acid secretion. Hydrochloric acid was identified as a component of gastric juice in the early 1800s by William Prout, but remained a controversial finding for the next 50 years because of the many claims that the gastric mucosa secreted phosphoric or lactic acid or other substances. Although direct evidence was lacking, it became generally accepted during this era that the parietal cell is the source of HCl secretion.

In the early twentieth century, major progress was made toward identifying the physiological regulators of the acid secretory response. The hormone gastrin was isolated by J. S. Edkins in 1905 and subsequently was shown to increase HCl secretion. Ivan Pavlov defined the "psychic phase" of gastric acid secretion by demonstrating that the sight, smell, and anticipation of eating were potent stimulants of acid secretion. Histamine was discovered in 1913 by Henry Dale and was shown, in 1916, to stimulate HCl secretion by Leon Popielski, a student of Pavlov's. This discovery, which was published in 1920, initiated a bitter controversy over the role of histamine in the regulation of acid secretion that continued for over 50 years. The first evidence linking brain pathways with gastric acid secretion was published in the 1930s by Cushing, who found that patients with intracranial lesions secreted high levels of gastric acid and developed peptic ulcers.

The sequencing of gastrin by Gregory and Tracy in 1964 added fuel to the scientific controversy over the respective roles of histamine and gastrin; the controversy continued long after the discovery of the gastric histamine-2 (H2) receptor by Sir James Black and colleagues in 1971. Two prominent opposing viewpoints were championed most strongly by Charles Code, who proposed histamine as the final common mediator, and Morton Grossman and colleagues, who believed that the gastric parietal cell possessed receptors for histamine, gastrin, and acetylcholine and that these secretagogues had potentiating interactions at the level of the parietal cell. In order to resolve these conflicting hypotheses, it became clear that cellular models were required. The first such model, the isolated gastric gland, was described in 1976 by Thomas Berglindh and Carl Johann Öbrink. The gland preparation continues to be a popular model for the study of acid secretory responses at the cellular level. An important characteristic of this cellular model is that normal connections between cells are maintained and cells within the glands retain their normal polarities. The presence of endocrine/paracrine cells in the glands can be an advantage or a disadvantage, depending on the research goals. Thus, this model is ideal for studies of paracrine regulation of parietal cells, but not for characterizing responses at the level of the parietal cell. To define "pure" parietal cell responses at both the physiological and biochemical levels requires preparations of highly enriched parietal cells. Shortly after the gland model was described, the first step toward addressing these shortcomings was made by Andrew Soll, who used centrifugal elutriation, a technique that separates cells in suspension based on size, to partially enrich parietal cells from mixed populations of gastric mucosal cells. These initial parietal cell isolates were enriched to ~50% purity. Since then, there has been a progression of improvements in the enrichment technique to the point where parietal cells can now be enriched to near homogeneity and maintained for several days in primary culture.

Another important milestone in defining acid secretory-related functions of gastric mucosal cells was the identification of histamine-containing enterochromaffin-like (ECL) cells by Rolf Håkanson and colleagues in 1986. Christian Prinz, George Sachs, and colleagues developed techniques to study these cells in isolation in the early 1990s and subsequent work has recently provided significant new information on the mechanisms involved in the regulation of gastric acid secretion.

GASTRIC MORPHOLOGY

General Organization of the Stomach and Regional Variations

Like the rest of the tubular gastrointestinal (GI) tract, the stomach is structurally organized into four concentric layers: the inner or luminal mucosa, the submucosa, the muscularis externa, and the outer serosa. The mucosa and submucosa form longitudinal folds, or rugae, that contain funnel-shaped invaginations at the mucosal surface. These invaginations, which are referred to as gastric pits, or foveolae, form the openings for ducts into which the gastric glands empty. Anatomically, the stomach is divided into four regions: the cardiac, which is a 2- to 3-cm-wide region at the esophageal junction; the fundus, which projects in a domelike fashion above the esophagus; the body, which forms the central and largest region of the stomach; and the pyloric antrum (*pyloros* being the Greek term for "gatekeeper"), which falls in the region between the angular notch and the duodenal junction (see Fig. 1 for an overview of the anatomy of the stomach).

Histologically, the gastric mucosa is divided into three, rather than four, separate regions: the cardiac, oxyntic, and antral or antropyloric. In this case, the

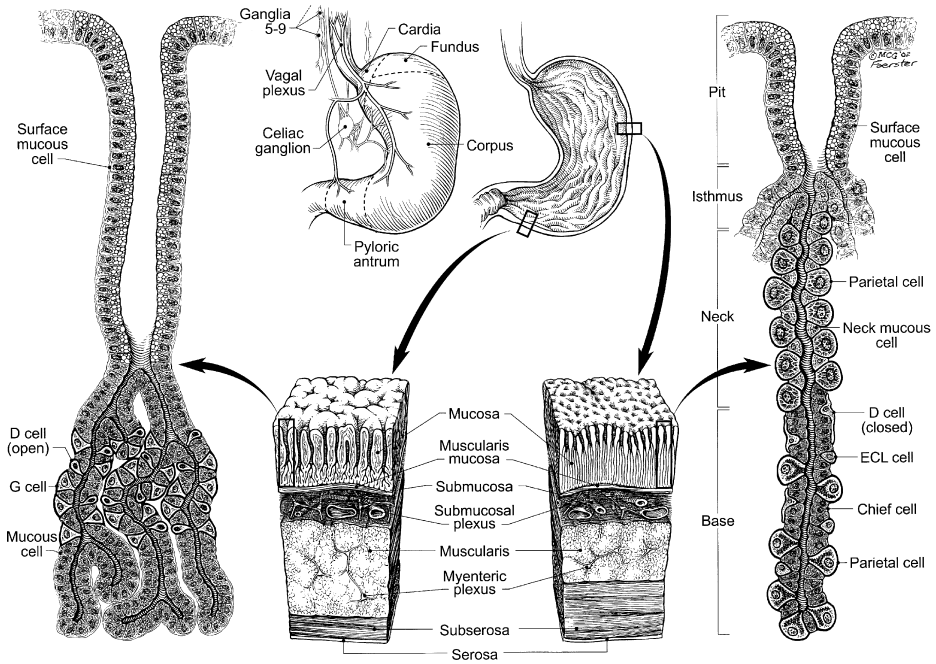

FIGURE 1 Anatomical overview of the stomach. Figure by John Forrester, copyright Medical College of Georgia.

regions are defined based on the structures of their glands. Although there is a common structural basis in gastric glands, the occurrence and distribution of different cell types within the glands vary from region to region. In humans, the cardiac region is a few centimeters wide and contains labyrinthine glands composed mainly of mucus-producing cells. The oxyntic mucosa, which is the acid-producing region of the stomach, extends through the fundus and body of the stomach. [It should be noted that this region is often referred to as the fundus rather than the oxyntic mucosa (see Table I, for example)]. Within the oxyntic mucosa, the glands are long and straight, and two or more glands open into a common pit. Columnar surface epithelial cells line the pit, extending down into the gland opening. The narrow region of the gland closest to the gastric pit is called the isthmus, or neck, region, and it contains mucous neck cells, stem cells, and a few immature parietal cells. The body of the gland begins immediately below the isthmus and extends to the base. Parietal cells are most numerous in the upper regions of the body, becoming less numerous near the base where pepsinogen-secreting chief cells predominate. ECL cells and other endocrine/paracrine cells, which are derived from the neural crest, are interspersed among secretory epithelial cells in oxyntic glands. In the antral mucosa, the gastric pits are deeper, and the glands have wide lumens with prominent branching at their bases. The predominant cell types in the antral mucosa are mucus-producing cells, gastrin-producing G cells, and serotonin-producing ECL cells. A few parietal cells are also present in this region.

Endocrine/Paracrine Cells Involved in the Regulation of HCl Secretion

ECL cells, G cells and somatostatin-producing D cells are known to play an important role in the regulation of HCl secretion. Other less well-characterized endocrine/paracrine cells are probably also involved in this process. In the gastric mucosa, endocrine/paracrine cells are almost exclusively localized within the glan-

TABLE I Distribution and Properties of Endocrine Cells in the Stomach of the Rat[a]

Cell type	Amine/amino acid	Regulator peptide	Location

dular epithelium at sites below the surface epithelial cells and the pits. Generally, but not exclusively, endocrine-like cells in the oxyntic mucosa contain different secretory products as compared to those in the antral mucosa. There are also different anatomical relationships between endocrine-like cells and neighboring cells in the two regions. These anatomical differences may reflect differences in the modes of delivery of secretory products and/or differences in stimulatory mechanisms. The locations of known endocrine/paracrine cells and their secretory products are summarized in Table I.

The Histamine-Storing ECL Cell

There are two types of histamine-storing cells in the stomach, ECL cells and classical mast cells. ECL cells are involved in the regulation of gastric acid secretion whereas mast cells are involved in mediating the immune response. Mast cells originate in the bone marrow and migrate to the stomach. In contrast, ECL cells originate in the gastric mucosa. The distribution of both ECL and mast cells varies with the species. In large mammals, including dogs, cats, pigs, and humans, mast cells are numerous and are scattered throughout the mucosa. In contrast, in the rat, mast cells are relatively few in number and are localized not only within the mucosal surface but also within the submucosal and muscle layers. ECL cells predominate in the lower gland region in birds and mammals, but in fish, amphibia, and lizards, they are present primarily in the upper half of glands.

In rats, the species in which these cells have been most extensively studied, ECL cells are the predominant histamine-storing cell, containing $\sim$80% of the total gastric histamine. They are also particularly abundant, composing $\sim$30% of the total endocrine/paracrine cell population. Transmission electron microscopy (EM) studies indicate that secretory vesicles in ECL cells have electron-dense cores surrounded by large halos. At the light microscopic level, ECL cells can be identified with antibodies directed against the histamine-synthesizing enzyme, histidine decarboxylase, and against the vesicular monoamine transporter subtype 2 (VMAT-2). In the human stomach, a subpopulation of ECL cells has immunoreactivity for the α subunit of human chorionic gonadotropin (hCG-α) as well as other constituents that are found in neuroendocrine cells, such as chromogranin/pancreastatin and synaptophysin.

The Gastrin-Storing G Cell

The G cells are flask-shaped, with apical surface microvilli that project into the lumen of the antral glands. Secretory granules in G cells have variable structures and densities, which may reflect the accumulation of different gastrin precursors within these granules. In general, endocrine cells in the GI tract have been classified based on their silver staining characteristics as well as the presence of chromogranin A, an ubiquitously expressed endocrine cell protein that is thought to play a role in the packaging of secretory products. Antral G cells stain strongly with both methods. The distribution of G-cells in antral glands is species dependent. In rats, G cells predominate in the basal region, but in humans, dogs, and cats, they appear in stratified layers between the base of the pits and the mucous cells. In pigs, G cells are distributed along the length of the glands.

Immunohistochemical analyses suggest that G cells contain other peptides in addition to gastrin, possibly including peptide YY (PYY), thyrotropin-releasing hormone (TRH)-like peptides, vasoactive intestinal peptide (VIP), proenkephalin gene-derived peptides, xenopsin, adrenocorticotropic hormone (ACTH), and human CG-α (hCG-α). The presence of these peptides in G cells has not yet been confirmed biochemically nor have their roles in the regulation of acid secretion been defined. Such analyses are presently difficult because G cells can be enriched to only $\sim$35% with current isolation protocols.

Somatostatin-Storing D Cells in Oxyntic and Antral Glands

The main secretory product of D cells is somatostatin, an inhibitory regulator of acid secretion, and the predominant form of somatostatin that is secreted by gastric D cells is somatostatin-14. Compared to somatostatin-28, which is the form present in the general circulation, somatostatin-14 appears to be a more physiologically relevant inhibitor of acid secretion. In humans and most mammals, the granules in D cells are large (100–400 nm), round, and of medium density. The granules in rodent D cells are smaller. In the gastric antrum, D cells are the "open" type whereas those in the fundus are the "closed" type. Is has been assumed that the open morphology allows antral D cells to sense the presence of acid in the stomach lumen; however, this assumption has not been proved. Both antral and fundic D cells have long processes, which were originally thought to form direct contacts with parietal and G cells. More detailed transmission EM studies suggest, however, that thin extensions from other cell types block direct contacts. If this is the case, somatostatin may be delivered to parietal and G cells through the local circulation rather than by simple diffusion. Somatostatin released from intestinal D cells into the general

circulation can also serve as an endocrine inhibitor of acid secretion. Experimentally, gastric D cells can currently be enriched to ~90% purity based on their small size and low buoyant densities (1.040 g/ml) using a combination of density gradient and centrifugal elutriation techniques similar to those that were initially used to prepare highly enriched parietal cell populations.

CELLULAR DIFFERENTIATION WITHIN OXYNTIC GASTRIC GLANDS

Within the oxyntic mucosa, there is constant turnover and regeneration of the different cell types. Landmark studies by Karam and Leblond during 1993–1995 defined gastric glands as "zymogenic units" that contain multipotent, undifferentiated, granule-free stem cells from which several different progenitors are produced, including "prepit precursors," "preneck cell precursors," and "preparietal cells." These stem cells are present in the isthmus of the glands. Surface or pit cells arise from differentiation of the prepit precursor lineage and migrate upward from the isthmus during migration. Mucous neck cells are derived from the preneck cell lineage and are the precursors of chief or zymogenic cells, which are present in the base of the glands. Preparietal cells appear to be derived from granule-free stem cells as well as prepit and preneck precursors. Preparietal cells appear to migrate from the gland isthmus in both directions: upward toward the pit and downward toward the neck and base of the glands. In contrast to surface epithelial cells, which survive for only a few days, parietal cells have a life span of several months, depending on the species. Fully differentiated parietal cells are mitochondria rich and possess an extensive tubulovesicular or tubulocisternal membrane system as well as a complex, F-actin-rich, apically directed internalized membrane region or intracellular canaliculus. These cells also express several proteins that are either not expressed at all or are expressed at much lower levels in other gastric mucosal cell types. The most prominent example of the former is the H^+,K^+-ATPase, which is a P-type ATPase that is responsible for proton secretion by the parietal cell. In contrast to gastric epithelial cells, G and D cells appear to be derived from a common multihormonal precursor cell that is present within the isthmus of glands.

INNERVATION OF THE STOMACH

The stomach, like the rest of the gastrointestinal tract, is extensively innervated by the autonomic nervous system (ANS). There are two major sources of autonomic innervation, extrinsic and intrinsic. The extrinsic nerve supply feeds into a self-contained, highly complex intrinsic nervous system, which is also referred to as the enteric nervous system. In addition to regulating acid secretion, neuronal messengers modulate a number of other important gastric functions, including motility, local blood flow, lower esophageal and pyloric sphincter tone, and hormone/paracrine release. Numerous neurotransmitters are present within the gastric mucosa, including acetylcholine, serotonin, nitric oxide, γ-amino butyric acid, and pituitary adenylyl cyclase-activating peptide (PACAP). Neuropeptide Y (NPY) may also be present in extrinsic sympathetic fibers. Peptide-containing neuronal fibers have also been found to contain abundant vasoactive intestinal peptide and gastrin-releasing peptide (GRP), with lesser concentrations of substance P, calcitonin gene-related peptide (CGRP), somatostatin, NPY, and galanin. Mucosal fibers may contain multiple transmitters. There is also a high level of nitric oxide synthetase (NOS) in the gastric mucosa. A neuropeptide, orexin A, has been recently immunolocalized to neuronal structures that express VIP and/or NOS. However, although NOS-containing nerve fibers are abundant in the smooth muscle layer, few such fibers are found in the gastric mucosa. Thus, much of the NOS activity may originate from mucosal epithelial cells.

Extrinsic Innervation and CNS Control

There are two sources of external or extrinsic neuronal pathways: the parasympathetic, via the vagus nerve, and the sympathetic, via the celiac ganglion and splanchnic nerves. Of the two, the vagus is the most important regulator of gastric acid secretion. Vagal activation stimulates acid secretion. However, there are a few exceptions (see *In Vivo* Regulation of Gastric Acid Secretion: Cephalic Phase). The effects of sympathetic stimulation on acid secretion are generally inhibitory and indirect, resulting from effects on contractility and blood flow.

In general, sympathetic and parasympathetic fibers release either acetylcholine or norepinephrine. Fibers that release the neurotransmitter acetylcholine are cholinergic; those that release norepinephrine are adrenergic (from adrenalin). Preganglionic neurons in both the sympathetic and the parasympathetic nervous systems are exclusively cholinergic. Most postganglionic sympathetic neurons are adrenergic, but a few are cholinergic. In contrast to sympathetic fibers, most parasympathetic fibers, including the vagal fibers innervating the stomach, pass uninterrupted all the way

to the innervated organ and, thus, are preganglionic and cholinergic at the level of the stomach.

Vagal fibers that innervate the stomach originate in the medulla from neurons present in the dorsomotor nucleus of the vagus and, to a lesser extent, the nucleus ambiguus and the nucleus tractus solitarius. The posterior region of the stomach is innervated by the right thoracic vagal trunk, whereas the lesser curvature and ventral stomach are innervated by branches of the left vagus. Once vagal fibers enter the stomach, they synapse with ganglia of the enteric nervous system. Acetylcholine that is released by vagal fibers binds to nicotinic receptors present on the ganglionic neurons. Nicotinic receptors are stimulated by nicotine as well as by acetylcholine. These receptors are distinguished from muscarinic receptors by selective inhibitors such as atropine, which blocks muscarinic receptors but not nicotinic receptors. There are five known muscarinic subtypes, M_1–M_5. Recent studies of muscarinic receptor knockout mice suggest the muscarinic M_3 receptor subtype is involved in the regulation of basal and vagally stimulated acid secretion, but the M_1 receptor subtype is not required for vagally stimulated secretion, at least in this species.

The Enteric Nervous System

Similar to most regions of the gastrointestinal tract, the stomach contains an extensive array of interconnected autonomic ganglia and their associated nerve fibers. This intrinsic (enteric) nervous system is often referred to as the "second brain" based on its complexity and the presence of many of the same neurotransmitters that are found in brain. There are three distinct plexuses within the enteric nervous system: the submucosal (Meissner's), myenteric (Auerbach's), and serosal. The submucosal plexus is located within the submucosa just below the mucosal layer and the myenteric plexus is located between the outer longitudinal and inner circular muscle layers. Nerve fibers interconnect the dense network of ganglia within each plexus and also form interconnections between the different plexuses. In laboratory animals, myenteric ganglia are large and much more numerous than submucosal ganglia and are the major source of innervation for the gastric mucosa as well as the submucosa and smooth muscle. Myenteric neurons also appear to be most extensively innervated by vagal preganglionic fibers. In humans, the submucosal plexus in the antropyloric region appears to be more much more elaborate as compared to rats and guinea pigs. Serosal ganglia are not yet well characterized. In addition to acetylcholine, the intramural plexuses appear to contain at least 20 potential neurotransmitters. Many of the neurotransmitters present within these plexuses have also been localized within endocrine/paracrine cells in the gastric mucosa as well as in other regions of the gastrointestinal tract.

IN VIVO REGULATION OF GASTRIC ACID SECRETION

Between meals, the human stomach secretes acid at approximately 10% of the maximal rate. The volume of gastric juice is low, and the pH is generally below 2. After ingestion of a meal, gastric acid secretion increases dramatically. Classically, and rather artificially, three phases of meal-stimulated gastric acid secretion have been described based on selected experimental approaches. These include (1) the cephalic phase, which is activated by the sight, taste, smell, chewing, and swallowing of food; (2) the gastric phase, which is activated by the presence of digestion products in the gastric lumen and by the distension of the stomach; and (3) the intestinal phase, which is activated by the presence of chyme in the small intestine. These secretory phases, like other functions of the gastrointestinal tract, are, in reality, initiated more or less simultaneously following the ingestion of a meal. Secretion in all three phases is regulated by a complex process that involves the meal-induced activation of extrinsic and intrinsic neuronal pathways and release of hormones and paracrines.

In vivo, the major activators of HCl secretion are histamine, gastrin, and acetylcholine; however, many additional factors regulate the release of each of these secretagogues at several different levels. Known negative regulators include somatostatin, prostaglandins of the E2 series, epidermal growth factor (EGF), secretin, cholecystokinin (CCK), gastric inhibitory polypeptide (GIP), serotonin, neurotensin, interleukin-1, glucagon-like peptides, peptide YY, substance P, calcitonin gene-related peptide, bombesin, corticotropin releasing hormone (CRH), amylin, orexin A, and galanin. Other factors such as leptin, which is present in fundic glands, and ghrelin in the CNS, can stimulate HCl secretion. In most cases, the physiological role of these factors in regulating gastric acid secretion has not yet been established. Those factors that are best characterized are discussed in the following sections.

Cephalic Phase

Chemoreceptors and mechanoreceptors in the mouth, nasal cavities, and upper esophagus are activated by the sight, smell, and thought of food as well as by the chewing and swallowing reflexes. The resulting

afferent nerve impulses are relayed by vagal afferents mainly to the dorsal motor vagal nucleus in the central nervous system (CNS), which signals the stomach via vagal efferent pathways. Stress and hypoglycemia also activate the cephalic phase of secretion.

In humans, the cephalic phase accounts for less than half of the total acid secretory response to a meal. The magnitude of the response depends on how appetizing the food appears to the individual. Because vagal stimulation does not elicit the maximal possible rate of HCl secretion, it has been concluded that this response involves both stimulatory and inhibitory effects. A current view of the mechanisms associated with the dual effects of vagal activation is as follows. In the fundus and body of the stomach, vagal stimulation induces the release of acetylcholine by both preganglionic and postganglionic enteric neurons. The postganglionic release of acetylcholine stimulates parietal cells to secrete HCl. In the antrum, however, the preganglionic release of acetylcholine can induce the release of both stimulatory and inhibitory neurotransmitters by postganglionic neurons. As yet, these neurotransmitters have not been unequivocally identified. One candidate is gastrin-releasing peptide, which is structurally related to the amphibian neuropeptide, bombesin. GRP can release gastrin from G cells and somatostatin from D cells. Other transmitters may also be released by vagal stimulation. Thus, the maximal rate of acid secretion that can be achieved by vagal stimulation depends on the balance of neurotransmitters released in the vicinity of the G and D cells as well as parietal cells. Because, for example, vagal stimulation is a more potent activator of HCl secretion in dogs as compared to in humans, the inhibitory pathways may be more predominant in humans. The relative contribution of gastrin to the cephalic phase of secretion also appears to be species dependent.

The relationship between the CNS and the overall regulation of gastric acid secretion is quite complex. Thus far, most information has been derived from mapping studies in which various neurotransmitters are injected into different regions of the brain. Intracerebroventricular injection of thyrotropin-releasing hormone, a three-amino-acid peptide, activates the vagus nerve and mimics cephalic phase stimulation. Thus, TRH appears to play an important role in mediating vagal stimulation of acid secretion. This effect can be inhibited by the injection of peptide YY. Mapping studies in which various peptides are injected into regions of the brain known to send projections of vagal and sympathetic nerves involved in secretory inhibition indicate that the hypothalamus is an important site for central inhibition. Medullary and spinal sites also appear to be involved. Peptides that increase the activity of centrally acting inhibitory pathways in dogs and rats include bombesin, CGRP, ß-endorphin, neurotensin, prostaglandins, interleukin-1β, CRH, and orexin A. Neuropeptide Y has either stimulatory or inhibitory effects, depending on the site of injection.

Gastric Phase

As food enters the stomach, acid secretion is further stimulated by distension of the gastric wall as well as by the presence of food and certain beverages. Other factors, such as caffeine, alcohol, and luminal calcium also stimulate HCl secretion. Acid secretion in this phase accounts for at least 50% of the total and is primarily mediated by the hormone gastrin. Ingested nutrients, in particular peptides and amino acids, potently stimulate gastrin release, apparently by a direct effect on G cells, whereas distension induces the release of gastrin by both cholinergic and noncholinergic reflex mechanisms. Depending on the species, distension can account for 20–50% of the total acid secretory response. Distension reflexes may be local but can also involve the extrinsic nervous system. In the latter case, extramural or vago-vagal reflexes send signals via vagal afferents to the vagal nucleus, activating efferent vagal pathways from the CNS that then stimulate parietal cells in the oxyntic mucosa and G cells in the antrum. Intramural or local reflexes are mediated by one or more neurons within the enteric nervous system. These reflexes stimulate the parietal cell more effectively than they stimulate the G cell. All distension reflexes are blocked by the anticholinergic drug atropine, indicating that they are mediated at some point by the cholinergic neurotransmitter acetylcholine. Because vagotomy reduces, but does not completely abolish, gastrin release in response to pyloric distension, the gastrin response may be mediated by both vago-vagal and local, or pyloropyloric, reflexes.

After the ingestion of a meal, secreted acid is initially buffered by the presence of food and protein digestion products in the stomach. With continued HCl secretion, the pH drops and negative feedback mechanisms are called into play. Acid secretion is inhibited when the pH reaches 2 and is almost completely suppressed when the pH drops below 1. The pH-dependent inhibition of HCl secretion is correlated with the release of somatostatin. Distension of the stomach also releases somatostatin by activation of cholinergic and noncholinergic neuronal pathways. Antral somatostatin, which inhibits the release of gastrin from G cells, presumably serves as a counterbalance to the stimulatory effect of gastrin. Recent evidence suggests that atrial natriuretic peptide

(ANP) may also play a role in the regulation of gastric somatostatin secretion. ANP release can be induced by the neurotransmitter PACAP (which is present in the enteric nervous system in two different forms, PACAP-27 and -38) and suppressed by activation of intramural cholinergic neurons.

With gastrin, there is also a positive feedforward mechanism. In this case, a rise in luminal pH is correlated with increased gastrin secretion. This response occurs, for example, when acid secretion is inhibited by potent pharmacological agents such as omeprazole and related H^+,K^+-ATPase or proton pump inhibitors (PPIs), which can almost completely suppress parietal cell HCl secretion (see Receptor-Mediated Responses at the Cellular Level: Regulation of HCl Secretion at the Level of the Parietal Cell). A similar response occurs in atrophic gastritis, a condition in which parietal cell function is reduced. The prolonged elevation of serum gastrin is correlated with gastric mucosal hypertrophy and increased ECL numbers.

Intestinal Phase

The intestinal phase probably accounts for less than 5% of the total acid secretory response. It can be initiated by perfusion of the jejunum with amino acids and may involve the action of a putative factor called "enterooxyntin" as well as the hormone gastrin, which is released from G cells in the upper part of the small intestine. Once acidic chyme enters the duodenum, negative neural and hormonal feedback mechanisms are activated, leading to a reduction in HCl secretion. This serves to protect the small intestine from damage that could be caused by too much acid or excessive hyperosmolarity. The mechanisms responsible for negative feedback from the small intestine to the stomach are poorly characterized. The older literature refers to an inhibitory factor called "enterogastrone" that was thought to be released from the small intestine. Subsequently, three major inhibitors or enterogastrones were described in many textbooks: secretin, cholecystokinin, and gastric inhibitory peptide (GIP). These factors were thought to be released in response to the presence of fat, acid, and/or carbohydrates in the duodenum. Today, it is recognized that several inhibitory pathways, including neural, hormonal, and paracrine, are probably activated by the gastric emptying of acid, fat, and hyperosmolar solutions into the duodenum. The search for physiologically relevant inhibitory factors is ongoing.

Fat is the most potent inhibitor of acid secretion, suppressing both meal-stimulated gastric acid secretion and gastric emptying. Fat probably induces the release of several inhibitors of acid secretion, including CCK, which probably acts on CCK-1 or A-type receptors present on somatostatin-containing D cells in the gastric antrum. The hormone secretin, which is released from S cells in the upper small intestine in response to a pH $\leq$ 4, fatty acids, protein digestion products, and bile salts, potently inhibits both gastrin release and acid secretion. Secretin inhibition may be mediated by the release of both somatostatin and prostaglandins. Although the mechanism of inhibition is unclear, current evidence suggests that secretin is released from S cells following activation of a capsaicin-sensitive vagal afferent pathway. (Capsaicin is a neurotoxin that ablates C-type unmyelinated sensory nerve fibers. It is frequently used to study the afferent limbs of neural reflexes.) Because the neurotransmitter PACAP can also induce the release of secretin, somatostatin, and prostaglandins, it is possible that PACAP is released on activation of this pathway.

The systemic administration of peptide YY inhibits acid secretion, and circulating levels of PYY increase after a meal. However, recent evidence suggests that PYY is not a physiological mediator of this response. GIP and neurotensin are also released from the small intestine in response to fat. Because GIP is a very weak inhibitor in humans, it is not thought to be a major mediator of the inhibitory response. In contrast, neurotensin is a potent inhibitor and, thus, is a strong candidate enterogastrone. The colon also has the capacity to release acid inhibitory factors or colonogastrones. These factors have not yet been identified, although PYY is a candidate for this response.

RECEPTOR-MEDIATED RESPONSES AT THE CELLULAR LEVEL

Cellular and molecular studies with isolated cells have provided a wealth of information on the specific receptors and receptor subtypes present on the parietal cell as well as on G cells, D cells, and ECL cells. An overview of the current understanding of this area of research is presented in Fig. 2.

Regulation of HCl Secretion at the Level of the Parietal Cell

Parietal cells express histamine H2-type receptors, muscarinic M_3 receptors, and gastrin/CCK-2 or B-type receptors. Although gastrin plays a central role in the stimulation of gastric acid secretion, this hormone has minimal effects on the acid secretory response when administered to parietal cells in isolation. In contrast, histamine is a potent acid secretory agonist that induces

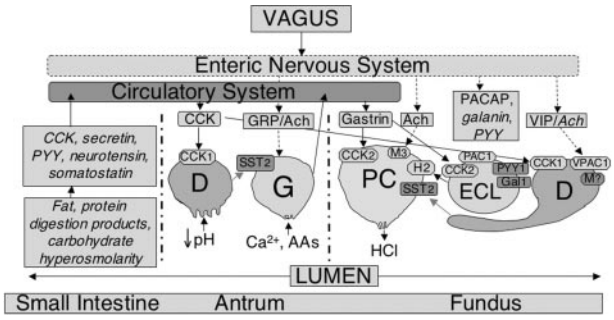

FIGURE 2 Overview of mechanisms of receptor-mediated secretory responses involving D, G, and parietal cells (PC) in the gastric mucosa and small intestine. CCK, Cholecystokinin; GRP, gastrin-releasing peptide; Ach, acetylcholine; PACAP, pituitary adenylate cyclase-activating peptide; PYY, peptide YY; VIP, vasoactive intestinal peptide; M_3, muscarinic type 3; H2, histamine-2.

a sustained acid secretory response and potentiates the secretory responses to gastrin and acetylcholine at the level of the parietal cell. When histamine binds to H2-type receptors on the parietal cell, the enzyme adenylyl cyclase is activated, leading to an increase in intracellular cyclic adenosine monophosphate (cAMP) concentrations. Histamine can also elevate intracellular calcium ($[Ca^{2+}]_i$) in parietal cells; however, the acid secretory response to this agonist appears to be mediated exclusively by the cAMP signaling pathway. The elevation of cAMP is correlated with dramatic morphological transformations in which the internalized, apically directed canalicular membrane expands and elongated microfilaments appear in the canalicular lumen. These morphological changes are accompanied by a substantial increase in oxygen consumption, which is required for the generation of protons. Proton secretion occurs following the activation of the proton "pump," or H^+,K^+-ATPase, which appears to depend on the translocation from an internal membrane complex, the tubulovesicular or tubulocisternal compartment, to the canalicular membrane. When the secretory stimulus is removed, oxygen consumption falls and the H^+,K^+-ATPase is returned to the tubulovesicular compartment by a poorly understood membrane retrieval process.

The magnitude of the acid secretory response to acetylcholine and analogues such as carbachol varies among species, but is generally transient when the effects of histamine are pharmacologically blocked by H2 receptor antagonists such as cimetidine (Tagamet) and ranitidine (Zantac). Compared to the H2 blockers, PPIs such as omeprazole are more potent and specific inhibitors of HCl secretion. This happens because (1) PPIs bind directly and irreversibly to the H^+,K^+-ATPase only in the highly acidic environment of the stomach and (2) H^+,K^+-ATPase activation is a common, terminal step in the acid secretory response.

In contrast to histamine, a rise in $[Ca^{2+}]_i$ is necessary to elicit an acid secretory response to acetylcholine. Acetylcholine and analogues such as carbachol elevate $[Ca^{2+}]_i$ by an inositol trisphosphate (IP_3)-dependent release of calcium from intracellular stores plus the influx of extracellular calcium through unidentified, nonexcitable calcium channels. IP_3 is produced along with diacylglycerol (DAG) on activation of the enzyme phospholipase C-β. DAG activates one or more protein kinase C isoforms. Because the general activation of protein kinase C (PKC) with phorbol ester inhibits the acid secretory response to histamine and acetylcholine, PKC may activate an inhibitory pathway. Such a dual mechanism may help to explain the transient nature of the cholinergic response. The potentiating effect of histamine on the cholinergic response can also be demonstrated indirectly in genetically engineered histidine decarboxylase-deficient mice in which carbachol stimulates only a weak and transient acid secretory response. (In mammals, histidine decarboxylase is an enzyme that is necessary for histamine synthesis.)

Gastrin also induces a rise in $[Ca^{2+}]_i$ but has little to no effect on the acid secretory response at the level of the parietal cell when the effects of endogenous histamine are blocked. Other endogenous inhibitors, such as prostaglandins of the E series, somatostatin, and EGF/transforming growth factor-α (TGF-α) partially inhibit histamine-stimulated acid secretion in isolated parietal cells and reduce the cAMP response to histamine. Thus, these inhibitors can regulate the acid secretory response by acting directly at the level of the parietal cell. They can also inhibit parietal cell HCl secretion indirectly by actions on other mucosal cell types (see later).

Regulation of Histamine Release from ECL Cells

Since it was discovered that ECL cells are distinct from classical mast cells, it has become clear that ECL cells play a central role in the regulation of gastric acid secretion. Thus far, experiments with isolated ECL cells have been performed mainly in rat and, to a lesser extent, rabbit models. Results to date indicate that ECL cells from rats secrete histamine in response to stimulation by gastrin (CCK-2 receptor subtype) and PACAP (PAC1 receptor subtype), but not by acetylcholine. PYY and the neurotransmitter galanin inhibit ECL cell histamine release by binding to PYY type 1 and galanin type 1 receptors, respectively. Somatostatin inhibits

histamine release by ECL cells by binding to a type 2 somatostatin (SST2) receptor; prostaglandin E2 inhibits by binding to an EP3-type receptor. Although both CGRP and γ-aminobutyric acid (GABA) stimulate histamine release in the intact stomach, they have no direct effect on ECL cells *in vitro*. Thus, these effectors must act indirectly to stimulate histamine release.

In contrast to its weak effect on the parietal cell, gastrin is a potent stimulant of ECL cell secretion. The differences in response patterns in these two cell types may be the result of gastrin-induced activation of mutually independent signaling pathways. For example, gastrin induces a significant rise in intracellular calcium concentrations and activates the Ras−mitogen-activated protein (MAP) kinase signaling pathway in ECL cells. In contrast, gastrin does not activate the Ras−MAP kinase pathway in isolated parietal cells and elevates $[Ca^{2+}]_i$ in only ∼one-third of these cells. Another important difference between parietal and ECL cells that may or may not be relevant to their differential responses to gastrin is that, unlike parietal cells, ECL cells possess excitable, voltage-dependent calcium channels. These differences in calcium channels may explain why the *in vivo* administration of classical calcium channel blockers partially inhibits acid secretion, although these inhibitors have no specific effect on isolated parietal cells.

The recent finding that PACAP induces histamine release from ECL cells conflicts with the *in vivo* observation that peripherally injected PACAP inhibits gastrin-stimulated acid secretion. This conflict appears to have been resolved by the findings that PACAP can also stimulate the release of inhibitors of gastric acid secretion, including somatostatin, PGE2, and secretin. Thus, PACAP probably acts on multiple cell types, with the local release of PACAP serving to sway secretion toward a stimulated or inhibited state. The observations that ECL cells are not stimulated *in vitro* by the muscarinic cholinergic agonist, acetylcholine, also conflict with findings that the *in vivo* administration of M_1 muscarinic receptor antagonists suppresses histamine release. The release of PACAP from nerve terminals impinging on ECL cells in response to cholinergic activation of the PACAP-containing neurons may explain these conflicting findings. However, it is more difficult to reconcile the absence of cholinergic receptors on ECL cells with earlier observations that the cholinergic agonist, carbachol, induces histamine release in isolated gastric gland preparations. As yet, it is not clear whether there are species differences in the cholinergic response, or whether the cholinergic release of histamine is mediated indirectly through the release of an unknown intermediate.

Synthesis and Release of Gastrin from G Cells and Gastrin Functions

The concept that gastrin regulates acid secretion at multiple levels is gaining acceptance. As discussed in the preceding section, gastrin acutely stimulates the release of histamine from ECL cells. However, from the early work of Leonard Johnson and others, it has been recognized for over 30 years that gastrin also regulates gastric mucosal growth. Disruption of gastrin gene expression in mice by targeted deletion suppresses the maturation of parietal cells and reduces their numbers. In contrast, overexpression of the gastrin gene is associated with an increased proliferation of the gastric epithelium that is accompanied by an increase in the number of parietal cells and an increase in secretion. This initial proliferative response is followed by a progressive decline in the number of parietal cells and acid secretion as the mice age. Because parietal cells do not undergo cell division, and the proliferating stem cells may or may not express gastrin receptors, the effects of gastrin on cell proliferation may be mediated either directly via a gastrin receptor or indirectly through the release of growth factors such as TGF-α, amphiregulin, and heparin-binding EGF, possibly from parietal cells. Gastrin may also release Reg-1-α from chief cells.

There are many different forms of gastrin. The major secretory product of G cells is amidated gastrin, which is one of several different peptides formed from progastrin by posttranslational modification. Although there are species differences in G cell processing of progastrin, the major initial cleavage product is G34-Gly, which is converted to G34 (34 amino acids). After the Gly-gastrins are produced, they are amidated by peptidyl-α-amidating monooxygenase. Cleavage of G34-Gly and G34 generates the respective G17 products (17 amino acids). In humans, G17 is the predominant product. Amidated gastrins appear to be to major stimulants of HCl secretion. The Gly-gastrins do not stimulate acid secretion directly; however, studies with gastrin knockout mice suggests that these forms of gastrin may serve to regulate the capacity of the parietal cell to respond to stimulation.

Studies with acutely isolated and cultured G cells have identified several potential regulatory pathways. Both GRP and the amphibian neurotransmitter bombesin (which has structural similarity to GRP) release gastrin. Acetylcholine also releases gastrin by binding to M_3-type muscarinic receptors. Luminal factors, including calcium and the aromatic amino acids phenylalanine, tryptophan, and tyrosine, may stimulate gastrin release by a direct action on luminal G cell receptors.

Until recently, the consensus was that the main stimulatory pathway for gastrin release was mediated by GRP that was released near G cells in response to vagal activation. However, recent studies with a GRP receptor antagonist have raised some disturbing questions. In essence, the GRP inhibitor was found to suppress acid secretion that was induced by test meals and sham feeding in human subjects, but was not found to inhibit the rise in plasma gastrin levels. In contrast, when GRP was infused, plasma gastrin levels did rise, and the GRP inhibitor blocked this response. These results suggest that although GRP is involved in mediating vagally stimulated HCl secretion, it is not the physiological mediator of vagally stimulated gastrin release. If these findings are validated, a new search will be necessary to identify the neurotransmitter involved in this response.

As in ECL cells, activation of SST2 receptors inhibits gastrin release from G cells. A low pH inhibits gastrin release whereas an elevated pH stimulates release. The pH effect appears to be indirect, possibly mediated by capsaicin-sensitive afferent neurons.

Regulation of Somatostatin Release from D Cells

Somatostatin released from D cells in both the oxyntic and the antral mucosa negatively regulates acid secretion. The inhibitory effect is tonic, and somatostatin can act in both a paracrine and endocrine fashion to suppresses the release of gastrin from G cells and histamine from ECL cells. Interestingly, uroguanylin, which is a peptide that appears to play a role in regulating water and electrolyte balance, has also been detected in gastric D cells. Thus, this peptide may also play a role in regulating acid secretion.

Although fundic D cells can currently be enriched to $\sim$90%, D cells in general are not yet as well characterized as ECL cells and parietal cells. The D cells in the fundus and antrum have different morphologies and differing responses to acidity and food, and, thus, may be differentially regulated. There may also be species differences associated with D cell regulation. To date, most data suggest that both fundic and antral D cells possess CCK-1 but not CCK-2 type receptors, the latter of which are present on parietal cells. In terms of the *in vivo* response, this appears to be logical because gastrin is a potent activator of the CCK-2, but not the CCK-1, receptor subtype, whereas the reverse is true for sulfated CCK. The presence of the CCK-1 receptor subtype on D cells provides an explanation for the mechanism through which CCK released from the intestine inhibits acid secretion. Thus, CCK stimulates somatostatin release from D cells via an action on CCK-1 receptors and gastrin stimulates acid secretion by acting on CCK-2 receptors present on both parietal and ECL cells.

Fundic D cells may also possess receptors for secretin, epinephrine, VIP, GRP and/or CGRP and the structurally similar peptide amylin, and acetylcholine. With the exception of acetylcholine, all of these agents stimulate the release of somatostatin in isolated D cells. Amylin may be released from D cells to act on the cells in an autocrine fashion. CGRP also stimulates somatostatin synthesis, which can indirectly regulate gastrin release. Acetylcholine appears to inhibit somatostatin release by acting through the heterotrimeric G protein, G_i.

EPILOGUE

From this brief discussion, it is apparent that the stomach is a highly complex organ that is controlled at multiple levels, ranging from the CNS, to the intestines, to local neuronal and cellular interactions. Over the past 20 years or so, work with isolated enriched populations of different gastric mucosal cell types has provided considerable information on the specific functions of these cells. The use of transgenic and knockout mice models has begun to open new avenues of exploration. The role that species differences will play in defining the mechanisms controlling gastric acid secretion in these new models is a question for the future.

Gastric Cancer Surveillance

EMMY LUDWIG AND PETER H. R. GREEN
Columbia University College of Physicians and Surgeons

dysplasia An unequivocally neoplastic proliferation of epithelium.

early gastric cancer Cancer involving the mucosa or submucosa (± lymph node involvement).

metaplasia Conversion of tissue into a form that is not normally present in that area.

Gastric cancer is the second most common cause of cancer-related deaths worldwide. Most cases present at advanced stages. Surgical resection remains the only curative therapy. The goal in reducing mortality from gastric cancer is via diagnosis at a treatable stage. The >90% 5-year survival for early cancer and the dismal prognosis for advanced cancer (<10% 5-year survival) make surveillance a necessary mission. The aim is to identify dysplasia and early cancer. In Japan, a decline in the mortality from gastric cancer in those that have undergone screening has confirmed the value of screening in geographic areas of very high incidence.

RECOMMENDATIONS

Currently there is no role for screening of the general population for gastric cancer in the United States and other developed countries, apart from areas with an exceptional rate. There are, however, subpopulations at increased risk.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) carries an increased risk of upper gastrointestinal cancer, accounting for most of the mortality in patients who have undergone prophylactic total colectomy. These malignancies arise in adenomas of the duodenum and stomach. Most gastric polyps in FAP patients are of the fundic gland type, a subset of polyp without malignant potential in non-FAP patients. Adenomas occur mainly in the antrum. All polyps in FAP should be biopsied and larger polyps should be removed. All FAP patients should be surveyed endoscopically and those with a large number of polyps and proven dysplasia should be followed more often.

Helicobacter pylori

Gastric Cancer Surveillance

EMMY LUDWIG AND PETER H. R. GREEN
Columbia University College of Physicians and Surgeons

dysplasia An unequivocally neoplastic proliferation of epithelium.

early gastric cancer Cancer involving the mucosa or submucosa (± lymph node involvement).

metaplasia Conversion of tissue into a form that is not normally present in that area.

Gastric cancer is the second most common cause of cancer-related deaths worldwide. Most cases present at advanced stages. Surgical resection remains the only curative therapy. The goal in reducing mortality from gastric cancer is via diagnosis at a treatable stage. The >90% 5-year survival for early cancer and the dismal prognosis for advanced cancer (<10% 5-year survival) make surveillance a necessary mission. The aim is to identify dysplasia and early cancer. In Japan, a decline in the mortality from gastric cancer in those that have undergone screening has confirmed the value of screening in geographic areas of very high incidence.

RECOMMENDATIONS

Currently there is no role for screening of the general population for gastric cancer in the United States and other developed countries, apart from areas with an exceptional rate. There are, however, subpopulations at increased risk.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) carries an increased risk of upper gastrointestinal cancer, accounting for most of the mortality in patients who have undergone prophylactic total colectomy. These malignancies arise in adenomas of the duodenum and stomach. Most gastric polyps in FAP patients are of the fundic gland type, a subset of polyp without malignant potential in non-FAP patients. Adenomas occur mainly in the antrum. All polyps in FAP should be biopsied and larger polyps should be removed. All FAP patients should be surveyed endoscopically and those with a large number of polyps and proven dysplasia should be followed more often.

Helicobacter pylori

Many studies have found an association between *Helicobacter pylori* positivity, the development of

 Copyright 2004, Elsevier (USA). All rights reserved.

atrophic gastritis, and risk for the development of gastric cancer. Although *H. pylori* should be eradicated in patients with peptic ulcer disease, the extremely high worldwide infection rate (>50%) makes endoscopic surveillance for gastric cancer impractical.

Gastric Polyps in Non-FAP Patients

Adenomatous gastric polyps are unequivocally neoplastic and have an increased incidence of carcinoma. Polyps with the greatest malignant potential are larger, are sessile, or have a villous component. Adenomas should be removed and the patient followed with surveillance endoscopy every 1 to 3 years to detect recurrent polyps or interval development of a carcinoma. Nonpolypoid mucosa should be biopsied to detect dysplasia and the degree of risk for subsequent malignancy. Flat adenomas are difficult to detect but are more likely to be dysplastic.

Postgastrectomy ("Gastric Stump Carcinoma")

Gastric carcinoma is a late complication of partial gastrectomy for benign ulcer disease. The relative risk of gastric cancer mortality in these patients is small and in some studies is associated with other risk factors such as smoking. Screening of this population is not recommended.

Chronic Atrophic Gastritis with Intestinal Metaplasia

Gastric cancer usually arises in a background of chronic atrophic gastritis. Population-based studies indicate that the risk of gastric cancer is increased in those with chronic atrophic gastritis, intestinal metaplasia (especially type III), and pernicious anemia. The overall risk is, however, small compared to the general population. For this reason, periodic endoscopic surveillance is not recommended. Pathology laboratories do not routinely type intestinal metaplasia. As a result, those with intestinal metaplasia at greatest risk for progressing to carcinoma cannot be identified.

FUTURE DIRECTIONS

The most effective approach to decreasing mortality from gastric cancer is early detection. The identification of genetic markers in high-risk families will facilitate screening. A major reduction in gastric cancer mortality on a worldwide basis will, however, require changes in nutrition and *H. pylori* eradication.

Gastric Emptying

DEIRDRE O'DONOVAN, CHRISTINE FEINLE-BISSET, KAREN JONES, AND MICHAEL HOROWITZ
University of Adelaide and Royal Adelaide Hospital, South Australia

chyme Mass of partially digested food that moves from the stomach to the duodenum.
gastroparesis Stasis of food in the stomach in the absence of mechanical obstruction.

Gastric emptying is a complex process designed to deliver chyme into the small intestine at a rate that optimizes digestion and absorption. This process is controlled by complex neurohormonal mechanisms, the most important of which result from the interaction of nutrients with small intestinal receptors. Historically, disordered gastric emptying, especially delayed gastric emptying or gastroparesis, was considered a rare disorder. However, advances in radioisotopic gastric emptying techniques have established that it is a common clinical problem, especially among patients with diabetes mellitus.

INTRODUCTION

This article reviews the motor mechanisms involved in gastric emptying, patterns of gastric emptying for both liquids and solids, factors that regulate gastric emptying, methods that are available to quantify gastric emptying, and approaches to the investigation and treatment of disordered gastric emptying.

PATTERNS AND DETERMINANTS OF GASTRIC EMPTYING

Cannon, in 1911, was the first to describe in animal studies that transpyloric flow was pulsatile rather than continuous. Thus, most liquefied chyme is delivered into the duodenum in a series of small gushes rather than on a continuous basis. The mechanical determinants of individual flow episodes are poorly defined; however, recent advances in techniques to quantify gastric emptying have provided an increased understanding of emptying patterns on a second-by-second basis. With these advances in technology, it is now clear that transpyloric flow is bidirectional, so that both antegrade and retrograde flow occurs.

Meal Composition and Volume

Overall patterns of gastric emptying are dependent on several characteristics of the ingested material, including nutritive and physical properties, so that solids, nutrient liquids, and nonnutrient liquids empty from the stomach at different rates. A fundamental property of the stomach is its ability to discriminate between liquid and solid meal components. Although liquid emptying occurs with relative mechanical ease, solid emptying is dependent on an initial process of "trituration," or grinding, of solid particles in the antrum before emptying proceeds.

Liquids

Liquid emptying is critically dependent on volume ingested as well as on osmolarity and nutrient content (Fig. 1). Nonnutrient and low-nutrient liquids empty relatively rapidly from the stomach, with an overall monoexponential pattern; the volume of liquid that is emptied into the duodenum in a given time period is proportional to the volume left in the stomach. Consequently, the rate of emptying is influenced by intragastric volume; posture is also important. In contrast, high-nutrient liquids are retained in the distal stomach for longer periods and empty more slowly as a result of feedback from small intestinal nutrient receptors. Posture and intragastric volume contribute minimally in the latter case. Gastric emptying of a nutrient liquid consists of an initial rapid phase, followed by a slower phase during which 2–3 kcal/minute will be delivered into the duodenum, essentially irrespective of the source of those calories. In addition to caloric density, characteristics of the nutrient may be important in the rate of liquid emptying—e.g., fructose is a less potent inhibitor of gastric emptying compared to an isocaloric load of glucose.

Solids

The emptying of digestible solids from the stomach proceeds at a much slower pace compared to nutrient and non-nutrient liquid emptying. The overall emptying rate of digestible solids is characterized by a

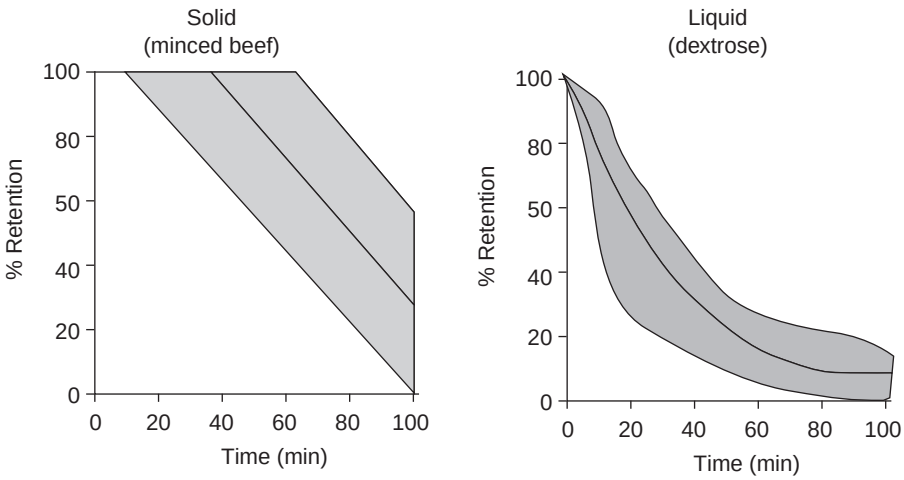

FIGURE 1 Gastric emptying for a meal consisting of both a solid (100 g of minced beef) and a liquid (150 ml of 10% dextrose), consumed in the sitting position, measured radioisotopically in a normal subject. The normal range (mean ± 2 SD) is shown in the shaded areas.

so-called lag phase during which little or no emptying occurs. The lag phase, which lasts from 20 to 60 minutes, is accounted for by an initial retention of the solid in the proximal stomach, followed by redistribution to the antrum, where, in most cases, solid particles undergo trituration before any emptying occurs. If the viscosity of the meal is increased sufficiently, the ability of the stomach to discriminate between large and small particles is impaired and much larger particles may be delivered into the duodenum. Following the lag phase, an emptying phase occurs that approximates a linear pattern with a relatively constant rate of emptying for at least the first 2–3 postprandial hours. The rate of emptying is to some extent load dependent; larger solid meals are delivered slightly more rapidly into the small intestine when compared with smaller meals. Larger indigestible solids have been thought not to empty until the return of migrating motor complex, during phase III, but a recent study has shown that they may empty earlier than this and during the postprandial period. The amount of liquid consumed with the solid can affect the rate of solid emptying. In a mixed meal of solid and liquids, up to 80% of the liquid phase empties before the solid, suggesting that the stomach is capable of discriminating between solids and liquids when presented simultaneously. Furthermore, the presence of liquid in the stomach, particularly if the liquid contains nutrient, prolongs the emptying of solids.

Fat

Foods high in fat are handled differently by the stomach and, therefore, are considered separately from liquids and solids. Fat represents a challenge to the stomach, because it is liquid at room temperature and coalesces to form large globules in the stomach. In the erect posture, fat is retained in the uppermost part of the stomach, floating on other gastric contents, and it is therefore not surprising that the gastric emptying of fat may be dependent on posture; due to the high nutrient density of fat, it can markedly delay the emptying of a low-nutrient liquid.

Small Intestinal Feedback

The major factor regulating gastric emptying of nutrients is feedback inhibition; this is triggered by receptors that are distributed throughout the small intestine and is mediated by both neural and hormonal mechanisms. The extent of small intestinal feedback is dependent on both the number and the site of the small intestinal receptors that are exposed, and is influenced by patterns of prior nutrient exposure; ingestion of a diet high in carbohydrate or fat accelerates subsequent emptying of glucose or fat. Fat and other nutrient-mediated slowing of gastric emptying is dependent on digestion taking place, e.g., hydrolysis of triglycerides to fatty acids, and therefore their effects on gastric emptying cannot proceed in the setting of impaired digestion, such as pancreatic exocrine insufficiency (Fig. 2). Cecoileal reflux of short-chain fatty acids and the presence of fat in the ileum, the so-called ileal brake, also contribute to the regulation of gastric emptying. Other factors that influence gastric emptying via a duodenal feedback loop include duodenal acidification and distension.

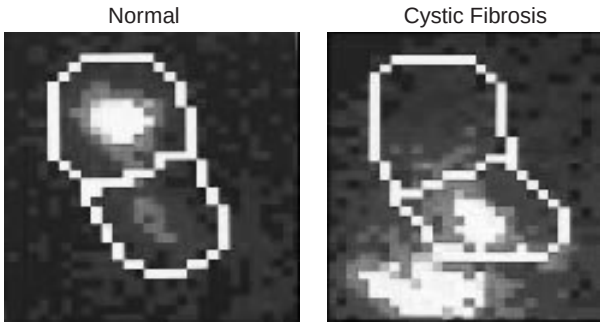

FIGURE 2 Scintigraphic images in a normal volunteer and a patient with cystic fibrosis, in the sitting position, showing the oil phase of a labeled liquid meal (60 ml of olive oil and 290 ml of low-nutrient beef consommé soup) 60 minutes postingestion. The total stomach region of interest is divided into proximal and distal regions. In the normal subject, most of the oil is in the proximal stomach, whereas in the cystic fibrosis patient, most of the oil has emptied from the stomach and most of the remainder is in the distal stomach.

Extrinsic Factors

A number of external factors influence the rate of gastric emptying in humans, including emotional state (anger, pain, and nausea may all slow gastric emptying). Chronic smoking is also associated with slower gastric emptying. Male gender and younger age are associated with slightly more rapid gastric emptying.

MEASUREMENT OF GASTRIC EMPTYING

During the past 25 years, the development and application of new techniques to quantify gastric emptying have greatly increased understanding of diagnosis and treatment of gastric emptying disorders in humans.

Scintigraphy

Scintigraphy remains the gold standard for the quantitative assessment of gastric emptying; it is relatively easy to perform and is noninvasive. The radiation dose approximates that received from a single abdominal radiograph. The technique involves the ingestion of a meal in which one (solid phase) or preferably two (solid and liquid phases) meal components have been labeled with a radiopharmaceutical, commonly gallium-67-labeled ethylenediaminetetra acetic acid (^{67}Ga-labeled EDTA) or indium-111-labeled diethylenetriaminepentaacetic acid (^{111}In-labeled DTPA) for the liquid phase and sulfur colloid labeled with technetium-99m (^{99m}Tc) for the solid phase (Fig. 3). An external gamma camera quantifies the disappearance of each isotope from the "region of interest," and from these data various parameters can be derived to describe gastric emptying. For both solids and liquids, the time taken for half of the meal to empty ($T_{1/2}$) is a frequently used parameter. In addition, intragastric meal distribution can also be assessed. Unfortunately, there is a lack of standardization of scintigraphic techniques, with substantial variation between different centers, particularly in relation to the volume and composition of the test meal, the posture of the subject during the gastric emptying measurement, the duration and mode of data acquisition, correction factors, and the calculation of gastric emptying rates. This renders comparisons between studies performed in different centers difficult, although there have been recent attempts to rectify this situation.

Carbon Breath Tests

Carbon breath tests (e.g., [^{13}C]octanoic acid) have recently been used to quantify solid and/or liquid gastric emptying. The [^{13}C]octanoic acid breath test involves ingestion of a test meal containing labeled octanoic acid, which, after emptying from the stomach, is absorbed in the small intestine and oxidized to CO_2, which is excreted by the lungs. Although these tests are

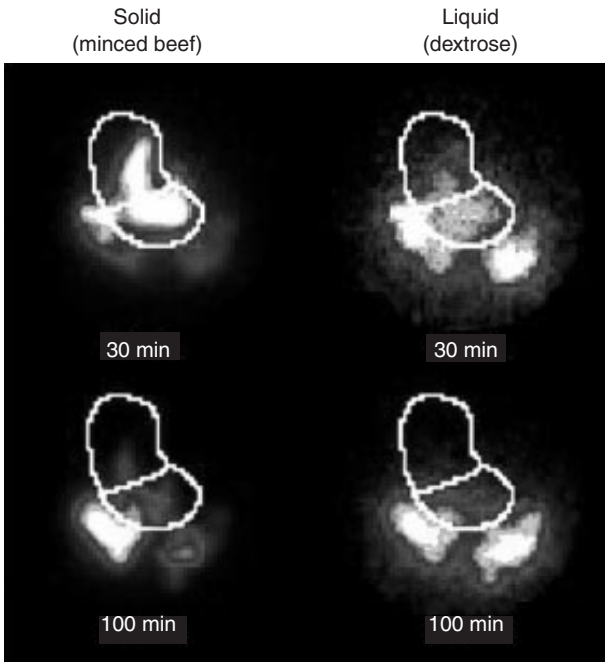

FIGURE 3 Scintigraphic images showing abdominal distribution of radioactivity at 30 and 100 minutes following a meal of 100 g of minced beef tagged with ^{99m}Tc-labeled sulfur colloid and 150 ml of 10% dextrose tagged with ^{67}Ga-labeled EDTA in a healthy volunteer. Total, proximal, and distal stomach regions of interest are illustrated.

cheaper and simpler than scintigraphy and, with the use of stable isotopes, avoid the use of irradiation, there is considerable debate as to the appropriate method of data analysis. Additional validation of these methods in patients with disordered gastric emptying, particularly those in whom gastric emptying is markedly delayed, is required before their use can be advocated. However, it seems likely that carbon breath tests will prove to be useful as a screening test for gastroparesis and in large epidemiological studies.

Ultrasound

High-resolution real-time ultrasound equipment has been used to measure gastric emptying and has the advantage of being noninvasive and does not involve radiation. Hence, it can potentially be repeated on many occasions. The development of Doppler techniques and three-dimensional ultrasound has also allowed more accurate assessment of transpyloric flow and intragastric volumes. The widespread application of ultrasound is limited by the high level of expertise required to perform and interpret the studies and the difficulty of performing the study in obese subjects or in the presence of excessive bowel gas. Ultrasound is, therefore, not recommended at present as a useful alternative to scintigraphy.

Radiological Measurement

Contrast studies with liquid barium sulfate have limited usefulness in the assessment of gastric emptying because of their nonphysiological nature, the high radiation exposure, and the inability to measure fractional stomach emptying. An abdominal X ray taken 6 hours after ingestion of radio-opaque markers has, however, been reported as a sensitive technique for assessing gastric emptying of nondigestible solids. This method probably assesses whether phase III of the interdigestive myoelectric complex is present in the stomach.

Electrical Impedance

Changes in electric impedance can be used to measure the volume of liquid meals remaining in the stomach. A large-volume liquid meal is administered and the impedance recorded at regular intervals. The values obtained over time represent the emptying of the meal. The technique is noninvasive and does not use radiation. Gastric emptying of solid meals, however, cannot be evaluated reliably. Acid secretion must be inhibited pharmacologically during measurements because the sensitivity of gastric contents changes when acid is secreted in the stomach. Impedance techniques are not suitable for measuring the rapid gastric emptying that may occur after gastric resections.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) allows detailed evaluation of gastric emptying (both total and regional) and intragastric distribution of a meal. However, its role in clinical practice is limited particularly as a result of its high cost and lack of accessibility.

Absorption Kinetics of Orally Administered Drugs

In humans, there is minimal gastric absorption of many orally administered drugs; the rate of absorption of a drug is therefore a measure of the rate of gastric emptying. Correct determination of the rate of gastric emptying by measurement of blood (or salivary) concentrations of intestinally absorbed solutes, such as paracetamol, is, however, fairly inaccurate and unsatisfactory for most circumstances in which there is a need to measure gastric emptying. However, there are recent developments with these techniques.

ETIOLOGY AND SEQUELAE OF DISORDERED GASTRIC EMPTYING

Many disorders are associated with abnormalities of gastric emptying and, potentially, with upper gastrointestinal symptoms, changes in oral drug absorption, and, in patients with diabetes, alterations in glycemic control. The causes of disordered gastric emptying are varied (Table I). Delayed gastric emptying, or gastroparesis, essentially describes stasis of food in the stomach in the absence of obstruction and represents the most common disorder of gastric emptying. Delayed gastric emptying can be divided into acute, and often reversible, and chronic (arbitrarily defined as lasting longer than 3 months) cases, and usually irreversible. It should be recognized that the magnitude of the delay in gastric emptying may be relatively modest and it has been suggested that a distinction should be made between "gastroparesis" and "delayed gastric emptying"; i.e., a diagnosis of gastroparesis should be reserved for those with grossly delayed gastric emptying. Patients with gastroparesis may present with symptoms such as nausea, vomiting, abdominal fullness, and early satiation, but patients also may be asymptomatic. Although historically it was assumed that symptoms were a result of delay in gastric emptying, it is now recognized that the relationship between severity of

TABLE I Causes of Gastroparesis and Rapid Gastric Emptying

Disorder	Cause
Transient delayed gastric emptying	Drugs (e.g., morphine, anticholinergics, nicotine, dopaminergics), postoperative ileus, viral gastroenteritis, electrolyte abnormalities (hyperglycemia, hypokalemia, hypomagnesemia), hypothyroidism, hyperthyroidism, hypopituitarism, Addison's disease, herpes zoster, critical illness, pregnancy
Chronic gastric stasis	Diabetes mellitus, idiopathic/functional dyspepsia, postsurgical (e.g., vagotomy), gastroesophageal reflux, atrophic gastritis, progressive systemic sclerosis, chronic idiopathic intestinal pseudo-obstruction, myotonia dystrophica, dermatomyositis/polymyositis, systemic lupus erythematosus, Duchenne's muscular dystrophy, amyloidosis, autonomic degeneration, spinal cord disease, tumor associated, anorexia nervosa and bulimia nervosa, central nervous system disease, brain stem lesions, Parkinson's disease, postirradiation, HIV infection, porphyria, liver disease
Rapid gastric emptying	Postsurgical, pancreatic insufficiency (fat), "early" type 2 diabetes, Zollinger–Ellison syndrome, duodenal ulcer disease

symptoms, at least when assessed as a total score, and the rate of gastric emptying is relatively weak. Certain symptoms, such as postprandial fullness and severe vomiting, may be potentially more sensitive. The causes of upper gastrointestinal symptoms in patients with gastroparesis are likely to be multifactorial; in patients with functional dyspepsia, symptoms may result from visceral hypersensitivity and impaired postprandial gastric relaxation. In patients with diabetes, symptoms may be modulated by the blood glucose concentration.

Acute Gastroparesis

Gastric emptying may be affected during generalized ileus due to surgery, severe infection, or metabolic derangement—e.g., in patients with diabetes mellitus, gastric emptying is slower during hyperglycemia and accelerated during hypoglycemia. In these situations, restoration of normal gastric function usually follows correction of the underlying problem. A number of drugs, such as levodopa and nicotine, may lead to delayed gastric emptying. In addition to delaying gastric emptying of other gastric contents, these drugs may affect their own absorption by delaying emptying of the remaining drug from the stomach. These effects are generally reversible on cessation of the drug.

Chronically Delayed Gastric Emptying

The most common causes of chronically delayed gastric emptying include diabetes mellitus, functional dyspepsia, gastroesophageal reflux disease, and postsurgical delayed gastric emptying, with prevalence rates between 30 and 50%. The main pathogenic factors involved in diabetes are autonomic neuropathy and acute changes in blood glucose concentrations. Even relatively minor changes in blood glucose concentrations within the physiological range affect gastric emptying; e.g., gastric emptying of a meal will be slower at a blood glucose concentration of 8 mmol/liter compared with 4 mmol/liter. There is evidence in patients with functional dyspepsia that the rate of emptying may also be associated with demographic factors, including gender and body weight. It is also well recognized that delayed gastric emptying may be a complication of malignancy in the absence of gastric or intestinal obstruction, particularly associated with carcinomas of the breast, lung, and pancreas. Gastric surgery, involving vagal interruption, gastric resection, and/or a drainage procedure (performed now much less frequently than before), may be associated with either delayed or more rapid gastric emptying; these cannot be discriminated on the basis of symptoms. Delayed gastric emptying occurs frequently in patients with anorexia nervosa, but often improves with recommencement of a significant nutritional intake and precedes significant weight gain.

Investigation of Disordered Gastric Emptying

Because of the poor correlation between symptoms and disordered gastric emptying, it is not always clear who should undergo clinical investigation and, if so, when. A general approach to investigation follows.

History and Physical Examination

Investigation of a patient with symptoms suggestive of disordered gastric emptying should start with a comprehensive history focusing on the course of symptoms and their relationship to the composition, volume, and timing of meals. Symptoms may follow a relapsing and remitting pattern. Anorexia, early satiation, weight loss, excessive abdominal bloating, nausea with food ingestion with or without vomiting, and vomiting of food

ingested more than 8 hours earlier may all be suggestive of delayed gastric emptying. Unfortunately, there is a poor correlation with symptoms (Fig. 4) and the presence of delayed gastric emptying, making assessment of the problem difficult. Physical examination is often unremarkable, but a succussion splash, suggestive of gastric dilatation, may be detected.

Further Investigations

Biochemical, hematologic, and urine analyses may reveal previously undetected metabolic disorders, including diabetes, hypothyroidism, hypokalemia, Addison's disease, and potential drug side effects. Following that assessment, conditions causing mechanical obstruction need to be excluded, usually by means of upper endoscopy. If negative, gastric emptying should ideally be measured, preferably by scintigraphy.

Approach to Treatment

Because the motor dysfunctions that contribute to delayed gastric emptying are poorly defined, targeted treatment to accelerate gastric emptying is often difficult. As a result, treatment is primarily aimed at symptom resolution or improvement. When symptoms are mild or absent, treatment may not be indicated, but many patients complain of persistent symptoms such as nausea, vomiting, and weight loss. It should be remembered that psychiatric abnormalities can contribute to symptom severity and should be addressed when appropriate.

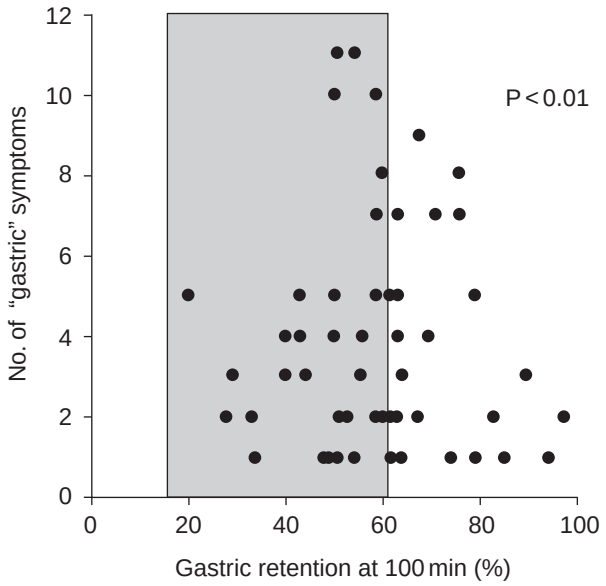

FIGURE 4 The relationship between symptoms (total score) referable to delayed gastric emptying and gastric emptying of a solid (minced beef) meal in patients with diabetes. The normal range for gastric emptying is shown in the shaded area.

Diet No formal evaluation of dietary modification has been performed. However, a stepwise approach is recommended, beginning with reducing the size and fat content of meals, aimed at decreasing the gastric load. Of vital importance is the maintenance of adequate nutrition. Supplemental calories can be supplied by liquid formula, and in severe cases, it may be necessary to start with liquid nutrition, either orally or intragastrically, because emptying of liquid is often less affected than that of solid. Parenteral nutrition should be avoided, if at all possible. However, dietary modification is successful alone in only a minority of patients and most will require drug treatment.

Prokinetic agents The use of prokinetic drugs currently forms the mainstay of treatment; these include cisapride, domperidone, metoclopramide, and erythromycin. In general, these drugs all provide dose-related improvements in gastric emptying, although their pharmacological mechanisms of action differ (Table II); the response to prokinetic therapy tends to be greater when gastric emptying is more delayed. With the exception of erythromycin, all of these drugs have been shown to improve symptoms and quality of life, but there is evidence that tolerance may develop to the gastrokinetic effects of erythromycin. However, erythromycin is the most potent drug when given intravenously (in doses < 3 mg/kg) and may be particularly useful in the early phase of treatment. It is worth noting that the response to erythromycin is attenuated during hyperglycemia; this effect probably applies to other prokinetic agents. The drug of choice for oral administration is probably cisapride, which acts by a 5-hydroxytryptamine isotype 4 (5-HT4) receptor-mediated effect. However, recent reports of adverse events, including serious cardiac arrhythmias (as a result of Q–T interval prolongation), have resulted in restrictions being placed on the use of cisapride in the United States and in many other countries. Alternative agents that act through a 5-HT4 effect, e.g., tegaserod, are now under development. At present, prolonged oral therapy can be achieved with the use of metoclopramide or domperidone (this latter drug is not available in the United States); the former has the advantage of being available as a subcutaneous preparation, which may be of use in those patients with intractable vomiting, but the possibility of potential central nervous system side effects with metoclopramide should be borne in mind. If symptoms are refractory to prokinetic therapy, placement of a feeding jejunostomy may be required to maintain nutrition.

Surgery In most cases, surgery is not recommended, and may be associated with clinical

TABLE II Prokinetic Drugs Used in the Treatment of Gastroparesis[a]

Drug	Mechanism of action	Route of administration	Oral dose
Cisapride	5-HT4 receptor agonist	po	10–20 mg tid
Domperidone	Dopamine D2 receptor antagonist	po	10–20 mg bid–qid
Metoclopramide	5-HT4 receptor agonist, D2 antagonist	po, sc, im, iv	10 mg tid
Erythromycin	Motilin receptor agonist	po or iv	250–500 mg tid

[a] Abbreviations: po, periorbital; sc, subcutaneous; im, intramuscular; iv, intravenous; tid, ter in die (three times/day); bid, bis in die (twice/day).

deterioration. However, with patients for whom medical treatment has failed and persisting weight loss is present, surgical treatment should be considered in specialist centers only, with a partial gastrectomy with Billroth I reconstruction being the procedure of choice. In patients with diabetes, there is evidence that pancreatic transplantation may improve both gastric emptying and symptoms.

Experimental approaches There has been renewed interest in gastric electrical stimulation as a therapy, whether using neural electrical stimulation at a high frequency, which probably stimulates vagal sensory nerves and may suppress the vomiting center, or gastric electrical pacing, in which the electrical stimulation of cholinergic motor neurones approximates the physiological frequency (~ 3 cycles/minute). Although the precise mode of action remains unclear, this method deserves further study. Preliminary results from ongoing trials suggest that the therapy provides significant relief of symptoms, including nausea and vomiting; however, its effects on gastric emptying are as yet unconfirmed.

gastric H^+,K^+-ATPase A P_2-type ion-motive ATPase enzyme that carries out an electroneutral exchange of cytoplasmic protons for extracytoplasmic potassium.

parietal cell The cell type in the gastric mucosa that contains H^+,K^+-ATPase enzyme and secretes HCl.

sarcoplasmic reticulum (SR) Ca^{2+}-ATPase A P_2-type ion-motive ATPase found in muscle sarcoplasmic reticulum that transports Ca^{2+} into the SR lumen.

Gastric H^+,K^+-ATPase is the enzyme responsible for the elaboration of HCl by the parietal cell of the gastric mucosa. It is a P_2-type ion-motive ATPase and allows the exchange of H^+ for K^+. This is an electroneutral exchange of cytoplasmic protons for extracytoplasmic potassium.

INTRODUCTION

Gastric H^+,K^+-ATPase consists of an α-subunit, which is composed of approximately 1034 amino acids, and a β-subunit, which is a glycoprotein composed of approximately 290 amino acids. The primary sequences of the α-subunits, as deduced from their cDNAs, have been reported. The pig gastric H^+,K^+-ATPase α-subunit sequence as deduced from its cDNA consists of 1034 amino acids and has a M_r of 114,285, the rat gastric H^+,K^+-ATPase consists of 1033 amino acids, and the rabbit and human gastric H^+,K^+-ATPases consist of 1035 amino acids. The degree of conservation among the α-subunits is extremely high (over 97% identity) among species. In addition, the gene sequence for the human H^+,K^+-ATPase α-subunit and the 5′ part of the rat H^+,K^+-ATPase α-subunit have been determined and indicate that the human gastric H^+,K^+ ATPase gene has 22 exons.

These H^+,K^+-ATPase α-subunits show a high level of homology ($\sim$60% identity) with the Na^+,K^+-ATPase catalytic α-subunit. The putative distal colon H^+,K^+-ATPase α-subunit has also been sequenced and shares 75% homology with both the H^+,K^+-ATPase and the Na^+,K^+-ATPase. The primary sequences of the H^+,K^+-ATPase β-subunits have been reported for rabbit, pig, rat, mouse, and human. The hydropathy analysis predicts that there is one membrane-spanning region, located at the region between amino acid sequence positions 38 and 63 near the N-terminus, and six or seven N-linked glycosylation sites. The function of the β-subunit is not clearly known, but this subunit appears to be required for the assembly and targeting of the catalytic subunit. The β-subunit plays a role in maintaining the structure of the α-subunit to enable effective binding of K^+ ions to the outside face of the α-subunit.

PHYSIOLOGY

The parietal cell generates acid secretion across the mucosal surface. These cells have histamine type 2, and muscarinic cholinergic receptors in the basolateral membranes. Histamine, is the major stimulant for acid secretion. Stimulation triggers dramatic morphological changes in the parietal cell from the resting state to the stimulating state. In the resting parietal cell, the gastric H^+,K^+-ATPase is present in smooth-surfaced cytoplasmic membrane tubules. On stimulation of acid secretion, the pump is found on the microvilli of the secretory canaliculus of the parietal cell. This morphological change results in a several-fold expansion of the canaliculus. In addition to this transition, there is activation of K^+ and Cl^- channels in the secretory membrane, which allows K^+ to access the extracytoplasmic face of the pump.

The gastric H^+,K^+-ATPase proton pump secretes gastric acid from the cytoplasmic region to the lumen, utilizing ATP. Activity of the gastric H^+,K^+-ATPase results in a primary secretion of 160 mM HCl into the secretory canaliculus. Since the pump is electroneutral, it is necessary to transfer the same amount of K^+ ions into the cytoplasmic region of the parietal cell during H^+ secretion. The K^+ is recycled from the cytoplasmic region to the lumen through a potassium channel in the apical membranes.

Gastric H^+,K^+-ATPase synthesis takes place in the endoplasmic reticulum of the parietal cell. Activation of the histamine-2 (H2) receptors by histamine results in a transient increase of mRNA of the H^+,K^+-ATPase

α-subunit, and H2 receptor antagonists suppress mRNA levels to slightly below basal levels. The α-subunit itself is not stable. The β-subunit is necessary to stabilize the α-subunit and to target it to the apical canalicular membrane. The half-life of the gastric H^+,K^+-ATPase is approximately 54 h in rats. However, H2 receptor antagonist treatment increases the half-life to 125 h. It seems that the resting state, when the gastric H^+,K^+-ATPase is located in tubular vesicles, enhances the enzyme stability dramatically compared to that of the stimulated state.

STRUCTURE AND ION TRANSPORT

The H^+,K^+-ATPase α-subunit has 10 transmembrane segments and the β-subunit has 1 transmembrane segment. The H^+,K^+-ATPase α-subunit has a strong association with the β-subunit. The lumenal loop between the seventh transmembrane segment (M7) and the eighth transmembrane segment (M8) of the α-subunit is associated with the β-subunit. The H^+,K^+-ATPase exists as an $(\alpha\beta)_2$ heterodimeric dimer. The cytoplasmic loop between the fourth and the fifth transmembrane segments is in close proximity to the two α-subunits. Structurally, based on the X-ray crystal structure of sarcoplasmic reticulum (SR) Ca^{2+}-ATPase, this enzyme can be divided into three domains, the cytoplasmic, membrane, and extracytoplasmic domains. The cytoplasmic domain contains four subdomains: a stalk domain, the N-domain, the P-domain, and the A-domain. The N-domain is a large cytoplasmic domain between M4 and M5 where ATP binds, the P-domain is a cytoplasmic domain near M4 where phosphorylation and dephosphorylation occur, the A-domain is a cytoplasmic domain between M2 and M3, which moves depending on conformational changes, and the stalk domain contains the extension of the transmembrane segments into the cytoplasmic region and forms a link for the passage of ions into the membranes. A proposed structure for the gastric α-subunit, based on the SR Ca^{2+}-ATPase structure, is shown in Fig. 1.

The H^+,K^+-ATPase catalyzes transport by means of conformational changes driven by cyclic phosphorylation and dephosphorylation of the catalytic subunit of the ATPase. The H^+ ion is transported from the cytoplasmic region to the lumen by a conformational change induced by phosphorylation and dephosphorylation. The H^+,K^+-ATPase initially binds hydronium ion (H_3O). On phosphorylation, the conformation changes from $E_1P \cdot H_3O^+$ to the $E_2P \cdot H_3O^+$ form. After H_3O^+ is released and K^+ is bound on the extracytoplasmic surface of the enzyme, the $E_2P \cdot K^+$ conformation is adopted. The $E_2P \cdot K^+$ conformation can be easily converted to the E_1K^+ conformation with dephosphorylation. The E_1K^+ conformation releases K^+ to the cytoplasmic side, allowing the new binding of H_3O^+.

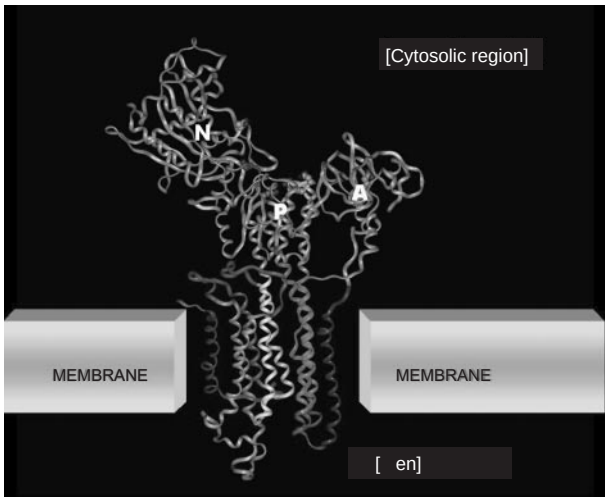

FIGURE 1 Proposed structure of the gastric H^+,K^+-ATPase α-subunit. The gastric H^+,K^+-ATPase α-subunit has 10 transmembrane segments (right represents 1st transmembrane segment, M1, and left shows 10th transmembrane segment, M10). A-, P-, and N-domains are proposed based on SR Ca^{2+}-ATPase crystal structure (E_1-Ca). ATP approaches the N-domain and phosphorylates Asp-386 in the P-domain and the N-domain tilts and docks on A-domain to form E_2-P.

The structural organization and changes in the cytoplasmic domains associated with the $E_1 \Leftrightarrow E_2$ conformational transitions involve several domain movements. The N-domain docks onto the P-domain with the A-domain displaced to one side in the E_1 or E_1P conformations, whereas the A-domain docks onto the P-domain and the N-domain is displaced from the P-domain in the $E_2(K)$ and E_2P conformations. Disruption of the interaction between the P-domain and the N-domain and formation of an A-domain to P-domain interaction during the $E_1 \Leftrightarrow E_1P \Leftrightarrow E_2P$ steps is associated with a change in ligation of Mg^{2+} ions from residues in the sequences TGDGVNDS (P-domain major) and near VAGDA (N-domain minor) in E_1 or E_1P to TGESE (A-domain major) and TGDGVNDS (P-domain minor) in E_2P. This change in ligation may be crucial in the change of reactivity of the phosphoenzymes, switching from ADP-sensitive in E_1P to water-sensitive in E_2P. Presumably, the cytoplasmic domain interactions accompanying E1 $\Leftrightarrow$ E_2 transitions are then relayed via the extended stalk helices of M4 and M5 to the transmembrane segments in which the transported cations are occluded. Changes in tilt, turn, or position of the transmembrane helices, driven by changes in the N-, P-, and A-domains, may allow the cations to dissociate at the opposite surface from that at which

they were occluded. The similarity of structural organization and conformational changes of the cytoplasmic domains of H^+,K^+-ATPase and Na^+,K^+-ATPase suggests that these features are common to other P-type pumps.

Many biochemical and mutagenesis studies provided evidence of a close association between M4 and M6 and between M5 and M7. This also indicates that M4, M5, and M6 are involved in the pathway transporting H_3O^+ outward and K^+ inward. When the Ca^{2+}-occluded E_1 conformation of the Ca^{2+}-ATPase is compared to the Ca^{2+}-free E_2 conformation, the dissociation of Ca^{2+} ions shows a dramatic rearrangement of 6 of 10 transmembrane segments (M1 to M6). M1 and M2 move upward to the cytoplasmic domain with a dramatic tilt of the region near the cytoplasmic domain (stalk domain). M3 and M4 shift downward to the lumen with a strong curve of M3. As the Ca^{2+} ion dissociates, helical bundles of M3, M4, M5, and M6 seem to be loose. The E_2 conformation shows more compact space for easy chelating of Ca^{2+} ion in the lumenal surface than the Ca^{2+}-occluded E1 conformation. It is likely that the gastric H^+,K^+-ATPase has a structural conformation very similar to that of Ca^{2+}-ATPase.

gastritis Inflammatory condition of the stomach, acute or chronic, that is sometimes due to an infectious pathogen.
gastropathy Disorder of the stomach that includes gastritis and other noninflammatory conditions.

A variety of pathogens other than *Helicobacter pylori* cause gastric disease by direct infection of the gastric mucosa and subsequent acute and/or chronic inflammation. Most pathogens involve other organs and other parts of the gastrointestinal tract primarily, and only occasionally produce gastric pathology, even less often with signs or symptoms of gastric disease. A few, such as cytomegalovirus, *Histoplasma*, and the nematodes that cause anisakiasis, produce gastric manifestations frequently in their risk groups. Increasing numbers of immunocompromised patients, particularly those undergoing immunosuppressive therapy or infected with human immunodeficiency virus, have an increased incidence of gastric infections overall. Most of these clinical syndromes have been described rarely in apparently immunocompetent hosts. Multiple gastric malignancies have also been associated to varying degrees with infectious agents. These include Kaposi's sarcoma (human herpesvirus-6), lymphoma (Epstein–Barr virus, *H. pylori*), gastric adenocarcinoma (*H. pylori*, Epstein–Barr virus, *Mycoplasma*, *Streptococcus*, *Rhizopus*), and anisakiasis polyadenoma (nematodes). These tumors are not discussed further here, and the focus is instead on the most common infectious causes of gastritis and gastropathy.

phlegmonous gastritis cases develop emphysematous gastritis, and diagnosis is based on the clinical presentation of an acute abdomen with systemic toxicity, and on radiographs demonstrating gas bubbles within the stomach wall. Risk factors include recent abdominal surgery, gastroenteritis, ingestion of corrosive substances, and alcohol binge drinking. Patients present with acute abdominal pain, nausea, vomiting, melena, and/or hematemesis. Symptoms may be more subacute in immunocompromised patients. Endoscopy shows edematous, darkened gastric mucosa. In a case series of 28 patients, the organisms most commonly involved were *Escherichia coli* (six cases), *Streptococcus* species (six cases), *Enterobacter* species (five cases), and *Pseudomonas aeruginosa* (three cases). The mortality rate was 61%. Long-term morbidity due to gastric strictures was reported in 21% of cases. Other reports have implicated *Clostridium perfringens, Clostridium welchii*, other Enterobacteriaceae, and *Staphylococcus* spp. Computed tomography may be useful both in establishing the diagnosis and for following the resolution of emphysematous gastritis. Therapy includes broad-spectrum antibiotics directed against enteric pathogens and surgery with drainage of pus or resection of necrotic tissue.

Mycobacterium tuberculosis infection involves the stomach in less than 1% of cases, particularly in children, and produces nonspecific symptoms such as nausea, vomiting, abdominal pain, and dyspepsia. Half of patients have evidence of tuberculosis involving other organ systems. Gastric tuberculosis may arise from primary invasion after ingestion of the organism or from dissemination during reactivation disease. Appearance at endoscopy is variable, and may include gastritis, ulcerations (single or multiple), nodules, or larger masses. Endoscopic brush cytology may demonstrate the organism, and standard histopathology reveals granulomatous inflammation. Treatment involves prolonged therapy with multiple agents, and prognosis is favorable assuming proper adherence to the medical regimen and attention to nutrition.

Mycobacterium avium-intracellulare complex (MAC), a common opportunistic infection in advanced autoimmune deficiency syndrome (AIDS), presents with findings of mesenteric lymphadenopathy, bacteremia, and involvement of multiple organs. The site of inoculation is the gastric or respiratory mucosa, and the organism is then taken up by macrophages and reaches the bloodstream via lymphatic channels. Presenting symptoms include fever, weight loss, diarrhea, abdominal pain, and malabsorption. Gastrointestinal obstruction due to massive lymphadenopathy has been reported. Disease manifestations directly involving the gastric mucosa, however, are much less common than those of the small intestine. Clinical presentation may be nonspecific abdominal complaints or upper gastrointestinal (GI) bleeding. Endoscopic findings include gastric ulceration, and histopathology reveals foamy macrophages loaded with mycobacteria. Treatment, as with tuberculosis, involves prolonged therapy with multiple agents.

Actinomycosis is a chronic suppurative infection due to a number of gram-positive, non-spore-forming, anaerobic bacterial species. Abdominal actinomycosis most commonly involves the appendix, terminal ileum, and cecum. Gastric involvement is usually caused by *Actinomyces israelii*, a mouth commensal. In the setting of defects in gastric mucosal integrity, such as peptic ulcer disease or gastric surgery, perigastric actinomycotic masses may form. Intramural gastric actinomycosis has also been described rarely, and the portal of entry may not be apparent. The presentation is characterized by a subacute development of epigastric pain, upper GI bleeding, and occasionally fever, weight loss, and development of a fistulous tract through the skin or into the lumen of the stomach. Radiographic and endoscopic evaluation reveals a mass lesion with or without ulcer, and the mass may infiltrate surrounding structures. Unless a fistulous tract draining inflammatory material containing organisms is present, diagnosis relies on histopathology with characteristic sulfur granules, which are clumps of the branched gram-positive filamentous organisms. Occasionally culture is helpful. Treatment options include surgical resection and penicillin or other active antibiotics for at least 3 months.

Syphilis is a complex multisystem infection that has experienced a resurgence during the first years of the twenty-first century. Secondary syphilis is characterized by early and late manifestations, and the stomach may be involved in either phase. Overall, gastric syphilis occurs in $<1\%$ of syphilis cases. Symptoms are nonspecific and include abdominal pain, vomiting, and weight loss, in addition to symptoms related to nongastric manifestations such as generalized lymphadenopathy and rash. Complications reported include upper GI bleeding, perforation, and obstruction. Endoscopic findings may include diffuse enlargement of gastric rugae, mucosal nodularity, erosive gastritis, and gastric ulceration, most commonly involving the antrum. These findings may mimic gastric lymphoma, linitis plastica, and hypertrophic lymphocytic gastritis. The classic radiologic finding on contrast radiographs (found in $<25\%$ of patients) is "hourglass stomach," produced by multiple ulcerations and prepyloric narrowing. Histologic specimens reveal ulceration and gastritis with an

atypical polyclonal plasma cell infiltrate. Diagnosis is confirmed by specific treponemal serologic testing and demonstration of spirochetes on Warthin–Starry and immunofluorescent stains of gastric mucosal biopsy specimens specific for *Treponema pallidum*. Gastric syphilis responds completely to penicillin therapy, often promptly, and some clinicians recommend antisecretory therapy as well to promote healing.

Gastrointestinal anthrax may involve the gastric mucosa. Herbivores, the usual human source for anthrax, become infected in rural parts of the world from ingesting spores in the soil. Humans ingest or inhale spores found on hides or hair of such exposed animals. When swallowed, anthrax spores may cause lesions from the oral cavity to the cecum. This underreported manifestation of anthrax may be rapidly fatal. Nausea, vomiting, abdominal distension, and severe abdominal pain are presenting symptoms of gastric involvement. The ulcerative lesions may bleed; hemorrhaging in severe cases may be massive. Based on limited reports of GI anthrax, the disease spectrum ranges from the asymptomatic to the fatal, by shock or sepsis. Diagnosis is based on culture or histopathology. Treatment includes effective antibiotics and supportive measures.

FUNGI

Gastric involvement by *Candida* spp. is difficult to define in terms of pathogenicity. Colonization of preexisting lesions with *Candida* is common, and invasion by this route may result in disseminated infection, particularly in immunosuppressed hosts. However, these same hosts may also develop primary mucosal candidiasis of the stomach, with shallow ulcerations and plaques of exudate noted at endoscopy. Oropharyngeal and esophageal candidiasis cases are much more common. Treatment with fluconazole is highly effective, although resistance may develop in immunosuppressed patients on long-term fluconazole maintenance for other invasive candidal infections. These patients may require amphotericin. The finding of *Candida* in a gastric lesion, particularly in an immunocompetent host, may not warrant specific therapy.

Disseminated histoplasmosis often involves the gastrointestinal tract, and presentation with symptoms of such involvement occurs in about 20% of cases. However, presentation with predominantly GI symptoms is rare, and these symptoms are nonspecific. Gastric ulcers and infiltrative lesions have been described due to both *Histoplasma capsulatum* and *Histoplasma duboisii*. Histological analysis reveals granulomatous inflammation with intra- and extracellular yeast forms. Treatment involves systemic antifungal therapy with or without surgical resection.

Gastrointestinal *Pneumocystis carinii* (PCP) has been reported in AIDS patients maintained on aerosolized pentamidine for PCP prophylaxis. Organisms have been detected in ascites fluid, and biopsy specimens from erosive gastritis and duodenitis with multiple small scattered nodules have noted massive infiltration of foamy granular exudates of *P. carinii*. Patients may present with fever, anorexia, upper abdominal pain, or ascites plus symptoms attributable to nongastrointestinal organ involvement. Treatment is as for PCP pneumonia, with trimethoprim–sulfamethoxazole or second-line regimens if there is intolerance to sulfonamides.

Mucormycosis, caused by fungi of the order Mucorales in the class Zygomycetes, may involve the stomach and has been reported in diabetics (particularly with acidosis) as well as renal, liver, heart, and heart–lung transplant recipients, the severely malnourished, and patients with AIDS, uremia, and hematologic malignancies. Corticosteroid use in particular appears to be a major contributing factor. Direct ingestion of spores is the presumed portal of entry. Less than 10% of invasive mucormycosis cases present as gastrointestinal involvement, and of these, at least 60% involve the stomach. The disease is rapidly progressive, and mortality remains high, although early diagnosis improves outcome. Postmortem diagnosis is common in reported case series. Patients may present with upper abdominal pain, anorexia, nausea, vomiting, and gastrointestinal bleeding. Emphysematous gastritis and perforation have been reported, and may occur early posttransplantation. Large, deep, gastric ulcers with a gray–black eschar have been described, with histological appearance of extensive necrosis, vascular invasion, thrombosis, and nonseptate right-angular branching hyphae and cultures of tissue that grow mucormycetes. Colonization of ulcer surfaces without tissue invasion has a less clear significance and much better prognosis. Standard therapy involves an amphotericin formulation with or without surgery.

Gastric involvement in basidiobolomycosis, caused by a fungus in the Entomophthorales order of the class Zygomycetes, which usually produces cutaneous disease, was recently reported in a case series of seven patients from Arizona. The presenting complaint was abdominal pain, and less often fever. Diabetes, pica, and use of histamine-2 (H2) blockers have been associated with this slowly progressive infection, and therapy includes surgical resection and itraconazole. Amphotericin resistance has been documented. Diagnosis was

based on histopathology demonstrating the fungal morphology and surrounding eosinophilic inflammation, but all patients in this series demonstrated peripheral eosinophilia as well.

VIRUSES

Gastropathy is an uncommon presentation of cytomegalovirus (CMV) disease but can manifest as gastric ulcers, acute gastritis, chronic persistent gastritis, and protein-losing hypertrophic gastropathy. In patients with human immunodeficiency virus (HIV) specifically, gastritis ranks in incidence only behind retinitis, esophagitis, and colitis. One study of 497 HIV-infected patients who underwent esophagogastroduodenoscopy (EGD) for upper GI symptoms noted CMV infection in 8 of 16 patients with gastroduodenal ulcers who had evaluable histology specimens, and in 1 of 20 patients without ulceration. CMV gastropathy has also been well described in patients with hematologic malignancies, and in both bone marrow and solid organ transplant patients. Gastric involvement is a more common manifestation of CMV disease in transplant populations. Recently, an association between Menetrier's disease and CMV infection has been more fully described. Diagnosis of invasive CMV infection of the stomach requires demonstration of characteristic cytomegalic inclusions and/or positive immunostaining in tissue specimens of CMV virus antigens. Treatment of CMV gastric infection is similar to other presentations of invasive CMV infection, and includes valganciclovir, ganciclovir, or foscarnet for 21 days. Data regarding maintenance therapy specifically for gastric infection are lacking, although some researchers extrapolate from data for other types of CMV disease. (Indications for prophylaxis in specific groups of immunocompromised patients differ, and full discussion is beyond the scope of this discussion.)

Non-CMV herpesviruses documented to cause gastropathy include varicella zoster virus (VZV) and herpes simplex virus (HSV). Esophageal involvement is far more common with HSV, but gastric lesions have been reported in predominantly immunocompromised patients. Histologic findings include the typical inclusion bodies and ground glass nuclei, and differentiation between viruses requires culture, molecular, or serologic techniques. Radiologically, a cobblestone pattern is described due to the superficial interconnecting of linear ulcers alternating with bleblike edema. VZV gastritis may present with abdominal pain, nausea, and vomiting before the skin lesions of disseminated zoster become visible. Endoscopic and histologic appearance may be nonspecific, although diagnosis may be confirmed using molecular techniques. Treatment for HSV and VZV gastritis is intravenous acyclovir.

PARASITES

Strongyloides stercoralis is a soil-borne intestinal nematode with worldwide distribution. *Strongyloides* filariform larvae are ingested or penetrate human skin. After penetration, the invasive filariform larvae migrate to the lungs. Larvae in the lungs penetrate the bronchioles and are expectorated and swallowed. The larvae in the upper gastrointestinal tract then mature into adult females that produce eggs through parthenogenesis (the direct production of viable offspring from the female without fertilization by the male). Adults and thin-shelled eggs are confined to the mucosa and are not present in stool. Eggs that embryonate and hatch release rhabditiform larvae, which may be detected in stool. Rhaditiform larvae become infective filariform larvae either in stool or in the soil after excretion, completing the life cycle. Alternatively, if infection does not occur, *Strongyloides* rhabditiform larvae in the soil are able to mature into male and female adult worms. Adult worms exist in the soil as saprophytes, mate, and produce eggs. These eggs release rhabditiform larvae, which may differentiate into infective filariform larvae.

Strongyloides has been reported to involve almost every organ system and can disseminate to cause fatal illness in an immunosuppressed host. *Strongyloides* may involve the stomach and present with nausea, vomiting, anorexia, diarrhea, weight loss, and postprandial epigastric pain. Hematemesis and gastrointestinal obstruction have been reported as well. Diagnosis is made by stool examination, small bowel biopsy, or duodenal drainage. Examination of multiple stool samples increases sensitivity. Peripheral eosinophilia may be a diagnostic clue. Literature reports describe gastritis and numerous serpiginous, white, very superficial lesions that appeared to be exudates about 5 to 6 mm in size in the body and antrum of the stomach. Histologic examination confirms the presence of *Strongyloides* larvae and shows dense eosinophilic infiltrates, focal atrophy, and inflammation and destruction of glands, especially in the vicinity of the parasites. The mucosa is intact. Treatment is thiabendazole.

Recent evidence suggests that gastric involvement in AIDS-related cryptosporidiosis can be demonstrated in up to 90% of AIDS patients with cryptosporidium diarrhea, but isolated gastric symptoms are rare. Gastric ulcer, gastritis, and partial pyloric obstruction with thickened, inflamed antral folds have been described endoscopically, and gastric histology has noted cryptosporidial

macrogametes and trophozoites attached to the luminal surface of gastric epithelial cells. Treatment is difficult, but options include nitazoxanide or paromomycin with or without azithromycin.

Gastric anisakiasis is caused by ingestion of raw fish, particularly salmon and herring, containing third-stage nematodal larvae. The larvae invade the gastric mucosa, causing acute upper abdominal pain with or without bleeding. Symptoms usually occur within 7 days of ingestion. Endoscopy reveals a submucosal mass with a protruding larval form. Removal by forceps is commonly practiced, although patients may pass the larva spontaneously. Histologic examination reveals an intense eosinophilic infiltrate. Recurrent episodes are associated with more severe symptoms, and chronic gastritis may occur if the parasite is not recognized and removed. Cooking and freezing are adequate methods of killing the larvae.

Gastric Motility

CHRISTINE FEINLE-BISSET, DEIRDRE O'DONOVAN, AND MICHAEL HOROWITZ
University of Adelaide and Royal Adelaide Hospital, South Australia

gastric accommodation Relaxation of the proximal stomach to "accommodate" food without a major increase in intragastric pressure.
migrating motor complex Cyclical motor pattern that occurs in the fasting gastrointestinal tract; consists of three phases (I–III) with distinct differences in activity.
motility Contractile activity of the wall of the gastrointestinal tract.

The fasting and postprandial motility patterns of the stomach, pylorus, and proximal small intestine are regulated by neural and humoral mechanisms, including those triggered by small intestinal nutrients. Various methods can be used to quantify gastric motility. The pathophysiology of disordered gastric motility is complex and poorly understood.

INTRODUCTION

In the early 1820s, Alexis St. Martin, a patient suffering from an abdominal gunshot wound, afforded his physician, William Beaumont, the opportunity to be the first to observe through an open gastric fistula that food, whether ingested or placed directly into the stomach through the fistula, induced gastric wall contractions that facilitated the breakdown of food into smaller particles. Two gastric regions with distinct motor activity were later identified by Walter Cannon, using roentgenography to investigate gastric motor function in his studies in dogs and cats.

The various compartments of the gastroduodenal region serve different functions. The proximal stomach has the capacity to relax, so that ingested food can be accommodated with minimal increase in intragastric pressure; distal stomach phasic contractions then mix and grind solid food and propel "liquefied" solids toward the pylorus. Tonic and phasic pyloric contractions regulate transpyloric flow, and the duodenum can modulate transit of chyme and, hence, the exposure of small intestinal receptors to nutrients. However, it is essential to recognize that the intragastric processing and subsequent delivery of nutrient into the small intestine at a rate that optimizes digestion and absorption are dependent on the integration of motility between these different regions.

PATTERNS OF FASTING AND POSTPRANDIAL GASTRIC MOTILITY

The motility of the stomach, as in other areas of the upper gastrointestinal tract, is organized into two basic patterns—fasting and fed—which have fundamental differences. In the fasted state, the proximal stomach is in a continuous state of partial contraction, maintained by a vagally mediated cholinergic input. In contrast, the contractile activity of the distal stomach is characterized by a pattern of cyclical activity, the so-called migrating motor complex (MMC) (Fig. 1), which consists of three distinct phases (I–III) and, in humans, has a cycle length of approximately 100 minutes. Approximately 80% of the cycles originate in the antrum,

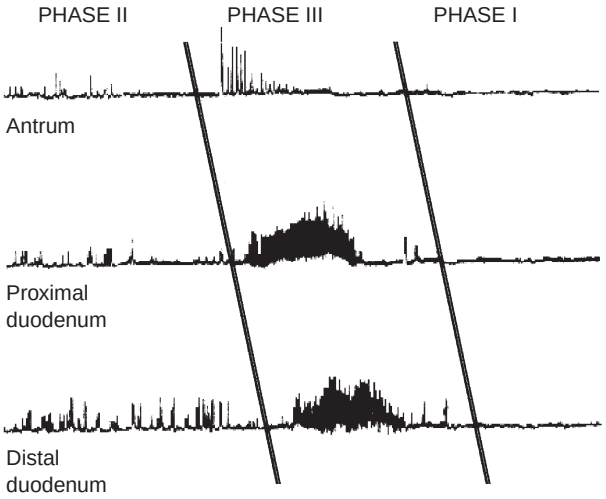

FIGURE 1 Motility patterns in the fasting gastrointestinal tract. The pattern of the fasting stomach and small intestine is characterized by cyclical activity, the so-called migrating motor complex, which consists of three distinct phases (I–III); in humans, the cycle length of the three phases is approximately 100 min. Reproduced with permission from Rao and Schulze-Delrieu (1993).

 Copyright 2004, Elsevier (USA). All rights reserved.

the remainder in the small intestine. Phase I is characterized by a period of quiescence in the antrum, lasting for ~40–60 minutes; phase II is a period of increasing, but irregular, phasic contractions and lasts for ~30–40 minutes; phase III consists of a short period of intense contractile activity for ~5–10 minutes. During phase III, the contractions are characterized by a high amplitude and occur at maximum frequency—that is, at the frequency of the electric pacemaker, which in the stomach is 3/minute. Phase III of the MMC is propulsive and, as it migrates from the stomach through the small intestine into the ileum, it "sweeps" undigested or indigestible food particles, dead cells, secretions, and bacteria, hence the terminology of the "gastrointestinal housekeeper."

Meal ingestion interrupts the cyclical motor pattern of the MMC and causes distinct changes in gastric motility, characterized by a relaxation of the proximal stomach, irregular, phasic contractile activity in the antrum, an increase in tonic and phasic pyloric pressures, and irregular contractile activity in the duodenum. The motor response to food is dependent on its physical state (solid or liquid) and nutrient content. Ingestion of water does not affect fasting motility, unless ingested in volumes >400 ml. Ingestion of a solid meal induces strong contractions in the antrum, whereas the same meal in homogenized form or nutrient-containing liquid meals induce less pronounced antral contractions. Hence, a solid meal is traditionally used for the clinical assessment of antral motor function.

The proximal gastric motor response to food ingestion may be divided temporarily into two phases. The first phase occurs during, and shortly after, the ingestion of a meal and consists of two relaxatory reflexes; "receptive relaxation" describes the relaxation of the fundus in response to swallowing, and this is followed by "gastric accommodation," whereby the proximal stomach relaxes so that a progressive increase in meal volume is not associated with a major increase in intragastric pressure. The second phase of postprandial proximal gastric motility consists of a continuous tonic contraction that gradually squeezes gastric content toward the distal stomach. However, because this tonic contractile activity is associated with little change in intragastric pressure, it cannot be recorded by standard manometric techniques. Changes in gastric tone can indirectly be quantified as a change in gastric volume using the electronic barostat (see later).

The functions of the distal stomach are accomplished by coordinated antral and pyloric contractile activity. In contrast to the proximal stomach, the motility of the antrum consists of phasic contractions that propagate toward the pylorus and serve to mix and grind food (Fig. 2). The pylorus exhibits both tonic and phasic pressures, with a narrow zone of contraction of approximately 2 mm. Stimuli that increase antral contractions include gastric distension; the physical consistency of gastric chyme (i.e., particulate vs. homogenized) also affects the depth of contractions. Each peristaltic wave originates in the midstomach, or corpus, as a shallow indentation and deepens as it moves more distally, but does not always entirely occlude the lumen, compressing liquids and solids within the distal antrum.

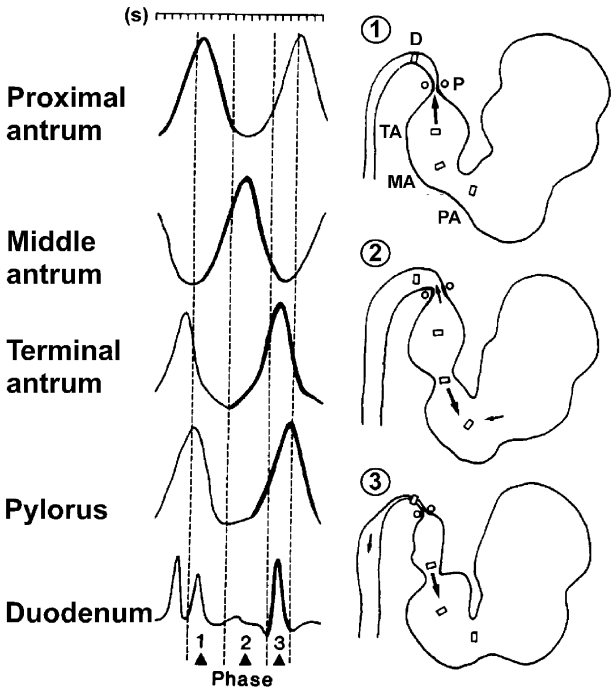

FIGURE 2 Relationship between antropyloroduodenal contractions (tracings, left) and movement of gastric content (diagrams, right) as recorded concurrently with fluoroscopy and strain gauge transducers (recording motility). The tracings show the progression of a peristaltic wave moving over the proximal (PA), the middle (MA), and the terminal (TA) antrum to the pylorus (P) and duodenum (D). (1) The wave moves over the proximal antrum. The terminal antrum and the pylorus relax. Gastric content is forced into the terminal antrum. (2) The wave travels over the middle antrum. Gastric content is evacuated through the pylorus and also retropelled into the proximal antrum. A subsequent wave moves over the gastric body, driving digesta into the proximal antrum. (3) The wave moves over the terminal antrum with increasing velocity. Contractions of the terminal antrum and pylorus enhance retropulsion and grinding. The subsequent wave advances the antrum. A propagative wave starts on the duodenal bulb. Reproduced from Ehrlein, H. J. and Schemann, M. (1990). Influence of food constituents. *In* "Gastropyloro-duodenal Coordination" (J. M. Van Nueten *et al.*, eds.). Wrightson Biomedical Publishing, with permission from H.-J. Ehrlein.

As the antral wave advances toward the pylorus, the pylorus is open, allowing some fluid and solid particles less than 1 mm in diameter to pass into the duodenum. Just before the antral wave reaches the pylorus, the latter closes, ceasing transpyloric flow. Pyloric closure is followed immediately by occlusion of the terminal antrum, generating pressures of more than 100 mmHg, and producing a forceful retropulsion of solid particles, which both grinds and mixes them with gastric juice. Relaxation of the terminal antrum is followed by pyloric opening and emptying of liquid and suspended particles, whereas the subsequent peristaltic wave is at the proximal antrum (Fig. 2).

Phasic and tonic pyloric contractions occur either in isolation or are coordinated with antral contractions and appear to control transpyloric flow by acting primarily as a brake, allowing flow to occur in a series of small gushes only when the pylorus is open. The mechanical determinants of individual flow episodes are still poorly defined. Flow could potentially reflect a local increase in antroduodenal pressure differences due to peristaltic antral contractions, or may be associated with a common-cavity pressure difference between the distal antrum and proximal duodenum during periods of relative antral motor quiescence, when either antegrade or retrograde flows could occur.

As already described, postprandial duodenal motility is characterized by a pattern of irregular contractile activity, consisting of isolated pressure waves that mix chyme with intestinal secretions, and some pressure wave sequences that move the chyme slowly more distally. In this way, absorption and the interaction between nutrients and small intestinal receptors are optimized.

NEURAL INNERVATION OF THE STOMACH

Digestive functions, including gastric motility, are controlled by a number of neural networks that are located in the wall of the gastrointestinal tract, prevertebral ganglia, spinal cord, and brain. These neural networks are fundamental to the integration of the functions of the proximal and distal stomach and the pylorus.

Gastric Electrical Pacemaker

The electrical stimulus for gastric (as well as small intestinal) smooth muscle contraction is provided by cells recently identified as a subtype of interstitial cells of Cajal. The latter generate so-called slow waves, or pacemaker potentials, and are located in the myenteric plexus (i.e., between the longitudinal and circular muscle layers) in the upper body. Slow waves, continuous, rhythmic changes in the membrane potential occurring in the human stomach at a maximum frequency of 3/minute, do not per se initiate contractions. The latter are generated by action potentials (as a result of rapid membrane depolarization), superimposed on the partial depolarization of the slow wave. Accordingly, phasic contractions in the antrum and pylorus are associated temporarily with the rhythm and propagation of the gastric pacemaker potential when stimuli enhance contractility above the basal level; the maximum contraction frequency is limited by the frequency of the slow wave, i.e., 3/minute in the stomach. Both neural and hormonal inputs can modulate the duration and the amplitude of the action potential, i.e., increase it above, or maintain it below, the threshold required for the triggering of a contraction.

Intrinsic Innervation of the Stomach

The enteric nervous system (ENS), also termed the "brain of the gut," because it is able to function without input from the central nervous system, is located within the walls of the stomach and small intestine. It consists of two systems of nerve plexus—the myenteric (or Auerbach) plexus, located between the circular and longitudinal muscles, and the submucosal (or Meissner) plexus, located beneath the mucosa. Within the ENS, there are three major types of neurons. Sensory neurons contain specialized receptors that detect changes in the environment (tension, contraction, chemical stimuli), which are then transformed into electrical signals, so-called action potentials, and transmitted along sensory nerve fibers to other parts of the nervous system. Interneurones form networks that process sensory information and control the behaviour of motor neurones, which are the final common pathway for the transmission of signals to the effector systems. Both excitatory (i.e., stimulating muscle contraction) and inhibitory (i.e., suppressing muscle contractions/stimulating muscle relaxation) exist. The major excitatory transmitters are acetylcholine and substance P, and the major inhibitory neurotransmitters are vasoactive intestinal peptide (VIP) and nitric oxide (NO). The enteric nervous system, thus, comprises local circuitries for the performance of integrative functions independent of extrinsic innervation.

Extrinsic Innervation of the Stomach

The stomach, like other parts of the gastrointestinal tract, is innervated by extrinsic nerves—the sympathetic and parasympathetic parts of the autonomic nervous system and sensory nerves that project to the

spinal cord (splanchnic and sacral afferents) and to the brain stem (vagal afferents). Gastric motility is controlled predominantly by the vagus nerve. Vagal afferents project to the nucleus tractus solitarius (nTS), where they form synapses with interneurons that project to the dorsal motor nucleus of the vagus (DMNV) and to higher brain centers. From the DMNV, efferent projections return to the stomach, modulating the activity of the muscle cells ("effector system") through activation of either inhibitory or excitatory motor neurons. This circuit is termed a "vago-vagal reflex." Vago-vagal reflexes are also modulated by input from other brain regions, including the forebrain and the area postrema (AP).

SMALL INTESTINAL REGULATION OF GASTRIC MOTILITY

Both nutrients and hormones, released in response to the presence of nutrients in the small intestine, modulate gastric motility.

Effects of Nutrients

The presence of dietary nutrients and osmotically active substances in the small intestine has pronounced effects on gastric and pyloric motility; the effect of nutrients is related to their energy content and the length / region of small intestine that is exposed to the nutrients. Direct infusion of nutrients into the small intestine is associated with relaxation of the proximal stomach, suppression of antral pressure waves, stimulation of tonic and phasic pyloric pressures, and slowing of gastric emptying (Fig. 3).

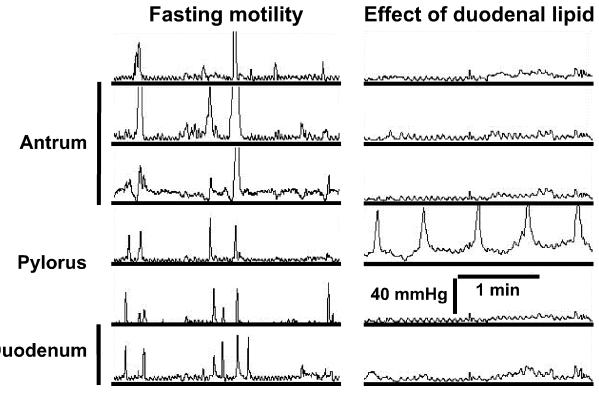

FIGURE 3 The effect on antropyloroduodenal motility of a duodenal lipid infusion. Duodenal lipid is associated with suppression of antral and duodenal pressure waves and stimulation of tonic and phasic pyloric pressures.

Humoral Mechanisms

Food ingestion stimulates the secretion of a large number of gastrointestinal hormones, which have modulatory effects on gastric motility. For example, fat and protein ingestion predominantly stimulates cholecystokinin (CCK) secretion and carbohydrate and fat ingestion stimulates glucagon-like peptide-1 (GLP-1) secretion. Exogenous administration of these peptides in apparently "physiological" concentrations induces relaxation of the proximal stomach, suppression of antral pressure waves, and stimulation of tonic and phasic pyloric pressures. Receptor antagonists for some of these peptides are available for use in humans. For example, the CCK-A receptor antagonist, loxiglumide, attenuates the effects of duodenal fat on the stomach and pylorus, suggesting that CCK mediates, at least in part, the effects of fat on gastric motility.

METHODS FOR THE ASSESSMENT OF GASTRIC MOTILITY

A number of techniques are available for the assessment of different aspects of gastric motility. According to their applications, they can be divided into techniques to assess gastric electrical activity (not discussed further here), gastric wall motion, proximal gastric relaxation, and intraluminal phasic pressures (Table I). In research studies, a number of techniques are frequently used concurrently. However, in contrast to the assessment of gastric emptying, a number of these techniques, including magnetic resonance imaging (MRI), single-photon emission computed tomography (SPECT), and three-dimensional ultrasound, are currently too expensive and labor intensive to be used in the clinical setting.

Assessment of Gastric Wall Motion

Techniques to assess gastric wall motion include scintigraphy, ultrasound, and magnetic resonance imaging (Fig. 4). Scintigraphy, the "gold standard" technique to quantify gastric emptying, also allows an assessment of intragastric meal distribution and antral contractile activity. The clinical utility of this latter technique remains to be established. Ultrasonography is well suited to evaluate gastric wall motion and intragastric volume. The recent development of three-dimensional ultrasound techniques has advanced the capacity to evaluate relationships between antral area/volume and contractile activity, transpyloric flow, and duodenal contractile activity concurrently. MRI has recently been used to detect peristaltic occlusive and nonocclusive movements of the gastric wall. However, due to its limited accessibility and high cost, it is unlikely that MRI

TABLE I Techniques for Assessment of Gastrointestinal Motility

Technique	Parameters assessed
Electrogastrography	Myoelectrical activity
Scintigraphy	Gastric emptying, intragastric distribution, and antral contractions
Ultrasonography	Antral area (two dimensional), volume (three dimensional), antropyloric contractions, and pyloric flow
Magnetic resonance imaging	Gastric emptying, intragastric distribution, and antral contractions
Single-photon emission computed tomography	Gastric volume (relaxation)
Barostat	Proximal gastric volume (relaxation) and gastric pressure–volume relationship
Intraluminal manometry	Lumen-occlusive contractions

will be used clinically for this purpose in the foreseeable future.

Assessment of Gastric Relaxation

Until the advent of the barostat, no technique was available to quantify relaxation of the proximal stomach. The barostat consists of a pressure transducer linked by an electronic relay to an air injection system. An infinitely compliant bag, located in the proximal stomach, is then connected via a double-lumen tube to the barostat. Once a pressure is set in the system (frequently 2 mmHg above basal intragastric pressure), the barostat can indirectly measure gastric relaxation by monitoring changes in intrabag volume at that pressure. Thus, when the stomach relaxes, air is injected into the gastric bag to maintain the pressure, while air is withdrawn when the stomach contracts. The barostat has significant limitations, because the air-filled bag in the proximal stomach disturbs normal physiology—for example, the presence of the bag affects antral motility. More recently, other techniques, such as single-photon emission computed tomography imaging, three-dimensional ultrasound, and MRI have been used to quantify proximal gastric motility in research studies.

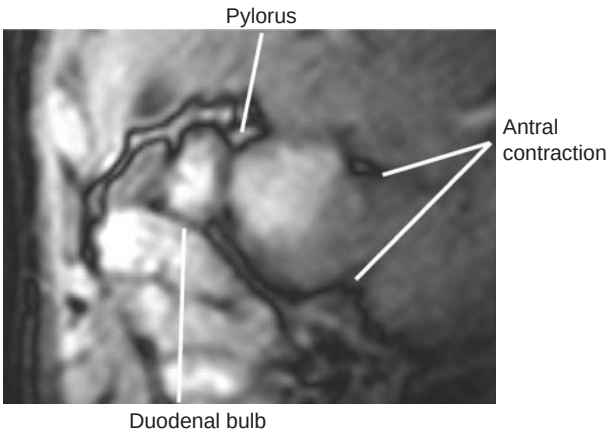

FIGURE 4 Magnetic resonance imaging scan of the antropyloroduodenal region. Wall motion in the antrum, reflecting an antral contraction, is clearly visible.

Measurement of Antropyloroduodenal Phasic Contractions

Manometry assesses intraluminal pressure changes due to contractile activity of the antropyloroduodenal region. In order to measure pressures over a segment of stomach or small intestine, a multilumen catheter with multiple, closely spaced side holes is used. Although both solid-state and water-perfused manometric catheters are potentially applicable, in most cases perfused systems are used; the system is connected to a pump with a water reservoir and perfused continuously. In order to be reliably detected, contractions must be lumen occlusive and occur at the site of a side hole. It is important to recognize that patterns of muscular contractions are not synonymous with patterns of lumen occlusion due to the variation in luminal diameters. For example, a recent study demonstrated that only 54% of contractile events, as recorded by MRI, were associated with a detectable pressure event, as assessed by manometry. It is impossible to position a recording side hole in the pylorus accurately, because it is a narrow and mobile structure, hence the so-called sleeve sensor or multiple closely spaced side holes are required to record pyloric pressures accurately. The sleeve sensor is a perfused channel in the manometric catheter that records the highest pressure point along its length. By spanning the length of the sphincter, the sleeve sensor is able to maintain contact to sense the maximum pressure reliably even if the catheter moves slightly.

PATHOPHYSIOLOGY OF GASTRIC MOTILITY

A number of acute and chronic conditions of diverse etiology are associated with disordered gastric emptying/gastroduodenal motility. The underlying pathology may potentially involve the gastric musculature, its extrinsic or intrinsic nervous innervation, or the interstitial cells of Cajal, although the number of histopathological studies has been limited. Increased small intestinal feedback could potentially also lead to slow gastric emptying.

Motor Dysfunctions Responsible for Slow Gastric Emptying

Abnormally slow gastric emptying, or gastroparesis, may theoretically result from defective mechanical breakdown of food, ineffective propulsion of intragastric content, and/or an abnormally high resistance to emptying. Postsurgical gastroparesis is associated with a reduction in gastric motility, particularly contractile activity of the antrum. The motor dysfunctions responsible for gastroparesis are poorly characterized; in part, this reflects the substantial technical difficulties associated with measurement of gastric motility—in most studies, only one or two motor components (most frequently the antrum) have been evaluated. It is, however, clear that, in many cases, the motor abnormalities are heterogeneous and that the organization of gastroduodenal contractile activity is frequently impaired. Proximal gastric motility is abnormal in many patients with impairment of gastric relaxation induced by a meal. Both fasting and postprandial antral hypomotility occur frequently, particularly a reduction in the number of antral pressure waves that are temporarily associated with duodenal waves. Increased pyloric motility does not appear to be a major factor contributing to gastroparesis. Abnormal proximal small intestinal motor function also occurs frequently, but has been poorly characterized. A knowledge of the motor dysfunctions responsible for disordered gastric emptying has potential implications for the efficacy of pharmacotherapy.

CONCLUSION

The motor activity of the stomach is characterized by two distinct motor patterns, fasting and fed, with markedly differing functions. Gastric motor patterns are governed by both extrinsic and intrinsic innervation and modulated by a number of factors, including nutrients and humoral factors. Abnormal gastric emptying is associated with a number of gastric motor dysfunctions.

gastric outlet obstruction A mechanical obstruction of the stomach as it empties into the duodenum or through a surgically created stoma.

proximal gastric vagotomy Also known as highly selective vagotomy or parietal cell vagotomy; an operation in which the vagal branches of the nerves of Laterjet are divided as they enter the lesser curvature of the stomach. This ameliorates vagally mediated gastric acid secretion from the parietal cell mass while preserving the motor branches to the antrum and the pylorus.

Gastric outlet obstruction occurs due to obstruction at or near the pylorus or a surgically created gastroenterostomy. By far, the most common causes of gastric outlet obstruction are peptic ulcer disease and adenocarcinoma of the gastric antrum. This article discusses the causes of this condition, its clinical manifestations, and the diagnostic strategies and potential therapeutic modalities involved in treating these patients.

ETIOLOGY

Since the 1970s, gastric adenocarcinoma has supplanted peptic ulcer disease as the most common cause of gastric outlet obstruction. Unusual causes of gastric outlet obstruction include benign neoplasms of the pylorus and stomach, Crohn's disease of the stomach or duodenum, adult hypertrophy of the pylorus, heterotopic pancreatic tissue at the pylorus, and fibrous intra-abdominal adhesions. Peptic ulcer disease associated with gastric outlet obstruction is usually localized to the duodenum, but pyloric channel and gastric antral ulcers may also cause obstruction. In these instances, an active ulcer crater is associated with acute edema, inflammation, and pylorospasm. Rarely is the obstruction due solely to the presence of a fixed fibrous scar. This explains those occasions in which medical management of the ulcer results in resolution of obstructive symptoms. Pyloric channel ulcers are often associated with gastric retention; in one early study, nearly 50% of the patients with ulcers within the pyloric channel had symptoms of gastric outlet obstruction.

Adenocarcinoma, as well as other gastric malignancies such as lymphoma, may present with signs and symptoms of gastric outlet obstruction. Differentiation of a benign ulcer from a malignant gastric ulcer may be difficult on endoscopic (or radiographic) inspection and

gastric outlet obstruction A mechanical obstruction of the stomach as it empties into the duodenum or through a surgically created stoma.

proximal gastric vagotomy Also known as highly selective vagotomy or parietal cell vagotomy; an operation in which the vagal branches of the nerves of Laterjet are divided as they enter the lesser curvature of the stomach. This ameliorates vagally mediated gastric acid secretion from the parietal cell mass while preserving the motor branches to the antrum and the pylorus.

Gastric outlet obstruction occurs due to obstruction at or near the pylorus or a surgically created gastroenterostomy. By far, the most common causes of gastric outlet obstruction are peptic ulcer disease and adenocarcinoma of the gastric antrum. This article discusses the causes of this condition, its clinical manifestations, and the diagnostic strategies and potential therapeutic modalities involved in treating these patients.

ETIOLOGY

Since the 1970s, gastric adenocarcinoma has supplanted peptic ulcer disease as the most common cause of gastric outlet obstruction. Unusual causes of gastric outlet obstruction include benign neoplasms of the pylorus and stomach, Crohn's disease of the stomach or duodenum, adult hypertrophy of the pylorus, heterotopic pancreatic tissue at the pylorus, and fibrous intra-abdominal adhesions. Peptic ulcer disease associated with gastric outlet obstruction is usually localized to the duodenum, but pyloric channel and gastric antral ulcers may also cause obstruction. In these instances, an active ulcer crater is associated with acute edema, inflammation, and pylorospasm. Rarely is the obstruction due solely to the presence of a fixed fibrous scar. This explains those occasions in which medical management of the ulcer results in resolution of obstructive symptoms. Pyloric channel ulcers are often associated with gastric retention; in one early study, nearly 50% of the patients with ulcers within the pyloric channel had symptoms of gastric outlet obstruction.

Adenocarcinoma, as well as other gastric malignancies such as lymphoma, may present with signs and symptoms of gastric outlet obstruction. Differentiation of a benign ulcer from a malignant gastric ulcer may be difficult on endoscopic (or radiographic) inspection and

 Copyright 2004, Elsevier (USA). All rights reserved.

is dependent on histologic examination of biopsy specimens of the margins of the ulcer.

CLINICAL PRESENTATION

The principal symptoms of gastric outlet obstruction are nausea and vomiting, which often develop over a period of weeks to months. The vomiting is often copious in nature and consists of poorly digested food. Many patients with gastric outlet obstruction from ulcer disease have a long history of ulcer-related pain; in several early studies, patients had symptoms of ulcer disease for nearly 10 years. Recent onset of upper abdominal pain or obstruction in the absence of abdominal pain should raise the possibility of a malignant etiology. Weight loss and malnutrition are common findings in patients presenting with either benign or malignant obstruction. Physical examination may identify a gastric succussion splash, upper abdominal distension (from a markedly dilated stomach), and perhaps visible gastric peristalsis. Physical evidence of poor nutrition and intravascular volume depletion may also be apparent. Intubation of the stomach with a nasogastric tube will yield at least 500 ml, and often significantly greater quantities, of fluid and undigested particulate matter.

Patients with gastric outlet obstruction will often be depleted of intravascular volume and have electrolyte disturbances associated with the loss of large volumes of gastric juice. Gastric juice in patients with gastric outlet obstruction contains approximately 100 mEq per liter of chloride, 45 mEq per liter of sodium, and 10 mEq per liter of potassium. The electrolyte disturbance associated with gastric outlet obstruction consists initially of a decrease in plasma chloride and an increase in bicarbonate. Over time, a sodium deficit develops (due to sodium losses in the vomitus and its enhanced excretion into the urine) and on depletion of the sodium reserves, hydrogen and potassium ions are excreted with the bicarbonate as sodium is preserved. This results in the paradoxical excretion of acidic urine in the setting of a metabolic alkalosis. The classic electrolyte disorder of patients with long-standing gastric outlet obstruction is a hypochloremic, hypokalemic metabolic alkalosis.

DIAGNOSTIC STRATEGY

Aspiration of gastric contents through a nasogastric tube will reveal substantial quantities of retained fluid. A gastric aspirate volume of more than 300 ml 4 h after a meal or greater than 200 ml after an overnight fast suggests impaired gastric emptying. In the past, the diagnosis was suspected based on a saline load test in which 750 ml of saline was placed into the stomach through a nasogastric tube; aspiration of more than 300 ml of fluid 30 min after instillation suggests delayed gastric emptying.

Mechanical obstruction of the gastric outlet may be confirmed with endoscopy and/or barium contrast radiographs. Endoscopy will allow visualization of the site of obstruction and often provide evidence of its etiology. This procedure may be helpful in differentiating a mechanical outlet obstruction from a functional obstruction (e.g., postvagotomy or postresection gastric stasis or diabetic gastroparesis). The importance of biopsy cannot be overestimated in differentiating benign from malignant gastric ulcers. Prior to this procedure, retained gastric contents should be evacuated with a large-bore gastric tube (e.g., an Ewald tube) to allow visualization of the gastric mucosa.

A plain abdominal radiograph may suggest gastric stasis by demonstrating a large gastric shadow with retained food particles that appear as patchy translucencies. An upright roentgenogram will show a high gastric air—fluid level. A barium contrast study of the stomach also may confirm the presence of outlet obstruction and provide evidence of its etiology. For example, the normal stomach will largely empty in approximately 2 h with a small residual amount of barium present after 4 to 6 h. In instances of gastric outlet obstruction, more than 50% of the barium will be retained within the stomach 4 to 6 h after the barium is swallowed. A barium contrast study may elucidate postoperative anatomy in patients who previously have undergone gastric operations for ulcer disease. Barium studies are occasionally helpful in differentiating a benign from a malignant ulcer or in demonstrating ulcer disease in the presence of postoperative gastric deformities.

TREATMENT

Many patients with gastric outlet obstruction require operative management. In general, this is preceded by a period of meticulous medical preparation, the aims of which are decompression of the dilated stomach, healing of the ulcer, correction of fluid and electrolyte abnormalities, and improvement in the general condition of the patient. A nasogastric tube is placed at the time of admission to decompress the stomach; a large-bore gastric tube may be necessary to remove large particulate matter prior to diagnostic studies. Intravenous fluid resuscitation with normal saline and potassium chloride will correct the intravascular volume deficit and replete the total body sodium, chloride, and potassium pools. Patients should receive appropriate medical treatment for peptic ulcer disease with either a proton pump

inhibitor or a histamine-2 receptor antagonist, given intravenously until the nasogastric tube is removed. Those patients with evidence of *Helicobacter pylori* infection should receive appropriate antibiotic therapy. Most clinicians will begin parenteral nutrition given the incidence of malnutrition in these patients and the often prolonged period of time prior to the patient again being able to tolerate oral feedings. Within a few days of this treatment, most patients will demonstrate significant improvement in their gastric emptying with a reduction in the volume of aspirate from their nasogastric tube. This will allow diagnostic studies and planning of definitive treatment.

Patients suffering gastric outlet obstruction from a distal gastric cancer should undergo operative treatment. The only chance for cure comes from total resection with or without adjuvant chemoradiation therapy (depending on the stage of the disease). Patients with more advanced disease may be palliated by the endoscopic placement of a stent across the obstruction or by the performance of a gastrojejunostomy at a site well proximal to the malignancy.

Some patients with gastric outlet obstruction from benign ulcer disease will respond to medical management of the ulcer alone. The long-term efficacy of medical management combined with endoscopic dilation of the stricture is unclear. Two recent reports suggest that nearly 70% of patients with gastric outlet obstruction due to peptic ulcer disease could be successfully managed medically along with endoscopic dilation. Kozarek reported that 16 of 23 patients undergoing balloon dilation of gastric outlet obstruction were asymptomatic up to 2.5 years later. However, medical management alone has a very high failure rate on long-term follow-up. Jaffin, for example, reported that 92% of patients with gastric outlet obstruction who were treated medically required operative management for recurrent or persistent symptoms within 3 years.

If surgery is required due to failure of medical/dilation therapy, the best operation for gastric outlet obstruction from benign ulcer disease is debated. Several papers, including one prospective randomized trial, demonstrated that proximal gastric vagotomy and gastrojejunostomy was superior to vagotomy and antrectomy or proximal gastric vagotomy and gastroduodenostomy. Others have reached similar conclusions, based on retrospective comparisons, that proximal gastric vagotomy and pyloroplasty is superior to vagotomy and antrectomy or truncal vagotomy and pyloroplasty. Donahue *et al*. reported that 93% of their patients undergoing proximal gastric vagotomy with drainage did well with no recurrent ulcers, no significant gastric atony, and minimal postoperative symptoms for as long as 4.6 years following surgery. Of note, there is significant experience to suggest that proximal gastric vagotomy with intraoperative dilation of the stricture alone is associated with an extremely high incidence of recurrent obstruction.

Gastric Polyps

STEFFEN MUEHLDORFER*, CHRISTIAN ELL†, AND MANFRED STOLTE‡

University of Erlangen, Nuremberg, †Horst-Schmidt-Kliniken, Wiesbaden, and ‡Institute of Pathology, Bayreuth, Germany

gastric polyp Benign or malignant lesion in the stomach that is elevated above the surrounding gastric mucosa.

polyposis Condition in which numerous polyps are present, usually due to a genetic defect.

Recommendations for diagnosis and treatment of gastric polyps remain controversial; no consensus exists regarding their malignant potential or the reliability of endoscopic forceps biopsy. According to the classification of gastric tumors and polyps established by the World Health Organization, the frequency of malignant transformation depends on histologic type. The cancer risk has been reported to range from 0 to 8.6% (average 2.1%) for hyperplastic polyps, to be approximately 5% for tubular adenomas, and to range from 28.5 to 40% for villous adenomas and pyloric gland adenomas. Therefore, a precise histologic classification is essential to therapeutic action. Especially important is the reliability of the histologic rating of forceps biopsy sampling with regard to the total polyp.

TABLE I Incidence of Various Gastric Polyps[a]

Type	Number	Incidence
Neoplasias		
Tubular adenoma	600	(16.7%)
Tubulopapillary adenoma	77	(2.2%)
Papillary adenoma	7	(0.2%)
Pyloric gland adenoma	13	(0.4%)
Adenocarcinoma	423	(11.8%)
Carcinoid tumor	95	(2.6%)
Total	1215	(33.9%)
Tumorlike lesions		
Hyperplastic polyp	2036	(56.7%)
Inflammatory fibroid polyp	192	(5.4%)
Heterotopia	111	(3.1%)
Peutz–Jeghers polyp	21	(0.6%)
Juvenile polyp	11	(0.3%)
Cronkhite–Canada polyp	2	(0.1%)
Total	2373	(66.1%)

[a] $n = 3588$; includes polyps seen in patients at the Institute of Pathology, Bayreuth, in the period 1969–1992, excluding fundic gland polyps, mesenchymal tumors, and polypous lymphomas.

EPIDEMIOLOGY

Gastrointestinal polyps are by definition lesions elevated above the surrounding mucosa. In the stomach, they are found in 1–5% of all gastroscopic examinations. The reported incidence varies because fundic gland polyps, which comprise of about 50% of all polyps, have been only inconsistently included in the surveys. More than one polyp can be found in around 25% of the patients. One of the largest histopathologic series evaluated almost 3600 gastric polyps. The absolute numbers and relative percentages of the various types of gastric polyps, excluding fundic gland polyps, are shown in Table I. Concerning the location of gastric polyps, it has been shown that pancreatic and Brunner's gland heterotopia as well as inflammatory fibroid polyps arise mainly in the antrum, whereas carcinoid tumors are predominantly found in the corpus. Hyperplastic polyps and adenomas distribute rather equally between antrum and corpus.

The age distribution of patients with gastric polyps differs according to the histologic type. Peutz–Jeghers polyps, juvenile polyps, and pancreatic heterotopias are usually diagnosed in patients younger than 50 years, and fundic gland polyps occur most commonly in the age range between 40 and 69 years; all other histologic types are found mainly in the age group 60 years and older.

PATHOLOGY

Polyps in the stomach are a heterogeneous group of tumors that comprise nonneoplastic polyps (such as fundic gland polyps), neoplastic polyps (such as adenomas or adenocarcinomas), "reactive" polypoid lesions (such as foveolar hyperplasia), and polypoid intramural masses. In contrast to the situation in the colon, most gastric polyps are nonneoplastic.

 Copyright 2004, Elsevier (USA). All rights reserved.

Fundic gland polyps are the most frequent types of polyps in the stomach (Fig. 1). They can develop after a shift of the proliferation zone into the gland area. Fundic gland polyps are multiple in most cases, are potentially reversible, and carry no neoplastic risk. The additional development of adenomatous changes and dysplasia in fundic gland polyps has been found in 1% of sporadic cases and in 25–44% of patients with familial adenomatous polyposis. Although fundic gland polyps are nonneoplastic, it can be shown that they signal an increased risk in a patient of harboring a colorectal adenoma or carcinoma.

Histologically, hyperplastic polyps are characterized by an elongation, twisting, branching, and cystic dilatation of the foveolae (Fig. 2). The surface is often eroded and the epithelium may show regeneration that

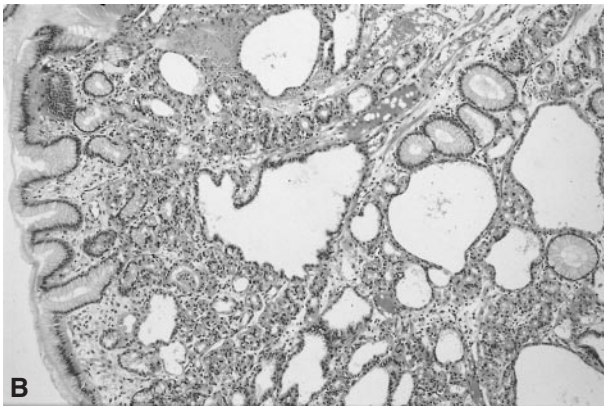

FIGURE 1 Fundic gland polyp. The diagnostic histological finding is the occurrence of cysts within the fundic glands. In this case, most of them are lined by columnar epithelium. (A) Magnification endoscopy (×115). (B) Hematoxylin and eosin stain, original magnification ×400.

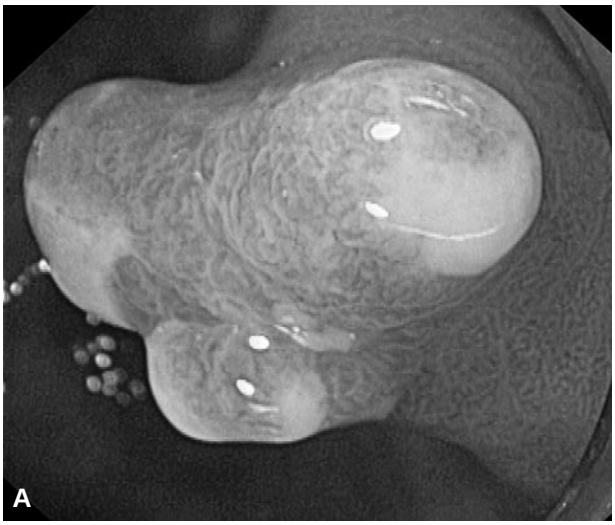

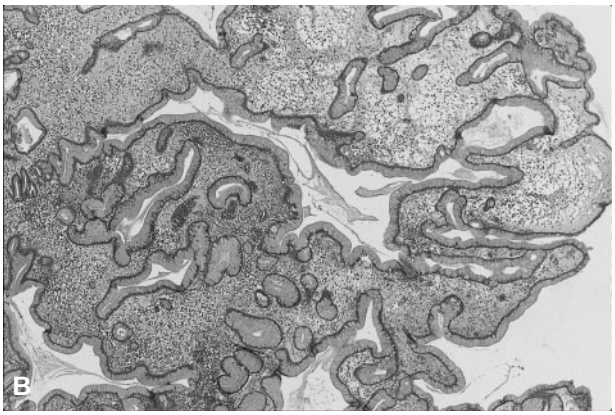

FIGURE 2 Hyperplastic polyp. In the center of the polyp, bordering the luminal area, the epithelial cells show stratification of the nuclei. The glands are cribriform in appearance, suggesting the development of a highly differentiated adenocarcinoma. (A) Hyperplastic polyp with erosions. (B) Hematoxylin and eosin stain, original magnification ×400.

can be misinterpreted as adenomatous or dysplastic changes. They are usually solitary, sessile lesions less than 1.5 cm in size. Focal foveolar hyperplasia is considered a potential precursor of hyperplastic polyps by the World health Organization (WHO). However, this is still a matter of debate. Although some pathologists claim to recognize differences on the basis of architectural and cytological criteria in forceps biopsy material, this does not hold true in common practice. Although the hyperplastic polyp is nonneoplastic, dysplastic changes and/or gastric adenocarcinoma may develop within the lesion. The risk of developing an adenocarcinoma within a hyperplastic polyp ranges from 0 to 8% (mean 2.1%). It has been recently demonstrated that hyperplastic polyps may disappear after *Helicobacter*

pylori eradication. *Helicobacter pylori* eradication therapy may, therefore, be a therapeutic option for hyperplastic polyps occurring in association with *H. pylori* gastritis. Hyperplastic polyps develop in atrophic gastric mucosa in 40–75% of cases and may thus reflect the presence of atrophic gastritis. The risk of patients with multiple hyperplastic polyps of developing a gastric carcinoma appears to be increased and may be as high as 3.6%.

Histologically, adenomas are characterized by columnar epithelium that is pseudostratified and shows elongated atypical nuclei and increased mitotic activity (Fig. 3). Adenomas represent approximately 10% of gastric polyps. Adenomas appear in tubular, tubulovillous, and villous forms or as pyloric gland adenomas.

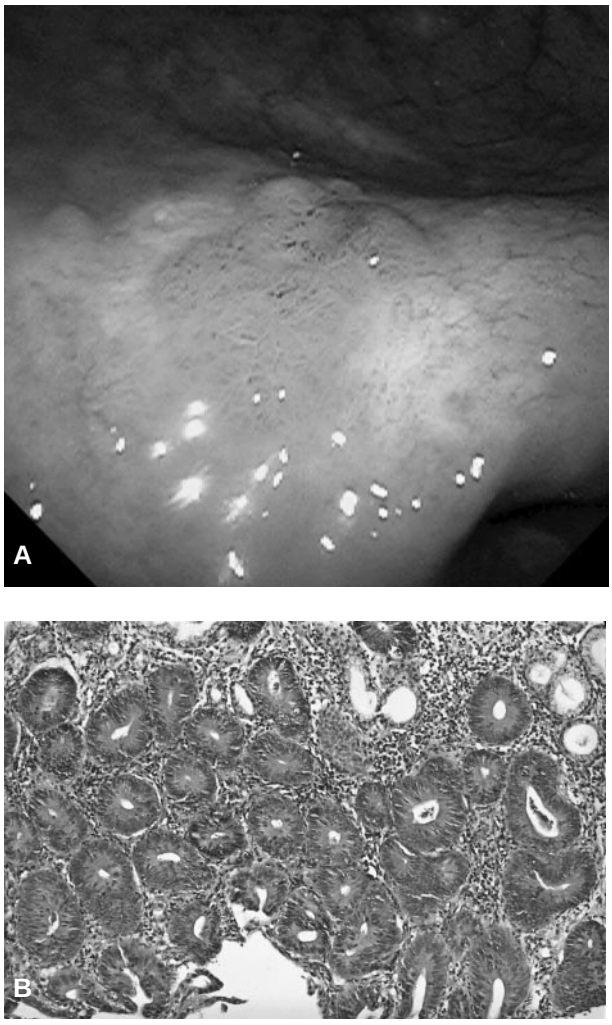

FIGURE 3 A pyloric gland adenoma composed of small tubules lined by gastric-type epithelium. (A) Adenoma in the cardia. (B) Adenoma; hematoxylin and eosin stain, original magnification ×400.

Adenomas are precancerous lesions, comparable to colonic adenomas. Therefore, high-grade dysplasia and frank carcinoma may develop in adenomas. The risk of developing adenocarcinoma in an adenoma correlates with its size and structure. Polyps more than 2 cm in diameter may harbor a focal adenocarcinoma in 40% of cases. Gastric adenomas are also a marker for an increased risk to develop a gastric carcinoma in the remainder of the stomach. According to the literature, coincident gastric carcinomas occur at a rate of 8–59%.

Mesenchymal polypoid tumors are characterized by a spindle cell or epitheloid appearance. Most of them are classified as gastrointestinal stroma tumors (GISTs). Generally, tumors with a diameter less than 5 cm, fewer than two mitoses/10 high-power microscope fields, and a lack of necrosis are held to have no or only a low malignant potential. The remainder are considered high-risk GISTs. Leiomyomas can be observed in 0.9% of gastric resection specimens. Rarely, leiomyosarcomas may develop in lesions greater than 2–3 cm in diameter. When 10 mitotic figures are found per 50 high-power microscope fields, the lesion is considered to be a leiomyosarcoma.

CLINICAL MANIFESTATIONS–DIAGNOSIS

In most cases, polyps are an incidental finding during routine endoscopy, because they only rarely produce symptoms, such as gastrointestinal bleeding with or without anemia or delayed gastric emptying. Bleeding is the consequence of an eroded surface of the polyp. Hyperplastic polyps, inflammatory fibroid polyps, adenocarcinoma, and leiomyomas are predisposed to bleeding. Obstruction of the gastric outlet caused by gastric polyps is a rare event. The symptoms are usually intermittent in case the polyp is pedunculated.

On endoscopy, some polyps can be differentiated by macroscopic characteristics. Fundic gland polyps present as multiple 2- to 3-mm sessile lesions coating the body and fundus; these can be plucked like grapes with the biopsy forceps. They may be difficult to differentiate from carcinoid tumors, which display similar characteristics but have a firm consistency. The presumptive endoscopic diagnosis of gastric tubular adenoma is relatively certain, because this lesion is mainly found in the form of a flat, only slightly elevated, polyp. Hyperplastic polyps are usually softer and more "shiny" compared to other polyps, and their surface is almost always eroded. Although the endoscopic appearance of some polyps may already be diagnostic, the final diagnosis must be based on a histological examination.

MANAGEMENT—TREATMENT

With the introduction of endoscopic polypectomy in the stomach in the early 1970s, an alternative to surgical ablation became available. Because forceps biopsies had been considered unreliable, the procedure enjoyed widespread use. However, complications soon led to a reconsideration of clearing the stomach of all polyps and to the use of forceps biopsy for decision-making.

Because most gastric polyps are not pedunculated, endoscopic mucosal resection techniques must be applied. The most widespread technique is the "strip-off biopsy," which consists of injection of saline in the submucosal layer to form a bleb, with the polyp on top, which is then cut by snare strangulation. Another important technique is endoscopic mucosal resection (EMR) using a transparent plastic cap (EMRC procedure). After a sufficient volume of saline has been injected, the mucosa, including the target lesion, is sucked into a cap attached to the tip of the endoscope, strangulated by a snare wire, and resected by electrocauterization. Endoscopic mucosal resection can generally be performed safely in the stomach because it has a relatively thick muscle layer. But at the lesser curvature in the upper and middle thirds, special attention should be paid to avoid muscle involvement, because stretching of the mucosa is primarily limited. Low-concentration epinephrine saline solution is effective in the control of bleeding during EMR in most cases. However, in case of a spurting bleeding in the stomach, placing a hemostatic clip is the most reliable and safe therapeutic modality to control the bleeding.

In many cases, a meticulous examination of forceps biopsy samples by an experienced pathologist leads to a correct histologic diagnosis without a complete polypectomy. However, foci of carcinoma are present in a small percentage of hyperplastic polyps and may be missed with biopsy sampling. In a recent survey, four such polyps (3.1%) were found in a total of 131 hyperplastic polyps, ranging from 10 to 50 mm (median 15 mm). In only one of these, the malignant focus was detected by forceps biopsy. Since the first description in 1978 of a hyperplastic polyp containing a carcinoma, several case reports have been published. Although at first it was thought that only hyperplastic polyps larger than 20 mm could contain malignant foci, this finding has more recently been observed in polyps of 5 mm.

A recommendation based on these data to remove all stomach polyps completely with the snare classified as hyperplastic on biopsy must be weighed against the possible risks of polypectomy, which seem to be higher than risks of polypectomy in the colon. In a recent prospective study, bleeding occurred in 7.2% of the procedures, but the bleeding could usually be managed endoscopically. This underscores the importance of proficiency in endoscopic hemostatic techniques by the endoscopic team as a prerequisite for performing polypectomy in the stomach. In view of the risk—benefit profile, complete endoscopic removal of even smaller polyps rated as hyperplastic on biopsy must be considered.

An alternative therapeutic option in patients with multiple small hyperplastic polyps or risk factors for polypectomy seems to be the eradication of *H. pylori*. In one study, 35 patients who had hyperplastic polyps at least 3 mm in diameter and evidence of infection with *H. pylori* were randomized to no treatment or to antibiotic therapy aimed at eradicating *H. pylori*. After 12 to 15 months, complete regression of polyps was observed more often in patients in the treated group in whom *H. pylori* was cured.

Regarding focal foveolar hyperplasia, this recommendation should be adapted to the endoscopic appearance of the polyp. For polyps with characteristic macroscopic features, i.e., size < 5 mm, multiple occurrence, and location in the antrum, no further action seems to be justified. For all other polyps rated as focal foveolar hyperplasia on biopsy, endoscopic polypectomy should be considered also, because, in the clinical, setting no unequivocal differentiation from other histological polyp types ,based on forceps biopsy specimens, seems to be possible at present. Of course, the patient's general condition (especially age and concomitant illnesses that might be exacerbated by possible complications) should also be a factor.

No controversy exists for the indication to remove adenomatous polyps, because the adenoma—carcinoma sequence holds true in gastric as well as in colorectal polyps. In one series, the concomitant presence of adenomatous and carcinomatous portions in a single polyp was observed in two specimens. Here—in contrast to carcinomatous foci in hyperplastic polyps—an underestimation on biopsy is not an issue, because all adenomas must be removed completely. Because the malignant potential of mesenchymal tumors is difficult to assess and most of them are not suitable for endoscopic resection, local surgical excision of tumors larger than 3—5 cm, with a margin of approximately 2 cm, is recommended.

Surveillance endoscopy 1 year after removing adenomatous gastric polyps is reasonable to assess recurrence at a prior excision site, new or previously missed polyps, and/or supervening early carcinoma in gastric mucosa apart from the site of coincident polyps. If

this examination is negative, surveillance endoscopy should be repeated no more frequently than 3- to 5-year intervals. No surveillance endoscopy is necessary after removal of nonadenomatous gastric polyps.

dyspepsia Symptoms originating in the upper gastrointestinal tract, including upper abdominal pain/discomfort, early satiety, postprandial abdominal bloating/distension, and nausea with or without vomiting.

functional dyspepsia Dyspeptic symptoms with no definable organic cause after evaluation usually consisting of history and physical examination, blood tests, and upper endoscopy.

nitric oxide A gas produced by cells of the brain, blood vessels, and immune system.

vasoactive intestinal polypeptide A polypeptide from the small intestine; it induces systemic vasodilation, hypotension, increased cardiac output, respiratory stimulation, and hyperglycemia.

During fasting, muscle fibers of the proximal stomach maintain a vagally mediated tonic contractile activity, which generates gastric fundus tone. During and after ingestion of a meal, relaxation of the proximal stomach occurs, which provides the meal with a reservoir and enables a gastric volume increase without a rise in pressure. This also allows the stomach to retain food and to allow passage to the duodenum at a rate that matches the duodenal absorptive capacity. Tone in the gastric antrum and its ability to function as a reservoir have not been established; the antrum seems to act predominantly as a muscular pump that grinds the food and promotes evacuation.

CONTROL OF THE ACCOMMODATION REFLEX

Studies in animals have demonstrated that the gastric accommodation reflex, which provides the meal with a reservoir and enables a gastric volume increase without a rise in pressure (Fig. 1), is mediated via a vagovagal reflex pathway that activates nonadrenergic noncholinergic neurons in the gastric wall. Several lines of evidence suggest a role for nitric oxide and vasoactive intestinal polypeptide as inhibitory neurotransmitters mediating gastric relaxation.

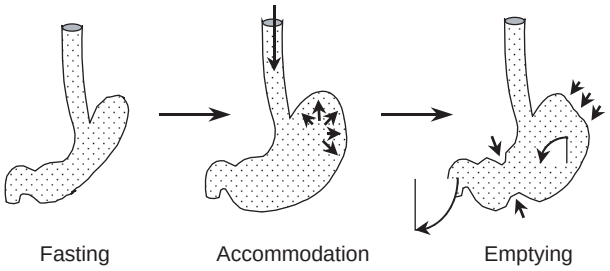

FIGURE 1 Schematic illustration of the role of accommodation to a meal. The accommodation reflex consists of relaxation of the proximal stomach, providing the meal with a reservoir and enabling a volume increase without a rise in pressure. Subsequently, the meal is emptied from the stomach at a rate that matches the absorbtive capacity of the duodenum.

In the mouse and in the guinea pig, involvement of 5-hydroxytryptamine (5-HT) receptors on intrinsic neurons in vagally mediated gastric relaxation has been demonstrated. More recently, it was demonstrated that 5-HT-induced relaxation of the guinea pig stomach is mediated via the release of nitric oxide through activation of a 5-HT_1-like receptor.

In humans, it is unknown whether the accommodation reflex also involves serotonergic activation of nitrergic neurons. The lack of suitable selective 5-HT ligands for *in vivo* use in humans hampers the investigation of this issue. However, the role of 5-HT in the control of gastric motility can be investigated in an alternative way. As in the central nervous system, a serotonin reuptake system is present in the enteric nervous system (ENS). The serotonin reuptake system in the ENS is also inhibited by selective serotonin reuptake inhibitors. Therefore, 5-HT reuptake inhibitors may increase the availability of synaptically released 5-HT, not only in the central nervous system, but also in the enteric nervous system. Physiological processes involving the release of 5-HT in the ENS are enhanced shortly after pretreatment with a selective serotonin reuptake inhibitor. This property has been used to investigate the role of 5-HT in the control of gastric motility in humans.

Twelve healthy volunteers underwent a gastric barostat study on two occasions, after pretreatment with placebo or the selective serotonin reuptake inhibitor paroxetine at 20 mg/day. Paroxetine significantly enhanced the amplitude of the meal-induced fundus relaxation. This observation suggests involvement of 5-HT in the gastric accommodation reflex in humans also. The 5-HT receptor involved and its localization cannot be determined from the present study. Selective serotonin reuptake inhibitors may act on neurons that are located centrally as well as peripherally. It was observed, however, that peripherally acting 5-HT_{1P} agonists or 5-HT_4 agonists are also able to enhance gastric accommodation to a meal, supporting involvement of one or both of these peripheral 5-HT receptors.

N^G-monomethyl-L-arginine (L-NMMA) is an inhibitor of nitric oxide synthase, suitable for use in humans. Recent studies using this agent have been able to demonstrate the involvement of nitric oxide in the control of interdigestive motility and in mediating transient lower esophageal sphincter relaxations in humans. These properties were used to test the hypothesis that nitric oxide is involved in the control of postprandial gastric tone in humans. Pretreatment with L-NMMA decreased the gastric accommodation to a meal in a dose-dependent manner, thereby establishing that the gastric accommodation reflex in humans involves activation of nitrergic neurons.

Taken together, these studies suggest that release of 5-HT, probably at the level of the enteric nervous system, with subsequent activation of nitrergic motor neurons, is involved in the control of the accommodation reflex in humans (Fig. 2). Animal studies have shown that intrinsic neurons in the stomach can be activated through a 5-HT_1-like receptor.

In the guinea pig, a 5-HT_{1P} receptor was shown to be present on nitrergic neurons in the myenteric plexus of the stomach, where it mediates a prolonged depolarization in response to the application of 5-HT. Recently, it was demonstrated that sumatriptan, a 5-HT_1 receptor agonist that is used in the treatment of migraine in humans, is an agonist at 5-HT_{1P} receptors on nitrergic myenteric neurons in the stomach. It was therefore investigated whether sumatriptan is able to induce relaxation of the proximal stomach in human and whether this relaxation is mediated through the activation of nitrergic neurons.

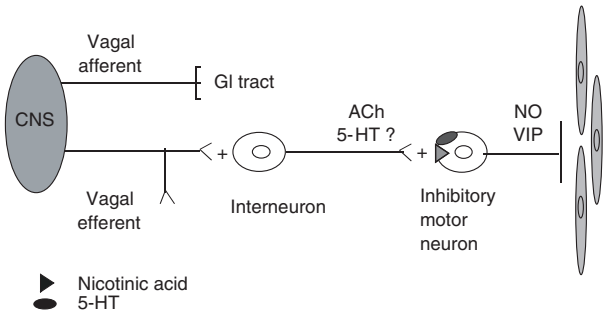

FIGURE 2 Neural control pathway of the accommodation reflex, based on animal studies. The accommodation reflex is mediated via a vagovagal reflex pathway that activates inhibitory motor neurons in the gastric wall to release nitric oxide and vasoactive intestinal polypeptide. Involvement of a 5-hydroxytryptamine receptor on intrinsic inhibitory neurons has been demonstrated.

Using a gastric barostat, it was demonstrated that the administration of sumatriptan induces relaxation of the gastric fundus in human. Pretreatment with L-NMMA decreased the gastric relaxatory response to sumatriptan in a dose-dependent manner, thereby establishing that the drug relaxes the proximal stomach in humans through a nitrergic pathway.

PATHOPHYSIOLOGICAL ROLE OF IMPAIRED ACCOMMODATION

Scintigraphic and ultrasonographic studies have demonstrated an abnormal intragastric distribution of food in patients with functional dyspepsia, with preferential accumulation in the distal stomach. This finding suggests defective postprandial accommodation of the proximal stomach. Consistently, studies using a gastric barostat have shown reduced proximal gastric relaxation in response to a meal in patients with functional dyspepsia. In view of the role of gastric accommodation in providing a reservoir during meal intake, it was hypothesized that the absence of normal accommodation might lead to early satiety.

Using a gastric barostat in 40 consecutive dyspeptic patients, it was shown that impaired gastric accommodation was present in 40% of these patients and this impairment was independently associated with early satiety. The relationship between impaired gastric accommodation and early satiety is also apparent from the correlation between the amplitude of the meal-induced relaxation and the number of calories ingested at maximum satiety in patients with early satiety.

These data suggest that impaired accommodation is the mechanism underlying the symptom of early satiety. According to this hypothesis, causing impaired accommodation in healthy subjects should induce symptoms of early satiety. Previously, it was reported that gastric accommodation is inhibited by pretreatment with L-NMMA. Administration of the motilin agonist erythromycin was shown to cause a contraction of the proximal stomach in the postprandial phase, thereby reducing the accommodation to a meal. These properties were used to investigate the hypothesis that inhibition of accommodation or administration of a fundus-contracting drug might enhance meal-induced satiety in humans.

Eight healthy subjects underwent a standardized satiety drinking test twice, after pretreatment with placebo or erythromycin at the start of the meal in a double-blind randomized cross-over fashion. Erythromycin significantly decreased the amount of food ingested and significantly increased the average satiety scores for the same number of kilocalories ingested (see Fig. 3). In 11 healthy subjects, the influence of L-NMMA on meal-induced satiety was tested using the satiety drinking test. Compared to placebo, L-NMMA significantly decreased the amount of food ingested to reach maximum satiety and significantly increased the average satiety scores for the same number of kilocalories ingested. These observations are in support of the hypothesis that impaired accommodation is a mechanism underlying the symptom of early satiety.

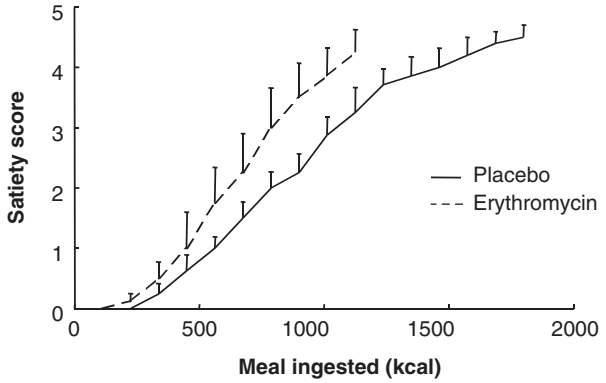

FIGURE 3 Influence of erythromycin on meal-induced satiety in eight healthy controls. Satiety scores for the same number of calories were significantly higher after pretreatment with erythromycin. Data are shown up to the highest number of ingested calories reached by all subjects.

The mechanism underlying impaired postprandial relaxation of the proximal stomach is unknown. Several possible pathways may be involved. Theoretically, impaired relaxation can result from a disorder at the level of the sensory apparatus, the vagal reflex pathway, or the intrinsic inhibitory innervation. Recently, it was demonstrated that patients with presumed postinfectious dyspepsia (acute-onset dyspepsia accompanied by infectious symptoms) have a high prevalence of impaired accommodation. It was also observed that these patients had an impaired relaxatory response to sumatriptan, whereas the stomach relaxed adequately in response to administration of the nitric oxide donor amylnitrite. This finding suggests a defect at the level of gastric intrinsic nitrergic neurons.

CONCLUSIONS

Gastric accommodation provides the meal with a reservoir and enables a gastric volume increase without a rise in pressure. Gastric accommodation in humans is controlled by a vagal reflex pathway that involves the release of serotonin and the activation of a nitrergic motor neuron. This is mimicked by administration of

the 5-HT_{1P} receptor agonist sumatriptan, which causes a relaxation of the proximal stomach in humans through a nitrergic pathway.

Almost half of the patients with functional dyspepsia have an impaired accommodation reflex and this is associated with early satiety and weight loss. Drug-induced inhibition of the accommodation reflex is able to induce early satiety in healthy subjects, thereby supporting the hypothesis that impaired accommodation is the mechanism underlying the symptom of early satiety. In a subset of patients, impaired accommodation seems to occur as a prolonged sequela of an acute gastrointestinal infection. In these patients, the defect seems to occur at the level of gastric intrinsic nitrergic neurons.

Gastric Stapling

MALCOLM K. ROBINSON
Harvard Medical School

abdomen Portion of the body that lies between the chest and the pelvis and contains several organs, including the stomach, intestines, liver, spleen, pancreas, kidneys, and bladder.

bariatric Field of medicine or surgery that encompasses the study and prevention of obesity, as well as the evaluation and treatment of obese individuals. It is derived from the Greek "baros," meaning weight, and "iatrike," meaning medicine or surgery.

body mass index Formulation that describes relative weight for height; used to define weight categories (e.g., underweight, normal, overweight, or obese).

bypass Procedure in which one structure is artificially connected to another so as to circumvent a normally intervening segment of tissue. For example, in a gastric bypass procedure, the stomach is connected to the second portion of small intestine such that food circumvents or "bypasses" the main part of the stomach and the first portion of the small intestine.

equilibrium State of balance in which opposing forces or processes exactly counteract each other.

gastric Pertaining to, affecting, or originating in the stomach. Derived from the Latin "gastricus," meaning stomach.

gastroplasty Surgical procedure in which the stomach is reshaped, reconfigured, or reconstructed with sutures or surgical staples.

morbid obesity Severe form of obesity that is frequently associated with a variety of conditions such as diabetes, heart disease, and high blood pressure. Any person with a body mass index equal to or greater than 40 kg/m^2 is considered morbidly obese.

stomach Part of the gastrointestinal tract that lies between the esophagus and first part of the small intestine; serves as a reservoir for swallowed food and is where food digestion is initiated. Although the terms "stomach" and "abdomen" are frequently used interchangeably, they are distinct entities and should not be confused.

Gastric stapling is the name used for a variety of surgical procedures that produce weight loss in obese people. As part of these procedures, surgical staples are used to partition the stomach so that the capacity of the stomach is drastically reduced. The amount of food consumed can be limited to 2–3 ounces per meal, resulting in significant weight loss over 12 to 15 months.

INTRODUCTION

Gastric stapling is most frequently used to refer to a specific procedure called "vertical banded gastroplasty" (VBG). Gastric stapling has recently been described in a more general way to include all types of weight loss surgery procedures, even though some of the procedures are quite different from a VBG.

Gastric stapling is used in reference to the medical field of "bariatric surgery," which encompasses the evaluation, surgical treatment, and management of morbidly obese individuals who have had or who are contemplating surgical treatment of their obesity. Bariatric surgeons perform a variety of bariatric surgical procedures, which are specifically designed to promote weight loss. It is estimated that 40,000 of these procedures were performed in the year 2000 in the United States alone. It is anticipated that this number will continue to increase rapidly given the dramatic increase in obese adults in the United States.

OBESITY AND ITS TREATMENT

The National Institutes of Health recommends using the body mass index (BMI) to determine weight category as the first step in determining what, if any, intervention is necessary to promote weight loss. The BMI generally correlates with total body fat content, although this index may be less useful in highly trained athletes, who have an unusually large proportion of muscle. The BMI is calculated by taking weight measured in kilograms and dividing by the square of height measured in meters (i.e., BMI = kilograms/meters^2).[1] A BMI of less than 18.5 kg/m^2 is considered underweight; 18.5–25 kg/m^2 is normal weight, 25.0–29.9 kg/m^2 is overweight, and greater than 30 kg/m^2 is considered obese. Extreme or morbid obesity is defined as a BMI greater than or equal to 40 kg/m^2. For the individual of

[1]Pounds can be converted to kilograms by dividing by 2.2 (e.g., 220 lb equals 100 kg). Inches can be converted to meters by multiplying by 0.0254 (e.g., 60 inches equals 1.524 m). Thus, a 220-lb person who is 5 feet tall has a BMI of 43.1 kg/m^2.

average height, a BMI of 30 kg/m^2 is approximately 30–35 pounds over normal weight and a BMI of 40 kg/m^2 is 100 pounds over normal weight. It is estimated that 97 million adults in the United States, or approximately 55%, are overweight or obese.

Weight gain or loss depends on the number of calories (i.e., food) consumed by a person relative to the number of calories that their body uses to fuel its many functions. When caloric consumption exceeds caloric utilization on a long-term basis, weight gain occurs. Conversely, when caloric utilization exceeds caloric consumption, weight loss occurs. When caloric consumption equals caloric utilization, a state of equilibrium is achieved and weight is neither gained nor lost.

The treatment of an overweight or obese person can include diet, behavior modification, exercise, prescription drugs, and/or surgery. All of these modalities, with the exception of exercise, result in decreased calorie intake. Exercise increases calorie utilization. Treatment recommendations depend not only on how overweight a person is but also on whether they have weight-related health problems. These conditions—such as high blood pressure, heart disease, and diabetes—significantly increase the risk of death and the development of other diseases.

People with a BMI of 35–39.9 kg/m^2 with weight-related health problems and those with a BMI of 40 kg/m^2 even without weight-related health problems are considered at extremely high risk for developing or exacerbating a variety of diseases. Not surprisingly, these individuals are also at extremely high risk of dying earlier compared to people of normal weight. Because of these risks, bariatric surgical procedures may be appropriate for those who are in the highest weight categories and fail to lose weight with other methods. Although surgery is the most aggressive and invasive form of obesity therapy, such therapy has a high success rate and low complications in the appropriately selected individual. In addition, surgery in these groups of people results in the most durable and greatest average weight loss compared to any other weight loss strategy. However, it is imperative to assess surgical risk, as well as patient motivation and psychological suitability, on a case by case basis before recommending surgery, because serious and life-threatening complications may occur with this intervention.

GASTRIC STAPLING AND GASTRIC BYPASS

Although several techniques are used to reconstruct the digestive system in a way that promotes weight loss, all bariatric procedures work by limiting food intake, limiting food absorption, or both, thus reducing calorie intake. As a person loses weight, the number of calories absorbed by their body will eventually equal the number of calories burned up by their body, at which point weight loss will stop. For patients undergoing bariatric surgery, this equilibrium generally occurs when they lose 50–80% of their excess body weight.

Gastric stapling is one major prototype of bariatric surgical procedures. The medical procedure for gastric stapling, vertical banded gastroplasty, involves a procedure in which the front of the stomach is stapled to the back of the stomach, so as to create a small stomach pouch, which is partitioned from the remainder of the stomach. The pouch is oriented vertically relative to the side of the stomach and only holds 2–3 ounces of food. The passageway or outlet leading out of this pouch is encircled with a plastic band to prevent the outlet from dilating over time. This is done to improve the durability of weight loss (see Fig. 1). Food absorption from the intestines is not altered because the rest of the intestinal tract is not manipulated in this procedure. Thus, a VBG promotes weight loss purely by limiting food intake.

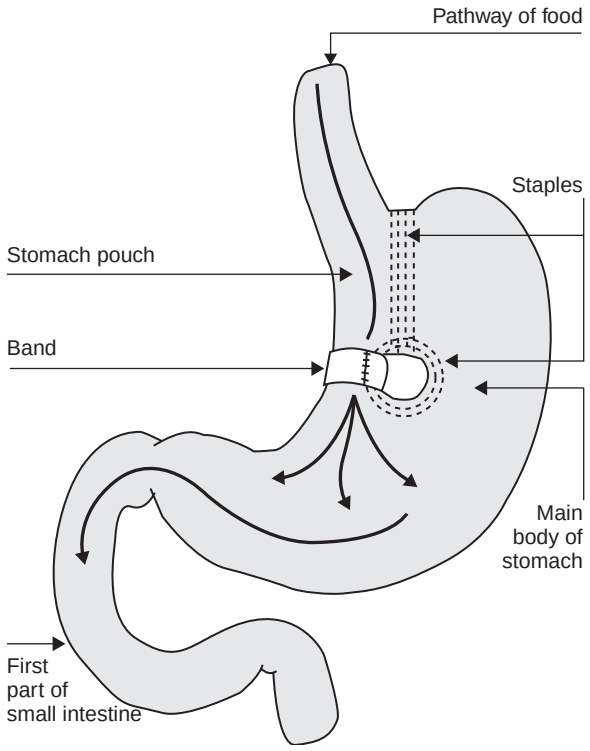

FIGURE 1 Gastric stapling, or vertical banded gastroplasty.

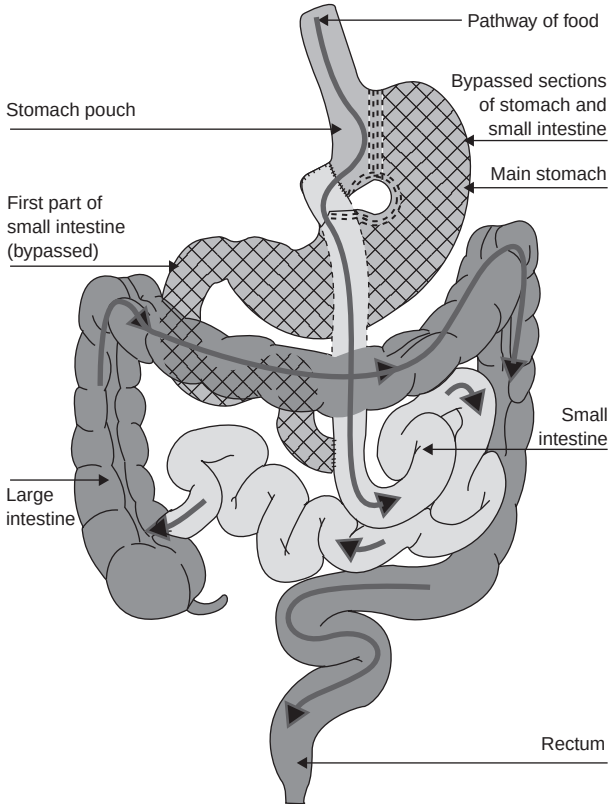

FIGURE 2 Gastric bypass.

The gastric bypass is another major prototype of bariatric surgical procedures. In this procedure, a small stomach pouch is constructed. A section of small intestine is attached directly to this pouch such that food goes from the mouth into the pouch and directly into the small intestine, "bypassing" the majority of the stomach and a significant portion of the beginning of the small intestines (see Fig. 2). Food intake is limited due to the small stomach pouch. In addition, any food that is consumed is not completely absorbed because it bypasses a significant portion of the stomach and intestines, which ordinarily would aid in complete food digestion and absorption. There are many ways to perform gastric bypass procedures, with variations in how the stomach pouch is constructed and the amount of intestine that is bypassed. However, all of the techniques share the principle of a small stomach pouch attached to a section of small intestine, which limits both food intake and food absorption. Currently, the gastric bypass is the most frequently performed type of bariatric surgical procedure in the United States.

Gastric Surgery

QUYEN D. CHU, GAZI ZIBARI, AND RICHARD H. TURNAGE
Louisiana State University Health Sciences Center and Overton Brooks Veterans Affairs Medical Center, Shreveport

gastric bypass Operative procedure performed for the treatment of morbid obesity; the stomach is divided proximally into a small gastric pouch, which is drained into a Roux-en-Y jejunal limb.

morbid obesity Defined by having a body mass index greater than 40 kg/m^2; this condition is associated with a number of metabolic and cardiopulmonary complications, including diabetes mellitus, hyperlipidemia, hypertension, sleep apnea, cardiomyopathy, coronary artery disease, and joint disease.

proximal gastric vagotomy Also called highly selective vagotomy and parietal cell vagotomy; specific division of the vagal nerve fibers as they innervate the lesser curvature of the stomach from the esophageal hiatus to the gastric incisura; commonly performed to prevent vagally mediated gastric acid secretion without interrupting the antral and pyloric motor function.

truncal vagotomy Division and resection of part of the vagus nerves as they exit the esophageal hiatus; commonly performed to prevent vagally mediated gastric acid secretion.

Gastric surgery is indicated for benign and malignant diseases of the stomach as well as to assist in the management of morbid obesity. The indications for operation, the types of commonly used operative procedures, and the results of surgical therapy for the management of patients with peptic ulcer disease, morbid obesity, and gastric malignancy are all important considerations.

OPERATIONS FOR PEPTIC ULCER DISEASE

Indications for Operation

The principal indications for operation in patients with peptic ulcer disease are the treatment of medically intractable symptoms and the management of acute life-threatening ulcer-related complications. In the 1960s and 1970s, nearly 50% of the operations for duodenal ulcer disease were performed to relieve chronic symptoms, principally intractable ulcer pain. Now, nearly all operative procedures for peptic ulcer are performed to treat an acute life-threatening ulcer complication, i.e., bleeding, perforation, or gastric outlet obstruction. Many factors are undoubtedly important in producing this change. Of particular note, a better understanding of the pathophysiology of peptic ulcer disease has led to refinements in medical management, such as the development of potent inhibitors of gastric acid secretion and effective antibiotic regimens for *Helicobacter pylori*. Recently, these refinements in medical management have become incorporated into the perioperative strategies for managing acute complications of ulcer disease, such as the eradication of *H. pylori* in patients undergoing omental patching of a perforated duodenal ulcer.

Operative Procedures

The most appropriate operation for patients with peptic ulcer disease depends on the location of the ulcer (gastric versus duodenal), the presence of ulcer-related complications, and the condition of the patient at operation. Patients undergoing operation for the elective management of gastric ulcer generally require partial gastrectomy (to include the ulcer) with either a Billroth I gastroduodenostomy (less commonly) or a Billroth II gastrojejunostomy (more commonly). Patients with duodenal ulcer disease requiring operation for intractable ulcer symptoms may be treated with truncal vagotomy and antrectomy, truncal vagotomy and drainage (either pyloroplasty or gastrojejunostomy), or proximal gastric vagotomy. The results of these procedures are summarized in Table I.

Truncal vagotomy denervates the parietal cell mass, thereby diminishing vagally mediated acid secretion, whereas antrectomy removes the antral G cells, the source of the potent gastric acid secretogogue, gastrin. Combination of truncal vagotomy and antrectomy reduces gastric acid secretion by 80–90% and is associated with a very low incidence of recurrent ulcer formation (1–2%). However, this more extensive procedure is also associated with higher rates of perioperative and postoperative morbidity (15–30%)

TABLE I Results of Elective Operations for the Treatment of Duodenal Ulcer Disease[a]

Procedure	Ulcer recurrence rate (%)	Perioperative morbidity rate (%)	Perioperative mortality rate (%)	Visick grades I+II (%)[b]
Truncal vagotomy and antrectomy	2	10–30	1–2	60–80
Truncal vagotomy and pyloroplasty	10–15	10	0.5–1	75
Proximal gastric vagotomy	10–20	5–10	0.2–0.7	80–95

[a] Morbidity and mortality rates are much higher for emergency operations performed for ulcer complications.
[b] Visick grades I and II indicate patients who are asymptomatic and require no medication (grade I) or asymptomatic and require over-the-counter medications occasionally (grade II).

and mortality (1–2%) compared to lesser procedures, particularly in medically compromised patients.

The proximal gastric vagotomy (also called parietal cell vagotomy or highly selective vagotomy) selectively denervates the parietal cell mass while preserving innervation of the antral pump and pylorus as well as the hepatic and celiac branches of the vagus. This procedure preserves normal (or near-normal) gastric emptying and hence no gastric emptying procedure is necessary. The ulcer recurrence rate associated with this procedure is higher than that associated with resectional therapies; in Jordan and Thornby's prospective study, the risk of recurrence after this procedure was 14% in 102 patients followed for up to 20 years. Prospective trials have demonstrated that the ulcer recurrence rates associated with a truncal vagotomy and drainage procedure vary from 7 to 28% with followup from 4 to 12 years. The perioperative risks and long-term complications are certainly greater than that associated with a proximal gastric vagotomy and in some series approximate that of vagotomy and antrectomy.

Truncal vagotomy and pyloroplasty are particularly well suited for the management of patients who are bleeding from erosion of a duodenal ulcer into the gastroduodenal artery. In this setting, the first portion of the duodenum and the pylorus are incised longitudinally and the bleeding vessel is oversewn through the posterior wall of the duodenum with a "U-stitch." Truncal vagotomy is performed to reduce the risk of ulcer recurrence and the duodenal and pyloric incision is closed transversely (Heineke–Mikulicz pyloroplasty). The longer operative times required for a truncal vagotomy and antrectomy or a proximal gastric vagotomy dissuade most surgeons from performing these procedures in patients suffering massive hemorrhage from a duodenal ulcer. Patients presenting with perforation of a duodenal ulcer require, at the very least, operative patching of the ulcer (Graham patch) with omentum or falciform ligament. Failure to treat underlying *H. pylori* infection is associated with an ulcer recurrence rate of 38% within 1 year, compared with 5% when treated with appropriate antibiotics. Patients with a long history of complicated ulcer disease may also benefit from a proximal gastric vagotomy, provided that the patient is able to tolerate a longer operative procedure and there is relatively limited soiling of the peritoneal cavity. The operative options for managing patients with gastric outlet obstruction from ulcer disease include truncal vagotomy and antrectomy (or partial gastrectomy) with a Billroth II gastrojejunostomy or truncal vagotomy and gastrojejunostomy.

Perioperative mortality is dramatically increased by the presence of acute ulcer-related complications. At the Massachusetts General Hospital, the death rate after elective ulcer procedures has been reported to be 1 in 200; the mortality rates associated with emergent operations for ulcer bleeding and perforation have been 1 in 5 or greater.

Complications of Operative Management

The complications of operations for ulcer disease include ulcer recurrence, mechanical obstructions, functional disorders of gastric emptying, and metabolic sequelae (see Table II).

TABLE II Long-Term Complications of Operations for Peptic Ulcer Disease

Ulcer recurrence	**Disorders of gastrointestinal motility**
Incomplete vagotomy	Gastric stasis with poor gastric emptying
Retained, excluded antrum	Early satiety
Mechanical obstructions	Dumping
Afferent limb obstruction	Chronic diarrhea
Efferent limb obstruction	
Gastric outlet obstruction	
Other	**Metabolic sequelae**
Weight loss/anorexia	Iron deficiency
Bile reflux gastritis	Calcium malabsorption with osteopenia
	Cholelithiasis

OPERATIONS FOR MORBID OBESITY

Indications for Operation

Individuals with morbid obesity are those with a body mass index (BMI) greater than 40 kg/m^2 or who weigh more than 100 pounds over their ideal body weight (IBW). These persons have a reduced life expectancy due to the severe metabolic and cardiovascular disorders associated with this degree of obesity. A National Institutes of Health (NIH) Consensus Development Conference held in March 1991 recommended that patients whose BMI exceeded 40 kg/m^2 are candidates for weight reduction procedures if they strongly desired substantial weight loss because of its impact on the quality of their lives. Furthermore, patients whose BMI was 35–40 kg/m^2 were also considered candidates for operative management if they had significant obesity-related comorbid medical conditions, such as severe sleep apnea, obesity-related cardiomyopathy, severe joint disease, and diabetes mellitus. This conference noted that these patients should first be treated with nonsurgical therapies, including dietary regimens, exercise routines, behavior modification, and psychologic support modalities associated with extremely high failure rates in this particular patient group.

Operative Procedures

The two principal gastric operations performed to facilitate weight loss in morbidly obese individuals, and the only two operations endorsed by the NIH Consensus Conference, are the vertical banded gastroplasty and the gastric bypass. The vertical banded gastroplasty (VBG) creates a 20-ml vertical gastric pouch with the outlet restricted to 32-French (around 1 cm) by a 1.5-× 5.0-cm strip of polypropylene mesh sutured to itself. The gastric bypass (GB) is characterized by a 15- to 20-milliliter gastric pouch, a vertical staple line dividing the stomach from the pouch, and reconstruction of gastrointestinal continuity with a Roux-en-Y gastrojejunostomy. These procedures have been found to improve weight-associated comorbid medical conditions, including sleep apnea, obesity-related hypoventilation, diabetes mellitus, hypertension, and hyperlipidemia. It is not yet known whether these beneficial effects are maintained long enough to prevent renal disease, stroke, myocardial infarction, and congestive heart failure. Multiple trials have demonstrated superior early and late weight loss in patients undergoing GB when compared with VBG. In one collected review, the average loss of excess weight was 53 and 69% at 1 year and 46 and 60% at 5 years for VBG and GB, respectively.

Complications of Operative Management

The immediate perioperative mortality rate is relatively low for both VBG and GB ($\leq$ 1%). Early postoperative morbidity has been reported to occur in as many as 10% of patients, with most complications due to wound infections and wound dehiscence, staple line dehiscence, stomal stenosis, marginal ulceration, various pulmonary complications (including pulmonary embolism and pneumonia), and deep venous thrombosis. Later complications include pouch and distal esophageal dilation, persistent vomiting (with or without stomal obstruction), cholecystitis due to preexisting gallstones or stones that develop due to rapid weight loss, incisional hernias, and, most importantly, failure to lose weight or maintain weight loss.

OPERATIONS FOR GASTRIC MALIGNANCY

The most common primary gastric malignancy is adenocarcinoma, representing 90% of gastric malignancies. At present, cure is possible only with resection. Chemotherapy and radiation therapy have been shown to extend survival when given in an adjuvant setting but have no such effect as primary therapy. The principal objectives of operations for gastric malignancies are to cure the patient of their disease or to ameliorate complications of advanced disease, specifically hemorrhage, obstruction, perforation, and/or intractable pain. The principal determinant of survival following resection for gastric cancer is the stage of the disease. Wanebo and colleagues reviewed the American College of Surgeons (ACS) Patient Care Evaluations and reported a 5-year survival of 60% for patients who had Stage I tumors, approximately 35% for patients with Stage II disease, 16–18% for Stage III disease, and less than 10% for patients with Stage IV disease.

Preoperative Evaluation and Indications for Operation

Preoperative assessment should attempt to detect local complications of the malignancy and evidence of advanced disease. The patient's performance status may be assessed using the Eastern Cooperative Oncology Group (ECOG) performance score. Physical

TABLE III Lymph Node Stations According to the Japanese Gastric Cancer Association

Dissection	Levels of lymph node stations or echelons removed

examination may provide evidence of advanced disease with supraclavicular lymphadenopathy (Virchow's node), a mass at the umbilicus (Sister Mary Joseph's node), and/or pelvic peritoneal metastases palpable on rectal examination (Blumer's shelf). Radiologic examination should include a chest X ray, abdominal and pelvic computed tomography (CT) scans, and, in selected cases, an endoscopic ultrasound exam of the tumor. Preoperative endoscopic ultrasonography will accurately determine the T stage of the tumor in 70–80% of cases. Staging laparoscopy has been shown to be more sensitive in detecting hepatic, nodal, and peritoneal metastases as compared to ultrasound and CT in one series, but has been considered to be of limited clinical utility in other studies.

Operative Procedures

Adequate surgical resection of gastric cancer requires a wide gastric resection to achieve margins free of tumor and an en bloc resection of regional lymph nodes. The extent of resection is determined by the location and extent of the tumor and involvement of adjacent organs. The two most common operations for the curative resection of gastric cancer are subtotal gastrectomy for tumors located in the distal third of the stomach and total gastrectomy for tumors of the proximal and middle third as well as for gastric cancers of the diffuse type (*linitus plastica*). Tumors of the cardia and gastroesophageal junction are generally treated as distal esophageal tumors, with an esophagogastrectomy and gastric tube reconstruction with the gastric remnant based on the gastroepiploic artery. Gross resection margins of 6 cm are necessary to achieve reproducibly negative histologic margins and to minimize local recurrence. Frozen section examinations of the resection margins are obtained to ensure that the margins are free of microscopic disease.

The involvement of adjacent organs by the tumor is not a contraindication to resection, but such involvement clearly affects the likelihood of cure. A curative en bloc resection of (T4) lesions may be achieved if there is no more than one organ involved, there is less than or equal to N2 lymph node involvement, there is no diffuse carcinoma, and there are no distant metastases. In cases meeting these criteria, 5-year survival rates of 25–30% have been reported. Unless directly involved with tumor, there is no survival advantage afforded by splenectomy and/or distal pancreatectomy in patients undergoing curative gastric resections; there is substantial evidence to suggest that these procedures significantly enhance the risks of perioperative morbidity and mortality.

The extent of lymph node dissection performed in patients with gastric adenocarcinoma is debated. The Japanese Classification for Gastric Carcinoma (JCGC) has defined the extent of lymphadenectomy according to the levels of lymph node stations or echelons removed (Table III). Results from several European randomized trials have failed to demonstrate a survival benefit with more extensive lymph node dissections and hence most centers in the United States and Europe perform a D1 or lesser lymph node dissection (D0) as part of their gastric resection. In one of these studies, patients undergoing D2 dissection had significantly higher rates of complications, perioperative mortality, and longer hospital stays than did those undergoing lesser lymphadenectomies (D1). Proponents for a D2 lymphadenectomy argue that 30% of the patients undergoing a curative D2 dissection are found to have disease outside of area encompassed by a D1 resection. Furthermore, they suggest that the higher rate of complications associated with more extensive lymphadenectomies may be decreased as the surgeons gain experience with these techniques.

A recent multiinstitutional randomized trial performed by the Southwest Oncology Group (SWOG) suggests that patients receiving adjuvant chemoradiation therapy may have a modest survival advantage over patients not receiving adjuvant therapy. Patients

randomized to undergo resection with adjuvant chemoradiation therapy (5-fluorouracil and leukovorin plus 4500 cGY) had a median survival of 36 months compared with 27 months in patients undergoing surgery alone.

biopsy urease test Provides indirect evidence, in gastric mucosal biopsies, of the presence of *Helicobacter pylori*, which produces the urease that metabolizes urea to ammonia and changes the pH indicator color.

cyclooxygenase Enzyme that exists in two isoforms, cyclooxygenase-1 and cyclooxygenase-2. Cyclooxygenase-1 is constitutive and regulates normal function in many organs. Cyclooxygenase-2 is inducible and is expressed by inflammatory cells to mediate inflammatory responses. A variant of cyclooxygenase-1 has been found in the central nervous system.

erosion Histologically defined as a defect that does not penetrate the muscularis mucosae; endoscopically, superficial mucosal breaks with a diameter less than 3–5 mm and with no perceptible depth.

Helicobacter pylori Spiral-shaped gram-negative bacilli with four to seven flagella at one pole; produce large amounts of urease.

nonsteroidal antiinflammatory drugs Compounds that nonselectively inhibit the cyclooxygenase enzyme and are potent antiinflammatory and antipyretic agents.

ulcer Defined histologically as a defect that penetrates the muscularis mucosa; the exact endoscopic definition remains controversial, with disagreement on the lesion size (usually 3–5 mm), but most agree perception of lesion depth is necessary.

Peptic ulcer formation in either the stomach or duodenum is due to an imbalance between erosive factors such as hydrochloric acid and pepsin and the protective mechanisms of the mucosa. Unlike duodenal ulcers, in which the importance of acid secretion is indisputable, gastric (stomach) ulcers can develop despite only minimal amounts of acid. Indeed, past studies have shown that the basal and maximal acid outputs in patients with gastric ulcers are no different than those in normal controls. The gastric mucosa has evolved to tolerate the high acidity of the stomach lumen via an intricate equilibrium of protective mechanisms. The gastric protective mechanisms (preepithelial, epithelial, and subepithelial factors) act in concert.

PHYSIOLOGY

Preepithelial protective gastric factors include the mucus–bicarbonate coating produced by the surface epithelial cells. This layer of mucus, which varies in thickness from 50 to 400 μm in humans, is composed of 95% water and 5% phospholipids and is effective in maintaining a near normal pH at the epithelial cell surface. Epithelial cells also secrete bicarbonate into the mucus layer, which creates a pH gradient from the lumen to the epithelial cell. Mucosal bicarbonate secretion is stimulated by luminal acid and prostaglandins and is dependent on an adequate vascular supply. Prostaglandins promote secretion of mucin from the epithelial cells and have an inhibitory role in the regulation of acid secretion.

Epithelial factors are the second line of defense. The surface epithelial cells are bound by tight junctional complexes to maintain a barrier to the luminal contents. Even if the mucus–bicarbonate layer is breached, the epithelial cells can still maintain a normal intracellular pH via Na^+/H^+ and Cl^-/HCO_3^- exchangers on the cell membrane. These transport mechanisms are also dependent on adequate HCO_3^- from the blood. When minor mucosal damage occurs, the epithelial cells can rapidly repair the damage by a process known as mucosal restitution. A mucoid cap formed over the breach provides an alkaline microenvironment that enables epithelial cells to migrate and repair the breach. This process does not require cell replication and is dependent on an adequate vascular supply. The repair of larger defects necessitates cell proliferation, which is dependent on endogenous prostaglandin and growth factors.

Subepithelial factors also contribute to mucosal defense against the luminal acid, pepsin. For each molecule of H^+ secreted by parietal cells, one molecule of HCO_3^- is transported across the basolateral membrane, creating (at least transiently) a "reservoir" of HCO_3^- in the submucosa. This reserve of HCO_3^- is transported by the rich submucosal vascular supply to the surface epithelial cells and is critical in providing an adequate quantity of HCO_3^- to maintain epithelial intracellular pH.

CAUSATIVE FACTORS IN GASTRIC ULCER FORMATION

Nonsteroidal Antiinflammatory Drugs

On a regular basis worldwide, more than 30 million people consume nonsteroidal antiinflammatory drugs

 Copyright 2004, Elsevier (USA). All rights reserved.

(NSAIDs), including low-dose aspirin. Low-dose aspirin is widely used because of its efficacy in reducing cardiovascular events. This has lead to an epidemic of ulcer complications. In the United States, NSAID use accounts for over 25% of all reported adverse drug reactions, with an estimated 16,500 arthritic patients dying every year from gastrointestinal toxicity. The mechanisms of NSAID-induced mucosal injury are incompletely understood but include both topical and systemic components.

NSAID users with negative baseline endoscopies who then have followup endoscopies 2–3 months after starting NSAIDs have a gastric ulcer incidence of 6–12%. In cross-sectional studies on chronic NSAID users, the prevalence of gastric ulcers range from 9 to 31%. In case-control studies in which NSAID users are compared with the matched control population, the relative risk of gastric ulceration is 4.0.

Topical Effects

NSAIDs can accumulate to very high levels within the surface epithelial cells by a phenomenon called "ion-trapping." Aspirin and many NSAIDs are weak organic acids that remain in the nonionized form in the strong acidic environment of the gastric lumen and can freely diffuse across the cell membrane. Once across the membrane, the high intracellular pH causes the H^+ to dissociate, trapping the negatively charged organic compound in the cell. As the nonionized form of the NSAID/aspirin remains in equilibrium across the cell membrane, more of the drug diffuses into the cell, leading to a much higher total drug concentration than outside the cell. The exact mechanism of NSAID-induced cellular toxicity is uncertain but may involve uncoupling of the oxidative phosphorylation necessary for energy metabolism, inhibition of ion transport, or alteration of membrane permeability.

NSAIDs also decrease mucus–bicarbonate secretion, compromise the hydrophobic properties of the mucus coat, and inhibit mucosal prostaglandin secretion. Some NSAIDs enter the enterohepatic circulation, leading to repeated exposure of the gastrointestinal mucosa to high intestinal NSAID concentrations. However, there is good evidence to suggest that these topical effects are not the major cause of NSAID-mediated injury. Previous attempts to minimize topical injury, such as the use of prodrugs, enteric-coated preparations, or parenteral administration, have failed to reduce the risk of ulcer.

Systemic Effects

The nonselective inhibition of cyclooxygenase (COX) by NSAIDs leading to depletion of endogenous prostaglandins is the most important cause of ulcer formation. Prostaglandins regulate mucosal blood flow, epithelial cell proliferation, epithelial restitution, mucosal immunocyte function, mucus and bicarbonate secretion, and basal acid secretion. Inhibition of prostaglandin synthesis probably weakens the gastric mucosal defense to resist luminal irritants. Animal studies involving immunization against prostaglandins (PGE2, PGI2, and PGF-2α), leading to their depletion, have produced gastric ulcers that macroscopically and histologically resemble NSAID-induced ulcers. Large-scale, placebo-controlled trials have shown that coadministration of the prostaglandin E1 analogue (misoprostol) with NSAIDs significantly reduces the incidence of gastric ulcer and its complications.

NSAIDs probably also damage the gastric mucosa via other mechanisms. Acute animal experiments have shown that neutrophil adherence to the endothelium of gastric microcirculation is critical in initiating NSAID injury. Neutrophil adherence damages the mucosa by liberating oxygen free radicals, releasing proteases, and obstructing capillary blood flow.

Role of Luminal Acid

Gastric acid plays a secondary role in the pathogenesis of NSAID-induced ulcer. Acid exacerbates NSAID injury by disrupting the basement membrane, producing deeper injury, interfering with platelet aggregation, and impairing ulcer healing. Concomitant use of high-dose histamine-2 (H2) antagonists or proton pump inhibitors has been shown to reduce the incidence of NSAID ulcers.

Helicobacter pylori

Helicobacter pylori accounts for about 70% of gastric ulcers. *Helicobacter pylori* infection induces mucosal injury not by direct invasion, but instead by the bacterial release of enzymes that destroy the surface mucin and phospholipids. *Helicobacter pylori* infection causes chronic inflammation through the release of cytokines and chemokines. Further injury is mediated by the production of ammonia, release of virulence factors, and induction of a hyperacidic state in some patients.

The patterns of gastritis associated with gastric and duodenal ulcers may differ. Duodenal ulcers are associated with an antrum-predominant gastritis whereas gastric ulcers are associated with a diffuse gastritis. Diffuse gastritis is associated with low acid output, gastric atrophy, and adenocarcinoma. Gastric acid appears to be an important factor in the distribution of *H. pylori* colonization. Despite being one of the most efficient producers of urease, which generates ammonia to

neutralize acid, *H. pylori* often colonizes the antrum because of the high acidity in the corpus. It has been demonstrated that acid suppression with proton pump inhibitors results in a proximal shift of *H. pylori* in the stomach, with increased colonization of the corpus. This leads to increased mucosal inflammation and further reduction in acid secretion. It is therefore postulated that the type of gastritis acquired may be dependent on various environmental factors, such as age of exposure, concurrent infection, and malnutrition, all of which may affect the parietal cell mass and acid-secreting capability.

Stress

Patients suffering from severe stress, such as critically ill patients in intensive care units, may develop stress ulcers. Stress-induced gastric mucosal injury has been reproduced in animal studies. Presence of coagulopathy, hypotension, and respiratory failure are key risk factors to development of ulcer bleeding. The mechanism of injury is unrelated to *H. pylori* and no inflammatory response is noted on biopsy of such ulcers. Although certain conditions may lead to acid hypersecretion, such as head injury or burns, it is believed that mucosal ischemia and reperfusion injury, with impairment of mucosal defense, are the main causative factors. Current evidence indicates that prophylaxis with proton pump inhibitors is effective in preventing bleeding from stress ulcers.

Other Causative Factors

Smoking

Cigarette smokers have a twofold increase in risk of developing ulcers compared to nonsmokers and there is a dose-dependent relationship between the amount of smoking and ulcer incidence. Risk of ulcer complications, such as perforation, has also been shown to be related to smoking in a dose-dependent relationship. Epidemiological studies have shown a strong association between *H. pylori* infection and smoking. Smoking may have an additive effect on the ulcer risk in chronic NSAID users. The exact mechanism of injury is unknown, but smoking reduces prostaglandin synthesis and increases generation of free radicals.

Genetic Predisposition

Patients who possess the blood group O antigen, the Lewis phenotype (a−b−), and the ABH nonsecretor trait have increased risk of peptic ulcers. However, it is believed that genetics plays only a minor role in the pathogenesis of peptic ulcers.

Other Factors

Alcohol intake, psychological factors, and diet have all been previously implicated as possible risk factors for ulcerogenesis. However, there is no compelling evidence to support a major role for these factors in ulcer formation.

EPIDEMIOLOGY

Gastric ulcers were the main form of ulcer disease until the early 1900s, when there was a marked increase in the incidence of duodenal ulcers. The incidence of gastric ulcers has remained relatively stable; a modest decrease in gastric ulcer mortality occurred from 1976 to 1986, but the mortality rate from gastric ulcer decreased from 3.5 per 100,000 in 1962 to 1 per 100,000 in 1979.

Epidemiological surveys conducted in the United States have demonstrated a significant increase in the hospitalizations of elderly patients for complicated ulcers that present with bleeding or perforation. This has been associated with an increase in mortality from ulcer disease in patients older than 75 years (despite the overall mortality being relatively static). This rise has been attributed to the widespread use of NSAIDs in the geriatric population. The aging of the population in developed countries and with the increased usage of NSAIDs in older patients have led to a marked increase in hospitalization rates for peptic ulcers in patients older than 65 years. The availability of H2 receptor antagonists, prostaglandin analogues, and proton pump inhibitors has not decreased the rate of ulcer complications.

Risk Factors for NSAID-Associated Ulcer Complications

The risk of developing ulcer complication in chronic NSAID users is about 2% annually. Epidemiological studies have identified a number of risk factors for NSAID-associated ulcer complications:

Past History of Ulcer Disease or Gastrointestinal Bleeding

A history of ulcer complications is the most important risk factor for recurrent ulcer complications associated with NSAID use. Ulcers tend to recur at the site of previous ulceration. This may be due to NSAID-related inhibition of ulcer healing, leading to more scarring and less reconstitution of normal gastric mucosa.

Elderly Population

Studies on age-related changes in gastric mucosal defenses have shown that prostaglandin synthesis,

mucosal blood flow, and bicarbonate secretion all decrease with age.

Dosage of NSAIDs

The risk of ulcer complications increases with higher doses of NSAIDs or use of multiple NSAIDs.

Concomitant Use of Anticoagulants or Corticosteroids

Although the use of corticosteroids alone does not increase ulcer risk, concomitant use of corticosteroids and NSAIDs substantially increases the risk of ulcer complications compared with the use of NSAIDs alone. The mechanism for this phenomenon is not currently understood. Use of anticoagulants in NSAID users increases the incidence of gastrointestinal bleeding, presumably by the NSAID antihemostatic properties.

DIAGNOSIS OF GASTRIC ULCERS

Clinical Features

Gastric ulcer disease is characterized by chronic relapsing and remitting epigastric pain that is dull in nature. However, at least 10% of ulcers are clinically silent, particularly in elderly patients and with the use of NSAIDs/aspirin. Many patients describe a nonspecific type of upper abdominal pain with no definite relation to food. The differential diagnosis of epigastric pain includes gastroesophageal reflux, gastric or pancreatic neoplasms, mesenteric ischemia (abdominal angina), or pancreatic or biliary disease. Pain may radiate from other areas (cardiac ischemia or aortic aneurysms/dissection). Ulceration of the stomach may be secondary to other systemic illness. Other presentations of gastric ulcer are the development of ulcer complications, such as hemorrhage, perforation, or gastric outlet obstruction. Examination of the patient may reveal nonspecific tenderness, but often the abdomen is normal to palpation.

Diagnosis

Endoscopy is currently the investigation of choice for the diagnosis of gastric ulcers. Although previous studies have shown that double-contrast studies performed by experienced radiologists have an equal accuracy in diagnosing gastric ulcers, use of endoscopy allows for biopsies or cytological brushings of any lesions detected. This is important because ulcerating carcinomas cannot be reliably distinguished from benign ulcers radiographically or endoscopically. Biopsies do not always exclude malignancy; 4% of ulcers initially labeled as benign eventually turn out to be malignant on repeated examinations. Hence, followup endoscopy is recommended to confirm ulcer healing for patients with gastric ulcers.

Complications of Gastric Ulcers

Hemorrhage

Ulcer bleeding is the most common complication of gastric ulcer and is more common in the elderly and in those on anti-platelet agents or anticoagulants. Mild cases may present only with iron deficiency or anemia, and in more severe cases present with coffee ground vomiting, melena, hematemesis, fresh rectal bleeding and hemodynamic compromise.

Perforation

Ulcer perforation is increasing in frequency in the elderly population, probably due to the increase in NSAID use. Chest radiographs may show free gas under the diaphragm but it should be stressed that absence of free gas does not exclude perforation. The ulcer can penetrate into adjacent organs or may be spontaneously sealed off, which may not give rise to signs of peritoneal irritation.

Gastric Outlet Obstruction

Ulcers near the gastroduodenal junction may lead to gastric outlet obstruction, either by inducing local inflammation and swelling or by mechanical obstruction from scarring. Gastric outlet obstruction may present with weight loss, poor appetite, abdominal pain, and vomiting. In severe obstruction, patients may have projectile vomiting and may not tolerate oral intake.

MANAGEMENT

Acute Management of Ulcers

Acid Suppressive Agents

Despite the fact that most gastric ulcer patients have a normal or reduced level of acid secretion, acid suppressive therapy is the mainstay of treatment. Gastric ulcer healing is related to the degree and duration of acid suppression. Antacids in large doses improve the healing of ulcers but have a high incidence of side effects. H2 receptor antagonists and proton pump inhibitors are currently the drugs of choice for the promotion of gastric ulcer healing. Gastric ulcers tend to heal more slowly than duodenal ulcers and smoking is known to retard the healing of ulcers. The ulcer healing rate with the use of H2 receptor antagonists is around 88% in 8 weeks. Proton pump inhibitors heal ulcers faster, and their ulcer healing rate is over 90%. Both

H2 receptor antagonists and proton pump inhibitors have excellent safety profiles.

Drugs Promoting Mucosal Defense

Sucralfate is a complex aluminum salt that forms an insoluble coating over the gastric and duodenal mucosa. The main mechanism of action of sucralfate is likely to be a barrier function against harsh luminal factors such as acid, pepsinogen, and bile salts. Sucralfate also has tropic effects on the gastric mucosa and stimulates secretion of prostaglandin and mucin. Studies have shown that sucralfate is as effective as H2 receptor antagonists, with an average ulcer healing rate of 88% in 8 weeks. Because sucralfate is only minimally absorbed, it has an excellent safety profile; the most common side-effect is constipation.

Misoprostol is a PGE1 analogue that has been approved in the United States. The main action of misoprostol is a local topical effect on the gastric mucosa; it acts by reducing acid secretion and stimulating the various mucosal defense mechanisms. Prostaglandin analogues also stimulate mucosal blood flow, which is important in ulcer healing. Misoprostol is very effective in the prophylaxis of gastroduodenal ulcers in patients taking NSAIDs. However, diarrhea is a common side effect, occurring in up to 30% of patients, and its effects on uterine pressure contraindicate its use in pregnancy.

Surgery

The development of effective and safe acid suppressive agents has relegated surgery to a secondary role in the management of benign gastric ulcer. Surgery is currently primarily used in gastric ulcer complications.

Management of Ulcer Complications

Hemorrhage

The first-line management of bleeding gastric ulcer is therapeutic endoscopy. Visible blood vessels are often visualized at the ulcer base during endoscopy. Treatment modalities include epinephrine injection (which creates a local tamponade effect and vasoconstriction), thermocoagulation with heater probe to coagulate the blood vessel, and application of endoclips to clamp the blood vessel. Intravenous acid suppressive agents alone cannot replace the role of endoscopy in hemostasis. However, use of intravenous proton pump inhibitors as an adjuvant therapy can reduce the risk of rebleeding after endoscopy in high-risk patients. In refractory bleeding that cannot be controlled with endoscopic therapy or after iatrogenic perforation of the ulcer during hemostasis, surgery is required. The ulcer is most often plicated, but in severe bleeding, a partial gastrectomy may be necessary.

Perforation

In spontaneous or iatrogenic perforation of peptic ulcers, surgery is required to lavage the peritoneal cavity and to repair the perforation. There have been reports of endoscopic closing of perforations with endoclips at specialist endoscopic centers, but the safety and efficacy of such procedures are still not established.

Gastric Outlet Obstruction

Gastric outlet obstruction can often be treated conservatively with acid suppressive therapy to allow ulcer healing and gradual reduction of inflammation and swelling around the pylorus. In refractory cases, endoscopic dilatation or surgical pyloroplasty may be necessary.

Prevention of Gastric Ulcer Recurrence in *Helicobacter pylori*-Infected Patients

Eradication of *H. pylori* has been shown to reduce recurrence of ulcers and is more cost-effective than providing long-term maintenance therapy. Effective and safe drug regimes for *H. pylori* eradication are available.

Prevention of Gastric Ulcer Recurrence in NSAID Users

Antiulcer Therapy

NSAID-induced gastric ulcers heal rapidly with conventional ulcer therapy once the NSAID is discontinued. By removing the causative factor, risk for ulcer recurrence is also low, provided there are no other causative factors, such as *H. pylori* infection. However, in patients who require long-term use of NSAIDs or aspirin, maintenance antiulcer therapy is necessary. A meta-analysis of 33 randomized controlled trials assessing the role of misoprostol, H2 receptor antagonist, and proton pump inhibitors in ulcer prophylaxis in chronic NSAID users showed that high-dose misoprostol (800 μg daily) is the only prophylactic agent to reduce ulcer complications. Standard doses of H2 receptor antagonists do not reduce the risk of gastric ulcers. Double doses of H2 receptor antagonist or proton pump inhibitors are effective in reducing gastric ulcers. High-dose misoprostol is likely the most effective prophylactic agent because it corrects NSAID-induced prostaglandin depletion and restores the normal gastric physiology. In patients with good drug compliance, it has been shown that 93% of patients on high-dose misoprostol do not develop ulcers at

12 weeks, in comparison to 82% of patients on proton pump inhibitors. However, the high incidence of side effects and drug noncompliance of misoprostol makes its efficacy comparable to proton pump inhibitors in the clinical setting.

COX-2 Inhibitors

Cyclooxygenase, the key enzyme in the production of prostaglandin, exists in three isoforms. COX-1 is constitutively expressed and is found in many organ systems, including the gastric mucosa, and is important in the maintenance of normal gastric function, COX-2 is proinflammatory and is up-regulated only during inflammation. COX-3 is a variant of COX-1 that has recently been identified in the brain. NSAIDs nonselectively inhibit all isoforms and hence have both beneficial antiinflammatory effects and harmful side effects (including gastrointestinal toxicity). Different NSAIDs have been observed to confer different risks of ulcer formation and ulcer complication. NSAIDs that are relatively selective for COX-2 produce a lower relative risk of ulcer complications.

Highly selective COX-2 inhibitors have been rapidly developed and marketed as effective antiinflammatory agents with reduced gastrointestinal side effects. Two large-scale studies (the CLASS study and the VIGOR study) have demonstrated that use of COX-2-selective inhibitors such as celecoxib and rofecoxib reduce the risk of ulcer complication compared to nonselective NSAIDs. These studies were largely based on average-risk patients and there are insufficient data on the gastric safety of COX-2 inhibitors in high-risk cases (i.e., patients with a history of peptic ulcer disease). The gastrointestinal protective effect of COX-2-selective inhibitors is offset by the use of low-dose aspirin and hence maintenance acid suppressive therapy may still be necessary for patients who require these agents for cardiovascular prophylaxis. Finally, in the VIGOR study, patients receiving rofecoxib had a significant increase in the incidence of acute myocardial infarction compared with patients receiving naproxen. It remains unclear whether this finding is due to the lack of antiplatelet effect or to unopposed inhibition of COX-2.

The use of selective COX-2 inhibitors is an exciting development in the management of chronic NSAID users who are at risk of ulcer disease. However, the safety profile of these drugs and the determination of which population of patients will actually benefit from COX-2 inhibitors are still under investigation.

Nitric Oxide-Releasing NSAIDs

There is currently much interest in the effectiveness of nitric oxide (NO) to reduce NSAID-induced gastric mucosal damage. Studies comparing the incidence of complications in NO plus NSAIDs versus conventional NSAIDs are currently underway.

Gastric Volvulus

WILLIAM HARFORD
University of Texas Southwestern Medical Center, Dallas

Borchardt's triad The combination of pain, unproductive vomiting, and the inability to pass a nasogastric tube in a case of acute gastric volvulus.
gastric volvulus Condition in which the stomach twists upon itself.
mesenteroaxial gastric volvulus Condition in which the stomach folds upon itself along its short axis.
organoaxial gastric volvulus Condition in which the stomach twists along its long axis.

Gastric volvulus occurs when the stomach twists upon itself. Such an event may be transient and produce few symptoms or it may lead to chronic or acute obstruction. If the vascular supply is compromised, acute gastric ischemia may occur.

ETIOLOGY AND PATHOGENESIS

In approximately two-thirds of cases, gastric volvulus is associated with a large diaphragmatic hernia. Sliding hiatal hernias do not lead to gastric volvulus.

Gastric volvulus may be organoaxial or mesenteroaxial (Fig. 1). Organoaxial volvulus is the most common type. The stomach twists along its long axis, which usually passes through the gastroesophageal and gastropyloric junctions. The antrum rotates anteriorly and superiorly and the fundus rotates posteriorly and inferiorly, twisting the greater curvature at some point along its length (Fig. 1, parts 3A and 3B). Less commonly, the long axis passes through the body of the stomach itself. In these cases, the greater curvatures of both the antrum and the fundus rotate anteriorly and superiorly (Fig. 1, parts 2A and 2B). Organoaxial volvulus is usually acute and vascular compromise with gastric ischemia may occur.

In mesenteroaxial gastric volvulus, the stomach folds on its short axis running across from the lesser curvature to the greater curvature. The antrum twists anteriorly and superiorly (Fig. 1, parts 1A and 1B). In rare cases, the antrum and pylorus rotate posteriorly. Mesenteroaxial volvulus is more likely than organoaxial volvulus to be chronic, with symptoms of incomplete and intermittent obstruction.

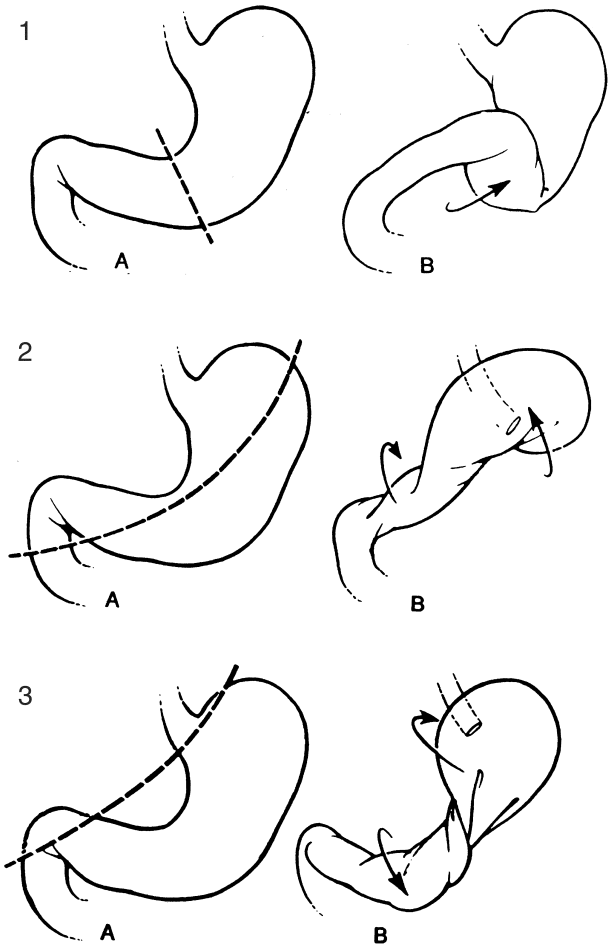

FIGURE 1 Gastric volvulus. (1A) Axis for potential mesenteroaxial volvulus bisecting the lesser and greater curvatures. (1B) Mesenteroaxial volvulus resulting from anterior rotation of the antrum along this axis. (2A) Axis for potential organoaxial volvulus passing through the body of the stomach. (2B) Organoaxial volvulus resulting from anterior superior rotation of the antrum along this axis. (3A) Axis for potential organoaxial volvulus passing through the gastroesophageal junction and the pylorus. (3B) Organoaxial volvulus resulting from anterior superior rotation of the antrum and posterior inferior rotation of the fundus along this axis. Redrawn from Carter, R., Brewer, L. A., and Hinshaw, D. B. (1980). Acute gastric volvulus. *Am. J. Surgery* 140, 101–102, with permission.

INCIDENCE AND PREVALENCE

Since many cases of gastric volvulus present with chronic, intermittent, and nonspecific symptoms, it is likely that many go undiagnosed and thus the incidence and prevalence are unknown. Approximately 15 to 20% of reported cases occur in young children with a congenital diaphragmatic defect. Among adults, men and women are equally affected and the peak incidence is in the fifth decade.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The presentation of acute gastric volvulus includes sudden severe pain in the upper abdomen or lower chest and persistent but unproductive vomiting. Because the volvulus causes gastric obstruction, it is often impossible to pass a nasogastric tube into the stomach. This combination of pain, unproductive vomiting, and inability to pass a nasogastric tube is termed Borchardt's triad. The differential diagnosis includes myocardial infarction, biliary obstruction, and acute pancreatitis. Physical examination may reveal evidence that the stomach is in the left chest. A large gas-filled structure may be seen in the chest on X ray. A barium upper gastrointestinal X ray or computerized tomography with oral contrast will confirm the diagnosis. If upper endoscopy is performed, it may show twisting of the gastric folds, but endoscopy is not prudent if gastric ischemia is suspected.

In contrast to acute gastric volvulus, chronic gastric volvulus is often associated with mild and nonspecific symptoms. These may include dysphagia, epigastric discomfort or fullness, bloating, and heartburn, particularly after meals. Symptoms may be present for months to years and it is likely that many cases are never diagnosed. Since the volvulus may be intermittent and transient, the diagnosis should be suspected if an upper gastrointestinal X ray shows a large diaphragmatic hernia, even if the stomach is not twisted at the time of the X ray.

TREATMENT AND PROGNOSIS

Acute gastric volvulus is an emergency and should generally be treated surgically once the diagnosis is confirmed. Surgery for gastric volvulus may be performed by open or laparoscopic techniques. Elective surgical repair is commonly performed with laparoscopic techniques. Once gastric torsion is reduced, the stomach must be fixed by gastropexy or tube gastrostomy and any associated diaphragmatic hernia must be repaired. Acute gastric volvulus has been associated with a high mortality in the past, but the prognosis has markedly improved in recent years.

Gastrin

CHRIS J. DICKINSON
University of Michigan Medical Center, Ann Arbor

cholecystokinin Peptide hormone produced by endocrine cells of the upper small intestine; secreted on ingestion of a meal; the major hormone responsible for pancreatic enzyme secretion and gallbladder contraction.
gastric development How the stomach grows and develops in a fetus.
gastrin Peptide hormone produced in the stomach; secreted into the bloodstream, enhances gastric acid secretion.
gastrointestinal cancers Tumors that arise from the gut tissues.
Helicobacter pylori Bacterium that lives in the stomach of humans; can cause peptic ulcers in some infected individuals.
H^+,K^+-ATPase Protein that pumps protons across the cell membrane in a 1 : 1 exchange for potassium ions.
parietal cell Acid-secreting cell of the stomach.
peptic ulcer disease Disorder caused by ulcers in the stomach or upper intestine (usually the duodenum); can arise from the action of gastric juices that contain acid and digestive enzymes such as pepsin.
signal transduction mechanisms Chemicals and other mechanisms by which a peptide binding to its receptor on the cell membrane results in some physiologic effect within a cell.
somatostatin Peptide hormone produced in the stomach; inhibits gastric acid secretion and gastrin secretion.

After the discovery of secretin by Bayliss and Starling in 1902, they surmised that a similar hormone might exert control over gastric acid secretion. Edkins then reported the identification of a substance, "gastrin," found in antral but not fundic mucosal extracts that stimulated gastric acid secretion. In 1962, Gregory and Tracy, purified an amidated heptadecapeptide now referred to as gastrin. Shortly thereafter, a gastrin peptide was synthesized, allowing investigators to examine the physiological actions of gastrin. The subsequent development of a gastrin radioimmunoassay helped researchers examine its secretion in physiologic and pathophysiologic states. It quickly became apparent that the regulation of gastric acid secretion was quite complex and that to elucidate those mechanisms, it would be necessary to examine all of the regulatory cells in isolation to determine the precise biological actions of gastrin and other gut peptides. Isolation of acid-secreting parietal cells, gastrin-producing G cells, and somatostatin-producing D cells from the stomach in primary culture became an important step in understanding gastrin secretion and biological actions. To explore the mechanisms of gastrin biosynthesis, investigators initially tried to identify larger molecular forms of gastrin that were presumed to be precursors of the mature peptide. Isolation of a complementary DNA encoding gastrin allowed investigators to hypothesize the presence of various precursors and then develop antisera to confirm the existence of the precursors in tissues and their relationship to the mature peptide. Finally, characterization and isolation of the receptor(s) for gastrin on various cells have allowed researchers to elucidate the mechanisms of gastrin's biological actions on target cells.

GASTRIN DURING DEVELOPMENT

Gastrin is transiently expressed in the neonatal pancreatic islets. However, the physiologic role of gastrin in the developing islet is unclear and gastrin-deficient mice do not have a known defect in islet function. Gastrin appears later in the stomach of the developing rat, as pancreatic gastrin diminishes. Gastrin-producing G cells can be detected in the human fetus as early as 12 weeks of gestation and increase to reach a maximum between 26 and 36 weeks of gestation.

Neonatal human plasma gastrin levels are approximately three times higher than those found in adults. Unfortunately, the physiological significance of neonatal hypergastrinemia is not known. It has been suggested that these elevated levels may play a role in the growth and development of the gastrointestinal (GI) tract. To explore the role of gastrin in gut development, two groups have developed gastrin-deficient mice. These mice are viable and develop normally with normal weight gain, suggesting that gastrin is not a vital hormone. However, both basal and stimulated gastric acid secretions are severely impaired in homozygous animals. Furthermore, there is a reduction in gastric mucosal thickness. Although cholecystokinin (CCK)

 Copyright 2004, Elsevier (USA). All rights reserved.

can bind to the gastrin receptor, CCK does not substitute for gastrin in knockout animals because gastrin-deficient and gastrin receptor-deficient mice share a similar gastric phenotype.

Antral gastrin content increases in the developing rat until the time of weaning. Early weaning or administration of corticosteroids or thyroid hormone increases antral gastrin content and promotes the maturation of the gastric mucosal gastrin receptors. It is unknown whether a similar phenomenon also occurs in the human stomach with a change in diet, but human plasma gastrin levels do remain elevated for several months after birth, when infants are primarily milk fed. The cause of neonatal hypergastrinemia is multifactorial and the rat seems to provide a suitable model for study. A milk-based diet that is high in known gastrin secretagogues such as amino acids and calcium may account in part for the hypergastrinemia. In both rats and humans, there is diminished gastric acid secretion due to a diminished number of functional acid-secreting parietal cells. In mature humans, this inhibits somatostatin secretion, which increases gastrin secretion. Consistent with this is the finding that the somatostatin content of the rat gastric antrum is low at birth and increases gradually until weaning, at around day 21. Moreover, infusion of somatostatin does not inhibit gastrin release in newborn rat pups until day 18 of life, suggesting that somatostatin receptor or postreceptor mechanisms are functionally mature until weaning. The combined effect of low somatostatin content and diminished response to exogenous somatostatin prior to weaning suggests that somatostatin plays a major role in neonatal hypergastrinemia.

GASTRIN RECEPTOR AND SIGNALING

Gastrin requires its carboxyl-terminal amide moiety for full biological activity. Thus, the isolation of a cDNA encoding the receptor that recognizes this motif represented a major advance in the understanding of gastrin physiology. This discovery allowed investigators to more fully elucidate the signal transduction mechanisms, structure/activity relationships, tissue distribution, and biological significance of gastrin. The gastrin/CCK-B, or CCK-2, receptor is a seven-transmembrane "heptahelical" receptor that is similar to the CCK-A, or CCK-1, receptor. The amino acid sequences of gastrin and CCK are quite similar and they share four identical amino acids at the amidated, C terminus of the mature peptide. CCK can bind to both the CCK-1 and CCK-2 receptors whereas gastrin binds to only the CCK-2 receptor at physiologic concentrations. Under normal physiologic circumstances, the serum concentration of CCK is far less than that of gastrin and thus CCK exerts almost no physiologic effects via CCK-2 receptors.

On ligand binding, the gastrin/CCK-B receptor binds to a G protein, which leads to the activation of phospholipase C (PLC); PLC in turn catalyzes the formation of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 effects the release of intracellular calcium, and DAG activates protein kinase C (PKC). Unlike CCK binding to the CCK-A receptor, gastrin binding to its receptor does not result in the accumulation of cyclic adenosine monophosphate (cAMP). This binding initiates a complex signaling cascade, as shown in Fig. 1. Several studies have shown that gastrin can stimulate the proliferation of gut cells as measured by an increase in either cell number, [^{3}H]thymidine incorporation, ornithine decarboxylase (ODC) activity, or expression of two genes known to regulate cell proliferation (c-*fos* and c-*jun*). Clinical examples of this effect can be seen with the overproduction of gastrin in tumors in the Zollinger–Ellison syndrome, which produces significant gastric hyperplasia. Many of these tropic effects can be blocked by gastrin/CCK-B

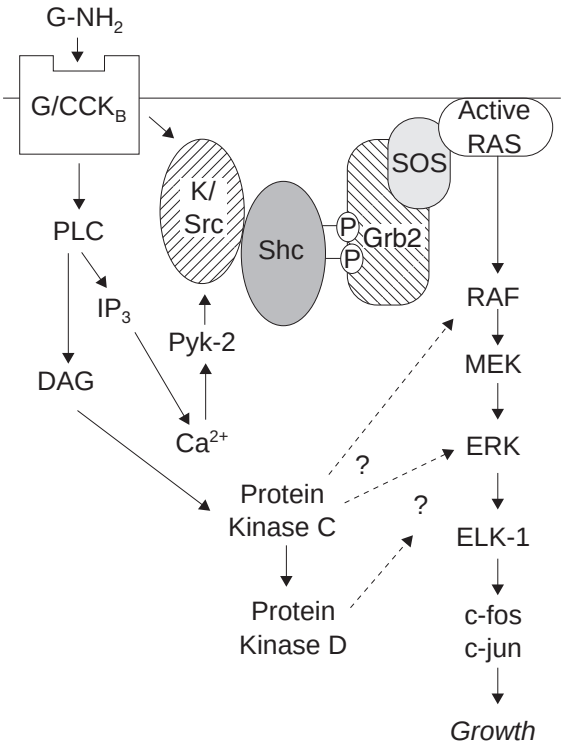

FIGURE 1 Model of gastrin signal transduction mechanisms.

receptor antagonists, suggesting that they are mediated by this receptor.

Although much work remains, progress has been made at characterizing the intracellular events that occur between the initial events at the cell membrane and the resultant actions in the nucleus (Fig. 1). It appears that in addition to activating the serine/threonine kinase (PKC) at the cell membrane, gastrin also activates tyrosine kinases (TKs; e.g., Src), which phosphorylate an adapter protein (Shc). Phosphorylated Shc then associates with two other proteins (Grb2 and a Ras activator, Sos). This complex can then stimulate the Ras-dependent activation of the mitogen-activated protein (MAP) kinase as well as the upstream activator of MAP kinase, a MAP and ERK kinase (MEK). ERK then phosphorylates a nuclear transcription factor (Elk-1) that enhances c-fos expression, after which c-fos combines with c-jun to induce transcription of other genes that regulate growth. Although gastrin receptor antagonists completely reverse the effects of c-fos expression, PKC inhibitors result in only a 40–50% reduction in gastrin-induced c-fos expression. This suggests that the tropic effects of gastrin are mediated by PKC-dependent and -independent pathways. The IP_3-mediated release of intracellular calcium induces tyrosine phosphorylation of the focal adhesion kinase Pyk-2 and Src. PKC can also activate protein kinase D, although the mechanisms by which PKD stimulates growth remain unknown. Other investigators have identified gastrin-mediated activation of the GTP-binding protein, Rho, which can stimulate growth via PKC- and MEK-independent pathways, presumably via changes in the cytoskeleton. It is anticipated that these and other mechanisms will soon be elucidated and will aid in understanding gastrin's potentially important growth-promoting effects.

GASTRIN PROCESSING AND PHYSIOLOGICAL RELEVANCE OF OTHER PROGASTRIN-PROCESSING PRODUCTS

Gastrin, as is the case with other regulatory neuropeptides, is initially synthesized as a large, biologically inactive precursor, progastrin (Fig. 2). Endoproteolytic processing of progastrin within G cells results in the formation of a glycine-extended form of gastrin (G-Gly) that is found in high concentrations in the developing rat gastric antrum. G-Gly serves as a substrate for the amidation enzyme, peptidylglycine α-amidating monooxygenase (PAM), that catalyzes the formation of fully processed mature, amidated

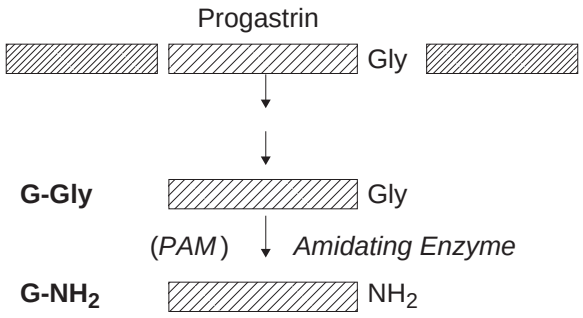

FIGURE 2 Progastrin posttranslational processing. Progastrin is sequentially processed to a glycine-extended form of gastrin (G-Gly). G-Gly then serves as a substrate for the amidation enzyme peptidylglycine α-amidating monooxygenase (PAM), which catalyzes the formation of amidated gastrin (G-NH_2). The C-terminal amide moiety is necessary for G-NH_2 binding to the gastrin/CCK-B receptor.

gastrin. Gastrin (G-NH_2) requires its carboxyl-terminal amide moiety for full biological activity mediated by gastrin/CCK-B receptors. Indeed, removal of the carboxyl-terminal amide in gastrin completely abolishes its acid stimulatory effects mediated by standard gastrin/CCK-B receptors, and the immediate precursor of amidated gastrins, G-Gly, is at least four orders of magnitude less potent than G-NH_2 in stimulating acid secretion from gastric parietal cells. Nevertheless, interest in the physiologic effects of G-Gly has been fueled by the observations that G-Gly is stored in brain and gut tissues, secreted with G-NH_2 from antral G-cells into the circulation, and achieves concentrations in plasma roughly equivalent to those of G-NH_2. Moreover, G-Gly is seen in greater concentrations than is G-NH_2 during development and in some malignant tissues that express gastrin, such as Zollinger–Ellison tumors and colon cancers. Finally, biosynthetic studies suggest that G-Gly may be a distinct end product of progastrin processing. Thus, the evidence points to a role for G-Gly as a growth factor but not as a direct acid secretagogue.

To further characterize the potential tropic effects of G-Gly, a study examined whether G-Gly might function as a growth factor in a fashion that could be distinguished from its relatively weak effects on the standard gastrin/CCK-B receptor. The abilities of G-NH_2 and G-Gly to stimulate DNA synthesis were compared. Both G-NH_2 and G-Gly stimulated [^{3}H]thymidine incorporation in a dose-dependent fashion. As expected, the stimulation induced by G-NH_2 was completely reversed by selective gastrin/CCK-B receptor antagonists. Further studies characterized a distinct receptor and signaling cascade for G-Gly that resulted in

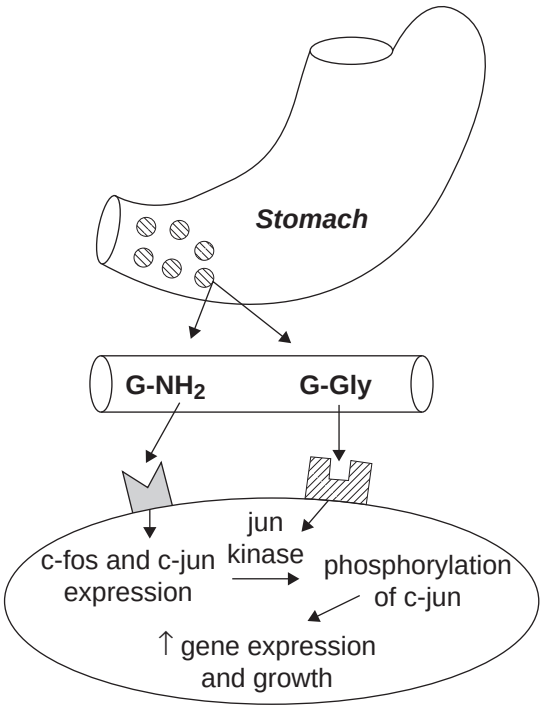

FIGURE 3 Mechanisms of G-NH_2 and G-Gly tropic effects. Amidated gastrin (G-NH_2) and its glycine-extended precursor (G-Gly) are released from G cells in the gastric antrum into the circulation. G-NH_2 acts through gastrin/CCK-B receptors to enhance the expression of c-fos and c-jun. G-Gly, via another distinct receptor and jun kinase, phosphorylates and thus bioactivates c-jun. c-fos and phosphorylated c-jun then induce the expression of other genes necessary for the proliferation of gut cells.

phosphorylation and activation of jun kinase but no changes in c-fos expression (Fig. 3).

The inability of investigators to isolate a cDNA encoding the putative G-Gly receptor has hampered further study in this area. Other data help to confirm the role that G-Gly may play in gastrointestinal physiology. G-Gly can stimulate growth in an autocrine fashion. Although acute administration of G-Gly has no effect on gastric acid secretion, chronic administration of G-Gly markedly enhances stimulated but not basal acid secretion from isolated parietal cells and *in vivo* via an increase in the expression of H^+,K^{+t}-ATPase within gastric parietal cells. G-Gly may play a role in the growth of the colon. Indeed, gastrin-deficient mice have a diminished colonic proliferative index and transgenic mice overexpressing G-Gly have enhanced colonic proliferation. Taken as a whole, these observations suggest that growth-related receptors for G-Gly work in concert with G-NH_2 to enhance the functional development of the gut.

GASTRIN, PEPTIC ULCER DISEASE, AND CANCER

Overview

The studies just described greatly expanded knowledge of the mechanisms of gastrin biosynthesis, release, and receptor/ligand interactions. However, the central clinical issue that initially drove these studies was elucidation of the mechanisms of peptic ulcer formation. For many years, peptic ulcer disease was a major cause of morbidity and mortality, and early studies seemed to confirm the notion that gastric acid was requisite to the formation of duodenal ulcers. Thus, it was hoped that a more thorough understanding of the regulation of gastric acid secretion would elucidate the pathogenesis of peptic ulcer disease. Early investigators identified gastrin as the primary postprandial regulator of gastric acid secretion.

The G cell is a classic gut endocrine cell, organized with microvilli on a luminal surface that allow the G cell to detect the presence of food within the stomach. Gastrin released from G cells into the circulation has three major effects mediated by gastrin/CCK-B receptors. First, gastrin can stimulate the release of acid directly from the parietal cell. Second, gastrin can also stimulate acid secretion by enhancing the release of histamine from enterochromaffin-like (ECL) cells, which then bind to histamine-2 (H2) receptors on the parietal cell (see Fig. 4). Third, gastrin also stimulates the release of somatostatin from gastric D cells. Somatostatin is a potent inhibitor of gastric acid secretion, acting directly on the parietal cell or blocking the continued release of

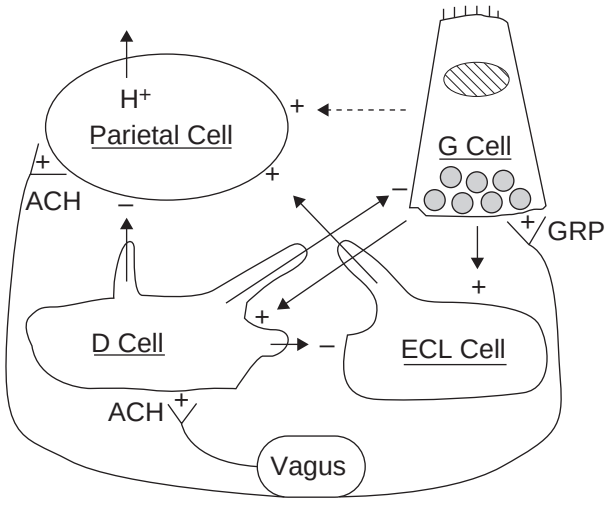

FIGURE 4 Interaction in the lumen between the G cell and other gastric cells regulating acid secretion. ACh, Acetylcholine; GRP, gastrin-releasing peptide; ECL, enterochromaffin-like cell.

gastrin from G cells and histamine release from ECL cells. Detailed reviews on the regulation of gastrin release have been published; a summary is provided herein.

Neural Control of Gastrin Secretion

During the cephalic and oropharyngeal phases of a meal, gastrin release is directly stimulated by acetylcholine (ACh) released from vagal fibers via muscarinic receptors. ACh released from other vagal fibers also inhibits the release of somatostatin from antral D cells, which indirectly enhances gastrin secretion. In addition to ACh, gastrin-releasing peptide (GRP) is also secreted from postganglionic vagal nerve fibers and directly stimulates gastrin release via GRP receptors on G cells.

During the gastric phase of a meal, antral distension evokes low levels of gastrin release; this is inhibited by low doses of atropine but is enhanced by atropine at higher doses. Because the gastrin release in response to antral distension is depressed by the β-adrenergic antagonists, an adrenergic sympathetic reflex may be involved. Antral distension in humans also activates inhibitory pathways of gastrin release because it inhibits GRP-stimulated release by an unknown mechanism.

Hormonal Control of Gastrin Secretion

A variety of peptide hormones also regulate gastrin release (detailed discussions of all of the mechanisms can be found elsewhere). Somatostatin is released from bulbous swellings at the end of cytoplasmic extensions of antral D cells onto G cells in many species. This intimate relationship of the D cell with the G cell provides a tonic inhibition to gastrin release and makes somatostatin the primary hormonal regulator of gastrin release. It also provides the mechanism for many of the indirect effects of other hormones on gastrin release.

Chemical Control of Gastrin Secretion

In accord with the presence of G cell microvilli extending into the lumen of the stomach, the G cell does respond to the presence of food within the stomach. In the perfused rat stomach or in antral mucosal segments, peptone stimulates gastrin and inhibits somatostatin release. Neurotoxins, such as tetrodotoxin, GRP antagonists, and atropine, abolish both stimulation of gastrin release and inhibition of somatostatin release, indicating that peptone-induced gastrin release is mediated, in part, by both cholinergic and GRP neurons. However, other groups have shown that amino acids and amines also stimulate gastrin release from isolated canine G cells. Other chemical stimuli, such as an increase in gastric acid production, completely suppress gastrin release. However, this is not a direct effect on the G cell, but is rather mediated by an increase in somatostatin secretion.

Helicobacter pylori, Ulcers, and Gastrin

Studies on the regulation of gastric acid secretion led to the discovery of H2 receptor antagonists that blocked the actions of histamine on the parietal cell. Although these and other gastric-acid-suppressive agents could heal the majority of duodenal ulcers with 6–8 weeks of therapy, the ulcer would generally reappear with cessation of therapy. Thus, the search for the cause of peptic ulcers continued. The discovery of a spiral bacterium (*Helicobacter pylori*) in the inflamed stomachs of patients with duodenal ulcers has led to a revolution in our understanding of ulcer pathogenesis and therapy. Because so many people are afflicted with peptic complaints, this discovery received a great deal of attention from scientists and the lay press. Although there was some initial skepticism regarding the relevance of this discovery, it is now widely accepted that the majority of patients with duodenal ulcers and 60–70% of those gastric ulcers are infected with *H. pylori*. Moreover, failure to eradicate the infection often results in recurrence of the ulcers, even with optimal antisecretory therapy. In contrast, eradication of *H. pylori* results in complete healing and a very low recurrence rate in the absence of reinfection.

Initially, these observations were difficult to mesh with our long-standing view that ulcers were secondary to a disorder in the regulation of gastric acid secretion. Not surprisingly, the view today is that both infection and alterations in gastric acid secretion appear to play a role in peptic ulcer pathogenesis. One observation that leads to this view is that although *H. pylori* is almost always present in patients with duodenal ulcers, the bacterium is more likely to be found in an inflamed gastric antrum than in the duodenum. Although initial infection with *H. pylori* is associated with gastritis and hyposecretion of acid, chronic infection leads to a moderate hypersecretion of gastric acid. It is believed that this chronic hypersecretion of acid results in ulcer formation in some patients. Patients infected with *H. pylori* have higher serum gastrins and decreased levels of antral somatostatin compared to noninfected controls, suggesting that *H. pylori* has some effect on the cells regulating gastrin release and acid secretion. Thus, recent investigations have focused on the mechanisms by which chronic *H. pylori* infection alters the regulation of gastric acid secretion.

When compared with *H. pylori*-negative subjects, patients with duodenal ulcers and *H. pylori* infection have several abnormalities in the regulation of gastric acid secretion. These include a two- to fourfold increase in basal acid secretion, an increased maximal response to exogenous gastrin, a marked increase in acid secretion to GRP, and an increased ratio of basal acid output to maximal gastrin-stimulated acid output. Interestingly, although *H. pylori*-infected patients have increased acid secretion and moderate hypergastrinemia, the level of hypergastrinemia cannot fully account for the increase in acid secretion. *Helicobacter pylori*-positive duodenal ulcer patients also have impaired acid inhibitory mechanisms. Because somatostatin-producing D cells mediate many of the gastric acid inhibitory pathways, the reduced amounts of antral somatostatin seen with chronic infection can contribute to the reduced acid. All of these abnormalities resolve within 1 year after eradication of infection except for the increased acid response to exogenous gastrin. It is doubtful that this response is due to an up-regulated acid secretory mechanism due to prolonged hypergastrinemia, because the *H. pylori*-induced hypergastrinemia resolves completely within 1 month after eradication. Furthermore, in patients with hypergastrinemia secondary to a gastrinoma, the enhancement of parietal cell mass fully resolves within 6 months after tumor resection. Thus, it is felt that patients who develop duodenal ulcers with *H. pylori* infection may have factors that increase their gastrin-stimulated acid secretory response.

To determine how *H. pylori* produces these effects in infected gastric mucosa, investigators have focused on the effects of bacterial products or inflammatory mediators on acid secretion. Because *H. pylori* infection is associated with an underlying gastritis, investigators have examined the effects of inflammatory mediators on the regulation of acid secretion. Interleukin-1β, interleukin-8, and tumor necrosis factor α augment gastrin release from G cells. These and other cytokines are elevated in infected gastric mucosa. Other recent investigations have suggested that inflammation, in general, rather than that specific to *H. pylori* infection, can elevate gastrin production and gastric acid secretion.

Cancer

The role of gastrin in gut tumors has been controversial for some time. Thus, it is useful to review the clinical conditions associated with hypergastrinemia. Hypergastrinemia produced by G cell neoplasms leads to the Zollinger–Ellison syndrome. In afflicted patients, serum gastrin concentrations exceed physiologic levels by severalfold. These slow-growing tumors are often found in the pancreas or duodenum and may not prove fatal for 20 or more years. Patients do exhibit markedly elevated gastric acid secretion and hypertrophy of the histamine-producing ECL cells, but rarely a frank ECL or carcinoid tumor, compatible with a model that gastrin alone is not a carcinogen.

Proton pump inhibitors are now widely prescribed because of their ability to block gastric acid secretion by virtue of their ability to bind to H^+,K^+-ATPase. Although treated patients do develop a mild hypergastrinemia while on medication, there seems to be little evidence of an increased cancer risk, even with long-term administration. In an analogous situation, patients with prolonged gastric inflammation (usually from *H. pylori* infection) often develop hypergastrinemia. A higher percentage of infected patients will develop gut tumors compared to noninfected controls. However, only a small minority ($< 1\%$) of infected patients develop gastric cancer, again suggesting that other factors must be involved.

Transgenic mice overexpressing fully processed, amidated gastrin have an early increased in parietal cell mass and ECL cell numbers similar to that found in human models of hypergastrinemia. Unlike the human condition, transgenic mice develop a late gastritis, and many succumb to gastric cancer. The progression to cancer can be significantly accelerated by concomitant infection with a mouse form of *H. pylori*, i.e., *Helicobacter felis*. Conversely, transgenic mice overexpressing G-Gly, but not amidated gastrin, have no alteration in gastric function, but rather develop an increased colonic proliferative index.

The role of gastrin in the development of colorectal cancer has been controversial for many years. Several studies have demonstrated a growth-stimulatory effect of gastrin or pentagastrin on colon cancers *in vivo* and *in vitro*, whereas others have failed to confirm this effect. Other human studies have been performed with conflicting results, but a recent epidemiological study suggests that prolonged hypergastrinemia associated with *H. pylori* infection may play a role in the development of some human colonic tumors. Because progastrin is often poorly processed in nonendocrine cells such as those found in the colon, it explains why "gastrin" antisera fail to detect significant quantities of amidated peptide. Consistent with this notion is that colon cancers contain large amounts of progastrin and other progastrin processing intermediates such as G-Gly, but little fully processed peptide, suggesting a role for G-Gly in colon cancer. In published phase II studies, investigators have developed a method of inducing antigastrin antibodies in patients with colon and pancreatic cancer. The antibody recognizes both amidated gastrin and G-Gly. Preliminary data suggest prolonged survival

of treated patients, furthering the claim that gastrin plays a role in gut cancers. However, many more data are needed to confirm this finding and to elucidate the mechanisms and circumstances under which gastrin exhibits these actions.

Gastrin-Releasing Peptide

ROBERT T. JENSEN
National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health

bombesin-related peptides Peptides related to the 14-amino-acid peptide, bombesin, which was originally isolated from the skin of the frog, *Bombina bombina*. Many of these peptides (ranatensin, phyllolitorin, litorin) were isolated from the skin of other frogs.

gastrin-releasing peptide A 27-amino-acid mammalian peptide that is closely related to bombesin and was isolated from porcine stomach.

neuromedin B A 10-amino-acid mammalian peptide isolated from porcine spinal cord that resembles the frog peptides, ranatensin and litorin.

Gastrin-releasing peptide (GRP) is a 27-amino-acid peptide that was isolated in 1978 from porcine nonantral gastric tissue. It is named GRP for its ability to stimulate gastrin release, which was used to monitor its activity during purification. GRP and a 10-amino-acid peptide, neuromedin B (NMB), isolated in 1983 from porcine spinal cord, are now known to be the mammalian members of the bombesin family of peptides previously described in invertebrates. Beginning in 1970 when the 14-amino-acid peptide bombesin was isolated from the skin of two European frogs, *Bombina bombina* and *Bombina variegata*, a number of related peptides were discovered and were named after the frog from which they were isolated. GRP closely resembles bombesin, differing in only 1 amino acid in its last 10 carboxyl-terminal residues, which explains their similar biological activities. NMB more closely resembles the 11-amino-acid peptide ranatensin, which was originally isolated from the skin of the North American frog, *Rana pipiens*, in 1970 and the nonapeptide, litorin, isolated from an Australian frog. NMB differs from the last 10 carboxyl-terminal amino acids of GRP (GRP-10) by 3 amino acid substitutions. A third subfamily of bombesin-related peptides exists: the phyllolitorins, which have no mammalian equivalents at present. Phyllolitorins are nonapeptides isolated from a South American frog and differ from GRP and NMB by having a serine instead of a histidine, 3 amino acids from the carboxyl terminus. These small structural differences between GRP and NMB are important because both a GRP-preferring receptor and an NMB-preferring receptor (NMB-R) have been identified in mammals. This article will concentrate on GRP and discuss NMB/NMB-R only briefly.

GASTRIN-RELATED PEPTIDE STRUCTURE AND GENE SEQUENCE

Gastrin-releasing peptide (GRP), like all bombesin (Bn)-related peptides, is amidated at its carboxyl-terminus (Fig. 1), which is the biologically active portion of the peptide. The carboxyl-terminal decapeptide (GRP-10) in most assays has biologic activity equal to that of the native GRP. Structure–function studies of GRP demonstrate that the Trp-21, His-25, and the carboxyl-terminal amidation are particularly important for high-affinity receptor interaction. The sequence for the precursor of human GRP has been cloned. The mRNA is approximately 850 bases in length with a 300-base 3′-untranslated region, a 100-base 5′-untranslated region, a 148-amino-acid precursor containing a signal peptide, a single copy of GRP-27, and a carboxyl-amino extension peptide. The gene is located on chromosome 18 and comprises three exons and two introns, which, because of alternate splicing at the second intron, produces three mRNAs that encode an identical GRP, but with variable carboxyl-terminal extension peptides present. The importance of the alternate splicing is unknown. GRP is produced from the 148-amino-acid precursor by proteolytic cleavage at both the amino- and carboxyl-termini and removal of the carboxyl-terminal Met-Gly extension by an amidation enzyme.

GASTRIN-RELATED PEPTIDE RECEPTORS, PHARMACOLOGY, AND THEIR CELL TRANSDUCTION MECHANISMS

A GRP-preferring receptor (GRP-R; also called the BB2 receptor) has been characterized in human and a number of other species (Table I). The human GRP-R (hGRP-R) is a 384-amino-acid protein with a predicted molecular weight of 43 kDa (Table I). It is a member of a G-protein-coupled receptor superfamily with hydropathy plots predicting the characteristic 7-transmembrane

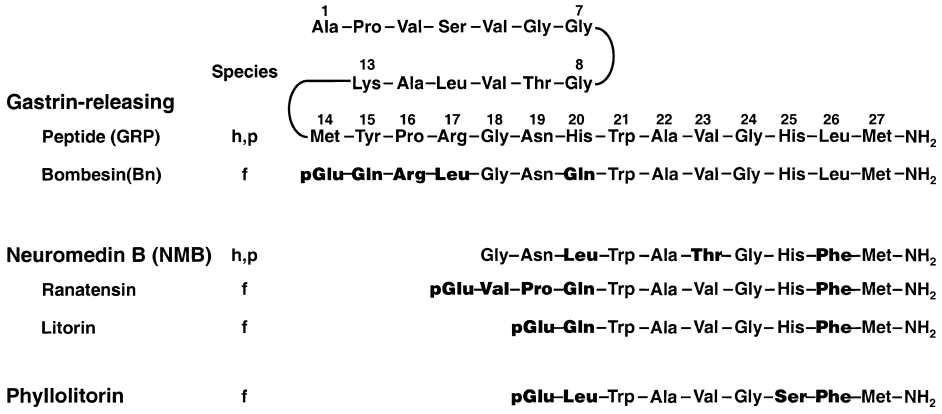

FIGURE 1 Amino acid sequences of gastrin-releasing peptide, neuromedin B, and phyllolitorin family of bombesin-related peptides. Sequence in boldface indicates differences from GRP sequence. Numbers at the top denote the position in GRP starting from the amino-terminus. f, frog; h, human; p, porcine.

domains. The GRP-R shows 55% amino acid identity with the neuromedin B-preferring receptor (NMB-R). The native hGRP-R has two potential glycosylation sites and in cells is 35% glycosylated with a molecular weight of 60 kDa. Studies of the murine GRP-R (mGRP-R), which has four potential glycosylation sites, demonstrate that all four sites are glycosylated and the glycosylation consists of four tri-antenary and/or tetra-antenary complex oligosaccharide chains containing no sialic acid. GRP-R glycosylation is necessary for receptor expression, ligand affinity, and G-protein coupling.

The hGRP-R has a higher affinity for GRP than for NMB, whereas the converse is true for the NMB-R (Table I). Recent studies demonstrate that the GRP-R's selectivity for GRP is primarily determined by amino acid differences between the third extracellular domains of GRP-R and NMB-R. Of the 20 amino acid differences between the GRP-R and NMB-R in the third extracellular domain, 2 differences are particularly important: the substitution in NMB-R of isoleucine for phenylalanine at position 185 of the GRP-R and, to a lesser extent, the substitution of isoleucine for alanine at position 198 of the GRP-R. Mutagenesis studies show the presence of an aromatic ring on the amino acid at GRP-R position 185 (mGRP-R) and, to a lesser extent, the size of the backbone substitution on the amino acid at position 198 are likely the important factors contributing to the different GRP affinities for these two receptors. It has been proposed that cation$-\pi$ or $\pi-\pi$ ligand receptor interactions may be important for mediating the marked effect of the aromatic amino acid at position 185 of GRP-R.

Five different classes of receptor antagonists have been described, two of which have a high degree of selectivity for the GRP-R over the NMB-R. These five classes include substituted substance P analogues, [D-Phe-12]Bn analogues, 13- to 14-amino-acid pseudopeptide analogues of GRP or bombesin (the CONH of Leu-13 is replaced by CH_2NH), des-Met-14 analogues of bombesin (or des-Met-27 GRP), and peptoids such as PD168368, which are nonpeptide analogues based on a single amino acid template. Some of the pseudopeptide analogues and des-Met-14 Bn analogues (Table I) have a greater than 1000-fold selectivity for the GRP-R over the NMB-R. These antagonists have proved useful for exploring the role of GRP-R in both physiological processes and pathological processes. For example, in human volunteers using the GRP-R antagonist, BIM26226

TABLE I Comparison of Characteristics of the Two Mammalian Bombesin (Bn) Receptors (GRP-R and NMB-R)

	hGRP-R (BB_2)	hNMB-R (BB_1)
Natural ligand	GRP	NMB
Gene location	Xp22	6q21
Amino acids	384	390
Pharmacology (affinity)

NMB	290 n*M*	7 n*M*
Bn	0.5 n*M*	44 n*M*
Antagonists		
[D-Phe^6]Bn(6-14)methyl ester	3 n*M*	>10,000 n*M*
PD 168368	630 n*M*	15 n*M*

([D-F5-Phe-6, D-Ala-11]Bn(6–13)methyl ester), GRP was shown to be a physiological regulator of gastric acid secretion; however, gastrin release was not under the control of GRP in human. The role of these antagonists in the possible treatment of various disorders, especially cancer growth, will be discussed in a later section.

GRP primarily couples to $G_{q/11}$ and its activation results in the stimulation of phospholipase C with the generation of inositol phosphates, mobilization of cellular calcium, and release of diacylglycerol with activation of protein kinase C (PKC). GRP-R activation also results in the activation of phospholipase D, protein kinase D, mitogen-activated protein kinases, Src kinases, and stimulation of tyrosine phosphorylation of a number of intracellular proteins including p125 focal adhesion kinase, p130Cas, and paxillin. Studies demonstrate that bombesin-induced tyrosine phosphorylation of these proteins occurs through a PKC- and Ca^{2+}-independent pathway and this pathway depends on the integrity of the actin cytoskeleton and participation of the small GTP-binding protein, Rho. GRP-R activation results in increased expression of c-fos, c-jun, and jun-B with increased activator protein-1 expression and DNA synthesis. In addition to G-proteins, studies support the conclusion that a number of low-molecular-weight GTP-binding proteins play an important role in GRP-R-induced stimulation of intracellular pathways including Rho, p21ras, and Rac.

DISTRIBUTION OF GASTRIN-RELATED PEPTIDE AND ITS RECEPTOR

GRP immunoreactivity (GRP-IR) exists widely in the alimentary tract in nerve fibers and cell bodies. In the stomach, GRP-IR is found in cell bodies and nerve fibers of both the oxyntic and antral mucosa and the circular muscle layer. Similarly, in both the small and large intestine, GRP-IR is found in nerve fibers and cell bodies of the myenteric plexus. In the colon, GRP-IR is found in myenteric neurons projecting to both the circular muscle and caudad. Both nerve fibers and cell bodies in the pancreas contain GRP-IR and the fibers project to both the acini and ducts, with a spare projection to islets. Sympathetic prevertebral ganglia have a dense innervation of fibers containing GRP-IR.

GRP-IR is also widespread in the central nervous system (CNS). It is present in a subset of spinal sensory ganglia, in layers 1 and 11 of the posterior horn, and in nerve terminals surrounded by large motor neurons in the anterior horn. Cell bodies in the brain containing GRP-IR are found in the pons (dorsolateral tegmental nucleus), hypothalamus (paraventricular nucleus), nucleus of the solitary tract, dorsal parabrachial nucleus, superior olivary nucleus, mesencephalic central gray matter, and anterior aspect of the interpeduncular nucleus. Nerve fibers in the brain containing GRP-IR in high density are found in the thalamic periventricular nucleus, hypothalamic nuclei, amygdala, dorsolateral tegmental nucleus, trigeminal complex, dorsal vagal nucleus, and nucleus of the tractus solitarius.

GRP-R receptors and (or) GRP-R mRNA have been shown to be widely distributed in the CNS, the gastrointestinal (GI) tract, and the urogenital tract. In the CNS, high densities of GRP-R mRNA are found in isocortex (layer 11), dentate gyrus, N-lateral olfactory tract, magnocellular preoptic nucleus, numerous hypothalamic nuclei (suprachiasmatic, supraoptic, paraventricular, medial preoptic, lateral mammillary), and the nucleus ambiguus. In the urogenital system, GRP-R has been identified in the bladder, seminal vesicles, uterus, and oviduct. In the GI tract, the highest density of GRP-Rs occurs over gastric antral endocrine cells. GRP-Rs also occurred on circular smooth muscle cells of the gastric fundus, gastric antrum, ileum, and the longitudinal smooth muscle of the gastric fundus and gastric antrum as well as on neural elements in the myenteric plexus in the stomach, antrum, and small intestine. In the colon, GRP-Rs are found in submucous plexi and the circular smooth muscle.

GASTRIN-RELATED PEPTIDE RELEASE AND METABOLISM

GRP is a neuropeptide that is primarily localized in neural structures; therefore, its plasma levels may not be an accurate reflection of its local release in tissues. Splanchnic nerve stimulation in the calf, but not the pig, results in the release of GRP-IR into plasma and interstitial lymph. GRP-IR is also released by vagal stimulation of the isolated perfused pig stomach and pancreas. Electrical stimulation of gallbladder nerves in the pig results in the release of GRP-IR and contraction of the gallbladder, which is inhibited by tetrodotoxin.

GRP-IR is rapidly removed from the plasma with a half-life of 1.4 min in the pig. The clearance of fragments of GRP, such as GRP-10, is faster than that of GRP-27. Neutral endopeptidase [NEP, EC3–4-24–11 (also called endopeptidase-24–11, enkephalinase)] is the major peptidase responsible for GRP degradation. GRP-10 is degraded by hydrolysis of the His8Leu9 peptide bond, which results in its inactivation. NEP is

expressed on the cell surface of many cells that are regulated by GRP including CNS neurons, pancreatic acinar cells, gastrointestinal smooth muscle cells, and gastric mucosal cells.

PHYSIOLOGICAL/PHARMACOLOGICAL ROLES OF GASTRIN-RELATED PEPTIDE

A brief list of the effects of GRP is given in Table II. Many of the reported effects are limited by two factors. First, which effects are physiological and which are pharmacological has, in general, not been addressed because only recently have potent specific antagonists been described or the use of immunoneutralizing antibodies applied. Second, many of the older studies were performed with bombesin, which has only limited selectivity for GRP-R over NMB-R (see Table I) and therefore, in some cases, activation of NMB-Rs could be contributing to the described responses. Two recent studies in human volunteers using a highly selective GRP-R antagonist demonstrate that GRP is a physiological regulator involved in meal-stimulated acid secretion and gallbladder contraction as well as gastric emptying and decreasing small bowel transit time. However, GRP was not a physiological regulator of gastrin release in humans as suggested by extensive studies in animals. GRP functions as a neurotransmitter and neuromodulator.

GRP is a potent contractant of almost all gastrointestinal and urogenital smooth muscle (Table II) and is also a potent stimulant of the release of many hormones and neurotransmitters such as gastric inhibitory peptide, cholecystokinin (CCK), pancreatic polypeptide, glucagon, insulin, prolactin, and growth hormone (Table II). GRP has a potent stimulatory effect on pancreatic secretion in all species examined. GRP can stimulate CCK release; however, GRP's pancreatic stimulatory effect in rats is not blocked by a CCK-A receptor antagonist and in almost all species examined including humans, the pancreatic acini possess GRP receptors, leading to the conclusion that GRP's pancreatic stimulatory action is due to a direct interaction with pancreatic acinar cells.

GRP has numerous effects in the CNS and the most well-studied is its ability to stimulate a decrease in body temperature. It also is involved in the regulation of circadian rhythm and in the regulation of feeding. Extensive studies in both animals and humans provide strong support for GRP as a satiety factor. Furthermore, GRP-R knockout mice not only no longer respond to the satiety effects of GRP, these mice eat significantly more at each meal than normal littermates and show a significant elevation in body weight.

TABLE II Physiological and Pharmacological Effects of GRP

- CNS effects
  - Regulation of circadian rhythm
  - Thermoregulation (↓ body temperature)
  - Food intake (↓)
  - Behavioral effects (↑ grooming)
  - Sleep (↓); memory (↑)
  - CNS–gut effects (gastric antisecretory effect, stimulates gastrin and mucus release, inhibits gastric emptying and motility)
- Gastrointestinal tract
  - Gastric
    - ↑ Acid secretion
    - ↑ Gastrin somatostatin, GIP release
    - Alter gastric antral (↑), corpus (↑, ↓) motility
    - ↑ Gastric emptying
  - Intestinal
    - ↑ CCK, motilin, neurotensin, VIP, enteroglucagon release
    - ↓ Intestinal transit time
    - ↑ Contraction isolated muscle
  - Colon
    - ↑ Contraction of isolated muscle
    - ↑ Na^+, K^+ secretion in distal colonic epithelium
  - Pancreatic
    - ↑ Enzyme secretion
    - ↑ PP, insulin, glucagon release
    - ↑ Pancreatic growth
  - Gallbladder
    - ↑ Contraction of GB/isolated muscle
  - Liver
    - ↑ Fluid and bicarbonate secretion from cholangiocytes
- Urogenital tract
  - ↑ Contraction of urinary bladder
  - ↑ Contraction isolated muscle of uterus, urinary bladder
- Endocrine
  - Adrenal
    - ↑ Corticosterone release
    - ↑ ACTH release
  - Pituitary
    - ↑ Prolactin, growth hormone, LH release
    - ↓ TSH release
  - Other endocrine
    - ↑ Calcitonin, renin release
- Respiratory
  - ↑ Growth of bronchial epithelial cells
  - Involved in lung development (↑ branching morphogenesis, cell proliferation, differentiation)
- CVS effects
  - Blood pressure (↑)

Note. ACTH, adrenocorticotropic hormone; CCK, cholecystokinin; CNS, central nervous system; CUS, cardiovascular system; GIP, gastric inhibitory peptide; LH, luteinizing hormone; PP, pancreatic polypeptide; TSH, thyroid-stimulating hormone; VIP, vasoactive intestinal peptide.

One of the most important effects of GRP-R activation is the stimulation of growth of normal cells and in pathologic conditions. The latter will be discussed fully in the next section. GRP has been shown to have a growth stimulatory effect on normal pancreatic acinar cells (increase in pancreatic weight, DNA content), stomach mucosa, colonic mucosa, bronchial endothelial cells, growth plate chondrocytes, keratinocytes, and melanocytes. Results from detailed studies of Swiss 3T3 fibroblasts and other tissues show that the growth stimulatory effect is due to a direct activation of the GRP-R by GRP and not an indirect effect due to the release of another stimulatory agent.

GASTRIN-RELATED PEPTIDE IN PATHOLOGIC CONDITIONS

The most important pathologic conditions in which GRP may be involved are listed in Table III. There is considerable experimental data supporting its possible role in cancer growth and lung diseases, whereas a single study suggests that GRP release may play a decisive role in the maintenance of intestinal microvascular integrity after ischemia and with reperfusion. No studies have established that alterations of GRP are clearly involved in human feeding, obesity, or body weight disorders, but animal studies as well as studies on humans have firmly established GRP as an important satiety factor. It has been proposed that GRP may play a role in various ingestive disruptions associated with anorexia (anorexia nervosa, acquired immunodeficiency syndrome, cancer anorexia), bulimia, obesity, and depression. This proposal has received some support recently from a study of cerebrospinal fluid (CSF) GRP concentrations in normal females and patients recovered from anorexia nervosa or bulimia nervosa. CSF GRP-IR levels were significantly lower in recovered bulimia patients than either normal controls or recovered anorexia nervosa patients. It was proposed that this persistent GRP abnormality in recovered bulimia nervosa patients could be contributing to their episodic hyperphagia.

TABLE III Pathological Conditions in Which GRP May Be Involved

Cancer autocrine growth factor
Small cell and non-small-cell lung cancer
Prostate cancer
Neuroblastomas
Squamous cell carcinoma of head and neck
Renal cell carcinomas
Breast cancer
Gastric adenocarcinomas
Pancreatic adenocarcinomas
Astrocyte–glial brain tumors
Colon cancer—? Growth factor or morphogen
Feeding/body weight abnormalities
Lung diseases
Hyperoxic lung injury
Bronchopulmonary dysplasia
Tobacco-related injury
Intestinal microcirculation after ischemia–reperfusion

In 1985, GRP-related peptides were shown to be an autocrine growth factor in human small cell lung cancer. Not only did small cell lung cancer secrete GRP-related peptides, the tumors possess GRP-R and its activation stimulated the growth of the tumor cells, which could be blocked by a neutralizing antibody to bombesin or GRP's carboxyl-terminus, the biologically active portion. Subsequent studies demonstrated that a large number of different tumors possess GRP-R or GRP/bombesin and these could be a growth stimulant for prostate cancer, neuroblastomas, astrocytic–glial brain tumors, squamous cell carcinoma of the head and neck, some renal cell carcinomas, breast cancers, gastric adenocarcinomas, and some pancreatic adenocarcinomas (Table III). In one recent study of 161 human tumors, 100% of the prostate cancers ($n = 12$), 100% of gastrinomas ($n = 5$), 72% of breast cancers ($n = 57$), 38% of renal cell cancers ($n = 16$), 33% of small cell lung cancers ($n = 9$), and 0% of intestinal carcinoid tumors ($n = 24$) expressed GRP-R that could be detected by autoradiographic studies. *In vitro* GRP-R antagonists or GRP neutralizing antibodies inhibit the growth of many of these tumors and have raised the possibility that such treatment might be effective in patients with these malignancies; however, few studies have been carried out to date. In one study, 13 patients with small cell lung cancer were treated with a monoclonal antibody (2All) that neutralizes GRP's action over 1 h, three times a week for 4 weeks. One of 12 (8%) evaluable patients had a complete resolution of radiographically detectable tumor lasting 4 months and 4/12 (33%) had stable disease. Whether this approach, which requires large amounts of GRP antibody or the use of GRP receptor antagonists, will be a useful therapeutic approach for these tumors is at present unclear.

The exact role of GRP-R in tumor growth has recently been raised from studies primarily of human colonic adenocarcinomas. Colon cancers ectopically express GRP-Rs and GRP has been shown in some studies to stimulate their growth. In one study, 84% of human colon cancers aberrantly expressed GRP or GRP-R with 62% expressing both the ligand and receptor, whereas expression was not observed in adjacent normal mucosa. However, GRP/GRP-R co-expression was seen equally frequently in stage A or D cancers and was rarely

detected in metastases. Furthermore, no difference in survival occurred in patients expressing or not expressing cancers with GRP/GRP-R. In fact, GRP/GRP-R was found exclusively in well-differentiated regions of the colon cancers. From these observations, it has been proposed that GRP is unlikely to be a clinically significant growth factor in human colon cancer but instead functions as a differentiation factor or morphogen. From these studies and a review of GRP/GRP-R expression in a variety of tumors, it has been proposed that GRP and GRP-R are likely onco-fetal antigens whose reexpression in these tumors reflects a recapitulation of their normal role in regulatory organogenesis.

Because many tumors overexpress GRP-R, the possibility of imaging tumors using radiolabeled GRP analogues or using cytotoxic GRP conjugates to target an antitumor treatment is receiving considerable attention. Cytotoxic GRP analogues such as AN-215, which consists of a GRP analogue (20−27) linked to 2 pyrrolino-doxorubicin-14−0-hemiglutarate, have been shown *in vitro* to inhibit growth of pancreatic cancers, lung cancers, prostate cancers, and gastric cancers. In a study of pancreatic cancers in golden hamsters, the cytotoxic GRP analogue AN-215 had significant antitumor activity and lower toxicity than the unconjugated cytotoxic radical. Recent studies have also reported the development of 99m techneticum (Tc)-labeled GRP analogues that can be used to image GRP-R-overexpressing tumors. In two phase 1 studies, 99m Tc-GRP analogues are reported to image small cell lung cancer, prostate cancer, and breast cancer in patients. In addition, biologically active GRP analogues have recently been reported with an attached chelator group that can bind various radionuclides with high affinity. This strategy to develop analogues that can image tumors overexpressing receptors as well as deliver receptor-targeted radionuclide therapy has been extensively investigated with analogues of somatostatin for the treatment of human neuroendocrine tumors. Using a similar approach, diethylenetriaminepentaacetic acid GRP conjugates that efficiently couple ^{111}In have been reported. ^{111}In is a γ and auger electron emitter and can be used for imaging tumors as well as for cytotoxicity. Also, dodecanetretraacetic acid GRP analogues that couple more efficiently β-emitters such as ^{90}Y and may be more effective for GRP-targeted radiotherapy have been synthesized. At present, the usefulness of these GRP analogues for imaging tumors or for delivering receptor−target cytotoxicity has not been established.

GRP is the major endogenous peptide implicated in promoting growth and maturation during fetal lung development in humans, rats, and mice. Not only does administration of GRP-related peptides in fetal mice increase cell proliferation and differentiation, administration of GRP-R neutralizing antibodies inhibits lung differentiation. During lung development, GRP is found in pulmonary neuroendocrine cells (PNECs). Numerous studies have demonstrated that lung injury in adult animals, whether it is caused by smoke inhalation, asbestos, or other causes, leads to hyperplasia of PNEC with resultant increases in the levels of GRP-related peptides. Using a baboon model of bronchopulmonary dysplasia (BPD), GRP-related peptides were shown to mediate the lung injury. In this postnatal model, GRP-like peptides acted as proinflammatory mediators of BPD and the use of GRP neutralizing antibodies markedly decreased the severity of the chronic lung disease. It has been proposed that one of the important differences between smokers who develop lung disease and those who do not develop lung disease may be the response of their PNECs in releasing GRP-like peptides and other growth factors when exposed to cigarette smoke.

Gastritis

MARK FELDMAN
University of Texas Southwestern Medical School at Dallas and Presbyterian Hospital of Dallas

achlorhydria The inability of the stomach to produce any hydrochloric acid.
gastritis A disorder of the stomach characterized by acute and/or chronic inflammation of the mucosal lining.

The term gastritis refers to a group of diseases that have in common the symptom of inflammation of the stomach. In most cases, the inflammation exclusively or predominately involves the gastric mucosal lining. By definition, a gastric biopsy is required to diagnose gastritis.

CLASSIFICATION AND ETIOLOGY

There is only a modest correlation between gastritis and symptoms such as pain and nausea. In fact, many patients with gastritis have no symptoms referable to the stomach. A classification of gastritis is presented in Table I.

By far, the most common category worldwide is infectious gastritis. *Helicobacter pylori* infection accounts for the majority of cases of gastritis. Cytomegalovirus (CMV) gastritis is most typically seen in immunocompromised patients, such as patients with the acquired immunodeficiency syndrome, patients with organ transplants receiving immunosuppressive drugs, and patients with hematologic malignancies, many of whom receive chemotherapy agents.

ASSOCIATIONS WITH OTHER DISEASES

Certain types of chronic gastritis are associated with an increased risk of cancer. For example, *H. pylori* gastritis is a risk factor for both gastric adenocarcinoma and B-cell gastric mucosa-associated lymphoid tissue lymphoma. Lymphocytic gastritis, which can be associated with *H. pylori* infection or with celiac sprue, may be a precursor of gastric lymphoma. Autoimmune atrophic gastritis is associated with an increased risk of gastric adenocarcinoma, possibly as a consequence of gastric achlorhydria and bacterial overgrowth of the stomach. Patients with autoimmune atrophic gastritis also frequently have reduced intrinsic factor secretion and may develop cobalamin (vitamin B12) deficiency, with hematological sequelae (pernicious anemia) and neurological consequences (optic neuropathy, dementia, subacute combined degeneration of the spinal cord).

Gastrinoma

PAUL N. MATON
Digestive Disease Specialists Incorporated, Oklahoma City

enterochromaffin-like cells Gastric fundic mucosa cells that release histamine in response to gastrin and other stimuli.

multiple endocrine neoplasia type 1 Autosomal dominant condition that is characterized by the development of hyperparathyroidism and pancreatic and pituitary endocrine tumors.

neuroendocrine tumors Growths that may occur in many tissues throughout the body; produce a variety of peptides and other agents, some of which are biologically active and produce distinctive hormonal syndromes.

octreotide Synthetic peptide that is related to the naturally occurring peptide somatostatin; has therapeutic uses and can be radiolabeled for use as a diagnostic agent.

secretin Naturally occurring peptide that is found in the duodenum; useful as a diagnostic test in gastrinoma.

Zollinger–Ellison syndrome Clinical syndrome defined by two physicians in 1995; described symptoms of two patients with severe ulcer disease, massive gastric acid hypersecretion, and islet cell tumors. This term has become synonymous with the clinical features of all gastrinomas.

Gastrinomas are tumors that produce and secrete a peptide, gastrin. Gastrinomas are a type of neuroendocrine tumor and usually arise near the pancreas. They may be benign or malignant; tumor growth and spread my cause direct effects, but the clinical effects are primarily due to the release of gastrin, which stimulates the production of large amounts of acid by the stomach. The definition of gastrinomas is restricted here to tumors that release gastrin into the circulation. Other neuroendocrine tumors may contain immunoreactive gastrin but release no biologically active peptide.

TUMOR BIOLOGY

Secretion of Gastrin

Gastrin is released into the circulation in normal individuals. Physiologically, gastrin is a mixture of two peptides, one of 17 amino acid residues and the other of 34 amino acid residues, with similar actions. Gastrin is released from the gastrin-producing cells (G cells) of the gastric antral and duodenal mucosa by various physiological stimuli, mainly the ingestion of food. In normal individuals, gastrin is carried in the circulation to the enterochromaffin-like (ECL) cells in the gastric body. Stimulated by gastrin, ECL cells release histamine, which acts on the parietal cells (the acid-producing cells) to stimulate acid secretion. The acid released into the gastric lumen subsequently comes into contact with the G cells in the gastric glands of the antrum and switches off gastrin release. There is thus a negative feed back control on gastrin release such that gastrin release is phasic and limited.

Gastrinomas are not subject to physiological control and thus patients with gastrinomas suffer the effects of continuously high circulating concentrations of gastrin. Gastrins secreted by gastrinomas are more heterogeneous compared to the physiological forms. Nevertheless, those that contain the C-terminal tetrapeptide sequence can interact with the gastrin receptor and are fully biologically active. These forms are also measured in the generally used gastrin radioimmunoassays. The main short-term effect of gastrin is to stimulate gastric acid secretion, and patients with gastrinomas have markedly increased acid output. Normal basal acid outputs are up to 4 mEq/hour in women and up to 7 mEq/hour in men. Patients with gastrinomas typically secrete more than 15 mEq/hour and often much more. This increased acid secretion in these patients initiates many of the clinical manifestations that result in the Zollinger–Ellison syndrome. This syndrome was described in 1955 as a triad of severe peptic ulcer disease, massive acid hypersecretion, and an islet cell tumor of the pancreas. Although it is now known that none of these is necessarily part of the syndrome of gastrinomas, the term has been retained.

Gastric acid hypersecretion can result in ulcer disease in the absence of gastric infection with *Helicobacter pylori* or ingestion of nonsteroidal antiinflammatory drugs. The ulcer disease may be extremely severe. Initial descriptions included multiple ulcers in unusual sites such as the distal duodenum, jejunum, and esophagus. Furthermore, bleeding and perforation are frequent. Indeed, in the years between the first description of

 Copyright 2004, Elsevier (USA). All rights reserved.

the syndrome and the advent of histamine-2 (H2) receptor antagonists, the complications of ulcer disease were responsible for 60–80% of the deaths due to gastrinomas. Probably due in part to the availability of anti-secretory drugs, ulcer disease even at presentation is typically less severe now, and patients are likely to have a single typical bulbar ulcer.

Increased gastric acid secretion has other effects within the gastrointestinal tract. The increase in acid secretion, accompanied by a corresponding increase in fluid secretion, may result in a secretory diarrhea. Indeed, some 25% of patients with gastrinomas present with diarrhea and never have any ulcer disease. The large amounts of acid may overcome the buffering capacity of the upper intestine and may inactivate pancreatic enzymes, resulting in malabsorption. Likewise, bile acids (particularly the glycine conjugates) may be precipitated, contributing to the steatorrhea. Gastric acid may also directly damage the intestinal mucosa and interfere with absorption. Patients have been described with vitamin B_{12} malabsorption, suggesting that even the terminal ileum may be damaged in some cases.

Gastrin has other long-term effects that are responsible for some of the clinical manifestations of Zollinger–Ellison syndrome. Gastrin is trophic to the gastric mucosa. There is an increase in the number of parietal cells, resulting in an increase in the maximal acid output, up to three or more times the upper limit of normal (20–50 mEq/hour). Gastrin also has marked trophic effects on the gastric ECL cells, causing ECL cell hypertrophy. This can progress to the development of ECL cell carcinoid tumors in some cases.

Although gastrin does not cause increase in numbers of cells in other gastrointestinal or extraintestinal tissues, it can cause increased cell turnover as measured by increased DNA synthesis. The mucosa of the colon is influenced in this way. This has led to the investigation of hypergastrinemia as an increased the risk for colon polyps and colon cancer. The studies suggest that there is no large effect, but a modest effect cannot be excluded.

Cell of Origin

Although gastrinomas were originally classed as islet cell tumors, normal G cells occur in the human pancreas only in embryonic life. A majority of the G cells occur in the gastric antrum and duodenum. In the antrum, they are found in the deeper parts of the gastric glands. In the duodenum, they occur in the crypts and Brunner's glands. If G cells are in sites where acid cannot reach the membrane of the cell, then those cells are not subject to physiological control. Thus, a nest of normal G cells protected from acid by an embryological accident or surgery could in theory give rise to the Zollinger–Ellison syndrome. However, studies suggest that at least in sporadic Zollinger–Ellison syndrome there is always a distinct gastrin-producing tumor.

For many years it was thought that most gastrinomas arose within the pancreas. However, it has become clear that in fact only a minority are pancreatic. This knowledge has come about in part through increasingly detailed prospective imaging studies, but mainly through the extremely detailed exploratory surgery performed by a small number of surgeons. Such studies have shown that patients may be cured of their disease by resection of extrapancreatic gastrinomas.

It had been known for many years that Zollinger–Ellison syndrome (and thus gastrinomas) occurred in two circumstances. In the majority of patients, Zollinger–Ellison syndrome occurs as an isolated disease. These patients have no family history and no other endocrine diseases. However, about 20–30% of patients with Zollinger–Ellison syndrome come from families in which a variety of endocrine diseases occur in each generation. These families have multiple endocrine neoplasia type 1 (MEN 1), an autosomal dominant disease in which >90% of affected individuals develop hyperparathyroidism, 66% develop Zollinger–Ellison syndrome, and smaller percentages develop other pancreatic endocrine tumors and pituitary tumors. Studies around 1990 demonstrated differences in site of origin in gastrinomas in patients with MEN 1 compared to gastrinomas in sporadic Zollinger–Ellison syndrome, and it was shown that these differences have implications for management.

In patients with sporadic gastrinomas, the tumors are nearly always solitary. About 40% occur in the mucosa of the duodenum, another 40% arise in the pancreas, 10–20% arise in peripancreatic lymph nodes, and 5% arise in other sites. Primary gastrinomas have been described in the liver, the bile duct, the jejunum, the kidney, the ovary, the heart, and the lung. Despite the fact that most G cells are in the stomach, gastric gastrinomas do not seem to occur.

In patients with Zollinger–Ellison syndrome and MEN 1, about 50% of gastrinomas are found in the mucosa of the duodenum. However, in contrast to sporadic duodenal gastrinomas, those in patients with MEN 1 are nearly always multiple and are distributed throughout the duodenum. In about 20% of cases the primary tumor is in peripancreatic lymph nodes, and in only 10% are primary tumors found in the pancreas. In 20% of patients with MEN 1 and Zollinger–Ellison syndrome, no gastrinoma can be found.

DNA Abnormalities in Gastrinomas

In recent years, much has been learned about abnormalities in DNA and the possible genesis of gastrinomas. Many of these insights have arisen from studies of patients with MEN 1. The genetic defect in MEN 1 is the loss of function of a single tumor suppressor gene on chromosome 11 at the 11q13 locus. In affected individuals, all cells are heterogeneous for this gene, with one functional copy and one defective copy. Different defects occur in different families.

In patients with MEN 1, analysis of the DNA of gastrinomas has demonstrated that in some, but not all, tumors, there is a loss of heterozygosity at the 11q13 gene locus, indicating that the sole functioning copy of the tumor suppressor gene has been rendered nonfunctional. In MEN 1 gastrinomas, mutations are found throughout the nine exons of the gene. Furthermore, not only do mutations differ in different individuals, but they also differ in different gastrinomas from the same individual.

Similar but different findings have been noted in sporadic gastrinomas. Deletions of the 11q13 locus are found in some but not all sporadic gastrinomas. Mutations include truncating, missense, and in-frame types. Unlike MEN 1 gastrinomas, most mutations in sporadic tumors occur between amino acid residues 66 and 163. In pancreatic and nodal gastrinomas, the mutations are commonly in exon 2, but mutations at this site are rare in duodenal tumors. In patients with sporadic tumors at more than one site, all the tumors have the same mutations, indicating that unlike MEN 1, the tumors in any one individual are monoclonal.

However, factors other than defects in the MEN 1 gene are important in gastrinoma development. In both sporadic and MEN 1 gastrinomas, only about 40% have abnormalities of the MEN 1 gene. Other defects have been found on chromosome 1, including aneuploidy and microsatellite instability, and in a study of various types of pancreatic endocrine tumors, defects were found on chromosomes 3, 11, 16, and 22. As yet no clinical correlations with allelic loss have been identified in gastrinomas or other pancreatic endocrine tumors.

Pathology

Gastrinomas may behave in a benign fashion or may be malignant and metastasize. In large series, approximately 30–50% metastasize. In some cases, the patient has had Zollinger–Ellison syndrome for many years and at surgery a single small tumor is found and resection results in cure. In other patients, there is a short history of <2 years and at presentation patients have disease metastatic to the liver. Initial metastases are to the lymph nodes, with subsequent spread to the liver and bone.

Gastrinomas that occur as part of MEN 1 appear to be malignant less often, compared to sporadic gastrinomas. However, malignant gastrinomas do occur in patients with MEN 1. In a recent study, 57 patients were followed for a mean period of 8 years. Hepatic metastases developed in 24%, with aggressive tumor growth in 13%. In general, liver metastases in patients with MEN 1 are associated with a long history of Zollinger–Ellison syndrome.

Histology

Histology of gastrinomas is typical for neuroendocrine tumors. Uniform cuboidal cells can be arranged in a solid nest of cells or in focal glandular, trabecular, or gyriform patterns. Histological features do not predict tumor behavior. Likewise, ultrastructural findings have not proved helpful. Gastrinomas usually, but not always, stain for gastrin. They generally also stain for neuron-specific enolase and for chromogranin A. In 20–50%, staining may also be positive for pancreatic polypeptide, glucagon, somatostatin, or ACTH.

Secretion of Other Products

At least 50% of sporadic gastrinomas contain other peptides as detected by immunoreactive staining. However, release of other peptides is less common and second endocrine syndromes are rare. The most frequently identified second peptides are chromogranins. The α and β chains of FSH are also released by some gastrinomas, as are motilin and pancreatic polypeptide. None of these peptides produces a second endocrine syndrome. About 4% of all sporadic gastrinomas and 17% of those with hepatic metastases secrete adrenocorticotropic hormone (ACTH), leading to the development of ectopic Cushing's syndrome. This is associated with a poor prognosis. Other peptides, including insulin and vasoactive intestinal peptide (VIP), are secreted much more rarely.

Gastrinomas may be only one type of endocrine tumor among many in a patient with MEN 1. It may thus be impossible in a patient with MEN 1 to be certain if the gastrinoma is secreting multiple peptides. These patients may have pancreatic tumors that secrete insulin, glucagon, pancreatic polypeptide, growth hormone-releasing hormone, or somatostatin. Furthermore, patients with MEN 1 may have circulating parathyroid hormone, or growth hormone, prolactin, follicle-stimulating hormone/luteinizing hormone (FSH/LH), or ACTH released from a pituitary tumor. Indeed,

Cushing's syndrome in a patient with Zollinger–Ellison syndrome and MEN 1 is more likely to be due to pituitary Cushing's than to ectopic ACTH production.

DIAGNOSIS OF ZOLLINGER–ELLISON SYNDROME

There are several steps in the diagnosis of a patient with Zollinger–Ellison syndrome. The most important step is to recognize that the patient may have the syndrome. Second, the diagnosis must be confirmed. Third, it is important to determine whether the patient has a sporadic gastrinoma or whether they have a gastrinoma as part of MEN 1. Finally, the site and extent of the gastrinoma need to be defined.

Clinical Features Suggesting Gastric Acid Hypersecretion and Zollinger–Ellison Syndrome

The features that suggest gastric acid hypersecretion are shown in Table I. Hypersecretion of acid gives rise to all the symptoms and clinical features in a patient with a gastrinoma unless the tumor is advanced. A duodenal ulcer is the commonest finding. Gastric ulcers do not occur in patients with gastrinoma. About 75% of patients present with abdominal pain with or without other symptoms. About 75% have diarrhea, 45% have heartburn, 17% experience weight loss, and only 5–10% have scarring of the esophagus or duodenum. About 25% have had gastrointestinal bleeding.

All members of families with MEN 1 are potentially at risk for gastrinoma. In most families, it is now possible to screen for the MEN 1 gene to determine whether an individual is affected. Most affected individuals will develop hyperparathyroidism first, but some develop Zollinger–Ellison syndrome or pituitary problems as the first manifestation. About 66% of patients with MEN 1 will develop gastrinoma at some stage.

Once the diagnosis of Zollinger–Ellison syndrome has been seriously entertained, the patient should have a fasting serum gastrin drawn and then be given 60–80 mg of a proton pump inhibitor per day while the rest of the work up is being performed.

TABLE I Clinical Features That Suggest Gastric Acid Hypersecretion

Recurrent or multiple duodenal ulcers
Helicobacter pylori negative?
No intake of nonsteroidal antinflammatory drugs?
Ulcers in unusual sites
Complicated ulcer disease with bleeding, perforation, or obstruction
Any patient who needs ulcer surgery
Large-volume nasogastric tube output after gastric surgery
Recurrent ulcers after surgery
Secretory diarrhea
Malabsorption
Family history of kidney stones, ulcers, and/or endocrinopathies
Ulcers and kidney stones
Thickened gastric mucosa seen on computer tomography scans or at endoscopy

Confirming the Diagnosis of Zollinger–Ellison Syndrome

To meet the criteria for Zollinger–Ellison syndrome, the patient should have hypergastrinemia and acid hypersecretion. A fasting measurement of serum gastrin is normally <100 pg/ml in the most commonly used immunoassay. The patient should be off all antisecretory medication, but care needs to be taken in doing this because a patient with Zollinger–Ellison syndrome can develop bleeding or a perforation in less than 48 hours off medication. Causes of hypergastrinemia are shown in Table II. If the gastrin concentration is >1000 pg/ml and gastric pH measured at endoscopy or by nasogastric aspiration is <2, then the diagnosis of Zollinger–Ellison syndrome is certain (if the patient does not have one of the very rare surgical causes of this combination—see later). In many patients with gastrinoma, however, the gastrin concentration is <1000 pg/ml, in which case gastric acid secretion must be measured. A nasogastric tube is placed in the dependent part of the stomach and the position is checked by recovery of >90% of 20 ml of water. Then gastric juice is aspirated in four 15-minute aliquots. Acid secretion is calculated from the titratable acidity (measured by back titration or calculated from standard tables) multiplied by the volume. Secretion of >15 mEq/hour (or >5 mEq/hour in a patient who has had a partial gastrectomy or a vagotomy) indicates gastric acid hypersecretion. Causes of gastric acid hypersecretion are shown in Table III. Mean acid outputs in a recent large series of patients with gastrinomas were 41 mEq/hour in patients with intact stomachs and 28 mEq/hour in patients with prior gastric surgery.

The only conditions that produce hypergastrinemia and hypersecretion of acid other than Zollinger–Ellison syndrome due to a gastrinoma are the retained gastric antrum syndrome, chronic partial gastric outlet obstruction, and, transiently, after massive small bowel resection. These conditions are generally easy to differentiate from gastrinoma.

The secretin test has been used in the past to help make the diagnosis of Zollinger–Ellison syndrome. The

TABLE II Causes of Hypergastrinemia

With hypochlorhydria	With normochlorhydria	With hyperchlorhydria
Gastric atrophy	Chronic renal failure	Zollinger–Ellison syndrome
Autoimmune (pernicious anemia)	*Helicobacter pylori* gastritis	Sporadic
Nonautoimmune (atrophic gastritis)	Vagotomy	As part of MEN 1
Helicobacter pylori-induced gastritis	Pheochromocytoma	Retained antrum syndrome
Chronic renal failure		Chronic gastric outlet obstruction
Proton pump therapy		Massive resection of small intestine (transient)
		Helicobacter pylori gastritis
		G cell hyperfunction

test involved administering a bolus of 2 IU/kg body weight of secretin in one arm and drawing blood from the other arm for serum gastrin assay at 15, 1, 2, 5, 10, and 20 minutes after injection. An increase in gastrin concentration of >200 pg/ml indicates Zollinger–Ellison syndrome. However, there is a 15% false negative rate, and false positives can also occur.

Diagnosis of the Type of Gastrinoma

Only about 25% of patients with gastrinoma will have MEN 1, and often this will be obvious. Most will have a family history or will have hyperparathyroidism or both (Table IV). However, sometimes Zollinger–Ellison syndrome may be the first manifestation, and occasionally there may be no family history. If there is any question as to whether the patient has MEN 1, plasma calcium and parathyroid hormone levels should be determined and imaging of the pituitary fossa should be done with magnetic resonance imaging (MRI). Plasma concentrations of prolactin, growth hormone, and LH/FSH should be measured.

Determination of Gastrinoma Localization and Spread

Many studies have examined the usefulness of a variety of imaging modalities for identifying the primary tumor and metastases. These include ultrasound, computer tomography (CT) scan, MRI scan, angiography, and portal venous sampling. Endoscopic ultrasound has not been subjected to a formal blinded trial. However, it is now clear that the single most useful imaging study is octreotide scanning. This is more sensitive and more specific than all the other modalities for detection of the primary tumor. Sensitivity is around 66% (less with smaller tumors and greater with larger tumors) and selectivity is 85%, with 12% false positives. Extraabdominal false positives can occur with thyroid disease, breast disease, and granulomatous disease. Within the abdomen, accessory spleens, previous operation sites, and renal parapelvic cysts may cause false positives. However, the only procedure more sensitive and specific than octreotide scanning is a very detailed laparotomy by an experienced surgeon (using Kocherization of the duodenum, intraoperative ultrasound, duodenal transillumination, and a duodenotomy).

For detection of metastases, octreotide scanning is also the best modality. Scanning detects more than 90% of hepatic metastases, whereas CT detects about 40% and MRI detects about 70%. Furthermore, octreotide is more specific than other modalities. In addition, octreotide scanning is the best modality for detection of bone metastases.

TABLE III Causes of Gastric Acid Hypersecretion

Idiopathic
Zollinger–Ellison syndrome
Sporadic
As part of MEN 1
Systemic mastocytosis
Retained antrum syndrome
Gastric outlet obstruction
Massive small bowel resection (transient)
Gastric carcinoid
Basophilic leukemia
Non-gastrin-producing ulcerogenic tumors

MANAGEMENT OF GASTRINOMA

In a patient with a gastrinoma, there are two management considerations. The first and most important is to control the acid hypersecretion. Once that has been achieved, treatment of the tumor should be considered.

Management of Gastric Acid Hypersecretion

Proton pump inhibitors have made the management of acid hypersecretion quite simple. Treatment with 60 mg/day of omeprazole or lansoprazole has been

TABLE IV Clinical Features That Suggest MEN 1

Family history of ulcer, kidney stones, and/or endocrinopathies
Past history of ulcers kidney stones and/or endocrinopathies
Hyperparathyroidism (>90%)
Islet cell tumors

Insulinoma
Nonfunctioning
Others
Pituitary tumors
Nonfunctioning
Acromegaly
Cushing's disease
Prolactinoma
Tumors producing follicle-stimulating hormone/ luteinizing hormone
Adrenal hyperplasia (usually nonfunctioning)
Multiple lipomas

shown to be a safe initial approach in virtually every patient with a gastrinoma. Fewer data are available for the other proton pump inhibitors, but 40–160 mg of pantoprazole or 60–120 mg of rabeprazole is sufficient, and 80 mg of esomeprazole will certainly be effective. However, the adequacy of acid control should be checked by the measurement of gastric acid output in the last hour before the next dose of drug. Output should be <10 mEq/hour in patients who have not had previous gastric surgery, <5 mEq/hour in patients who have had a vagotomy, and <1 mEq/hour in patients who have had a partial gastrectomy. In the latter patients, adequacy of therapy should also be confirmed by endoscopy. In patients with normal anatomy, drug dose can probably be slowly reduced over weeks or months if acid output is monitored carefully.

For patients who are unable to take oral medication, intravenous pantoprazole (80 mg every 12 hours, or occasionally every 8 hours) will control acid hypersecretion safely in all patients. This is therefore the best option in the perioperative period or if patients are vomiting.

The role of surgery to control acid hypersecretion is now mainly of historic interest. A total gastrectomy is rarely indicated and a partial gastrectomy is dangerous in these patients and should never be performed. A highly selective vagotomy has been shown to reduce drug requirements in patients for whom a surgical cure is not possible. A parathyroidectomy is very useful for patients with a gastrinoma and hyperparathyroidism. If such patients are rendered normocalcemic, acid output and serum gastrin will fall, sometimes to within normal limits.

Management of Tumor Growth and Spread

Localized Sporadic Gastrinomas

Patients with sporadic gastrinomas that are localized are potential candidates for surgical cure. Sporadic gastrinomas are usually single and experienced surgeons can now expect to find gastrinomas even when imaging studies are negative. In a recent series, tumors were found in the last 83 patients that were operated on. Patients with sporadic gastrinoma that has metastasized to local lymph nodes are also candidates for surgery. Life table analysis of such patients shows that such patients have a life expectancy of >80% over 10 years, which is not different from those who are cured by surgery.

Localized Gastrinoma in Patients with MEN 1

Patients with MEN 1 and localized gastrinomas are not generally candidates for surgery. These patients have multiple tumors and are not curable. Furthermore, they may have other types of neuroendocrine tumors that may produce peptides or be nonfunctioning. Thus, it may not be clear at surgery whether the tumors removed are indeed gastrinomas. At one major center, patients with MEN 1 were operated on if there were no hepatic metastases and one or more tumors were >2.5 cm in diameter. The rationale was that in other neuroendocrine tumors the propensity to metastasize is related to the size of the primary. At surgery, most of these patients had multiple tumors and 70% had tumors in lymph nodes. A small percentage of those operated on were found unexpectedly to have a tumor in the liver. None of the patients operated on was cured, and the 15-year survival in those patients with liver tumor was 52%. However, the 90% survival rate in the others was similar survival of patients with no tumor identified or with small tumors. It was concluded that surgery was useful in patients with MEN 1 and large localized tumors.

Metastatic Gastrinoma

Patients with metastatic gastrinoma have a reduced life expectancy. In one large survey, the 15-year survival rate in patients with localized tumor was 93%, the survival rate in those who developed hepatic metastases after diagnosis was 68%, and in those who presented with hepatic metastases the 10-year survival was 26%. Patients with metastases beyond the liver had a shorter survival rate. Overall, 10-year survival in those with liver metastases alone was 82% and in those with liver and bony metastases 20%. Some of these patients have undergone resection of localized hepatic metastases. Others have received chemotherapy, interferon α, or octreotide or had embolization of the liver or a combination of these. None of these approaches has proved

efficacious. Clearly, it is important to identify patients with gastrinomas before they metastasize to the liver. The recent report suggesting that the widespread use of proton pump inhibitors has led to delay in the diagnosis of Zollinger–Ellison syndrome is cause for concern.

MANAGEMENT OF OTHER ISSUES IN PATIENTS WITH GASTRINOMAS AND MEN 1

Patients with MEN 1 may have complex problems concerning pituitary tumors that may be functioning or non-functioning. They may also have a variety of problems related to the different types of pancreatic islet cell tumors that may occur. Although these issues are outside the scope of this article, two problems are of concern with respect to the gastrinoma.

As mentioned above, hyperparathyroidism exaggerates the hypergastrinemia and hyperacidity, and correction of the hyperparathyroidism lowers both acid and gastrin. These patients require either a subtotal parathyroidectomy or total parathyroidectomy with an implant placed in the forearm. Otherwise, recurrent hyperparathyroidism is almost universal.

Gastric ECL cell carcinoid tumors occur in up to 30% of patients with gastrinomas and MEN 1, but are much rarer in patients with sporadic gastrinomas. Gastrin is trophic to the ECL cells, and ECL cell carcinoids occur in other hypergastrinemic states, including pernicious anemia. However, in patients with MEN 1, the ECL cell carcinoids demonstrate loss of heterozygosity of the tumor suppressor gene at the 11q locus and thus share this abnormality with other neuroendocrine tumors in patients with MEN 1. Gastric ECL cell carcinoid tumors may be multiple but are usually benign and generally require no therapy. Antral carcinoids also occur in patients with Zollinger–Ellison syndrome and MEN 1, but these have the characteristics of sporadic carcinoids.

Gastritis

MARK FELDMAN
University of Texas Southwestern Medical School at Dallas and Presbyterian Hospital of Dallas

achlorhydria The inability of the stomach to produce any hydrochloric acid.
gastritis A disorder of the stomach characterized by acute and/or chronic inflammation of the mucosal lining.

The term gastritis refers to a group of diseases that have in common the symptom of inflammation of the stomach. In most cases, the inflammation exclusively or predominately involves the gastric mucosal lining. By definition, a gastric biopsy is required to diagnose gastritis.

CLASSIFICATION AND ETIOLOGY

There is only a modest correlation between gastritis and symptoms such as pain and nausea. In fact, many patients with gastritis have no symptoms referable to the stomach. A classification of gastritis is presented in Table I.

By far, the most common category worldwide is infectious gastritis. *Helicobacter pylori* infection accounts for the majority of cases of gastritis. Cytomegalovirus (CMV) gastritis is most typically seen in immunocompromised patients, such as patients with the acquired immunodeficiency syndrome, patients with organ transplants receiving immunosuppressive drugs, and patients with hematologic malignancies, many of whom receive chemotherapy agents.

ASSOCIATIONS WITH OTHER DISEASES

Certain types of chronic gastritis are associated with an increased risk of cancer. For example, *H. pylori* gastritis is a risk factor for both gastric adenocarcinoma and B-cell gastric mucosa-associated lymphoid tissue lymphoma. Lymphocytic gastritis, which can be associated with *H. pylori* infection or with celiac sprue, may be a precursor of gastric lymphoma. Autoimmune atrophic gastritis is associated with an increased risk of gastric adenocarcinoma, possibly as a consequence of gastric achlorhydria and bacterial overgrowth of the stomach. Patients with autoimmune atrophic gastritis also frequently have reduced intrinsic factor secretion and may develop cobalamin (vitamin B12) deficiency, with hematological sequelae (pernicious anemia) and neurological consequences (optic neuropathy, dementia, subacute combined degeneration of the spinal cord).

TABLE I Classification of Gastritis

Infectious gastritis
Bacterial
Helicobacter pylori
Mycobacterium tuberculosis or *M. avium/ M. intracellulare* complex
Treponema pallidum (syphilis)
Others (rare)
Viral
Cytomegalovirus
Herpes simplex virus (rare)
Varicella/zoster virus (rare)
Others (rare)
Fungi
Candida albicans and other *Candida* species
Others (rare)
Parasites (rare)
Granulomatous gastritis (noninfectious)
Crohn's disease
Sarcoidosis
Others (rare)
Idiopathic (rare)
Distinctive forms of gastritis (based on microscopic appearance)
Eosinophilic
Collagenous (rare)
Lymphocytic
Graft-versus-host disease
Gastritis cystica profunda (rare)
Autoimmune gastritis
Atrophic
Others

Note. Common forms of gastritis are shown in boldface type.

EOSINOPHILIC GASTRITIS

Eosinophilic gastritis is a relatively uncommon condition of uncertain etiology characterized by peripheral eosinophilia, eosinophilic infiltration of the gastrointestinal tract, and upper gastrointestinal symptomatology. Eosinophilic gastritis is classified according to the layer of gastrointestinal tract involved (i.e., mucosal disease, muscle layer disease, and subserosal disease). Patients with mucosal involvement present symptoms similar to those of other patients with gastritis. Patients with muscle layer disease generally have pyloric obstruction and related symptoms such as nausea, vomiting, and early satiety. Patients with subserosal eosinophilic infiltration develop eosinophilic ascites. Individuals with eosinophilic gastritis often have food allergies and other allergic manifestations. Other parts of the gastrointestinal tract can be involved, such as the small intestine or colon. Eosinophilic gastritis typically responds to therapy with oral glucocorticoids.

THERAPY

Treatment of other forms of gastritis depends upon the underlying etiology (e.g., broad-spectrum antibiotics plus a proton pump inhibitor for *H. pylori* gastritis, gancyclovir for CMV gastritis, penicillin for syphilitic gastritis, and corticosteroids and/or other anti-inflammatory drugs for Crohn's disease or sarcoidosis).

gastritis Inflammation of the mucous membrane of the stomach.

Helicobacter pylori A bacterium that can cause a transmissible infection of the gastric mucosal surface.

ulcer A break in the lining of the stomach, duodenum, or esophagus, where hydrochloric acid and pepsin are present is known as a peptic ulcer. Ulcers formed in the stomach are known as gastric or stomach ulcers.

Peptic ulcer disease affects 5 million Americans yearly and is a significant cause of morbidity in the United States. The economic cost of this disease now exceeds $4 billion annually. The recent literature suggests that *Helicobacter pylori* plays a major role in the pathogenesis of this disease and a significant correlation between the presence of *H. pylori* and histologic gastritis, duodenal ulcers, and gastric cancer has now been established. Since its first isolation 22 years ago, *H. pylori* infection continues to generate considerable interest in the medical and scientific community. Today, *H. pylori* is considered one of the most common bacterial infections of mankind, infecting nearly one-half of the world's population. Despite this worldwide distribution, the pathogenesis of *H. pylori*-associated gastroduodenal disease remains poorly understood. What is clear is that *H. pylori* infection rarely resolves spontaneously and that the chronic gastritis that accompanies infection plays an etiologic role in the development of peptic ulcer disease and gastric cancer. Evidence confirming that *H. pylori* infection plays a role in the pathogenesis of peptic ulcers comes from clinical studies demonstrating a significant reduction in ulcer relapse rates if the affected patient is cured of the *H. pylori* infection. Similarly, a number of epidemiological studies have demonstrated that chronic *H. pylori* infection can ultimately predispose an individual to a significantly increased risk of developing gastric cancer. These studies were so compelling that the World Health Organization has classified *H. pylori* as a type I human carcinogen.

INTRODUCTION

Effective antimicrobial therapies to treat *Helicobacter pylori* have been developed and, with proper compliance, are over 85% successful. However, individual and population-based problems with pharmaceutical treatment support a role for vaccination in the control of *H. pylori* infection. Current therapies require the patient to ingest multiple agents several times a day for at least 1 week. Treatment can be accompanied by nausea, diarrhea, abdominal pain, and pseudomembranous colitis. These adverse effects contribute to patient noncompliance and reduce the efficacy of the therapy. Additionally, these therapies are prohibitively expensive in developing nations where *H. pylori* infection is endemic, with rates of infection as high as 80–90%. Widespread treatment of *H. pylori* could also result in the development of antibiotic-resistant strains, which has already been observed in patients treated with triple therapy who failed to be cured of infection. Recent research has focused on preventing or curing the infection as well as identifying the mechanisms by which chronic *H. pylori* infection promotes the development of gastroduodenal disease; these findings will be summarized below.

Prior to the discovery of *H. pylori* by Marshall and Warren, a number of investigators identified "spirochetal" bacteria in the gastric mucosa of animal species and similar microorganisms were identified in human gastric tissue. Despite occasional reports documenting the presence of spiral microorganisms in association with the gastric mucosa, skepticism by the medical community was fueled by studies that were unable to confirm the presence of spiral organisms in human gastric tissue. In 1982, Marshall and Warren demonstrated an association between these microorganisms and gastroduodenal disease by culturing spiral *Campylobacter*-like organisms (later renamed *H. pylori*) from human gastric tissue. *H. pylori* is now routinely isolated from both adults and children with gastritis and peptic ulcer disease.

Support for a pathogenic role for *H. pylori* in humans initially came from independent studies performed by Marshall and Morris, who satisfied Koch's postulates by creating histologically confirmed gastritis following the ingestion of a suspension of viable organisms.

MICROBIOLOGY

Morphologically, *H. pylori* resemble the *Campylobacter* species and were initially called *Campylobacter*-like

 Copyright 2004, Elsevier (USA). All rights reserved.

organisms. The organism underwent a number of name changes including *Campylobacter pyloridis* and finally *Campylobacter pylori*. However, morphologic, biochemical, and genetic differences between these spiral organisms and other *Campylobacter* species were noted, indicating that these organisms were unique. Unlike most *Campylobacter* organisms, *H. pylori* has a smooth cell wall with multiple unipolar sheathed flagella. In addition to these morphological differences, *H. pylori* contains a number of enzymes, including a high concentration of urease, that are not present in other *Campylobacter* species. Accordingly, *C. pylori* was given a new genus and species name, *H. pylori*. *Helicobacter* organisms do not stain well with common histologic stains, such as hematoxylin and eosin, but can be demonstrated using silver containing stains, such as Warthin-Starry or Steiner stain.

CLINICAL FEATURES AND EPIDEMIOLOGY OF *H. PYLORI* DISEASE

H. pylori are most abundant in the mucus coat overlying the gastric epithelium and are rarely observed intracellularly. Thus, *H. pylori* infection is always associated with histologic gastritis, which is characterized by the presence of acute and chronic inflammation localized within the gastric antrum. Since the isolation and culture of *H. pylori* 22 years ago, the terms diffuse antral gastritis and multifocal atrophic gastritis have been introduced in an effort to explain the fundamental role that this organism plays in the development of gastroduodenal disease. According to the Sydney system for grading gastritis, individuals at risk for developing peptic ulcers (particularly duodenal ulcers) will develop diffuse antral gastritis, which is characterized by minimal inflammation within the fundus and little or no evidence of intestinal metaplasia within the antrum. In this situation, *H. pylori* can often be found in the duodenum, colonizing islands of gastric metaplasia that are present within the duodenum. Epidemiological studies have suggested that an individual with both *H. pylori* gastritis and gastric metaplasia of the duodenum has a 50-fold increased risk of developing a duodenal ulcer. The majority of patients diagnosed with peptic ulcer disease have evidence of *H. pylori* infection. Finally, combinations of acid-suppressive drugs and antimicrobial agents not only eradicate *H. pylori* and heal duodenal ulcers, but markedly decrease the recurrence rate of duodenal ulcers. Twelve-month recurrence rates of $<10\%$ have been reported in patients successfully treated for *H. pylori* infection.

A number of epidemiological studies have also demonstrated that chronic long-lasting *H. pylori* infection, particularly when acquired in childhood, can significantly increase the risk of developing gastric cancer and/or mucosa-associated lymphoid tissue lymphoma. *H. pylori*-infected individuals at risk for the development of gastric adenocarcinoma usually develop multifocal atrophic gastritis, which is characterized by pangastritis and the presence of significant intestinal metaplasia. These studies were so compelling that the World Health Organization has recently classified *H. pylori* as a human carcinogen.

Most epidemiological studies of *H. pylori* infection have been performed in adults, who likely had been infected for decades before diagnosis. Studies from all continents have documented that the acquisition of *H. pylori* infection occurs primarily during childhood. It is now well established that the overwhelming majority of individuals in developing countries are infected with *H. pylori* during childhood. Data to support the early acquisition of *H. pylori* infection come from retrospective studies that estimate the incidence of new *H. pylori* infections to be 0.37% per patient year. At present, it is known that *H. pylori* infection clusters within families and that the acquisition of this infection is strongly linked to conditions associated with lower socioeconomic status during childhood, such as residential crowding. Observations such as these support the hypothesis of person-to-person transmission of *H. pylori* either via the oral–oral route or via the fecal–oral route. The oral–oral route of transmission is supported by isolated reports confirming the transmission of *H. pylori* from the use of contaminated endoscopes and pH probes. Furthermore, there have been reports confirming the presence of viable *H. pylori* organisms recovered from the oropharynx and dental plaque. Arguments for a fecal–oral route of transmission are based on studies confirming that viable *H. pylori* can be cultured from human feces. Water and pets have also been suggested to be environmental sources of *H. pylori* infection. Additional studies to determine the route of transmission of *H. pylori* are under way so that adequate preventive strategies for this extremely common infection of mankind can be developed.

ROLE OF *H. PYLORI* INFECTION IN CHILDREN WITH ULCERS AND GASTRITIS

Although all children infected with *H. pylori* appear to develop chronic active gastritis, the majority of these children are asymptomatic and never have clinically evident disease. Only a minority of children develop peptic ulceration or gastric cancer, the more severe

manifestations of *Helicobacter* infection. The only known risk factors for the acquisition of *H. pylori* in childhood are minimal education and low socioeconomic status. The association of *H. pylori* infection and recurrent abdominal pain in children is controversial. With the exception of one study by Chong and Lou in 1995, there does not appear to be an association between *H. pylori* infection and an increased prevalence of recurrent abdominal pain. Therefore, routine evaluation for *H. pylori* in patients without symptoms of peptic ulcer disease is not warranted. There is no clear evidence that treatment of *H. pylori* will alleviate symptoms in children who have *H. pylori* gastritis and recurrent abdominal pain.

BACTERIAL PATHOGENESIS

The entire *H. pylori* genome has now been sequenced. Analysis of the genome has lent support to previously described biochemical and physiological observations that led to the designation of the new *Helicobacter* genus. The genome sequence has also suggested the presence of several characteristics common to other mucosal pathogens, including systems for motility, iron scavenging, complex adhesin systems for host–pathogen interactions, and regulatory networks. Additionally, the genetic machinery is present not only for DNA restriction and modification but most probably to provide mechanisms of antigenic variation.

Several virulence factors of *H. pylori* that either play a direct role in the ability of the bacteria to colonize the gastric mucosa or may contribute to the pathogenesis of disease have now been identified. The enzyme urease, which gastric *Helicobacter* species produce in large quantities, is located on the bacterial surface and was one of the first colonization/virulence factors described. It has been suggested that urease, which hydrolyzes urea into CO_2 and NH_4OH, may allow *H. pylori* to survive in the highly acidic environment of the gastric lumen by surrounding itself with a "cloud" of ammonia. Studies in gnotobiotic pigs using a chemically induced urease-negative mutant of *H. pylori* demonstrated that urease is essential for the colonization of the gastric mucosa by *H. pylori*. The ammonia produced by the hydrolysis of urea may also have direct toxic effects on the gastric epithelium. Additionally, some strains of *H. pylori* produce a potent cytotoxin, VacA, which causes vacuolization of tissue culture cells and most likely causes epithelial damage *in vivo*. It is also likely that motility is important in allowing the organism to penetrate the gastric mucus and localize to the gastric epithelium. Recent studies in the pig model using isogenic flagellin knockout strains of *H. pylori* indicated that motility is involved in the virulence and pathogenesis of *H. pylori*. Although *H. pylori* is not generally considered to be an invasive pathogen, it does bind to gastric epithelium both *in vitro* and *in vivo*. There is growing evidence that one or more of a relatively large number of putative adhesins may be important in the pathogenesis of *H. pylori* infections.

In addition to the colonization factors listed above, it has been suggested that phenotypic or genotypic differences among bacterial isolates may be important in the progression of disease. Studies investigating differences among bacterial strains were prompted by observations indicating that although approximately 50% of the world's population is infected with *H. pylori*, less than 10% of the infected population appears to exhibit any disease symptoms. A 120 kDa protein originally identified by gastric immunoglobulin A (IgA) antibodies in infected subjects was found to be coexpressed in bacterial strains expressing large amounts of VacA and was subsequently named CagA (for cytotoxin-associated gene A). There is accumulating evidence that individuals infected with strains of *H. pylori* that express VacA and/or CagA are more likely to develop peptic ulcers or gastric cancer than are individuals who are infected with VacA- or CagA-negative strains. Studies examining the relationship between the presence of CagA and the expression of interleukin-8 (IL-8) by epithelial cells suggest that the CagA protein is a marker for a series of genes within an *H. pylori* "pathogenicity island." Other putative virulence genes have also been identified. *IceA*, an *H. pylori* gene induced by contact with the epithelium, is selectively up-regulated following contact with the gastric epithelium. Two distinct allelic families have been identified (*IceA*1, *IceA*2), with *IceA*1 being the predominant allele in *H. pylori* strains recovered from patients with peptic ulcer disease; it is also associated with increased mucosal concentrations of IL-8. Although these bacterial factors probably play important roles in the diseases associated with *H. pylori* infection, by themselves they cannot explain the observed variations in clinical outcome. Fifty percent or more of all *H. pylori* strains fall into the "type I" designation yet only a small minority of individuals infected with type I strains develop serious disease. Some researchers believe that the host response to infection also plays an important role in determining *H. pylori* disease outcome.

IMMUNE RESPONSES TO *H. PYLORI* INFECTION ARE NOT PROTECTIVE

The inflammatory infiltrate associated with *H. pylori* infection primarily affects the antral region of the

stomach and is accompanied by epithelial degenerative changes. Ultimately, the inflammation associated with *H. pylori* infection is characterized by the infiltration of polymorphonuclear cells and mononuclear cells into the gastric lamina propria and hyperproliferation of the gastric epithelium. The mononuclear cells consist primarily of IgA plasma cells, B cells, and $CD4^+$ T cells. Interestingly, organized lymphoid aggregates not generally seen in the normal stomach are also present in the submucosa and may in part explain the nodularity noted in the gastric antrum of children infected with *H. pylori*.

Since *H. pylori* is a noninvasive bacterium that resides in the gastric mucus, its exposure to immune effector mechanisms is minimal. However, it is able to induce an inflammatory response that cannot eliminate it. A prominent feature of this frustrated inflammatory response is the enhanced presence of IL-8, a neutrophil-activating chemokine, in the gastric mucosa of infected individuals. The recruitment of neutrophils to the lamina propria initiates a cascade of pro-inflammatory events that eventually results in chronic active gastritis. As mentioned above, *H. pylori* strains carrying a pathogenicity island that encodes factors that increase IL-8 production tend to be more inflammatory than those strains that lack the pathogenicity island.

In addition to initiating pro-inflammatory events in the gastric mucosa, *H. pylori* itself is somehow "seen" by the host immune system, which results in *H. pylori*-specific antibody and T-cell responses. It is well documented that infection with *H. pylori* is accompanied by both gastric and serum antibody responses and, as discussed below, the presence of *H. pylori*-specific serum antibodies is often used as an indicator of infection. Local, gastric antibodies have been observed to bind to *H. pylori* in immunohistochemical staining analysis yet the response does not clear the infection.

In 1990, it was demonstrated that the T cells from *H. pylori*-infected patients specifically proliferate in response to *H. pylori* antigens. However, subsequent studies have yielded conflicting results regarding the role of cell-mediated immune responses in *Helicobacter* infections. Although some investigators have detected a *Helicobacter*-specific cellular immune response in infected patients, other investigators have found that lymphocytes from both *H. pylori* seropositive and *H. pylori* seronegative individuals will proliferate *in vitro* in response to *Helicobacter* antigens. In the latter case, *H. pylori* seropositive patients sometimes actually show a decrease in responsiveness compared to *H. pylori* seronegative individuals. This had led to the suggestion that *H. pylori* may down-regulate the cellular immune response toward itself. Until recently, the T cells used in these proliferation studies have employed peripheral blood mononuclear cells. However, several investigators have now examined the local gastric T-cell responses from *H. pylori*-infected patients. The T cells isolated from gastric biopsies are predominantly interferon-γ (IFN-γ)-secreting cells. Since IFN-γ is a pro-inflammatory T helper 1 (T_H1)-type cytokine, it has been suggested that T-cell responses may actually play a role in the gastritis associated with *Helicobacter* infections.

The authors' laboratory has used murine models of *Helicobacter* infection to demonstrate that the host response plays a role in *Helicobacter*-associated pathogenesis. One murine model that has been used extensively to study host responses is the *H. felis* model described by Lee and colleagues. Despite the fact that *H. felis* apparently lacks the *cag* pathogenicity island, it does yield a vigorous inflammatory response in several strains of mice. A series of inbred strains of mice (BALB/c, C3H, C57BL/6, and MHC congenic partners on the BALB/c and C57BL/6 backgrounds) infected with a single strain of *H. felis* were studied. Following infection, these strains of mice exhibited differences in both the extent and magnitude of infection and the nature of the inflammation. The BALB/c background had minimal inflammatory responses after *Helicobacter* infection, but mice with a C57BL/6 background had more severe inflammation. In addition, C57BL/6 mice, like humans infected with *H. pylori*, also exhibited an inflammatory response that increased in severity over time. Additional studies examining the host inflammatory response to *Helicobacter* infection using congenic partners on the BALB/c and C57BL/6 backgrounds suggest that non-major histocompatibility complex (MHC) background genes play the major role in determining disease character. These results have been confirmed by others who have shown similar results with *H. pylori*. These results suggest that the nature of the host immune or inflammatory response is also important in determining disease outcome after *H. pylori* infection of humans.

Participation of both innate and adaptive immune mechanisms in the *H. felis*-associated gastritis model was shown by experiments performed in severe combined immunodeficiency (SCID) mice. The magnitude of the inflammatory response in SCID mice and that of wild-type immunocompetent control mice on a BALB/c background (a low inflammatory mouse strain) were comparable but low. However, when SCID mice on a C57BL/6 background were infected with *H. felis*, they demonstrated a much lower inflammatory response than the wild-type immunocompetent C57BL/6 mice (a high inflammatory mouse strain). In fact, the inflammation in the C57BL/6 SCID mice was equivalent to that in the BALB/c wild-type mice and the BALB/c SCID mice. These results demonstrate that the immune

response contributes to the observed differences in disease outcome among various strains of mice infected with *H. felis* and strongly suggest that the immune response contributes to the different clinical disease outcomes seen in humans chronically infected with *H. pylori*.

Either antibodies or cell-mediated immune responses could play a role in the disease process. A role for antibodies in exacerbating *Helicobacter*-associated gastritis was suggested by the discovery of anti-*Helicobacter* antibodies in *H. pylori*-positive patients and mice that were cross-reactive for antigens in the gastric mucosa. Recently, the autoantibody theory of *Helicobacter* pathogenesis has fallen out of favor. Studies using μMt mice infected with *H. felis* that demonstrated no reduction in gastric inflammation also tends to rule out a role for antibodies in the pathogenesis of this infectious disease.

As mentioned above, the T cells present in the inflammation associated with an *H. pylori* infection are primarily IFN-γ producers. These cells are generally believed to be pro-inflammatory in nature. The authors' experiments using the *H. felis* mouse model are consistent with these observations. Adoptive transfer of *Helicobacter*-specific T_H1 cells into mice results in increased inflammatory responses in the gastric mucosa following challenge with *H. felis*. The extent of the T-cell-mediated inflammation seems to be dictated by the genetics of the host. When Balb/c mice (T_H2 biased) and C57BL/6 mice (T_H1 biased) are infected with *Helicobacter* simultaneously, only the C57BL/6 mice will develop significant inflammation of the gastric mucosa. This difference is not due to MHC usage; by treating infected Balb/c mice with IL-12, a T_H1 regulatory cytokine, inflammation levels rise to those observed in C57BL/6 mice.

The authors' laboratory has also used the *H. felis* mouse model to further explore the role of T cells in *Helicobacter* immunity. It has been observed that, as in humans, splenic lymphocytes from both infected and naive mice exhibited significant proliferation in response to heat-killed antigens and that the T cells from these mice are predominantly IFN-γ secretors. When C57BL/6 mice (T_H1 bias) were infected with *H. felis*, the resulting *Helicobacter*-specific T cells were IFN-γ producers. The levels of IFN-γ produced correlated with the level of inflammation in individual mice. The magnitude of the inflammation was reduced if mice were treated with anti-IFN-γ antibodies. Additionally, when *H. felis*-specific T_H1-cell lines were adoptively transferred into recipient mice that were then infected with *H. felis*, the recipient animals demonstrated enhanced gastric inflammation. Thus, the mouse model supports the data from human studies indicating that an inflammatory T_H1 cellular immune response plays a role in the gastric inflammation observed in *Helicobacter*-infected individuals.

DIAGNOSTIC METHODS

Diagnosis of *H. pylori* infection can be accomplished by several different methods. Although *H. pylori* infection appears to be a chronic lifelong infection, there is a robust host systemic and mucosal humoral immune response to this organism. Therefore, serologic tests have now become the mainstay for noninvasive screening diagnosis of this infection. Commercially available serologic tests can now be performed in a central laboratory, on whole blood using a rapid office-based test, and there are even suggestions that the serologic diagnosis can be made by screening saliva. All of these tests appear to be capable of initially diagnosing an *H. pylori* infection but have limited ability to confirm a cure. Histologic demonstration of *H. pylori* initially was dependent on silver staining (Warthin-Starry) techniques. Using this time-consuming, expensive, and technically difficult technique, spiral microorganisms can be seen clearly in the mucus coat overlying the gastric epithelium. Although the Gram stain is a simple and rapid technique, it is not recommended for *H. pylori* since these gram-negative rods stain poorly and are difficult to visualize. A number of other stains have been evaluated, including Giemsa, phase contrast, acridine orange, Brown-Hopps, and Genta stain, in an effort to develop a cost-effective and reproducible stain to identify *H. pylori* in human tissue.

Since *H. pylori* produces a large amount of urease, the immediate placement of biopsy material into urea-containing broth or agar yields an immediate (within 2 h) color change from yellow to pink, allowing rapid identification. Additional diagnostic techniques have been developed in an attempt to eliminate the need for endoscopy and biopsy. The stable isotopic ^{13}C nonradioactive urea breath test has been used diagnostically since urease is not present in mammalian gastric cells. The recovery of labeled $^{13}CO_2$ in exhaled air following the ingestion of stably labeled urea indicates *H. pylori* infection. The breath test is a useful, noninvasive, nonradioactive means of diagnosing *H. pylori* gastroduodenal disease.

As noted above, several enzyme-linked immunosorbent assay-based commercial kits that measure anti-*H. pylori* serum IgG antibody titers in adults. When used in children, the sensitivity and specificity of these tests is quite variable and seems to depend a great deal on the test used. Children under the age of

12 years also seem to have more false-negative serologies. Therefore, a negative serology does not rule out infection in young children. In children, the [^{28}C]urea breath test may offer some important advantages over the serologic tests. It is noninvasive, easily performed, and easily repeated in order to evaluate response to treatment. This test measures the actual bacterial colonization in gastric mucosa. However, this test is currently not validated or approved by the Food and Drug Administration (FDA) for use in children. Recently, guidelines for the diagnosis and treatment of *H. pylori* infection in children were endorsed by the Academy of Pediatrics and published. Based on the current available data, the use of serology or a urea breath test for the diagnosis of *H. pylori* infection in children is not recommended. These guidelines recommend endoscopy with biopsy for the evaluation of children with symptoms consistent with peptic ulcer disease. The purpose of the endoscopy is to identify organic etiologies for the dyspepsia, not simply to screen for *H. pylori*.

TREATMENT

Despite the fact that the National Institutes of Health consensus conference and numerous authorities all agree that patients with *H. pylori* infection and peptic ulcers should receive therapy targeted at eradicating the *H. pylori* infection, no therapeutic combinations were officially approved by the FDA until recently. However, the FDA has now officially approved a number of therapies for the treatment of *H. pylori*-associated peptic ulcer disease in adults. Specifically, a combination of clarithromycin 500 mg tid and omeprazole 40 mg qid for 2 weeks followed by 2 additional weeks of omeprazole therapy or a second combination of clarithromycin 500 mg tid and ranitidine/bismuth citrate 400 mg bid for 4 weeks has received approval. Finally, a PeptoBismol/metronidazole/tetracycline triple therapy has also been approved by the FDA for the eradication of *H. pylori* infection. Despite these approvals, numerous research groups continue to search for therapies giving better eradication rates. The addition of metronidazole to the omeprazole/claritromycin dual therapy appears to be superior and may allow physicians to shorten the length of therapy.

Compliance is a very important factor in achieving eradication of *H. pylori* in children. Several regimens were published, including 1-week therapy with colloidal bismuth subcitrate, clarithromycin, and metronidazole (eradication in 21 of 22 subjects) or 1-week treatment with lansoprazole, amoxicillin, and clarithromycin. The latter study had an eradication rate of 87%. Treatment for a 2-week period with metronidazole, clarithromycin, and omeprazole was successful in 93% of the children treated. Although concerns about the use of bismuth salts in children have been expressed, none of the potential side effects have been reported when used for the treatment of *H. pylori* in children. Table I summarizes the recommended eradication therapies for *H. pylori*-associated disease in children.

TABLE I Recommended Eradication Therapies for *Helicobacter pylori*-Associated Disease in Children

Medication	Dose mg/kg/day bid	Duration of treatment
Amoxicillin	50	14 days
Clarithromycin	15	14 days
Proton pump inhibitor	1	1 month
Amoxicillin	50	14 days
Metronidazole	20	14 days
Proton pump inhibitor	1	1 month
Clarithromycin	15	14 days
Metronidazole	20	14 days
Proton pump inhibitor	1	1 month

Unfortunately, attempts to cure large populations of individuals infected with *H. pylori* has led to the acquisition of antimicrobial resistance. A large number of *H. pylori* clinical isolates have acquired resistance to clarithromycin and metronidiazole. Drug therapies for eradication of *H. pylori* from the gastrointestinal tract continue to have a number of limitations, including poor compliance, adverse side effects, and antimicrobial resistance. Therefore, a number of laboratories began to investigate the possibility of developing a vaccine to prevent *H. pylori* infection. The results of this work have not only demonstrated the feasibility of a prophylactic vaccine, but have also demonstrated the feasibility of a therapeutic vaccine that is capable of curing patients already infected with *H. pylori*.

VACCINES FOR THE PREVENTION OF *H. PYLORI* INFECTION

In addition to its role in pathogenesis, there is potential for the immune response to play a role in controlling *Helicobacter* infection. The authors initially used the *H. felis*/mouse model to develop an oral immunization protocol that is capable of inducing protective immunity against infectious challenge. This protocol, which employs *Helicobacter* antigens in combination with the mucosal adjuvant cholera toxin (CT), has now also been applied to the *H. pylori* model by the authors' laboratory and other laboratories. Surprisingly, not only can

protective immunity be induced by prophylactic immunization of healthy mice, but in both mouse and ferret models of *Helicobacter* infection, immunization appears to be an effective immunotherapy to eradicate the organism from infected hosts.

One major question relating to *Helicobacter* immunity concerns why it is that both immunization and infection induce local immune responses but only the immunized animals are protected. It has been previously demonstrated that *Helicobacter*-specific antibodies are sufficient to provide passive protection in mice when applied directly to the stomach. Additionally, distinct differences in the antigenic specificities between mice that are infected with *Helicobacter* and those that are protectively immunized have been described. However, a recent study employing IgA knockout mice showed that they could be protected in the absence of secretory IgA. Additionally, when κMT knockout antibody-deficient mice were used to further investigate the role of antibodies in protective immunity, it was demonstrated that antibodies are not required for protection. Thus, it appears that the primary difference in the immune responses between protected and infected groups is probably in the T-cell response.

A role for T cells in protective immunity against *Helicobacter* is supported by experiments in which adoptively transferred $CD4^+$ T cells from *Helicobacter*-immunized mice, but not those from infected mice, were sufficient to provide protection from challenge. A role for the T_H2-type immune response was suggested by the finding that adoptively transferring a T_H2-cell line could reduce the bacterial load but using a T_H1-cell line could not. Furthermore, a switch from T_H1 to T_H2 cytokine production following successful therapeutic vaccination also supports a role for T_H2 cells in immune protection from *Helicobacter* infection. All of these data have been generated from immunization studies using CT or *Escherichia coli* heat-labile toxin (LT) as mucosal adjuvants for oral immunization and the observations supporting a role for T_H2-based immunity are consistent with the known activities of mucosal adjuvants such as CT or LT. Therefore, it appears that immunization to prevent and/or cure chronic *H. pylori* infection may be the ideal therapeutic approach.

VACCINE STUDIES IN HUMANS

Since greater than half of the world's population is chronically infected with *H. pylori*, an effective vaccine regimen is a realistic goal. Successful eradication of chronic *Helicobacter* infections in the three animal models discussed in this article is an encouraging finding. A therapeutic vaccine would be more cost-effective and result in fewer potential complications than the administration of multiple antimicrobial agents to affected populations. Recently, a clinical trial was performed on volunteers to test an oral therapeutic vaccine consisting of recombinant *H. pylori* urease apoenzyme in combination with the mucosal adjuvant *E. coli* LT. The results were encouraging as subjects receiving the test vaccine had significant reductions in gastric *H. pylori* density compared to those receiving placebo controls. Additionally, anti-*H. pylori* urease IgA-producing cells from the circulation were significantly elevated in those patients receiving the vaccine compared to controls. Although a significant number of patients experienced diarrhea due to the LT, and complete bacterial eradication was not observed in any of the subjects, this study was an important first step in suggesting that improved vaccine formulations and safer adjuvants may achieve satisfactory outcomes.

SUMMARY

There is now considerable evidence that *H. pylori* is a human pathogen. The strong association between *H. pylori* and gastroduodenal disease is well documented. A number of hypotheses have been suggested for the pathogenic mechanisms of *H. pylori*-induced gastroduodenal disease including the presence of bacterial virulence factors, the production of inflammatory mediators, dysregulation of acid secretion, and the host immune response. Although animal models in which protective immunity can be induced by oral vaccination have been developed, the technology has not been advanced for use in humans. At present, treatment with a combination of antimicrobial agents and proton pump inhibitors continues to be recommended for the treatment of *H. pylori*-associated peptic ulcer disease in children.

enteric nervous system Division of the autonomic nervous system that behaves like an independent integrative nervous system within the wall of the digestive tract.

gastro-colic reflex Meal-induced change in motility of the large intestine.

irritable bowel syndrome Persistent symptoms of abdominal pain and alterations of bowel habit not explainable by any apparent physical or biochemical abnormality.

mechanoreceptors Molecules on sensory neurons that detect and signal mechanical energy changes such as contractile tension or stretch of a muscle.

As early as 1909, A. F. Hertz reported that ingestion of a meal is the most powerful of all stimuli for motor activity of the colon in humans. Hertz did a fluoroscopic examination of an individual who had eaten a supper of porridge containing bismuth oxychloride on the previous evening; fluoroscopy before breakfast showed the cecum and ascending colon and most of the transverse colon, and the terminal ileum was also faintly visible. By 45 minutes after breakfast, the ileum was no longer visible and the shadow of the whole colon, as far as the junction of the iliac with the pelvic colon, was clearly seen. The breakfast clearly acted as a powerful stimulant for forward propulsion of the contents of the colon and of the terminal ileum. Hertz believed that the effect of food entering the stomach on the terminal ileum and large intestine was a reflex action, which he called the "gastro-colic reflex."

INTRODUCTION

As described by Hertz in 1909, there is a propulsive response of the bowels following ingestion of food (Fig. 1). Normally, the desire for defecation is felt following a meal, and most often after breakfast. Stimulation of the gastro-colic reflex by food entering an empty stomach after a fast of 12 hours is greater than that produced by food taken in the middle of the day or in the evening at a comparatively short interval after a noon-day meal. Investigators during the early 20th Century observed that under natural conditions, the passage of feces along the colon was mainly due to a rapid mass movement, repeated three or four times a day, in the direction of the anus along a considerable length of bowel. It was thought that these movements were produced by a powerful peristaltic propulsive wave. The propulsive wave was characterized by manometric studies of the human colon several decades later. Manometric studies found that a high-amplitude propagating contraction (HAPC) of the colonic musculature accounted for the mass movements of feces.

The increased colonic motility in response to a meal occurs even in patients who have had their stomach removed. Occurrence of meal-evoked movements in the colon of these individuals suggests that the gastro-colic reflex can be evoked both by entry of food into the stomach and by entry of food into the upper small intestine.

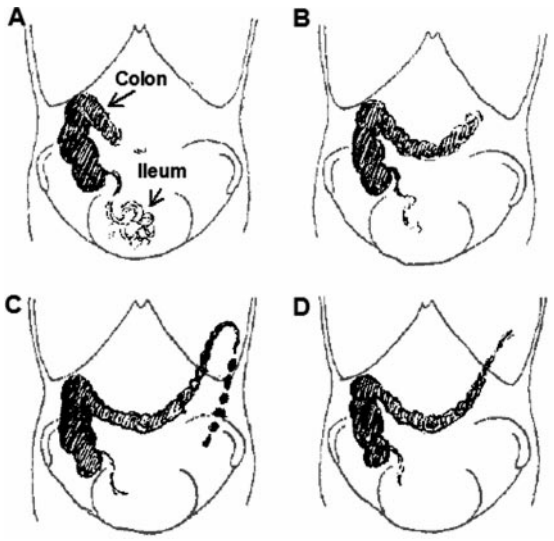

FIGURE 1 An early radiographic study by A. F. Hertz, with bismuth as the contrast material, illustrating the gastro-colic reflex. (A) Prior to the morning meal, contrast material ingested the previous evening was localized to the terminal ileum, ascending colon, and proximal region of the transverse colon. (B) Postprandial motility moved the contrast material into most of the transverse colon and emptied the terminal ileum 25 minutes after the morning meal. (C) The contrast material appears throughout the transverse colon and in the descending colon down to the recto-sigmoid colon 45 minutes after the meal. (D) By 60 minutes after the meal, defecation emptied the left colon.

CLINICAL SIGNIFICANCE

Exaggeration of the stimulating action of a meal on colonic motility appears to be the cause of the symptoms frequently observed in patients with the irritable bowel syndrome (IBS); these patients experience abdominal pain, diarrhea, and urgency of defecation following ingestion of a meal. Ingestion of a meal, particularly one rich in fat, results in powerful contractions of the left colon that propagate rapidly to the sigmoid colon. Motility studies show that the powerful contractions that propagate from the proximal colon to the distal colon, including the sigmoid colon, are HAPCs. The luminal pressure in the colon can increase to a level as high as 500 mmHg during the HAPCs in IBS patients (Fig. 2).

When HAPCs occur in the left colon, the IBS patients often experience sensations of urgency to defecate. These observations imply that the sensation of urgency followed by defecation after breakfast is due to a movement of colon contents caused by powerful propulsive HAPCs. On the contrary, in patients with severe constipation associated with thoracic spinal injury, multiple sclerosis, or diabetes mellitus, the colonic motor response to a meal is absent.

NEURONAL MECHANISMS

Understanding of detailed mechanisms of meal-induced changes in colonic motility is still in its infancy; nevertheless, the evidence suggests that neurohormonal mechanisms are the underlying factors responsible for the gastro-colic reflex. The nervous system extrinsic to the stomach and colon has been suggested to be involved in the mechanisms that evoke colonic motor response to ingestion of a meal. In patients with thoracic spinal injury and multiple sclerosis, the colonic motor response to eating is either absent or impaired. In diabetic patients with severe constipation, there is no postprandial increase in colonic motor activity. In diabetic patients, an autonomic neuropathy (i.e., malfunction of the extrinsic innervation of the colon) may be responsible for absence of the postprandial gastro-colic response.

Involvement of the extrinsic nervous system in the control of colonic motility has been demonstrated in experimental animal models. In the monkey, reversible cooling of the vagus nerves significantly decreases colonic motility both in fasting and in the postprandial state. Reversible vagal cooling also reduces spontaneously occurring colonic motility in the ferret. Moreover,

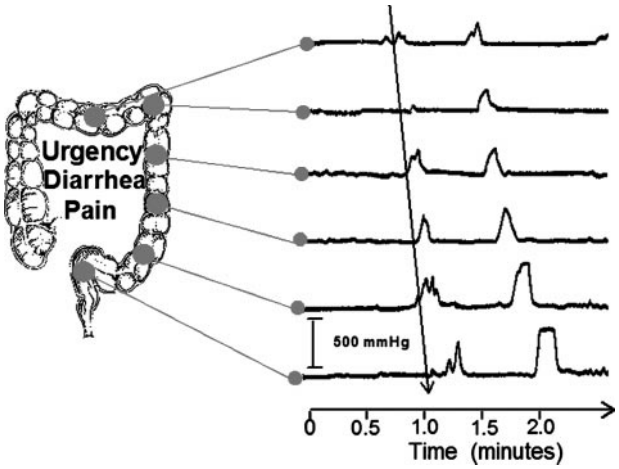

FIGURE 2 In patients with irritable bowel syndrome, high-amplitude propagating contractions occur after meals. Amplitudes of the contractions may exceed 500 mmHg when detected with manometric sensors positioned within the colonic lumen at six locations. High-amplitude propagating contractions occur twice on the manometric record. They are first recorded in the midtransverse colon and propagate rapidly to the rectosigmoid colon. The high-amplitude propagating contractions are associated with lower abdominal cramping pain, sensations of fecal urgency, and diarrhea in patients with irritable bowel syndrome. Reprinted from Chey *et al.* (2001). With permission from the American College of Gastroenterology.

in anesthetized ferrets, electric stimulation of either the cut central or peripheral end of a branch of the abdominal vagus nerve evokes a large-amplitude contraction of the colon. The response is not blocked by atropine or atropine plus adrenergic blockers, suggesting that neither acetylcholine nor norepinephrine is involved. Two separate vagal motor pathways to the colon influence colonic motility. One pathway releases the neurotransmitter acetylcholine and is referred to as cholinergic. The second pathway involves neither acetylcholine nor norepinephrine and is therefore referred to as a noncholinergic–nonadrenergic pathway.

John Wiley *et al.*, have demonstrated the presence of mechanoreceptors in the human stomach that respond to gastric distension and that appear to be the starting point for a reflex increase in rectosigmoid motility. The response to gastric distension is abolished by atropine, indicating that it is mediated via a cholinergic pathway. A recent finding in IBS patients is that the colonic motor response with HAPCs to ingestion of a meal or to administration of the hormone cholecystokinin is abolished by a drug that blocks the 5-hydroxytryptamine subtype 3 (5-HT3) receptor for serotonin. Thus, both cholinergic and serotonergic receptors appear to be involved in gastro-colonic responses, probably via the enteric nervous system.

HORMONAL MECHANISMS

In as few as 5 minutes after ingested liquids and solids enter the stomach, the liquefied component of the contents leaves the stomach and enters the duodenum. Thus, the colonic motor response that occurs in a half hour after a meal is probably due not only to distension of the stomach with food and signaling of gastric distension by mechanoreceptors, but also to gastric contents entering the upper small intestine. Of the nutrients that enter the duodenum, fat and its digestive products are the most potent stimulants for triggering increases in colonic motor activity, particularly that of the left colon, to produce mass movements that lead to defecation. The action of fat is mediated via chemoreceptors in the upper small intestinal mucosa and is partially atropine sensitive. Atropine blocks the muscarinic type receptor for acetylcholine, and the action of atropine in this case suggests the involvement of neural pathways that release the neurotransmitter acetylcholine.

Cholecystokinin (CCK) is an important gut hormone that is released by fat. Although intravenous administration of CCK has long been known to stimulate contractile activity of the human sigmoid colon and rectum, it was initially unknown whether fat-induced colonic motility was mediated by release of CCK as a hormonal signal. This was clarified by observations that fat-induced elevation of CCK in the blood was incapable of increasing rectosigmoid motility in healthy volunteers. Moreover, a drug that blocks receptors for CCK does not affect postprandial colonic motility in healthy subjects or in patients with IBS. That release of CCK as a hormonal signal in normal conditions cannot account for the increased rectosigmoid motility that occurs after a fat-containing meal is now clear. Aside from CCK, other hormones are released in response to normal and fat-rich meals. These meal-stimulated hormones include peptide YY and motilin. Whether these hormones are involved in the signaling of the gastro-colic reflex remains as an open question.

Acute gastroenteritis is a common, generally self-limiting disease characterized by rapid onset of watery diarrhea and associated symptoms such as nausea, vomiting, fever, and/or abdominal pain. In some cases, nausea and vomiting may be the predominant symptoms. It is estimated that this illness occurs at an overall rate of 1.2 to 1.5 episodes per person per year in the United States and at higher rates among children under the age of 3 years (1.3 to 2.3 episodes per child per year). Although gastroenteritis may be caused by many infectious agents, viruses are the most common cause in industrialized countries. Rotaviruses are the leading cause of severe diarrhea in childhood; noroviruses are a diverse group of viruses responsible for a large proportion of outbreaks of gastroenteritis in adults, and sapoviruses, astroviruses, and enteric adenoviruses are other viral agents of gastroenteritis.

been learned about their important role in causing epidemic and sporadic gastroenteritis. The noroviruses have been especially challenging to study, because they cannot be cultivated in cell culture, infected individuals may not shed large quantities of the virus, and there is no small animal model that can be infected. Molecular characterization of the viral genome has greatly improved diagnostic capability and epidemiological surveillance. Noroviruses are now considered to be a major cause of acute gastroenteritis globally. Although viral gastroenteritis is generally self-limiting, with a benign course, dehydration may be a complication requiring prompt medical attention, particularly in infants and the elderly.

VIRAL PATHOGENS

The viral pathogens that cause acute gastroenteritis represent four distinct viral families. Rotaviruses are members of the family Reoviridae and have a segmented, double-stranded RNA genome enclosed in a triple-layered capsid. Noroviruses and sapoviruses constitute two genera of the family Caliciviridae, with a positive-sense RNA genome inside a capsid composed of a single structural protein. Astroviruses, of the family Astroviridae, are also nonenveloped viruses with a positive-sense RNA genome, but their capsid is composed of several structural protein subunits. Enteric adenoviruses represent a unique subgroup of the family Adenoviridae and have a double-stranded DNA genome enclosed in a characteristic icosahedral capsid. Each of these viruses also can be distinguished by electron microscopy by their characteristic morphologic features.

Rotaviruses

Group A rotaviruses are the most important cause of severe dehydrating diarrhea in children. On a global scale, it is estimated that there are 125 million cases of rotavirus diarrhea, including 8 million cases of severe diarrhea and 600,000 deaths. In the United States, it is estimated that there are 1 million cases of rotavirus diarrhea annually, with 65,000 requiring hospitalization and less than 20 deaths.

Children between the ages of 3 months and 3 years are most susceptible to infection. Because immunity to reinfection is not complete, rotavirus disease can also occur in otherwise healthy adults, as well as in patients who are elderly or immunosuppressed. Infection in children living in temperate climates usually occurs in the cooler months. In the United States and Europe, a wave of illness has been observed to spread from the Southwest to Northeast, starting in the autumn. In tropical climates and among adults, there does not appear to be seasonal variation.

Infection is transmitted primarily through the fecal–oral route in a highly efficient manner that owes to the large amount of viruses shed in feces. Food- and waterborne transmission is not common, but has also been reported. The incubation period ranges from 1 to 3 days and is followed by the abrupt onset of fever, malaise, vomiting, and watery diarrhea. Duration of illness varies from 3 to 8 days. Severely immunocompromised children may have a protracted course. Dehydration, with associated mild elevation of blood urea nitrogen (BUN) and mild metabolic acidosis, may require treatment with oral rehydration solutions.

If specific diagnosis of rotavirus infection is needed, enzyme immunoassays, with >90% sensitivity and specificity, are commercially available. Other diagnostic methods, including immune electron microscopy, nucleic acid hybridization with or without reverse transcriptase and polymerase chain reaction (RT-PCR), RNA electrophoresis, and cell culture isolation, are not as widely available.

Caliciviruses

Norovirus

Norovirus is the new name for a genus of the family *Caliciviridae* that includes a genetically diverse, but related, group of nonenveloped, single-stranded RNA viruses that are a major cause of acute gastroenteritis in humans. This group of viruses had previously been called "Norwalk-like viruses" (NLVs), after the prototype Norwalk virus that was isolated from a 1968 outbreak in Norwalk, Ohio, or "small round structured viruses" (SRSVs), a name based on their ultrastructural appearance. It is estimated that 23 million people become ill with noroviruses each year in the United States.

In 1972, the Norwalk virus was identified by immune electron microscopy, providing the first proof that a virus was the cause of a syndrome that had been called "winter vomiting disease." It was not until the early 1990s that the viral genome was cloned and sequenced, and the virus could be classified as a calicivirus. Sequence information also provided a basis for diagnosis by RT-PCR. The discovery that expression of the capsid protein spontaneously yields recombinant virus-like particles (VLPs) further enhanced studies of virus structure and immunity.

Between the early 1970s and the early 1990s, human volunteer studies were the main research tool to study viral pathogenesis. Norwalk virus infection was associated with broadening and blunting of villi in the

jejunum, crypt cell hyperplasia, cytoplasmic vacuoles, and polymorphonuclear and mononuclear cell infiltrates in the lamina propria. Intestinal brush border enzyme activity was decreased. Delayed gastric emptying was also documented and may have contributed to the symptoms of nausea and vomiting. Both structural and functional abnormalities returned to normal after resolution of the infection.

Immunity to infection with noroviruses is not completely understood. Studies have shown that only about half the people who are exposed to noroviruses develop illness, although asymptomatic infection can be documented in an additional 30%. Short-term immunity (a few weeks to a few months) can be demonstrated in infected individuals who mount an immune response, but the level of serum antibody does not predict whether the individual will be protected from reinfection or illness when challenged with the same norovirus in the long term. Some studies find no evidence for long-term immunity; those individuals who become ill with the initial exposure to the virus paradoxically become ill with repeated challenges several months to years later. Recent studies have suggested the possible role of blood group antigens in viral pathogenesis and determining susceptibility to infection. Persons belonging to blood group O may be most susceptible to severe norovirus infections. Recombinant Norwalk VLPs also show promise in further investigations of viral immune response and vaccine development.

Recent epidemics of gastroenteritis on cruise ships have sharply focused attention on the noroviruses, but it is well known that outbreaks can occur in many different settings and can be associated with the ingestion of contaminated food or water (less common). Raw or inadequately cooked shellfish pose a higher than average risk because viruses can be concentrated in these filter feeders. Uncooked or previously cooked foods that require extensive preparation and handling by food workers have also been associated with outbreaks. In most outbreaks, primary attack rates are 50% or more and secondary attack rates are 30% or more. Transmission occurs primarily through the fecal–oral route, but transmission through the airborne route and by fomites may also contribute. It has been estimated that infection can occur with the ingestion of as few as 10 viral particles.

Typically, after an incubation period of 12 to 48 hours, patients will experience the acute onset of nausea, abdominal cramping, diarrhea, and vomiting, frequently associated with headache, body aches, and low-grade fever. The symptoms last for 12 to 60 hours, after which there is complete resolution of the illness, although viral shedding may persist for up to 2 more weeks. Children tend to have more vomiting and less diarrhea; the reverse is observed for most adults. Severe dehydration is rarely encountered, but elderly patients with severe chronic diseases should be monitored for this potential complication and treated as clinically indicated.

The most widely used assay at present for diagnosing norovirus infection is RT-PCR, which can detect 10^2 to 10^4 viral particles/ml of stool. Because of the high level of sensitivity of this assay, care must be taken to avoid contamination of samples. The genetic diversity of the noroviruses has made it difficult to design primer sets that are capable of detecting all strains of virus, but current assays based on sequences from conserved regions of the genome encoding the viral RNA-dependent RNA polymerase are capable of detecting multiple strains. Sequence analysis of successfully amplified segments can help to determine the genogroup or genetic cluster of a particular norovirus, trace outbreaks to their source vehicle(s), and establish links between outbreaks.

Sapovirus

Sapporo virus, a calicivirus with classic morphology, is the prototype of the newly named genus *Sapovirus*. The genome organization of this group of viruses is more like those of animal caliciviruses, such as rabbit hemorrhagic disease virus, than that of the noroviruses. *Sapovirus* infection has different epidemiologic features, compared to noroviruses. Sapoviruses cause acute gastroenteritis primarily in infants and young children, but infection involving elderly adults has also been reported. *Sapovirus* outbreaks have also been reported to occur in institutional settings, although not as frequently as noroviruses.

Seroprevalence studies indicate that nearly all children have acquired *Sapovirus* antibodies by the age of 12 years, and these antibodies seem to confer long-term resistance to reinfection. Infection is most likely transmitted through the fecal–oral route. Oysters and cold foods have also been implicated as vectors of transmission. Following an incubation period of 24 to 72 hours, patients develop vomiting and diarrhea acutely, with associated abdominal pain, fever, and respiratory symptoms. The symptoms, which resemble those of a mild rotavirus infection, last for 24 to 48 hours. The infection can be diagnosed by direct electron microscopy, given the large quantities of viruses shed in feces and their distinctive appearance. There is no commercially available enzyme immunoassay, and tests based on viral nucleic acid sequence are not as far along as for the noroviruses.

Astroviruses

Human astroviruses primarily cause acute gastroenteritis in children, but illness has been reported to occur among elderly patients residing in institutions and in immunocompromised individuals (HIV-infected individuals and bone marrow transplant recipients). Most adults who are otherwise healthy do not tend to become infected or to develop symptoms. Similar to the sapoviruses, astrovirus antibodies are acquired early in childhood, with antibody prevalence rates in the range of 70% by school age. Astrovirus antibodies are also detected in gamma globulin pools from the United States and Japan.

The medical importance of astrovirus infection has been demonstrated by epidemiological surveys that show astrovirus to be second only to rotavirus as a cause of viral gastroenteritis among children attending outpatient clinics in Thailand. An Australian study has shown that among children hospitalized for diarrhea, rotaviruses are the most common etiology (as expected), followed by astroviruses. A typical case of astrovirus gastroenteritis in an immunocompetent child consists of a mild, watery diarrhea, vomiting, fever, and abdominal pain, which begin after an incubation period of 1 to 4 days. The symptoms last 2 to 3 days. In some immunocompromised patients, protracted and severe illness may occur.

Normal individuals are protected from repeated astrovirus infections by serum antibodies and CD4+ T cells in the gut lamina propria that recognize astrovirus antigens in an human leukocyte antigen (HLA)-restricted manner. When CD4+ T cells are depleted by the use of chemotherapeutic agents, such as fludarabine, patients may develop a prolonged course of astrovirus infection. In such patients, treatment with immunoglobulin (intravenously and/or orally) has been attempted in a small number of cases and has shown variable success rates. This type of treatment requires further study in controlled clinical trials.

Because astroviruses are shed in large quantities during infection and because at least 10% of the viruses display a distinctive surface star, diagnosis can be made by direct electron microscopy. Because astroviruses have been erroneously identified, the caveat is that accurate identification of astroviruses may require an experienced microscopist; a monoclonal antibody that can detect all eight serotypes of the human astrovirus is available.

Enteric Adenoviruses

Enteric adenoviruses are members of the Adenoviridae, a large family of DNA viruses that are associated with a wide spectrum of illnesses. Enteric adenoviruses that consistently cause gastrointestinal illness in infants and young children have been assigned to subgroup F, serotypes 40 and 41. Nonenteric types of adenoviruses have been identified in the stools of HIV-infected patients with acute or chronic diarrhea, but it has not been clearly demonstrated that these types of adenoviruses have an etiologic role.

Enteric adenovirus infections have a worldwide distribution, primarily infecting children under the age of 2 years. They are, in general, a less common cause of acute gastroenteritis, compared to astroviruses or noroviruses. However, in one study from Guatemala, enteric adenovirus infection was found to be more common than rotavirus infection (14 vs. 4.7%, respectively). There is no seasonal variation associated with enteric adenovirus infection.

After an incubation period of about 7 days, patients develop watery diarrhea and vomiting (less commonly). Respiratory symptoms and low-grade fever may also develop during the course of illness. Infection can range from mild to severe, but the majority of cases are mild. Viral shedding in stool lasts for up to 2 weeks, substantially longer than for rotavirus. The clinical course may be complicated by prolonged lactose intoleration and malabsorption. Whether adenovirus infection has any relationship to the development of celiac disease has not been resolved. The preferred method to detect the presence of enteric adenovirus in stool is the enzyme immunoassay, which is based on monoclonal antibodies to each type of enteric adenovirus. The assay is highly sensitive and specific and is commercially available.

TREATMENT AND PREVENTION

There are no specific antiviral therapies at the present time. Treatment is aimed at rehydration and supportive care, including early refeeding. Nonspecific treatment such as bismuth subsalicylate may decrease the severity of abdominal cramping in norovirus infection. For patients who develop dehydration, oral rehydration therapy, as recommended by the World Health Organization, is usually successful. In rare cases of severe vomiting or shock, parenteral hydration may be required. Once rehydration is accomplished, resumption of a regular diet is encouraged, even though some degree of infection-associated lactase deficiency may be present.

Prevention of foodborne infections begins with good handwashing and safe practices for food preparation. Public education about the risks associated with eating certain foods and transmission of viruses is essential.

Improved methods to decontaminate food or for rapid detection of gastroenteric viruses in food should also be helpful. Given the magnitude of the problem, a major approach to prevention of rotavirus illness has focused on vaccine development. Although several live attenuated vaccine candidates have yielded promising results, no vaccine is currently available for widespread use.

stomach is connected to the jejunum. Gastrojejunostomy is the most frequently used type of gastroenterostomy (see Figs. 1 and 2).

SURGICAL INDICATIONS FOR GASTROENTEROSTOMY

There are two main indications or situations in which a surgeon may use a gastroenterostomy. The first reason is to reestablish continuity between the stomach and the small intestine following partial removal of the stomach. For example, a patient may have a large benign (i.e., non-cancer-containing) mass of the stomach near the duodenum. The surgeon may choose to remove the part of the stomach with the mass plus a piece of the duodenum to ensure that the entire mass has been removed. The surgeon must now reconnect the remaining part of the stomach to the small intestine so that food and juices can pass from the stomach to the intestine as before. This is accomplished using a gastroenterostomy. The surgeon may choose to connect the stomach to the remaining duodenum (i.e., a gastroduodenostomy; see Fig. 1A) or to the side of the jejunum (i.e., a gastrojejunostomy; see Fig. 1B).

A gastroenterostomy may also be used to circumvent an area of the stomach that is blocked. This may occur for a variety of reasons. For example, a patient may have a cancer that blocks the passage of food from the stomach into the duodenum. If the cancer has grown too large to be removed safely, one option is for a surgeon to connect the stomach to the side of the jejunum (i.e., a gastrojejunostomy) without the necessity of removing the mass or any part of the intestinal tract. This allows food to travel directly from the stomach to the jejunum, bypassing the blockage in the duodenum (see Fig. 2).

There are a large number of techniques for constructing gastroenterostomies and the versatility of this procedure makes it useful in a wide variety of circumstances.

Gastroesophageal Reflux Disease (GERD)

J. PATRICK WARING
Digestive Healthcare of Georgia, Atlanta

Barrett's esophagus A condition that develops when the normal squamous tissue in the esophagus is repopulated by intestinal epithelium.
fundoplication Surgical procedure in which the fundus of the stomach is mobilized and wrapped around the distal esophagus.
gastroesophageal reflux disease Mucosal injury or persistent symptoms that develop in response to reflux of gastric contents into the esophagus.
proton pump inhibitors Medications that block the production of gastric acid secretion by inhibiting the H^+,K^+-ATPase pump.

Gastroesophageal reflux disease (GERD) is a very common problem. As many as 7% of adult Americans have daily heartburn. Patients with GERD may present with a variety of symptoms, ranging from typical symptoms, such as heartburn or regurgitation, to atypical symptoms, such as chest pain, asthma, laryngitis, or chronic cough. GERD may cause complications, such as esophagitis, esophageal ulceration, esophageal strictures, or Barrett's esophagus. Most patients with GERD will have a chronic problem requiring long-term therapy. Seventy-five percent of patients with chronic heartburn have moderate to severe symptoms. Many patients with GERD have an impaired quality of life, as assessed by the Gastrointestinal Symptom Rating Scale, the Health-Related Quality of Life scale, and the Psychological General Well-Being scale. Interestingly, there is little correlation between quality of life scoring and severity of esophagitis. Even patients without esophagitis have a markedly impaired quality of life. Quality of life scores improve to the normal range with successful medical or surgical therapy. The goals of modern medical therapy for GER are threefold: first, eliminate symptoms; second, heal injured esophageal mucosa; and third, manage and/or prevent complications.

PATHOPHYSIOLOGY

Gastroesophageal reflux disease (GERD) occurs as a consequence of gastric contents, predominantly acid, refluxing into the distal esophagus. The complicated pathophysiology includes competence of the lower esophageal sphincter (LES), the ability to clear refluxed gastric acid from the esophagus, esophageal mucosal defenses, and abnormalities of gastric function. The most important aspect of the pathophysiology of GERD is the competency of the anti-reflux barrier. Factors contributing to its integrity include the LES pressure, the presence or absence of a hiatal hernia, and the occurrence of transient lower esophageal sphincter relaxations. LES pressure less than 6 mm Hg, LES length less than 2 cm, and intra-abdominal length less than 1 cm are strongly associated with GERD. The crural diaphragm contributes substantially to the integrity of the LES. When patients have a hiatal hernia, the crural diaphragm and the LES are displaced from each other and consequently the sphincter is less competent. The most common pathophysiologic event at the time of a reflux episode is a transient lower esophageal sphincter relaxation. Poor esophageal clearance may lead to prolongation of the acid reflux events. Abnormalities of gastric function, such as hyperacidity, delayed gastric emptying, or duodenogastric reflux, may contribute to the severity of GERD by making the refluxate more noxious. It is important to remember that severe discomfort from acid reflux does not require severe injury to the esophageal mucosa. Acid exposure in the distal esophagus causes destruction of the tight junctions between the epithelial cells. This leads to penetration of the acid deeper into the epithelial lining. Sensory neurons are only two to three layers deep and when exposed to the acid may create a painful stimulus that may last for several hours. These histopathologic findings are found on electron microscopy in patients with and without esophagitis. Attempts to withdraw gastroesophageal reflux (GER) therapy are frequently unsuccessful because medical therapy offers no permanent resolution of pathophysiologic abnormalities.

SYMPTOMS

Most physicians are well acquainted with the typical manifestations of gastroesophageal reflux disease, such as heartburn and regurgitation. Heartburn is

 Copyright 2004, Elsevier (USA). All rights reserved.

defined as a burning retrosternal discomfort. Regurgitation is the effortless movement of food or fluid from the stomach to the esophagus. At least 10% of patients with GERD have what are known as extra-esophageal manifestations. The more common complaints include chest pain, laryngitis, chronic cough, and asthma. Other complaints that are postulated to be associated with GERD, although not as well proven, include laryngeal cancer, otitis media, globus sensation, vocal cord granulomas, halitosis, and dental erosions. Interestingly, these extra-esophageal manifestations may be present with or without typical reflux symptoms. As such, management of the extra-esophageal manifestations of GERD can be rather challenging.

As many as 30% of patients undergoing cardiac evaluation for chest pain have no cardiac lesions. Unexplained chest pain has been linked to microvascular angina and esophageal, pulmonary, musculoskeletal, and psychological causes. For years, it was thought that esophageal spasm or another esophageal motility disorder was the most common cause of unexplained chest pain. However, evidence of gastroesophageal reflux is seen in 50–70% of patients with unexplained chest pain. Esophageal pain from GERD may or may not respond to antacids or nitroglycerin. Neither a rapid response nor the lack of a response to symptomatic therapy is a reliable indicator of the cause of the chest pain. Patients with GERD-related chest pain frequently have typical reflux symptoms as well. It is important to have the patient describe exactly what he or she is feeling. Some patients use the words heartburn, indigestion, and chest pain interchangeably. Most patients are able to distinguish between the burning sensation and pressure sensations very nicely. Others may be unable to tell whether they have one or two painful sensations. Patients should be asked about heartburn, a separate burning sensation in the midchest. Some patients may experience this for years prior to developing the chest pain. Many patients do not have heartburn and chest pain at the same time. This does not exclude gastroesophageal reflux as the cause of the chest discomfort.

GERD and asthma commonly coexist. GERD may worsen asthma either by direct acid injury to the lungs or by a vagally mediated reflex bronchospasm. Asthma may worsen GERD by altering dynamics at the LES or promoting reflux episodes by coughing and wheezing. Efforts to identify asthmatics that will respond to antireflux therapy may be very difficult. Since many intrinsic and extrinsic factors can exacerbate bronchospasm, the cause and effect relationship between GERD and asthma is not obvious. Furthermore, GERD and asthma may occur in the same patient with no apparent association.

Acid and peptic injury to laryngeal strictures can lead to persistent symptoms of throat discomfort, throat clearing, hoarseness, voice loss, and chronic cough. The pathophysiologic abnormality in this situation may actually be at the upper esophageal sphincter. Gastric acid must travel all the way up the esophagus, past the upper esophageal sphincter, and onto the vocal cords. The majority of these patients actually have mild reflux, but even small amounts of acidic gastric juice may be quite injurious to the vocal cords. More controversial symptoms that may be reflux related are chronic sore throat and neck pain. True dysphagia is rare, but an uncomfortable sensation during swallowing is not. This should be distinguished from the globus sensation, the feeling that something is stuck in the throat, when there is obviously nothing there. The most common laryngeal finding in these patients is posterior laryngitis; however, it is not specific. Other causes of laryngeal irritation, such as voice abuse, heavy smoking, endotracheal intubation, and exposure to toxic fumes, should be considered. Approximately half of patients with posterior laryngitis will not have typical symptoms of heartburn to suggest the presence of GERD. Studies from the late 1980s suggested that laryngeal cancer occurs in patients with reflux disease in the absence of smoking or alcohol. However, there have been only limited data published since then. At this point, it does not seem likely that reflux predisposes patients to laryngeal carcinoma.

GERD is the third most common cause of chronic unexplained cough following postnasal drip and asthma, occurring in 10 to 21% of patients. Typical symptoms, such as heartburn, are frequently absent. Ambulatory pH monitoring may be the only abnormal test. It should be considered in patients refractory to antihistamine–decongestant therapy, in patients without typical reflux symptoms, and in patients who fail an empiric trial of anti-reflux therapy.

COMPLICATIONS

Barrett's esophagus is a premalignant condition in which specialized intestinal metaplasia replaces the normal squamous esophageal mucosa. This occurs almost always in response to chronic gastroesophageal reflux. Barrett's esophagus is the only known risk factor for esophageal adenocarcinoma. The reported incidence of esophageal adenocarcinoma for these patients has ranged from 0.2% to as high as 2.1% per year. Over the past two decades, the incidence of adenocarcinoma of the esophagus and gastric cardia has increased at a rate exceeding that of any other cancer in several developed countries, including the United States. Patients

with Barrett's esophagus are 30 to 40 times more likely to develop adenocarcinoma of the esophagus than the general population. Nearly all studies on Barrett's esophagus show a strong correlation between that condition and the presence of chronic reflux symptoms for greater than 5 years. The incidence of Barrett's esophagus in patients with chronic GERD symptoms is thought to be approximately 10–12%, although several studies suggest rates near 20%, particularly if male Caucasians with chronic reflux symptoms are targeted.

Patients with chronic GERD symptoms, such as heartburn or regurgitation, should have an endoscopy to look for evidence of columnar epithelium. Identifying patients with Barrett's esophagus is the major role of endoscopy in GERD. Patients with columnar epithelium should have a biopsy to look for evidence of specialized intestinal metaplasia. These patients are at greatest risk for the development of esophageal adenocarcinoma. Patients with Barrett's esophagus should be enrolled in a surveillance program to look for signs of dysplasia.

GERD is the most common cause of a benign esophageal stricture. Historically, nearly 10% of patients with GERD seeking medical attention have esophageal strictures, although this number is probably much smaller now. This condition is related to chronic fibrosis and scarring in response to prolonged esophageal acid exposure. Patients often complain of heartburn and regurgitation, as well as dysphagia. Reflux strictures are almost always located at the gastroesophageal junction. Rarely, the strictures may be long and have a ringed appearance. Strictures in patients with Barrett's esophagus usually occur at the squamocolumnar junction. Pill-induced esophageal injury may be confused with GERD. Up to 20% of patients with suspected reflux strictures may actually have pill-induced strictures. All pills have the potential to produce esophageal injury, but tetracycline, doxycycline, potassium chloride, quinidine, nonsteroidal anti-inflammatory drugs (NSAIDs), and alendronate are the most recognized for causing esophageal strictures. Medications may also be a cofactor with GERD, leading to esophageal stricture formation. Patients who have GERD and a stricture are far more likely to be taking aspirin or NSAIDs than patients who have GERD but no stricture.

DIAGNOSTIC TESTING

There is no ideal diagnostic test for gastroesophageal reflux disease. Most patients with GERD will have a normal endoscopy, esophageal manometry, or upper gastrointestinal X ray. History alone is good, but not perfect, with an accuracy of approximately 80%. Other problems, such as cardiac, biliary, gastric, or psychological abnormalities, may cause symptoms that are confused with chronic heartburn. Many physicians are offering patients an empiric trial of therapy prior to diagnostic testing if the history is consistent with GERD. In fact, a response to empiric therapy could be considered a positive diagnostic test. In one study, the sensitivity of a 7-day course of omeprazole 40 mg daily was 27%, but increased to 83% with a 7-day course of omeprazole 40 mg bid. An empiric trial of therapy may reduce diagnostic testing costs by 53–65% compared to endoscopy or pH monitoring. Indeed, recent guidelines have advocated empiric therapy as the initial approach for patients with chronic heartburn symptoms.

The role of endoscopy in patients with GERD has changed over the past few years. There appears to be little difference in symptom severity or treatment outcomes between patients with esophagitis and those without esophagitis. Consequently, the value of early endoscopy has been questioned. The degree of esophagitis no longer appears to be helpful in guiding therapy. Endoscopy should be considered in two situations. In patients with bothersome symptoms, such as weight loss, intestinal bleeding, nausea, vomiting, dysphagia, or odynophagia, an endoscopy should be performed to rule out more serious causes of these problems. Endoscopy is also indicated for patients with long-standing reflux symptoms to exclude Barrett's esophagus. Current guidelines recommend an endoscopy in anyone who has had heartburn at least twice a week for at least 5 years.

For many patients, ambulatory esophageal pH monitoring of the esophagus is the only test that will be abnormal. Here, a catheter with an antimony pH electrode is passed nasally into the distal esophagus, 5 cm above the lower esophageal sphincter. The pH can be recorded every few seconds over a prolonged period of time. Some investigators have demonstrated that an accurate reading may be obtained in as little as 3 h; however, the standard length of time remains 24 h. A reflux episode is defined as beginning when the esophageal pH drops below 4.0. Patients at the author's clinic are asked to eat normally and be active during the study period. There have been several "normal" values published, but in general, a study is considered abnormal if the pH in the distal esophagus is <4 at least 4.2% of the time. It is important to review the pH tracing to exclude artifacts. This may include drifting of the pH value to acidic levels, rather than an abrupt drop of a pH value that occurs with a reflux episode. Additionally, lead-positioning problems may create a deceptively abnormal study; for example, when the pH value is always in the range of 1–2, the pH probe is likely in the stomach.

The pH value may abruptly become 0 or 9 if there are reference electrode problems. Most computerized programs allow the physician to exclude these artifacts and obtain an accurate study.

Ambulatory esophageal pH monitoring should be performed in two major circumstances. The first is when the physician does not know whether the patient has GERD, but must determine this. For example, for patients with non-erosive or atypical reflux who are considering anti-reflux surgery, it is imperative to document an abnormal amount of acid exposure in the distal esophagus prior to anti-reflux surgery. In general, patients with erosive esophagitis considering anti-reflux surgery do not need a pH study. Second, it may be useful to follow a patient's response to therapy. Many patients with atypical reflux symptoms, such as chest pain, asthma, laryngitis, or chronic cough, will have an incomplete response to treatment. Documenting whether or not there is adequate acid suppression with medical therapy may help determine whether the refractory symptoms are related to continued acid reflux.

There are a variety of ways to alter this study to obtain more information. It can be performed on or off medical therapy. The pH study should be performed "off-therapy" simply to document whether or not acid reflux is present, for example, in a patient considering anti-reflux surgery. Occasionally, a patient will present with such unusual symptoms that they are probably not related to acid reflux. A normal pH test off-therapy would be helpful to exclude reflux as a possibility. The study should be performed "on-therapy" in patients with an incomplete response to treatment. It is reasonable to offer patients double-dose proton pump inhibitor (PPI) therapy for a couple of months before investigating with a pH study. This is more likely to occur in patients with atypical GERD symptoms. This may help determine whether the refractory symptoms are related to continued acid reflux or to some other medical problem. Placing the pH probe 1 cm above the upper esophageal sphincter is an intriguing way to look for problems in patients with laryngeal symptoms. Several papers suggest that this is far more sensitive for identifying reflux into the hypopharynx than traditional ambulatory esophageal pH monitoring. However, there are no established normal values. Gastric pH monitoring may be useful for identifying patients who will respond to advancing treatment to very high doses of PPIs or anti-reflux surgery. Many patients with refractory GERD symptoms simply do not demonstrate a suppression of gastric acid with PPI therapy. An attachable pH probe has just recently been developed. Preliminary data suggest that it is well tolerated and at least as accurate as traditional pH monitoring. This technology could cause a revision in the role of ambulatory esophageal pH monitoring. If a safe, simple, accurate, and well-tolerated pH test becomes available, clinicians may be inclined to use it earlier in the course of the patient's illness.

One theoretical advantage of ambulatory pH monitoring is the ability to correlate symptoms with reflux episodes. Several authors have created scoring systems, such as the symptom index, the symptom sensitivity index, or the symptom association probability. The last system may be the most accurate. It calculates the probability of a reflux event being associated with a given symptom by creating a 2×2 table comparing 2 min intervals with and without symptoms versus reflux episodes. The number of reflux-associated symptomatic periods should be greater than that expected by chance. Unfortunately, there are no clinical trials to prove that any of the symptom association scores actually predict a true cause and effect relationship. As with most aspects of ambulatory pH monitoring, symptom association often requires a good deal of clinical judgment.

The barium swallow is of limited benefit in patients with GERD, because of its poor sensitivity and specificity. It is very useful in the evaluation of dysphagia, but in general is not helpful in patients with GERD.

Provocative tests, such as the acid perfusion test or tensilon challenge, were popular in the 1980s for the evaluation of unexplained chest pain, although they are of limited usefulness now that ambulatory pH monitoring is available.

MEDICAL THERAPY

The selection of a particular medical regimen depends on the severity of disease, the effectiveness of the therapy, and the cost and convenience of the medical regimen. Historically, physicians have used the step-up approach, which involves using the least effective regimen and intensifying therapy only if necessary. However, in patients with frequent or severe symptoms or those with signs of GERD complications, beginning the regimen with intensive PPI therapy is a reasonable choice. Unlike healing of peptic ulcers, healing of esophagitis requires more aggressive acid suppression. Patients with atypical symptoms of GERD also may require more aggressive therapy.

Five PPIs, omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole, are currently available in the United States. These medications profoundly inhibit the secretion of acid into the gastric lumen, but rarely eliminate gastric acid secretion. All five PPIs have comparable ability to control symptoms and

heal esophagitis. Their effectiveness is dose-dependent. Most studies have shown that the PPIs heal esophagitis in 85–96% of patients. PPIs are far superior to all other forms of medical therapy. Long-term safety and effectiveness have been demonstrated.

PPI therapy improves heartburn symptoms in 60–80% of patients without esophagitis. Again, PPIs are vastly superior to other medical therapies for control of heartburn symptoms for patients with and without esophagitis. PPI therapy can normalize Health-Related Quality of Life, Gastrointestinal Symptom Rating Scale, and the Psychological General Well-Being scores.

Four histamine-2 receptor antagonists (H2RAs), cimetidine, ranitidine, famotidine, and nizatidine, are available in the United States in prescription and over-the-counter formulations. H2RAs inhibit gastric acid secretion to a lesser extent than PPIs. H2RAs provide successful symptomatic relief in 60–70% of patients who are treated for 6–8 weeks. Only 25–45% of patients with esophagitis will remain free of mucosal injury after 1 year of H2RAs, perhaps because of developing tolerance to their effects. One study found that only 41% of patients had improvement in heartburn symptoms after 8 weeks with ranitidine 150 mg bid. Patients were then randomized to continue the standard dose (150 mg) bid or to use a higher dose (300 mg bid). Interestingly, complete heartburn resolution was observed in less than 20% of the patients after an additional 8 weeks in either group. This finding suggests that standard-dose H2RAs are moderately successful at improving heartburn symptoms, but the common practice of doubling the dose of ranitidine is not particularly helpful. With the exception of patients with mild disease, standard doses of H2RAs probably have a limited role in the management of GER complications.

Metoclopramide, a prokinetic agent, may improve symptoms of GER but does not heal esophagitis. It also does not improve esophageal peristalsis or acid clearance. Furthermore, it also has frequent side effects. Metoclopramide has virtually no role as the sole therapy in the management of GER. Cisapride and domperidone are not available in the United States. Antacids are very useful in symptomatic relief in patients with mild intermittent heartburn. They are no better than a placebo for the healing of esophagitis. They may be used with other medical therapy as an adjunct for breakthrough GER symptoms. There are conflicting data regarding the effectiveness of sucralfate therapy in GER. Considering that there are other more superior and more convenient treatment options, sucralfate has a limited role, if any, in the modern medical therapy of GER.

Lifestyle modifications may help patients with mild or intermittent symptoms of GERD. However, lifestyle modifications alone will be effective in less than 30% of patients with esophagitis. Consequently, it is not appropriate as the sole initial therapy for patients with frequent or severe symptoms of GERD. Diet alteration is perhaps the most useful of the lifestyle modifications. A variety of foods, such as chocolate, peppermint, raw onions, and fatty foods, decrease LES pressure. Certain liquids, such as coffee, colas, and beer, increase gastric acid secretion. The effect of coffee is greater in patients with LES dysfunction. Coffee and citrus juices are directly irritating to the esophageal mucosa. Patients are advised to avoid eating 2–3 h before bedtime, to elevate the head of the bed 6–10 in. during sleep, and to stop smoking cigarettes.

Weight loss is commonly associated with improvement in symptoms of GER, although there are no control studies regarding this observation. In fact, obesity has not been shown to be associated with LES or esophageal acid exposure. It is possible that the observed improvement with weight loss may be due to the dietary modifications implemented to produce the weight loss. Medications, such as theophylline and calcium channel blockers, can inhibit the LES pressure. Theophylline worsens esophageal acid exposure in asthmatics with GERD. If possible, these medications should be stopped or another medication should be prescribed.

It seems easy to lump the extra-esophageal symptoms into one category, but these symptoms can be quite different. Patients with chest pain usually have esophageal symptoms such as heartburn, regurgitation, or dysphagia. They tend to respond over a 2- to 4-week period with PPI therapy. Patients who fail PPI therapy often improve with an empiric trial of a low-dose tricyclic antidepressant. Asthmatics also frequently have other esophageal symptoms. It may be more difficult to determine whether gastroesophageal reflux is the cause of these symptoms, because asthma often improves or worsens indepent of GERD. Three to 4 months of therapy is probably indicated before deciding whether or not the asthma is truly reflux-related. Patients with reflux-related chronic cough usually respond promptly; however, profound acid suppression is often required. Patients with reflux-related laryngitis often require therapy with high-dose PPIs for 2 months or more before they experience improvement.

Intensive medical therapy is a very important adjunct to dilation in the management of reflux strictures, especially in those who also have erosive esophagitis. Two studies have shown that patients who received omeprazole have greater relief of dysphagia and required fewer re-dilations than patients who received ranitidine. Successful anti-reflux surgery decreases the need for further dilation as well. Patients

who already present with dysphagia are at greater risk for pill-induced injury by worsening an existing esophageal stricture.

SURGICAL MANAGEMENT

Since its introduction approximately 10 years ago, laparoscopic surgery for gastroesophageal reflux disease has become one of the more common operations performed in the United States. It is interesting that there is still no consensus among physicians as to the proper role of this procedure in the management of GERD. In most published series, the average patient having anti-reflux surgery has nearly complete relief of symptoms and a markedly improved quality of life. In fact, most comparative studies demonstrate the superiority of surgical therapy compared to medical therapy. However, individual complications have prompted some gastroenterologists to be cautious about recommending anti-reflux surgery.

The classic operation is a Nissen fundoplication. Here the fundus is fully mobilized; specifically; the short gastric blood vessels are disconnected or "taken down" from the fundus. A 1.0 to 1.5 cm plication is made using the fundus to wrap around the distal esophagus. Three sutures are usually placed, securing the wrap to the stomach and the esophagus. The hiatal hernia is reduced and the diaphragmatic crurae are closed. Many surgeons will sew the fundoplication to the diaphragm to prevent it from moving postoperatively. This is often performed over a large dilator to prevent the wrap from being too tight. However, there have been reports of perforations, which have led some experienced surgeons to abandon this part of the procedure.

The success rate with anti-reflux surgery, defined by Visick I or II, is over 90%. In one study, 100 patients were followed for an average of 21 months. Ninety-six percent of patients had a good outcome and 71% were completely free of symptoms. Only 3 patients were back on medical therapy. Two patients experienced worsening of symptoms after the procedure. Dysphagia was present in only 2 patients up to a year after surgery. Clinically significant complications occurred in 4 patients. The study was limited to patients with positive 24 h pH studies and "typical" symptoms of GERD. This study is noteworthy because these patients are ideal candidates for anti-reflux surgery. Additionally, the surgeons in this study were highly skilled and very experienced. Consequently, these are probably the best results that one could hope for.

The opinions of the author regarding the long-term durability of laparoscopic anti-reflux surgery come from a handful of studies with at least 5 years of follow-up. Long-term data from centers of excellence suggest a 96% satisfaction rate between 5 and 8 years after surgery. However, 6% of patients have symptoms of chest pain, 6% have heartburn, 6% have regurgitation, 20% have abdominal bloating, 12% have diarrhea, 27% have some difficulty swallowing, and 7% require an esophageal dilation. The same results may not apply to less experienced centers. A recently published study from the Veterans Administration (VA) showed that 62% of patients having surgery required medications for heartburn after 10–13 years. Another study showed only a 57% satisfaction rate, with 67% of the patients developing new symptoms, such as difficulty swallowing or bloating. Additionally, 6.7% of the patients needed a repeat operation rate in less than 1 year.

There are two large published studies comparing medical and surgical therapy: the VA Cooperative Study and the Nordic study. The VA study enrolled patients with complicated GERD in the mid-1980s. It showed that surgical therapy was markedly superior to medical therapy of the era, H2-receptor blockers and metoclopramide. The Nordic trial enrolled 310 patients with erosive esophagitis; 155 patients were randomized to continuous omeprazole therapy and 155 patients were randomized to open anti-reflux surgery. At both 3 and 5 years of follow-up, there were far more treatment failures in patients who were randomized to omeprazole treatment. However, the protocol also allowed dose adjustment to either 40 or 60 mg daily in case of symptom recurrence in patients randomized to omeprazole therapy. If this fact is considered, the failure rates still remained in favor of surgery, although the difference was not quite statistically significant. Quality of life assessment revealed values within normal ranges in both therapy arms during the 5 years of follow-up.

Numerous studies show that medical or surgical therapy improves but does not always relieve the symptoms of chest pain, asthma, chronic cough, and hoarseness. In one study, heartburn was relieved by fundoplication in 93% of patients compared to only 56% of patients with atypical symptoms. Success with medical therapy was the only factor that predicted a successful surgical outcome. The success of anti-reflux surgery will parallel that of intensive medical treatment with high-dose PPIs. The only possible exception is in asthmatics. There are no comparative trials, but several studies on anti-reflux surgery in asthmatics are pretty impressive. Seven of nine patients who required daily oral corticosteroids for asthma were able to discontinue this treatment entirely after successful anti-reflux surgery. In patients with a partial response to medical therapy, repeated ambulatory pH monitoring may be of benefit in separating the true medical failures from

those patients with refractory atypical symptoms due to other causes.

The approach to postfundoplication symptoms is not difficult. Postoperative symptoms can be divided into two categories: recurrent or new. Recurrent symptoms after surgery suggest that the surgery simply did not work. New postoperative symptoms suggest a complication at the time of surgery. On the other hand, the surgical management of these problems is very complex. The success rates for repeat operations are in the range of 75–85%, with a morbidity rate in the range of 20–30% and a mortality rate of over 1%. Conservative management, if successful, is always preferable to a repeat operation. The decision to redo a fundoplication should not be taken lightly and the surgery should probably be performed at a center with vast experience in these matters.

There are two reasons for a patient to have the same symptoms postoperatively: either the surgery was ineffective or the original diagnosis was incorrect. If the surgery simply did not work, the postoperative symptoms would be the same. Alternatively, there is no reason to believe that a patient will improve if the preoperative symptoms were not related to reflux in the first place. An incorrect original diagnosis is much more likely in patients who had no response to medical therapy preoperatively, especially those with atypical reflux symptoms. The initial approach to a patient with the same postoperative symptoms would be an empiric trial with a PPI for 1 or 2 months and this is frequently helpful. If the patient cannot stop the PPI without relapse of symptoms, it may be reasonable to simply continue the medical therapy. One may consider a surgical revision if chronic PPI therapy is required. However, given the high morbidity and mortality associated with second operations, this course of action should be discouraged. If there is no improvement with this empiric therapy, further evaluation will be needed. These patients should have assessment of the fundoplication with a barium swallow and/or an endoscopy. Certainly, if a second surgery is contemplated, a pH study must be performed to document the presence of reflux, especially if the patient has atypical GERD or if the fundoplication appears satisfactory.

The major new postoperative symptom is dysphagia. Dysphagia in the early postoperative period is very common. In fact, most patients are on soft diets for the first few weeks. Patients who are unable to drink liquids after 2 weeks or who are unable to eat solid foods after 6 weeks should be evaluated. The most important predictive factor in the management of postoperative dysphagia is the integrity of the fundoplication. A barium swallow and an endoscopy are complementary in the assessment of the integrity of the wrap. A barium swallow is better for examining the length of the fundoplication, whereas an endoscopy is better for assessing the location and orientation of the fundoplication. If the fundoplication is short (1–2 cm), parallel to the diaphragm, and at the top of the stomach, dilation therapy followed by watchful waiting will help the great majority of patients. The use of large dilators, i.e., 46 to 54 French, is very safe. There are conflicting reports on the use of the 3.0 cm pneumatic balloons. If the fundoplication is not intact, if it is too long, if it is twisted, or if gastric folds are seen above or alongside the wrap, surgical revision is usually necessary.

Surgical therapy is associated with serious, albeit infrequent complications. There is little doubt that successful anti-reflux surgery corrects the underlying pathophysiology, improves symptoms, normalizes quality of life scores, reduces health care utilization, and appears as good as or better than medical therapy in large comparative trials. Given the safety of PPI therapy, one must wonder if even the small risk of surgery is worthwhile in patients with uncomplicated GERD that responds to medical therapy. The decision to have anti-reflux surgery must be individualized. All patients undergoing long-term medical therapy for GERD should receive advice on the safety and wisdom of staying on that therapy, as well as information on anti-reflux surgery. Fundoplication should be considered in three circumstances: (1) It should be considered for individuals who are intolerant of proton pump inhibitor therapy because of side effects. However, this circumstance will be less common now that there are five PPIs available. (2) Fundoplication may be warranted for patients who are poorly responsive to proton pump inhibitor therapy. This outcome is probably not that common, given the effectiveness of the currently available PPIs. Such an outcome will be more common in patients with atypical GERD. The gastroenterologist should be as certain as possible that the patient not only has GERD, but that the patient's symptoms are reflux related. (3) Fundoplication may also be considered when a patient desires a permanent solution in order to be free of the need to take medications. These patients must be warned about potential suboptimal results, including the frequent need for medication within a few years of having the procedure, as well as the small, but real possibility of becoming worse after the operation. Even in experienced hands, 1–2% of patients are worse after the procedure.

Gastroesophageal reflux is a common, chronic problem that has great influence on the quality of life of patients. Excellent medical and surgical therapies are available. Diagnostic testing is largely reserved for

excluding complications such as Barrett's esophagus and evaluating those few patients who do poorly with therapy.

Gastroesophageal Reflux Disease (GERD) and Congenital Esophageal Obstructive Lesions, Pediatric

COLIN D. RUDOLPH
Medical College of Wisconsin and Children's Hospital of Wisconsin, Milwaukee

Barrett's esophagus Intestinal metaplasia of the esophageal mucosal lining.
esophageal stricture A narrowing of the esophageal lumen.
esophageal web A membrane obstructing the esophageal lumen.
gastroesophageal reflux The passage of stomach contents into the esophagus.
gastroesophageal reflux disease The disease that occurs when gastroesophageal reflux results in symptoms or signs, such as chest pain, esophagitis, chronic cough, or recurrent pneumonia.
histamine-2-receptor antagonists Medications that decrease gastric acid secretion by blocking the histamine-2 receptor.
Plummer-Vinson syndrome A disorder characterized by dysphagia, iron deficiency anemia, and a proximal esophageal web.
proton pump inhibitors Medications that decrease gastric acid secretion by inactivating the gastric proton pump that secretes acid from the parietal cells.
Schatzki ring A fibrous ring of tissue at the esophago-gastric mucosal junction that can cause dysphagia.
transient lower esophageal sphincter relaxation An episode of relaxation of the lower esophageal sphincter that is not associated with a swallow event.

Gastroesophageal reflux (GER) is a physiological event that occurs in normal infants, children, and adults. In the child and adult, refluxed gastric contents enter the esophagus and return to the stomach following transient episodes of relaxation of the lower esophageal sphincter. In the infant, the refluxed material often passes through the esophagus and mouth, resulting in regurgitation or vomiting of gastric contents. Gastroesophageal reflux can result in gastroesophageal reflux disease (GERD) when normal protective mechanisms fail. Inadequate esophageal clearance of the refluxed material results in esophageal inflammation and complications, such as stricture formation or Barrett's esophagus. Abnormalities of airway protective mechanisms may result in respiratory symptoms, such as pneumonia, apnea, laryngitis, and exacerbations of reactive airway disease. The first challenge in diagnosis and management of GERD is to determine whether GER is causing a specific symptom or sign since a variety of different pathogenic factors other than GER may present similarly in each case. Once the diagnosis is established, appropriate therapies need to be selected to balance risks of the disease versus the risks associated with each therapeutic option.

EPIDEMIOLOGY

During infancy, recurrent regurgitation or vomiting of gastric contents is frequent, occurring at least once per day in 50% of infants in the first 3 months of life, in 67% of infants who are 4 months old, and in 5% of infants who are 10 to 12 months old. Very few infants develop symptoms or signs of gastroesophageal reflux disease (GERD), which include feeding difficulties, irritability, hematemasis, anemia, failure to thrive, or respiratory disorders, such as apnea, stridor, chronic cough, or recurrent pneumonias. Little is known about the prevalence of GERD in children and adolescents. Preschool children may have problems, such as intermittent vomiting or vague complaints of abdominal pain. Older children and adolescents have presenting symptoms more similar to those of adults, such as complaints of heartburn. The incidence of supraesophageal complications of GERD in childhood is not known.

Although one study suggests that adults with GERD symptoms recall symptoms of gastroesophageal reflux (GER) during childhood more frequently than adults without GERD symptoms, there are very limited data regarding the natural history of GERD in infants and children. One retrospective study reports that in Finnish children diagnosed with GERD but without severe esophagitis, there was no progression of disease severity for 2 years after diagnosis but no longer term follow-up studies are available. Despite this lack of data, it is clear

 Copyright 2004, Elsevier (USA). All rights reserved.

that medical therapy for possible GER is frequently prescribed in adolescents. Pharmaceutical industry data from the United States indicate that 2% of adolescents and 3% of children are prescribed some form of antireflux therapy each year.

Families with multiple affected individuals with GERD have been described and it appears that there may be a genetic predisposition for GERD but no clear pattern of inheritance or genetic locus has yet been identified. A genetic locus associated with GERD was proposed to exist on chromosome 13q14 but these findings have not been replicated.

PATHOPHYSIOLOGY OF GASTROESOPHAGEAL REFLUX DISEASE

As in adults, most episodes of GER occur during transient lower esophageal sphincter relaxation (TLESR) episodes. These episodes are stimulated by gastric distension and allow venting of the stomach. Following the TLESR, secondary peristaltic contractions propel the refluxed gastric contents back into the stomach. Subsequent swallowing of saliva further neutralizes residual acid, returning the esophageal pH to normal and preventing inflammation. In normal infants, children, and adults, episodes of GER occur several times following meals and the esophageal pH returns to normal within minutes. Prolonged exposure to acid results in esophageal inflammation that may lead to scarring (stricture formation) or mucosal metaplasia (Barrett's esophagus).

Most episodes of GER do not reach the pharynx in normal adults or children. As refluxed material enters the upper esophagus, distension of the esophagus results in an initial reflex increase of the upper esophageal sphincter pressure, which tends to prevent most episodes of GER from reaching the pharynx. However, if the upper esophagus is rapidly distended, the upper esophageal sphincter relaxes and allows refluxed material to enter the pharynx. Simultaneously, airway protection mechanisms are invoked, including apnea and laryngeal closure to protect the airway from the refluxed gastric contents. Refluxed gastric contents can be vomited out of the mouth or may be reswallowed, clearing the pharynx before breathing resumes. Defects in esophageal clearance or airway protective mechanisms result in the diverse presentations of GERD outlined below (see Approach to the Gastroesophageal Reflux Disease Symptoms in Infants and Children).

DIAGNOSTIC EVALUATION FOR GASTROESOPHAGEAL REFLUX DISEASE

No single test can reliably differentiate whether GER is the cause of a specific symptom and sign. All of the tests have limitations and must be interpreted in the context of the specific clinical scenario.

Clinical History and Physical Exam

In infants and children, the clinical history and examination alone are often adequate to allow a diagnosis of uncomplicated GER. If warning signs (see Table I) suggest potential complications of GER, further diagnostic testing is indicated.

Radiographic Upper Gastrointestinal Series

Radiographic upper gastrointestinal series are used to evaluate the anatomy of the esophagus and upper gastrointestinal (GI) tract. This test is useful to exclude disorders that may present in a fashion similar to GER, such as an obstruction due to an esophageal stricture, achalasia causing dysphagia, aspiration during swallowing or a tracheoesophageal fistula causing recurrent pneumonia, or an anatomic disorder causing vomiting, such as pyloric stenosis or a malrotation. Findings of GER noted during the upper GI series are not a reliable predictor for GERD but often the evaluation of possible GER symptoms requires an upper GI series to exclude other disorders.

Esophageal pH Monitoring

Esophageal pH monitoring records the pH in the esophagus for 24 h using one or more pH electrodes.

TABLE I Warning Signals in the Vomiting Infant

Bilious vomiting
GI bleeding: hematemesis, hematochezia
Forceful vomiting
Onset of vomiting after 6 months of life
Failure to thrive
Diarrhea
Constipation
Fever
Lethargy
Hepatosplenomegaly
Bulging fontanelle
Macrocephaly/microcephaly
Seizures
Abdominal tenderness, distension
Genetic disorders

Traditional systems connect the sensor sites to an external recording device via a transnasal catheter. Recently, a system using telemetry connections was introduced such that in adults and older children the catheter may not be required. Normal values for the percentage of the 24 h recording time with esophageal pH being less than 4 (reflux index) vary depending on the site of the sensor in the esophagus and the age of the patient. Prolonged acid exposure correlates with an increased risk of esophagitis and it may be help determine whether GER is exacerbating asthma symptoms. Routine esophageal pH monitoring does not exclude GER as the cause of awake apnea in infants, recurrent pneumonia, or other supra-esophageal complications of GER. Esophageal pH monitoring may help clarify whether there is a temporal association between GER and the occurrence of a particular symptom, such as apnea, chest pain, or irritability. Calculation of the "symptom index" (the number of episodes of a symptom associated with GER divided by the number of episodes of a symptom) may help to determine the likelihood that GER is causing a specific symptom. Esophageal pH monitoring may be most useful to determine whether adequate GER therapy is being administered in a patient with persistent symptoms or signs despite aggressive medical therapy.

Esophagastroduodenoscopy and Biopsy

Esophagastroduodenoscopy (EGD) and biopsy involve the use of flexible fiber endoscopes to visualize and biopsy the esophageal mucosa. Small endoscopes with diameters as small as 5 mm allow endoscopy in infants and children with minimal morbidity. Sedation or anesthesia is usually necessary. Endoscopy and biopsy are useful to determine whether esophagitis is present and to confirm that GER is the most likely cause of esophagitis. Other causes of esophagitis, such as infection, Crohn's disease, eosinophilic esophagitis, or pill esophagitis, can also be identified. The stomach and small intestine can also be visualized during the same procedure so that EGD is useful for the evaluation of patients with symptoms including abdominal or chest pain, hematemasis, dysphagia, or odynophagia. EGD will also identify complications of GER, such as stricture or Barrett's esophagus.

Nuclear Scintigraphy

Nuclear scintigraphy is performed by the oral ingestion or instillation of technetium-labeled formula or food into the stomach. The areas of interest, the stomach, esophagus, and lungs, are scanned for evidence of GER and aspiration. The predictive value of this test for any complication of GER has not been established.

Esophageal Impedance Monitoring

Esophageal impedance monitoring measures both acid and nonacid episodes of GER. This new technology measures the electrical impedance between sequential sites in the esophagus. GER episodes are detected by changes in impedance. The use of this method remains experimental but it may be particularly useful for the diagnosis of airway-related complications of GER.

TREATMENT OPTIONS FOR GASTROESOPHAGEAL REFLUX DISEASE IN INFANTS AND CHILDREN

Treatment options for GERD are listed in Table II.

Conservative Therapy

Dietary changes may be useful in the treatment of infant GER. The number of episodes of vomiting and the amount of GER can be reduced by thickening infant

TABLE II Treatment of Gastroesophageal Reflux in Infants and Children

Conservative therapy
Infants
Thickening of formula with rice cereal or commerically available anti-reflux formula
Consider time-limited trial of protein hydrolysate formula
Rarely, consider prone positioning
Children
Sleep with head of bed elevated
Avoid caffeine, chocolate, spicy foods
Lose weight if obese
Pharmacologic Therapy
Antacids (use only for symptomatic relief in children and adolescents)
Magnesium hydroxide
Aluminum hydroxide
H2 blockers
Cimetidine
Ranitidine
Nazitidine
Famotidine
Proton pump inhibitors
Omeprazole
Lanzoprazole
Pantoprazole
Rabeprazole
Esomeprazole
Prokinetics
Surgical therapy

formula with up to 1 tablespoon of infant cereal per ounce. This very thick formula can be difficult to suck so that it is necessary to slit the nipple to allow easier flow. New formulas with starch solutions that thicken on contact with gastric acid are available. These formulas are easier for the infant to ingest and are effective in decreasing GER. Since cow's milk allergy can cause vomiting that is indistinguishable from GER in the infant, it is reasonable to consider a 2-week trial of a protein hydrolysate formula as treatment for an infant with recurrent vomiting. If there is a marked reduction in GER symptoms, it is reasonable to suspect that allergy may have caused the infant's vomiting.

Prone positioning decreases GER but infants that sleep in the prone position are at substantially increased risk of sudden infant death syndrome. Therefore, prone positioning during sleep is not recommended unless there is a substantial risk of possible aspiration with GER such as occurs in a child with an upper aerodigestive tract anomaly prior to surgical correction.

In children and adolescents, there is some evidence that avoidance of caffeine, chocolate, and spicy foods that provoke symptoms is useful for the treatment of GERD. There is also limited evidence that weight loss if obese and the avoidance of tobacco and alcohol may reduce GER. It is not known whether lifestyle changes have an additive benefit in patients receiving pharmacological therapy.

Pharmacologic Therapy

The medications currently available for the treatment of GERD in children are classified into those that decrease gastric acid secretion (anti-secretory agents) and those that decrease the number of GER episodes by improving gastrointestinal and/or esophageal motility (prokinetics). The anti-secretory agents include histamine-2 receptor antagonists (H2RAs) and proton pump inhibitors (PPIs). Both provide effective treatment for esophagitis but the PPIs are far more potent and result in more rapid healing. Long-term use of PPIs appears to be safe in infants and children. Hyperplastic and glandular gastric nodules and polyps may develop in children but this does not appear to be associated with an increased risk of gastric dysplasia or cancer. No effective prokinetic agents for the treatment of GERD are available in the United States. Metoclopramide does not decrease GER. Bethanechol is inadequately studied and has substantial side effects. Sucralfate has been used for the treatment of esophagitis in adults but there are inadequate data to support its use in children.

Surgical Therapy

As in adults, several approaches are available for surgical therapy of GERD in children. The Nissen fundoplication and modifications of this procedure are the most commonly performed operations. All of these procedures alter the anatomy at the diaphragmatic hiatus and increase the length of the intra-abdominal esophagus. Significant complications of the surgery include breakdown of the wrap, small bowel obstruction, gas bloat syndrome, dumping syndrome, infection, atelectasis or pneumonia, perforation, persistent esophageal stricture, and esophageal obstruction. These procedures are now frequently performed laparascopically, even in premature infants, which decreases the immediate postoperative morbidity. Alteration of the integrity of the fundoplication is more likely to occur in children who have neurological disease or in those with robust coughing (cystic fibrosis, asthma) and/or retching. Surgical therapy is usually not indicated for the treatment of infants with GERD unless the risks of complications of GERD outweigh the risks of surgery, since a combination of medical therapy and maturation often prevents the need for surgery. Surgical therapy may be more effective than medical therapy for the treatment of airway complications of GER, such as asthma or recurrent aspiration. In children and adolescents, growth and development are unlikely to alleviate symptoms. The decision to consider surgical therapy versus prolonged medical therapy requires balancing the risks and benefits of surgery with those of medical therapy. Recent studies indicate that despite surgical therapy, a large proportion of adults with GERD still receive PPIs when evaluated 5 years after surgery, indicating that surgery often does not lead to complete lifelong symptom resolution of GERD.

APPROACH TO GASTROESOPHAGEAL REFLUX DISEASE SYMPTOMS IN CHILDREN

The evaluation of each symptom presentation of GERD varies because the differential diagnosis, relative utility of different diagnostic tests, and consequences of making an incorrect diagnosis differ depending on the presenting symptom. The discussion below provides a brief overview of each symptom presentation and outlines symptom-directed diagnostic and therapeutic approaches.

Uncomplicated Gastroesophageal Reflux in an Infant

Normal infants have frequent episodes of GER with effortless, painless regurgitation. Simple "spitting up" must be distinguished from true vomiting, as each has different clinical implications. A large number of disorders can present with vomiting in infants but in the absence of warning symptoms and signs (Table I), parental education, reassurance, and anticipatory guidance are all that is required for management of simple GERD. No treatment is necessary if there are no symptoms in an otherwise well-appearing child but therapies including a time-limited trial of a hypoallergenic formula or use of thickened formulas may be used if desired. Recurrent GER generally decreases in frequency over the first year of life and resolves by 12 to 18 months of age. If symptoms worsen or do not improve by 18 to 24 months of age or are unresponsive to therapy much earlier, further evaluation including an upper GI series may be indicated.

Inadequate Weight Gain in an Infant

Attempts to curb the vomiting associated with uncomplicated infant GER by limiting the quantity of formula ingested can cause iatrogenic weight loss. If an infant is ingesting adequate calories without restrictions and weight loss persists, it is important that other causes of failure to thrive be considered before it is assumed that GERD is the cause. Vomiting due to allergy is indistinguishable from that due to GER so a time-limited (2 weeks) trial of administration of a hypoallergenic formula may be considered. Rarely, infants are unable to gain adequate weight due to problems of vomiting resulting from gastroesophageal reflux. If no other cause of vomiting or poor weight gain is identified, alternative management strategies include the administration of higher caloric density feedings (24 to 30 cal/oz), nasogastric tube feedings, or nasojejunal tube feeding. Pharmacologic therapy with a prokinetic would potentially be useful but no prokinetic agents that aid in management of GER are available. If the infant has concomitant delayed gastric emptying, metoclopramide or domperidone therapy may be helpful.

Excessive Irritability in an Infant

GER is rarely the cause of excessive irritability or colic in infants. Normal infants fuss or cry for an average of 2 h daily, with many normal infants crying for up to 6 h per day. Crying peaks at 6 weeks of age. There is no strong evidence demonstrating a relationship between excessive crying and GER; however, GERD is frequently invoked as a cause of irritability based on the frequency of vomiting in infants and extrapolations from the adult experience with heartburn. No good controlled studies demonstrate a response of irritability to GER therapy. In infants with severe irritability, other causes, such as neurologic disorders, urinary tract infection, allergy, or small intestinal disorders, need to be ruled out before a trial of empiric therapy for GERD is considered. A clear relationship between GER and episodes of irritability can be established by obtaining an esophageal pH monitoring study and determining the symptom index (see Diagnostic Evaluation for Gastroesophageal Reflux Disease). A trial of therapy of GER can be considered if other causes of irritability are excluded and episodes of irritability are associated with GER documented by vomiting or by esophageal pH monitoring.

Heartburn or Chest Pain in the Older Child

GER may cause symptoms of heartburn or chest pain in children. Some children have difficulty localizing pain and complain of "tummy" pain. In children with intermittent symptoms, initial empiric therapy with antacids, H2RAs, or PPIs can be considered. If symptoms recur following cessation of therapy or do not improve with empiric therapy, then diagnostic upper endoscopy with biopsy should be considered. Other disorders that cause esophagitis, including eosinophilic esophagitis or inflammatory bowel disease, and infectious esophagitis can present with similar symptoms. Some patients without esophagitis experience pain during physiologic reflux episodes. In these patients, it is reasonable to continue treatment with either H2RAs or PPIs to relieve symptoms despite the absence of esophagitis.

Feeding and Swallowing Difficulties

Feeding difficulties are associated with the presence of GER in infants and children but it is unclear whether GER (even in the presence of esophagitis) actually causes feeding problems in infants. Adults with relatively severe esophagitis rarely complain of significant dysphagia unless they develop stricture. No study has demonstrated that treatment of GER improves feeding in infants. Because a large variety of disorders may contribute to feeding difficulties or dysphagia in the infant and older child, empirical therapy for GER is generally not recommended. However, if there are other signs or symptoms suggestive of GERD, then a time-limited course of medical therapy can be considered. Usually, a diagnostic evaluation with a radiographic contrast study should first be performed to identify anatomic abnormalities, such as strictures or vascular rings,

and motility disorders, such as achalasia. Upper endoscopy with biopsy is also usually performed to rule out other causes of esophagitis.

Other Esophageal Symptoms and Signs

Esophagitis causes other symptoms including hematemasis and atypical seizure-like movements with torsion of the neck known as Sandifer's syndrome, esophageal stricture, and Barrett's esophagus. When erosive esophagitis is demonstrated during endoscopic evaluation, treatment with H2RAs or PPIs is usually indicated. PPI therapy is highly effective for treatment of esophagitis resulting from GER. Biopsy is mandatory to rule out other causes of esophagitis. Typical biopsies in GERD reveal thickening of the basal cell layer (>25% of mucosal thickness), increases in papillary height (>50% of mucosal thickness), and infiltration with neutrophils (>1 per HPF) or eosinophils (>1 and <15 per HPF). Barrett's esophagus is presumed to result from esophagitis. It is characterized by intestinal metaplasia of the mucosa and is associated with an increased risk of adenocarcinoma of the esophagus. Other causes of esophagitis include eosinophilic esophagitis, allergy, inflammatory bowel disease, infections, caustic esophagitis, and pill esophagitis, all of which are characterized by different findings on biopsy. The best approach to management of erosive esophagitis and Barrett's esophagus in children remains controversial. Due to the long-term risk of adenocarcinoma, many experts recommend that children with this diagnosis should undergo surveillance esophagoscopy and biopsy every 3 to 5 years. Treatment of GER-induced esophagitis should focus on reducing the acid exposure of the esophagus. No studies show a benefit of surgical anti-reflux therapy compared to long-term PPI therapy for prevention of GER complications including stricture or adenocarcinoma. The relative long-term risks and benefits of medical versus surgical therapeutic approaches are unclear.

Apnea

Cessation of breathing when gastric contents reflux into the pharynx is a normal physiologic protective mechanism that prevents aspiration. This reflex response appears to be somewhat more robust in the infant than in the adult such that laryngeal stimulation is more apt to cause cough in the child or adult but will cause apnea in early infancy. This relationship has led to a widely held belief that GER is a common cause of apnea of prematurity and of acute life-threatening events (ALTEs) in infancy. There is no good evidence to support a relationship between GER and the central apnea observed in premature infants. ALTEs are episodes in infants characterized by a combination of apnea, change in color (cyanosis, pallor, rubor, plethora), change in muscle tone (limpness, stiffness), and choking and gagging that requires intervention by the caretaker. GER is only one of many potential causes of an ALTE and those due to GER generally occur while the infant is awake, supine, and usually within 1 h of feeding. Prior to invoking GER as the cause of ALTE, it is essential to rule out other potential causes including anatomic airway obstructive disorders, central apnea, cardiac, central nervous system and infectious disorders, and possible intentional suffocation observed with Munchausen-by-proxy syndrome. Definitive demonstration that apnea is caused by GER in an individual patient is often difficult because the episodes occur sporadically. Thus, even during 24 h of monitoring, an episode often does not occur. Furthermore, it is impossible to determine whether GER is causing the episode or whether it results from the respiratory effort associated with obstructive apnea. Therefore, if esophageal pH monitoring is being performed to document a relationship between the apneic episodes and GER, it is useful only if combined with simultaneous recording of heart rate, chest wall impedance, nasal airflow, and oxygen saturation to detect obstructive apnea. Esophageal impedance recording may be more useful because it will detect acid and nonacid GER episodes, both of which could cause awake apneic episodes. Generally, it is reasonable to initiate therapy for presumed GER-related apnea without any diagnostic testing if there is a characteristic history combined with appropriate testing to exclude other causes of ALTEs. Conservative medical therapy for GER and possibly the administration of antisecretory agents decreases the frequency of episodes. Surgical therapy is usually not required since the frequency of episodes almost always decreases as the infant matures and the risk of morbidity from surgery generally exceeds the risk from the awake apneic episodes.

Asthma

Although the prevalence of GER in children with asthma is approximately 50%, GER exacerbates but does not cause asthma. Animal studies suggest that esophageal acid exposure may increase the reactivity of the airway through vagal reflex mechanisms. Microaspiration of refluxed gastric contents may also alter airway reactivity. Vigorous anti-reflux therapy (high-dose proton pump inhibitors) may decrease the severity of symptoms in some patients, especially those with coexisting symptoms of esophagitis. In patients without any symptoms suggestive of GER, esophageal pH

monitoring should be considered in those with asthma and recurrent pneumonia, those with nocturnal asthma more than once a week, those requiring either continuous oral corticosteroids or high-dose inhaled corticosteroids (more than two courses per year of corticosteroids), and those with persistent asthma unable to wean medical management. If esophageal pH monitoring demonstrates an increased frequency or duration of esophageal acid exposure, a trial of prolonged medical therapy for GER should be considered. In patients who respond to therapy, a decision to consider surgical management must balance the risks of long-term medical therapy versus surgical therapy. Some studies suggest that surgical therapy may be more effective than medical therapy, but these studies did not treat patients with high doses of PPIs.

Recurrent Pneumonia

In children with abnormal airway protective mechanisms, such as those with neurologic disease or with laryngeal anatomic defects, GER may cause recurrent pneumonia. Pulmonary fibrosis and chronic lung disease can result. Unfortunately, it is difficult to prove that GER is the cause of chronic lung disease. Normal esophageal pH monitoring does not exclude GER as a cause of recurrent aspiration. Bronchoalveolar lavage with large numbers of lipid-laden macrophages suggests that aspiration may be present, but it may be difficult to determine whether aspiration occurs during swallowing or only during episodes of GER. Regardless, treatment of GER is often indicated once other causes of recurrent pneumonia are ruled out, such as an immunodeficiency, cystic fibrosis, or anatomic defects, such as a tracheoesophageal fistula. Medical therapy may be tried in children with only moderate pulmonary disease, but in children with more severe pulmonary disease, antireflux surgery should be considered.

Hoarseness and Recurrent Croup

Hoarseness and recurrent croup have been associated with GER. The approach to diagnosis and treatment of GER-related laryngeal disease is at present undefined but a trial of aggressive anti-reflux therapy with a high-dose proton pump inhibitor is reasonable. If symptoms resolve and then recur with the cessation of therapy, GER is likely responsible. Decisions regarding long-term therapy must balance the risks of long term medical or surgical therapy versus the severity of underlying symptoms.

Other disorders, such as sinusitus, otitis media, and dental erosions, have been suggested to be related to GER but there is little evidence to support these contentions at this time.

CONGENITAL ESOPHAGEAL OBSTRUCTIVE LESIONS

Congenital Esophageal Stenosis and Web Diaphragms

Congenital esophageal stenosis and web diaphragms rarely occur (i.e., 1 in 25,000 live births) and usually present with dysphagia when feeds are advanced to puréed or solid consistencies. Diagnosis is made by radiographic contrast studies or endoscopy. Webs and fibromuscular stenosis usually can be successfully dilated using endoscopy- and/or fluoroscopy-guided balloon or bougie-type dilators. However, dilation of a stenosis resulting from ectopic cartilage (i.e., tracheobronchial remnant), which on endoscopy is more irregular and firmer than the fibromuscular type, seems somewhat more likely to result in perforation, leading some experts to recommend primary surgical resection of these lesions.

Acquired Esophageal Webs

Acquired esophageal webs are very uncommon in children. Plummer-Vinson syndrome, characterized by dysphagia, iron deficiency anemia, and an esophageal web in the upper esophagus, has only rarely been reported in childhood. Treatment of the iron deficiency and dilation of the web is therapeutic. An association with celiac disease has been reported and probably resulted from the severe iron deficiency sometimes observed in celiac disease.

Schatzki Rings

Schatzki rings are fibrous mucosal thickenings at the esophageal–gastric junction and are also very uncommon in children, presenting with progressive dysphagia of solids or acute food impaction. Although uncommon, this lesion can be seen in children with esophagitis and is treated with dilation.

Esophageal Duplications

Esophageal duplications are rare lesions that present as a tubular mass in the posterior mediastinum. Secretions cause distension with pressure on contiguous structures that can cause dysphagia or respiratory symptoms. Simple surgical excision is curative.

Congenital Esophageal Diverticulae

Congenital esophageal diverticulae are rare lesions that occur through the muscle layer located just above the cricopharyngeus muscle. They may present with symptoms of choking, coughing, and dysphagia in an older child. More commonly, acquired diverticulae without a muscle layer occur in neonates after traumatic efforts at airway intubation. Perforation results in infection and edema, which may cause obstruction. Antibiotic therapy and the cessation of oral feedings usually allow resolution of perforation if it is recognized early.

Vascular Rings

Vascular rings may also present with dysphagia or airway obstruction. Diagnosis is usually made by radiographic contrast esophagrams. The most common anomaly is that of an aberrant right subclavian artery, which crosses behind the upper esophagus and is seen in approximately 1% of the population. It usually is asymptomatic but in some children it may cause obstruction (dysphagia lusorum). If this occurs, other causes of dysphagia should be ruled out before surgical therapy is considered. The other most common vascular obstruction of the esophagus is a double aortic arch, which usually results in dysphagia and respiratory symptoms.

Gastrointestinal Matrix, Organization and Significance

RICHARD C. BATES
Beth Israel Deaconess Medical Center and Harvard University

basement membrane A specialized, sheet-like, extracellular matrix structure that separates the connective tissue from the epithelia, blood vessels, muscle fibers, and nerves.

lamina propria The connective tissue compartment located just below the epithelium consisting of interstitial matrix as well as various cell types (fibroblasts and immune cells).

mucosa The most highly differentiated layer of the gastrointestinal tract, comprising the epithelium, basement membrane, lamina propria, and layer of smooth muscle known as muscularis mucosae. Tissue specialization and surface shape are correlated with functional differentiation along the tract.

restitution The process that repairs damage to the epithelium above the lamina propria, involving epithelial cell migration and spreading across the site of injury in order to resurface it.

The mucosal layers of the stomach, intestine, and colon are well-differentiated tissues that display variations in cell type and structure, reflecting the functional specialization of the gastrointestinal tract. However, these mucosa share a common anatomy comprising epithelial cells, underlying connective tissue regions rich in extracellular matrix components and mesenchymal cells, and also smooth muscle. The biochemical components of the matrix form supramolecular complexes that provide physical support for the overlying epithelium and interact, via specific domains, with cellular receptors capable of influencing signal transduction pathways and gene transcription. Thus, the gastrointestinal matrix forms a regulatory network that directs such fundamental cellular processes as proliferation, differentiation, and migration to influence organ function.

INTRODUCTION

The extracellular matrix (ECM) network supporting the gastrointestinal tract is a rich milieu of structural proteins, proteoglycans, growth factors, and matricellular proteins. This stromal compartment also contains cells of mesenchymal origin, such as fibroblasts and immune cells, that are responsible for the maintenance of mucosal integrity. This article describes the major structural components of the matrix, which in general tend to be multifunction, multidomain molecules whose interactions are mediated through specific modules. Localization of these proteins into distinct subepithelial structures and/or regions suggests that functional specialization accompanies differentiation in the gastric mucosa. In addition to providing architectural support, it is now known that the matrix itself promotes signaling that is critical for cellular function, primarily via the integrin family of adhesion receptors. Indeed, matrix-derived signals direct such fundamental processes as proliferation, differentiation, maturation, and survival—which in turn affect tissue homeostasis, organ topography, and, ultimately, gastrointestinal function.

STRUCTURE AND COMPOSITION

Basement Membrane

Along the gastrointestinal tract, a simple columnar epithelium resides upon a basement membrane that also provides an interface with the lamina propria beneath it (Fig. 1). At the electron microscope level, the basement membrane appears as a continuous sheet of electron-dense material and is composed primarily of laminins, type IV collagen, nidogen, and heparin sulfate proteoglycans (HSPGs) integrated into a common structure, instead of simply being layered. Additional ECM components, such as fibronectin and tenascin, as well as associated proteins, such as SPARC (secreted protein, acidic and rich in cysteine), are also present in the basement membranes of the gastrointestinal tract. It is now appreciated that the interactions between components of the basement membrane are regulated through multiple, mostly domain-specific mechanisms.

Laminins, Nidogen, and Type IV Collagen

Laminins are a major component of the basement membrane. All laminins are large heterotrimeric glycoproteins composed of α, β, and γ subunits that

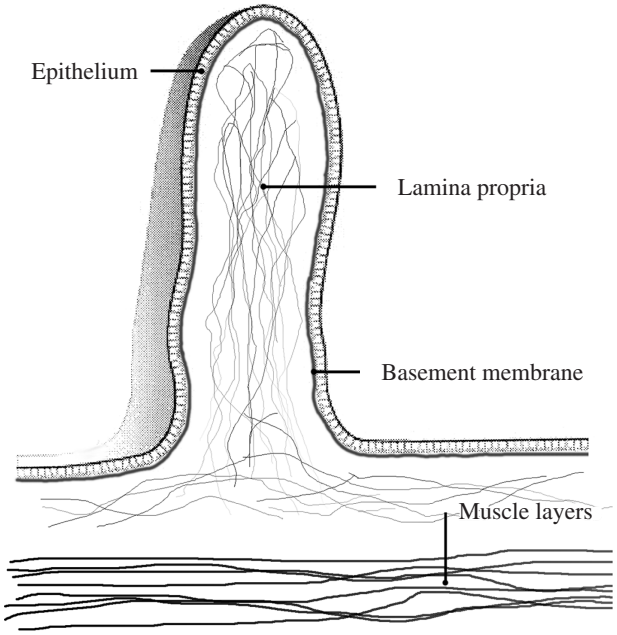

FIGURE 1 Schematic overview of an intestinal villus demonstrating the ultrastructural arrangement of the gastrointestinal mucosa layer. A columnar epithelium sits upon a basement membrane, which also provides an interface with the underlying loose connective tissue, the lamina propria. A smooth muscle layer defines the extent of the mucosa proper.

associate to form a cross-like structure. Five distinct α, three β, and two γ chains associate to form at least 11 currently known laminin isoforms, of which laminins-1, -2, -5, and -10 are most abundantly expressed in the intestinal matrix. Furthermore, these laminin proteins are often expressed in a developmental- and tissue-specific manner, suggesting a functional diversity of the individual variants. For example, laminin-1 and -2 show a complementary pattern of expression along the crypt–villus axis in the adult human intestine: laminin-1 presents a decreasing gradient of intensity from the tip of the villus to the crypt mouth, whereas laminin-2 is exclusively present in the basement membrane that surrounds the bottom of the crypts. At the C-terminal region of the heterotrimer, all laminins possess a large globular domain that contains modules via which laminin molecules interact with cells as well as other matrix molecules. In addition to self-assembly, laminins do associate with other laminin isoforms and other ECM molecules. Indeed, the ECM glycoprotein nidogen functions as a laminin–collagen IV bridge that is essential for the structural integrity of the basement membrane. Nidogen forms a link between the laminin and type IV collagen networks and, similarly, mediates the formation of a tertiary complex between laminin and the core protein of the proteoglycans. Because nidogen appears to play such an important role in basement membrane formation, it is not surprising that isoforms of this protein have now been discovered.

Collagens, which represent the most abundant proteins of the body and function as extracellular building blocks, are encoded by a family of at least 30 genes. Each gene encodes a precursor chain, known as a pro α chain; these chains assemble together in a tight triple-helix composed of three chains both as homotrimers and as heterotrimers. Of this family, type IV collagen is the major structural component of the basement membrane. It is composed of three of six genetically distinct α (IV) chains. The distribution of the α (IV) chains varies with tissues: α1 (IV) and α2 (IV) chains are widely distributed, whereas α3–6 (IV) chains are restricted to certain basement membranes. The presence of these multiple chains that give rise to at least five distinct type IV isoforms adds to the complexity of the basement membrane organization. Not surprisingly, during development and in the adult organs, type IV collagen expression parallels that of laminin-1 in the gut.

Proteoglycans

Proteoglycans are large proteins that carry sulfated polysaccharides (glycosaminoglycans) as side chains and are ubiquitously expressed in virtually all mammalian tissues. Heparin sulfated proteoglycans (HSPGs) are typical constituents of basement membranes, with the most prominent HSPG in the gastrointestinal tract being perlecan, which consists of a 400 to 500 kDa core protein with three heparin side chains. Incorporation of proteoglycans into the basement membrane involves heparin binding to laminin and type IV collagen, as well as core protein binding to nidogen.

Fibronectin and Tenascin

Additional ECM components fibronectin and tenascin are also present in the basement membranes of gastrointestinal tissues. Fibronectin is a large, multidomain adhesive glycoprotein that is an essential constituent of many extracellular matrices found throughout the body and also occurs as a soluble form in plasma. The amino acid sequence of fibronectin reveals three types of internally homologous repeats separated by short connecting sequences. There are 12 type I, 2 type II, and 15 type III modules and homologous domains are also found in other proteins, especially the type III repeat. Fibronectin is synthesized by cells as a soluble protomer and then converted into an insoluble form that becomes incorporated into the fibrillar meshwork

of the lamina propria (see below) or included into the basement membrane itself.

Tenascin-C (Tenascin-cytoactin) is the prototype member of a family of glycoproteins that arise from alternative splicing of a single gene. Their molecular structure is that of a hexameric oligomer with a striking symmetrical appearance. Six polypeptide chains emanate from a central core where the amino-termini are linked via a tenascin assembly domain; each arm contains a row of epidermal growth factor-like as well as fibronectin type III repeats and the terminal knob is composed of a globular domain resembling the carboxy-terminal region of the β and γ chains of fibrinogen. During embryogenesis, tenascin is broadly expressed, but its expression in adult tissues is far more restricted.

Interestingly, tenascin and fibronectin exhibit opposing gradients of expression in the basement membrane of the crypt–villus axis, consistent with a proposed fibronectin-antagonizing role for tenascin. Tenascin shows a gradient of increasing immunoreactivity toward the tip of the villus and it has been suggested that tenascin promotes the sloughing of intestinal epithelia into the gut lumen, which occurs at the top of the villi in the small intestines and on the surface of the colonic mucosa. Conversely, fibronectin reactivity is strongest in the lower regions of the crypts, with decreased staining intensity in basement membranes toward the surface of the villus.

SPARC

SPARC is a multifunctional glycoprotein that belongs to the group of matricellular proteins that mediate cell–matrix interactions, but do not serve primarily structural roles, as opposed to fibronectin, laminin, and the collagens. Other members of this group of proteins include thrombospondin and tenascin, as outlined above. SPARC modulates cellular interactions with the ECM by binding to structural matrix proteins, in particular collagen, as well as exerting a counteradhesive effect on cells. It has a broad tissue distribution, but in the adult appears to be most highly expressed in remodeling tissues and those with high rates of epithelial turnover, such as the gut, bone, and tissues undergoing repair.

Lamina Propria

The lamina propria constitutes the layer of loose connective tissue and interstitial matrix located just below the epithelium. In the stomach, the lamina propria tends to be relatively inconspicuous, filling the interstitial spaces between the tubular gastric glands. It is more expansive in the small intestine, where it occupies the cores of the villi and envelops the crypts. In the colon, it again becomes more retracted based on morphology, restricted largely to the regions between crypts. The structural composition of this zone differs fundamentally from that of the basement membrane in terms of its high content of fibrillar collagens and proteoglycans. However, as shown in Fig. 2, there is some overlap in terms of content with basement membrane-associated proteins. Notably, in addition to their reciprocal expression pattern seen in the basement membrane, both tenascin and fibronectin are found as part of the meshwork of the lamina propria interstitial matrix. Functionally, this region provides the structural support for the lymphatics and vasculature. Furthermore, the lamina propria of the stomach and intestine is also particularly cell-rich, including fibroblasts, lymphocytes, macrophages, plasma cells, and mast cells. This large proportion of cells with immune function provides an effective secondary line of defense against potential invading microorganisms and aggregations of lymphoid nodules within the lamina propria of the small intestine give rise to the specialized areas known as Peyer's patches. The lamina propria extends to the thin layer of smooth muscle, or muscularis mucosae, which together with the epithelium and basement membrane constitutes the mucosa of the gastrointestinal tract.

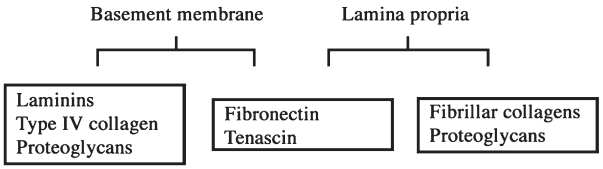

FIGURE 2 Summary of the major extracellular matrix protein components and their distribution within the basement membrane and lamina propria.

DERIVATION OF THE MATRIX

Both basement membrane assembly and lamina propria synthesis result from a complex interplay between epithelial and mesenchymal cells. Clearly, basement membrane assembly must occur in the extracellular environment at the interface of these two layers. With regard to the laminin family of proteins, evidence suggests that individual epithelial or mesenchymal cells are capable of producing several laminin chains and isoforms simultaneously, before depositing them together into the adjacent basement membrane. For example, epithelial cells produce laminin-1 and mesenchymal cells produce laminin-2. The mesenchymal compartment is thought to be the principal source of endogenous type IV collagen. Similarly, nidogen, whose crucial

role as a intermolecular cross-linker is required for basement membrane assembly, has been shown to be a mesenchymal product. In contrast, HSPG molecules located in the basement membrane of the developing intestine appear to be produced by the epithelial cells exclusively. Fibronectin is produced by epithelial cells, but is also synthesized by cells within the lamina propria, such as fibroblasts. Taken together, these findings reinforce the concept that epithelial–mesenchymal interactions play an important role in the formation of a complete basement membrane.

SIGNALING FROM THE MATRIX

Far from merely providing a static architectural role, it is now established that the matrix composition of the gastrointestinal tract defines the necessary microenvironment essential for multiple cellular functions including differentiation, proliferation, migration, and even survival. The best characterized ECM adhesion receptors are the integrins, which constitute a diverse family of integral membrane glycoproteins. Integrins function as noncovalently linked αβ heterodimers and, in addition to their ability to support cell adhesion, they activate signal transduction pathways via their cytoplasmic domains. The dual ability of these receptors to promote adhesion and influence signal pathways and gene expression in response to matrix proteins has established them as the principal mediators of specific signaling from the matrix. As demonstrated by the complementary gradients of laminin-1 and -2 expression, and the opposing expression profiles of fibronectin and tenascin in the basement membrane, specific regional differences in the biochemical composition of the matrix would be expected to influence epithelial cell behavior. Additionally, changes in integrin receptor expression by the epithelial cells themselves dictate their functional responses to the underlying matrix.

The complexity of integrin expression and function is highlighted by studies of the laminin-binding integrins in the gastrointestinal tract. Expression is complex and exhibits variations, for example, during development and even along the crypt–villus axis in the adult intestine. Here, it has been shown that two potential laminin-binding receptors exhibit complementary staining patterns along the crypt–villus axis, with α2β1 predominant in the crypts and α3β1 more highly expressed along the villus. Although α2β1 expression appears to correlate with that of laminin-2 in the crypts, this integrin actually has a higher affinity for laminin-1 binding than laminin-2. Since the crypt basement membrane is devoid of laminin-1, and α2β1 can also bind to collagen, it appears that this integrin is actually functioning as a collagen receptor in the intestine. Additional complexity arises when it is considered that α3β1 is further capable of binding multiple ligands including fibronectin, type IV collagen, and nidogen; thus, any of these components could influence gene expression in the epithelial cells by activating this receptor. Furthermore, other integrins such as α6β1, α7β1, and α6β4, all of which function exclusively as laminin receptors, are also co-expressed by these same cells and appear to have more uniform distributions. This apparent redundancy suggests that these different receptors must serve distinct signaling functions when binding to the same matrix protein.

MATRIX REGULATION OF RESTITUTION AND MUCOSAL HEALING

The mucosal epithelium of the gastrointestinal tract serves as an important barrier to a wide variety of noxious and potentially harmful agents. It is essential, therefore, that the epithelial layer is rapidly resealed following injury, for example, as the result of gastric ulceration, bacterial infection, inflammatory bowel conditions, ischemia, or radiation. This is accomplished by a process known as restitution, whereby viable epithelial cells migrate from regions proximal to the site of injury to cover the denuded surface. This response reestablishes epithelial continuity more rapidly than can be achieved by cell proliferation and helps prevent deeper mucosal damage. In order to do so, the epithelial cells temporarily and reversibly lose their polarized appearance and assume a more squamous morphology, best described not as dedifferentiation but rather as redifferentiation toward a motile phenotype. Restitution is subject to strict regulatory controls, directed in part by soluble mediators such as growth factors and bioactive peptides, as well as nonsoluble factors, including the extracellular matrix itself. The molecular architecture of the matrix, with its adhesive protein constituents, provides a physical substrate permitting traction and the generation of forces needed for migration and thus directly influences the rate of cellular motility. Furthermore, the matrix can also directly and specifically modulate signal transduction pathways within the epithelial cells themselves, at the level of protein activation, synthesis, and localization. The same adhesive components, including the collagens and fibronectin, have been shown to influence cell morphogenesis and differentiation, mediated largely through integrin activation and signaling. These signaling pathways direct the cytoskeletal changes and adhesive responses seen in migrating cells. Moreover, it is emerging that matrix-dependent motility-related

signaling is likely to be involved in cross talk with signals provided by other stimuli, such as growth factors, adding yet another level of complexity in the regulation of this critical homeostatic process.

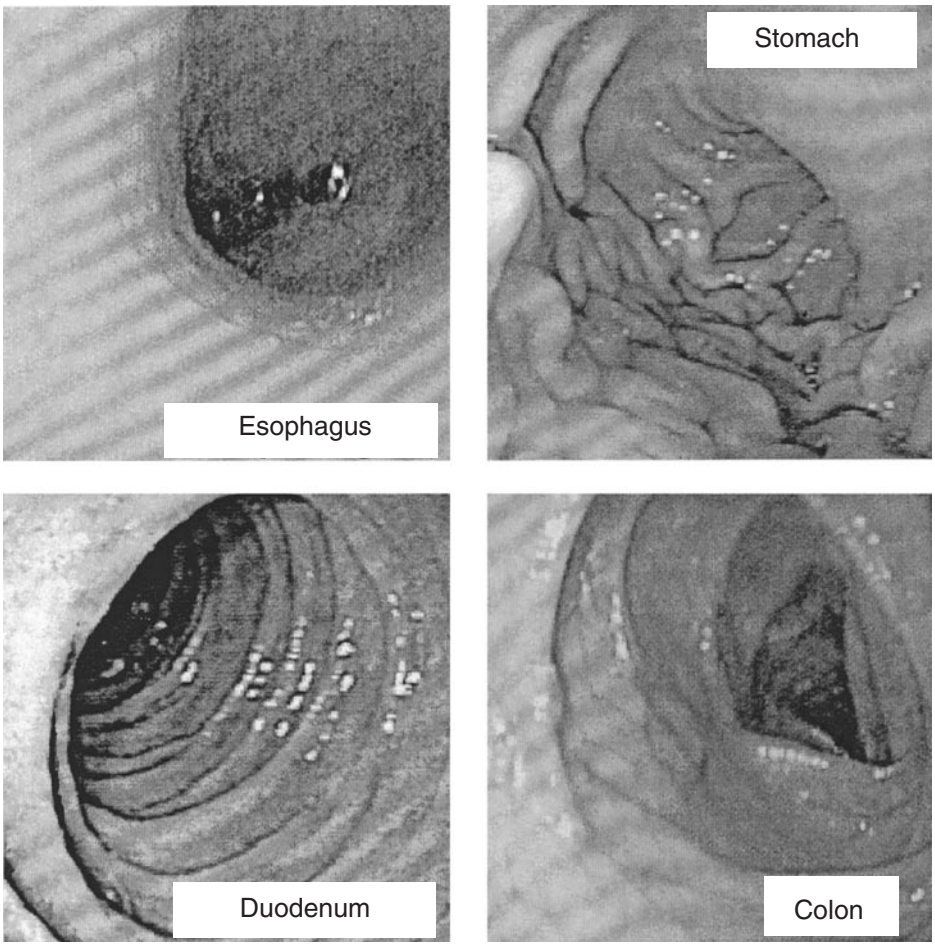

FIGURE 1 Endoscopic survey of the gastrointestinal tract. Endoscopic views of the esophagus, stomach, duodenum, and colon. The squamous mucosa of the esophagus is smooth and pink, without folds. In contrast, the gastric rugae are prominent. These stretch and flatten when the stomach is distended. In the duodenum, the plicae circularis are circumferential. The villi are appreciated as a velvety mucosal surface. The colonic mucosal folds are not circumferential and are tethered at sites corresponding to the teniae coli, resulting in a triangular profile.

third draining into the portal vein (via the gastric veins). With this rich vasculature, ischemia of the esophagus is uncommon. Unfortunately, this also makes the vascular network accessible to esophageal tumors and vulnerable to early local metastasis.

The esophagus begins in the pharynx, at the cricoid cartilage, and passes through the posterior mediastinum behind the aortic arch and left main stem bronchus. The esophagus then courses anterior to the aorta as it passes through the diaphragm, to the gastroesophageal junction. From the lumen outward, the esophageal wall is composed of the mucosa, submucosa, muscularis propria, and adventitia, respectively.

The principal esophageal function, transport of substances from the oral cavity to the stomach, is accomplished by coordinated contraction of the muscular layers. Like the entire gastrointestinal tract, the muscularis propria is composed of inner circular and outer longitudinal layers. Unlike the remainder of the gastrointestinal tract, the muscle layers include both skeletal (voluntary) and smooth (involuntary) muscle. Muscle in the upper third of the esophagus is composed primarily of skeletal muscle, while muscle in the middle third of the esophagus is a mixture of skeletal and smooth muscle, and that in the distal third is entirely smooth muscle. Thus, when food or liquid is ingested, a swallow is initiated voluntarily by coordinated relaxation and contraction of upper esophageal skeletal muscle. This continues involuntarily, as food is propelled via waves of contraction into the distal esophagus

and stomach. Auerbach's plexus lies between the circular and longitudinal muscles and generates the neural signals that control these contractions.

Entry into and exit from the esophagus is restricted by contractile muscle bundles termed the upper and lower esophageal sphincters, respectively. At rest, both sphincters are contracted, or closed; the upper esophageal sphincter closes to prevent air entry and the lower esophageal sphincter closes to prevent reflux of gastric contents. Relaxation of each sphincter must occur in coordination with a swallow to allow the appropriate passage of food and liquids. Failure of lower esophageal sphincter relaxation prevents passage of food from the esophagus into the stomach, resulting in the disease known as achalasia. In contrast, insufficient contraction of the lower esophageal sphincter results in gastroesophageal reflux and esophagitis. Commonly used substances, such as caffeine, alcohol, and nicotine, can prevent complete closure of the lower esophageal sphincter and cause or aggravate gastroesophageal reflux disease (GERD).

The esophageal lining is normally pink, moist, and covered by stratified squamous epithelium, much like the skin (Fig. 2). This ends abruptly at the Z-line, which marks the transition to the columnar epithelium of the stomach. The submucosa of the esophagus contains modified salivary glands that secrete mucus (for lubrication), growth factors (to augment epithelial cell growth and aid in repair), and, in the distal esophagus, bicarbonate (to neutralize acids).

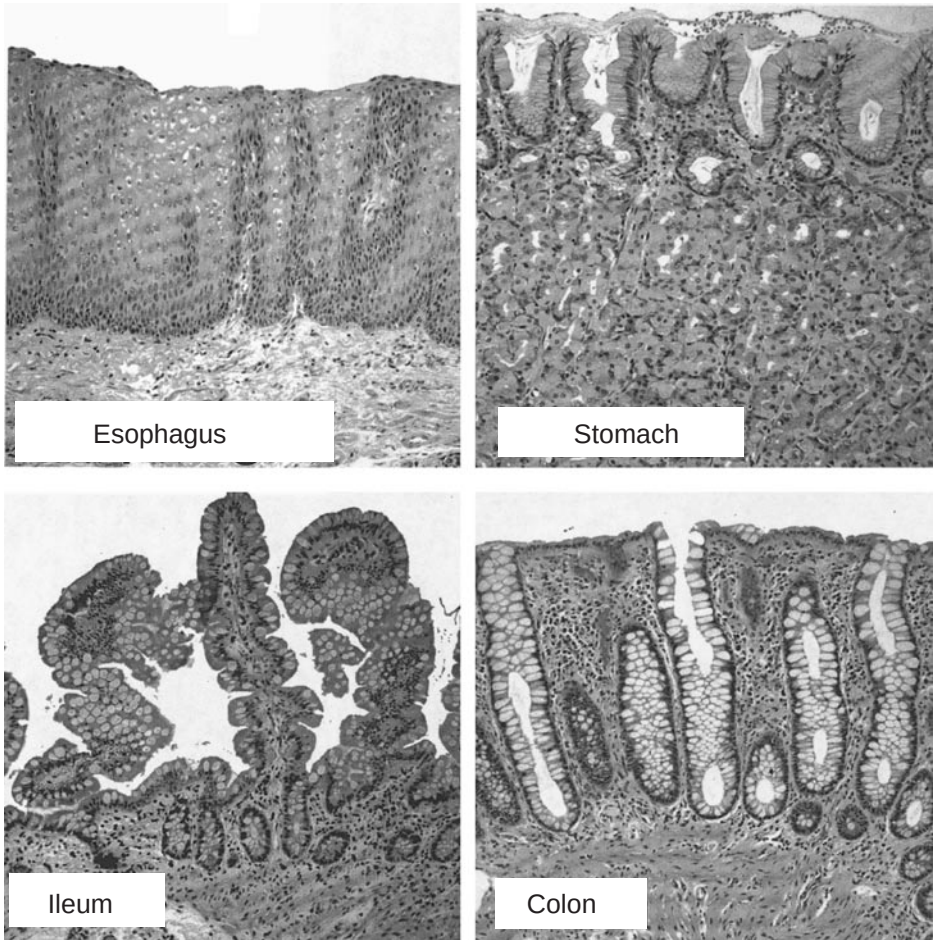

FIGURE 2 Histology of the esophagus, stomach, ileum, and colon. The esophagus is lined by a multilayered squamous epithelium, with the basal proliferative zone represented by the darker region at the bottom of the epithelium. The gastric body is lined superficially by mucus cells. Specialized parietal and chief cells are seen in deeper layers of the mucosa, in the glandular compartment. The ileum of the small intestine is distinguished by the presence of villi. These are absent in the colonic mucosa, which is dominated by crypts that are normally arranged in a uniform array.

STOMACH

The stomach is a distensible saccular portion of the gastrointestinal tract between the esophagus and the small intestine. Food enters the stomach through the gastroesophageal junction. While in the stomach, food is mixed with gastric acid and digestive enzymes to form chyme. Thus, the stomach serves, in part, as a reservoir, holding ingested food and chyme and delivering the latter to the small intestine at a controlled rate. As chyme exits the stomach, the narrow pyloric channel acts as a sieve, preventing large food particles from entering the duodenum until they are adequately processed.

The stomach is located in the left upper quadrant of the abdomen. In general, the stomach is J-shaped, but there is considerable variation based on the volume of the gastric contents. Sites within the stomach are commonly described based on two curvatures; the lesser curvature of the stomach forms the right upper border and the greater curvature forms the left lower border. The stomach receives arterial circulation from branches of the celiac artery.

The mucosal surface of the stomach forms prominent folds, or rugae, in an empty state (see Fig. 1). The gastric wall consists of four layers: mucosa, submucosa, muscularis propria, and serosa. The mucosa contains the secretory glands. The submucosa is mainly connective tissue containing lymphocytes, plasma cells, and neurovascular elements. The muscularis propria contains three layers: longitudinal fibers, circular fibers, and oblique fibers. The circular fibers course around the body of the stomach and thicken at the exit from the stomach, forming the pyloric sphincter.

The stomach can be divided into cardia, fundus, body, antrum, and pylorus. The cardia is a small section of the stomach located next to the gastroesophageal (GE) junction, just left of the midline. The Z-line marks the abrupt mucosal transition from the esophagus to the cardia. The fundus is a dome-shaped region projecting upward and to the left of the GE junction. The body is the largest section, beginning below the fundus and extending to the incisura angulus, a notch in the lesser curvature. The glands of the body and fundus are composed of parietal, chief, mucus, and endocrine cells (Fig. 2). Parietal cells secrete acid as well as intrinsic factor, which is necessary for the absorption of vitamin B_{12} in the terminal ileum. Lack of intrinsic factor causes an inability to absorb vitamin B_{12} in the ileum, resulting in pernicious anemia. The antrum extends from the incisura angulus and its border with the body to the pylorus. The pylorus contains the pyloric sphincter, a thick ring of muscle that regulates release of gastric contents into the duodenum. Hypertrophy of this muscle results in the inability of food to pass, resulting in projectile vomiting, and is most commonly seen in infants. The antrum, similar to the cardia, contains mainly mucus-secreting cells, but also includes endocrine and gastrin-secreting cells. The vagus nerve is one source that stimulates this secretion.

SMALL INTESTINE

The small intestine receives the contents of the stomach and is the primary site of nutrient absorption. It consists of three parts, duodenum, jejunum, and ileum, for a total length of about 6 m in the adult. The celiac trunk provides the arterial supply to the proximal duodenum and the superior mesenteric artery supplies the distal duodenum, jejunum, and ileum.

From the lumen outward, the small intestinal wall consists of four layers: mucosa, submucosa, muscularis propria, and serosa. Like the other sections of the gastrointestinal tract, the muscularis propria contains outer longitudinal and inner circular muscle layers, with the ganglion cells of Auerbach's plexus between the layers. The submucosa contains lymphatics, connective tissue, and Meissner's plexus. The submucosa also contains Brunner's glands in the duodenum and Peyer's patches in the ileum.

The duodenum is 25–30 cm in length and makes a C-shape to curve around the head of the pancreas. At the proximal end of the duodenum is the duodenal bulb, which has a smooth, featureless mucosal surface. The duodenum can be distinguished histologically by the presence of Brunner's glands, which secrete mucus. Distal to the duodenal bulb, the small intestinal mucosa is thrown into circular folds, termed plicae circulares, which decrease in number distally (Fig. 1). The ampulla of Vater, which drains secretions from the pancreatic and biliary ducts, is located in the second portion of the duodenum. Ampullary obstruction, as occurs with impacted gallstones or tumors, can result in pancreatitis.

The ligament of Treitz fixes the junction of the duodenum to the jejunum and marks the division of the upper and lower gastrointestinal tracts. Lymphoid follicles, present throughout the small intestinal mucosa, are most prominent in the ileum, where they form aggregates known as Peyer's patches. Intestinal infection may result in significant hyperplasia of these lymphoid nodules. The small intestine ends at the terminal ileum, where the ileocecal valve, made of two mucosal folds, forms the entrance into the colon.

The epithelium of the small intestine, consisting of crypts and villi (Fig. 2), is specialized to maximize

absorption. Villi are fingerlike projections into the lumen, where absorption occurs. They are covered by absorptive enterocytes (intestinal cells) and amplify their surface area further with a microvillus brush border. Blunting of villi, as occurs in celiac disease, results in significant malabsorption. Similarly, small intestinal infections can cause malabsorption and diarrhea. The brush border contains digestive enzymes and the transporters and ion channels necessary for efficient nutrient absorption. The crypts contain Paneth and endocrine cells as well as stem cells that differentiate as they migrate toward the villus. The majority of nutrient absorption takes place in the duodenum and jejunum. However, as noted previously, the ileum is essential for absorption of vitamin B_{12} and bile salts.

COLON

The colon begins at the ileocecal valve and continues through the rectum. It is approximately 1–1.5 m in length and is divided into cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. Although the small intestine is mobile, the colon is relatively fixed. Significant landmarks include the hepatic flexure (adjacent to the liver), where the ascending colon joins the transverse colon, and the splenic flexure (adjacent to the spleen), where the transverse colon joins the descending colon. The main functions of the colon are absorption of water and electrolytes and storage of waste products before excretion.

The layers of the colonic wall are similar to those of the small intestine. Unlike the small intestine, however, the longitudinal muscle is organized into three separate bands, the teniae coli. These run from the appendix to the rectum. The outpouchings between the teniae are called haustra (Fig. 1). The superior mesenteric artery supplies the colon from the cecum to the proximal transverse colon. The inferior mesenteric artery supplies the remainder of the colon, excluding the rectum, which is supplied by rectal, or hemorrhoidal, vessels.

The cecum is the first section of the colon and is dilated relative to the remainder of the colon. It contains the appendix, a small, blind pouch enriched in mucosal lymphoid tissue. Inflammation of this tissue, resulting from retained material, results in appendicitis, a surgical emergency. The cecum is relatively mobile and therefore is more susceptible to volvulus, or twisting upon itself. Because it is dilated, a mass lesion or tumor in the cecum may go undetected for a long period of time.

The ascending colon extends from the cecum upward toward the liver, along the right side of the abdomen. At the hepatic flexure, it joins the transverse colon, which can be mobile as it drapes across the abdominal cavity toward the splenic flexure. Here the transverse colon joins the descending colon that courses along the left abdominal cavity to join the sigmoid colon in the lower abdomen. The sigmoid colon is S-shaped. It is the narrowest region of the colon, thus mass lesions in this area are generally symptomatic early.

The epithelium of the colon, unlike that of the small intestine, lacks villi. The mucosa consists of crypts containing goblet cells and absorptive enterocytes. Because the small intestine, rather than the colon, is responsible for the bulk of fluid absorption, the diarrhea associated with colonic disease is not as dramatic as that seen with small intestinal disease.

During development, ganglion cells of both Auerbach's and Meissner's plexi migrate in a proximal to distal direction. Failure of this migration results in Hirschprung's disease. The distal, aganglionic, segment of colon lacks inhibitory input and is tonically contracted, without normal peristaltic contractions. This results in obstruction and requires surgical removal of the aganglionic segment.

Gastrostomy

ZARA COOPER AND MALCOLM K. ROBINSON
Harvard Medical School

abdomen Portion of the body that lies between the chest and the pelvis and contains several organs, including the stomach, intestines, liver, spleen, pancreas, kidneys, and bladder.
gastrostomy Artificial opening in the stomach wall, usually created by surgical means.
gastrostomy tube Flexible, rubberlike tube that is inserted through a gastrostomy into the stomach.
stomach Part of the gastrointestinal tract that lies between the esophagus and first part of the small intestine; serves as a reservoir for swallowed food and is where food digestion is initiated. Although the terms "stomach" and "abdomen" are frequently used interchangeably, they are distinct entities and should not be confused.
volvulus Twisting or knotting of the stomach or intestines; obstructs passage of fluid and food.

A gastrostomy is a surgical procedure that creates an artificial opening in the stomach wall. Insertion of flexible tubing into the opening provides a means to introduce nutrients directly into the stomach, to drain stomach fluids, and to repair gastric volvulus.

GASTROSTOMY AND GASTROSTOMY TUBES

The medical procedure known as gastrostomy involves cutting a hole cut into the stomach wall with surgical instruments or a needle. An artificial opening is thus obtained. A flexible, rubberlike tube known as a "gastrostomy tube" (g-tube) can be inserted through this opening such that one end of the tube lies within the stomach cavity. This end is usually enlarged and shaped like a mushroom to prevent the tube from coming out of the stomach inadvertently. The other end of the g-tube is narrower and is pulled through another surgical opening that is made in the wall of the abdomen. This procedure thus creates a conduit between the stomach and the outside of a person's abdomen (see Fig. 1). Gastrostomy and insertion of a gastrostomy tube go hand in hand, and thus these terms are frequently used interchangeably.

MEDICAL INDICATIONS FOR GASTROSTOMY

There are three major medical indications or reasons for insertion of a gastrostomy tube. First, gastrostomy tubes are used in people who have a normal stomach and intestines but are unable to take food and medications by mouth for a prolonged period of time (e.g., 6 or more weeks). This is the most common reason for a gastrostomy. Insertion of a g-tube for this indication may be appropriate, for example, in persons who are in the intensive care unit and sedated, in those with dementia who refuse to eat, and in patients who have cancer of the throat. In such people, liquid food and medications are infused via the g-tube directly into the stomach for

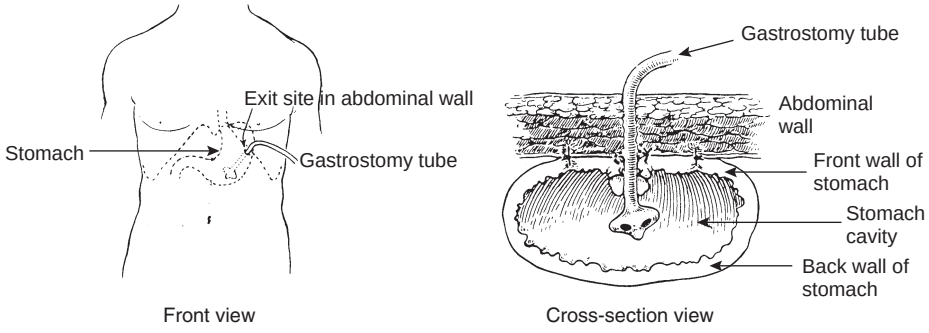

FIGURE 1 Gastrostomy tube.

 Copyright 2004, Elsevier (USA). All rights reserved.

digestion and subsequent passage into the intestines, where further digestion and absorption occur.

Second, gastrostomy tubes are used to drain fluid from the stomachs of those patients whose stomachs cannot propel food and secretions into the intestines. This may occur if the stomach or intestines are blocked (e.g., by a cancerous mass) or if the stomach and intestines stop contracting. Buildup of fluid and food in the stomach due to blockage or poor contraction eventually leads to vomiting. This may be avoided by draining fluid from the stomach via a g-tube. Fluid can accumulate in the stomach under these abnormal conditions even without eating. This is because fluid is constantly secreted into the stomach and intestines regardless of food consumption.

Finally, g-tube insertion may be indicated as part of treatment for a gastric volvulus. In the treatment of this condition, the stomach is untwisted and is then "fixed" in an untwisted position by inserting a g-tube through the abdominal wall and into the stomach via a gastrostomy. Recurrent volvulus is prevented because the stomach is no longer mobile enough to twist on itself. Volvulus of the stomach is a rare condition, and therefore this is an uncommon indication for g-tube insertion.

Genetic Counseling and Testing

ERIC ROSENTHAL
University of California, San Diego

genetic counselor Professional with master's-level training in medical genetics, counseling, and the psychosocial/legal issues associated with inherited disorders and genetic testing. Most practicing genetic counselors are board certified by the American Board of Genetic Counseling.

genetic testing Analysis of chromosomes, genes, and/or gene products (e.g., proteins or enzymes) to determine whether a genetic alteration related to a specific disease or condition is present in an individual.

hereditary cancer syndrome Collection of clinical features, including cancers, attributable to an alteration in a single gene that can be passed from parents to their children.

Genetic counseling is a communications process dealing with the medical and psychosocial problems associated with the presence of, or the risk for, a genetic disorder. Genetic counseling is an essential element in the management of patients with hereditary cancer syndromes, particularly when genetic testing is offered. Genetic counseling and testing for hereditary cancer syndromes are best provided by genetic counselors, genetics nurses, and physicians with specialized expertise and experience in dealing with the unique issues and challenges associated with this rapidly evolving area of medicine.

INTRODUCTION

Recent years have seen an explosion of knowledge concerning the genetic basis of hereditary cancer syndromes (HCSs). An ever-increasing number of genetic tests are available to identify gene alterations that can increase lifetime risks for gastrointestinal tumors to as high as 100%. Utilization of these tests can identify patients who will benefit from increased surveillance, prophylactic surgery, chemoprevention, lifestyle and diet modifications, or other targeted interventions with the potential to reduce morbidity and mortality from cancer. However, the decision to utilize genetic testing should not be made without careful

digestion and subsequent passage into the intestines, where further digestion and absorption occur.

Second, gastrostomy tubes are used to drain fluid from the stomachs of those patients whose stomachs cannot propel food and secretions into the intestines. This may occur if the stomach or intestines are blocked (e.g., by a cancerous mass) or if the stomach and intestines stop contracting. Buildup of fluid and food in the stomach due to blockage or poor contraction eventually leads to vomiting. This may be avoided by draining fluid from the stomach via a g-tube. Fluid can accumulate in the stomach under these abnormal conditions even without eating. This is because fluid is constantly secreted into the stomach and intestines regardless of food consumption.

Finally, g-tube insertion may be indicated as part of treatment for a gastric volvulus. In the treatment of this condition, the stomach is untwisted and is then "fixed" in an untwisted position by inserting a g-tube through the abdominal wall and into the stomach via a gastrostomy. Recurrent volvulus is prevented because the stomach is no longer mobile enough to twist on itself. Volvulus of the stomach is a rare condition, and therefore this is an uncommon indication for g-tube insertion.

Genetic Counseling and Testing

ERIC ROSENTHAL
University of California, San Diego

genetic counselor Professional with master's-level training in medical genetics, counseling, and the psychosocial/legal issues associated with inherited disorders and genetic testing. Most practicing genetic counselors are board certified by the American Board of Genetic Counseling.

genetic testing Analysis of chromosomes, genes, and/or gene products (e.g., proteins or enzymes) to determine whether a genetic alteration related to a specific disease or condition is present in an individual.

hereditary cancer syndrome Collection of clinical features, including cancers, attributable to an alteration in a single gene that can be passed from parents to their children.

Genetic counseling is a communications process dealing with the medical and psychosocial problems associated with the presence of, or the risk for, a genetic disorder. Genetic counseling is an essential element in the management of patients with hereditary cancer syndromes, particularly when genetic testing is offered. Genetic counseling and testing for hereditary cancer syndromes are best provided by genetic counselors, genetics nurses, and physicians with specialized expertise and experience in dealing with the unique issues and challenges associated with this rapidly evolving area of medicine.

INTRODUCTION

Recent years have seen an explosion of knowledge concerning the genetic basis of hereditary cancer syndromes (HCSs). An ever-increasing number of genetic tests are available to identify gene alterations that can increase lifetime risks for gastrointestinal tumors to as high as 100%. Utilization of these tests can identify patients who will benefit from increased surveillance, prophylactic surgery, chemoprevention, lifestyle and diet modifications, or other targeted interventions with the potential to reduce morbidity and mortality from cancer. However, the decision to utilize genetic testing should not be made without careful

Copyright 2004, Elsevier (USA). All rights reserved.

consideration. This process is time consuming and requires the participation of professionals with specialized knowledge and skills.

HEREDITARY CANCER SYNDROMES

A partial list of HCSs with gastrointestinal (GI) involvement is presented in Table I. HCSs are caused by mutations in genes that play a role in preventing cells from becoming malignant. These genes are often involved in DNA repair and/or the regulation of cell division. When a person inherits an altered version of one of these genes, from either parent, certain tissues in their body are more susceptible to the random events that cause cells to become cancerous. Lifetime risks for various malignancies vary dramatically depending on the gene involved. The exact form of the mutation within the gene may also have an effect. Some mutations confer a risk for a specific cancer that is only slightly increased over that for the average population. Other mutations in the same gene may generate lifetime risks for certain cancers that approach 100%, as is the case for colon cancer and certain adenomatous polyposis *APC* gene mutations.

HCSs are usually inherited in a dominant fashion, which means that an individual is affected when they inherit an altered gene from only one of their parents. Each child of an affected parent has a 50% chance of inheriting the syndrome. New mutations arise periodically, which accounts for affected individuals who seem to be the first in their family to display signs of the syndrome. Other explanations, such as inaccuracies in the family history, or misattributed parentage, should also be considered in these cases.

RECOGNIZING SIGNS OF A HEREDITARY CANCER SYNDROME

The presence of a hereditary cancer syndrome is suspected when one or more of the following factors present in a family:

1. Cancer at unusually young ages.
2. Similar cancers, or cancers known to be related, occurring in several relatives, across more than one generation.
3. Individuals with multiple primary cancers in the same or different organs.

TABLE I Representative Hereditary Cancer Syndromes with GI Involvement

Name	Major features	Incidence	Gene(s) responsible
Hereditary nonpolyposis colon cancer	Colorectal cancer, endometrial cancer, ovarian cancer, gastric cancer, transitional cell cancer of the ureter and renal pelvis, other cancers, sebaceous adenomas	Estimates vary; ~5% of colorectal cancer	*MLH1*, *MSH2*, *MSH6*, *PMS1*, *PMS2*, others?
Familial adenomatous polyposis	>100 adenomatous colorectal polyps, colorectal cancer, cancer of the ampulla of Vater, duodenal cancer, epidermoid cysts, desmoid tumors, osteomas, congenital hypertrophy of the retinal pigment epithelium	1 : 10,000; ~1% of colorectal cancer	*APC*
Cowden syndrome, or PTEN hamartoma tumor syndrome	Hamartous polyps of the colon and stomach, breast cancer, papillary or follicular thyroid cancer, mucocutaneous lesions, endometrial fibroids, macrocephaly	1 : 300,000	*PTEN*
Peutz–Jeghers syndrome	Hamartous gastrointestinal polyps; cancer of the colon, stomach, small intestine, and pancreas; ovarian sex cord tumors; adenoma malignum of the cervix; pigmented skin lesions	1 : 200,000	*LKB1*, others not yet identified
Familial atypical mole–malignant melanoma	Dysplastic nevi, melanoma, pancreatic cancer	Unknown	*p16* (*CDKN2*), others not yet identified

4. The presence of rare or unusual cancers.
5. The presence of precancerous lesions (i.e., adenomatous polyps) at unusually young ages or in unusually large numbers.
6. The presence of other clinical findings consistent with known HCSs (i.e., desmoid tumors and congenital hypertrophy of the retinal pigment epithelium in familial adenomatous polyposis).

ELEMENTS OF A GENETIC COUNSELING ASSESSMENT FOR A HEREDITARY CANCER SYNDROME

The genetic counseling process should begin with an exploration of the patient's concerns, goals, and cancer risk perception. Many patients grossly over- or underestimate their cancer risks and this can impact their compliance with screening recommendations. Even when no testing is performed, genetic counseling can have a significant impact by providing reassurance or raising awareness.

The value of the risk assessment is dependent on the accuracy and completeness of the medical and family history information provided by the patient, and whenever possible, verified by medical records. Construction of at least a three-generation pedigree is the standard of care, including information about types of primary cancers, age of diagnosis for all primary cancers, and current age or age at death for all unaffected as well as affected relatives. Information about clinical features other than malignancy is essential, so patients must be queried about surgeries, hospitalizations, unusual skin features, and chronic use of medications. Patients evaluated for GI cancer syndromes should always be asked about the results of sigmoidoscopies, colonoscopies, or other examinations of the colon. Ethnic background is also important, because certain conditions are more common in some groups.

Family history information is used to predict the likelihood that the pattern of cancers in a family is due to a HCS, and the probability that genetic testing will find a mutation in one of the known genes. These analyses are based on data that are being updated at a rapid pace, which is one of the reasons why professionals engaging in genetic counseling for HCSs must devote a heroic effort to keep up with current information.

MAKING DECISIONS ABOUT GENETIC TESTING

A positive genetic test result, indicating that a patient has a high risk for certain malignancies, can provide valuable information to guide management. A negative test result can reduce anxiety and obviate the need for expensive and uncomfortable screening in family members whose risk is not elevated. Nevertheless, genetic testing is not feasible for many patients referred for genetic counseling. The family history may not be consistent with any of the known HCSs. Many patients lack insurance coverage for genetic testing, especially those in Medicare and Medicaid programs. Clinical testing is not yet available for genes, i.e., the PMS1 and PMS2 genes involved in hereditary non-polyposis colon cancer. Testing through research protocols is sometimes possible, but this approach requires that patients understand the limitations of investigational testing.

Patients may decline testing because of concerns that positive results will adversely impact their access to health and life insurance, or employment. State and federal laws provide some protection, but the situation remains unsettled, and these are legitimate concerns that often require lengthy discussion. Patients who wish to have their test results remain confidential may chose to pay laboratory costs "out of pocket" and request that no record be placed in their medical charts.

The value of genetic testing is equivocal in situations in which results will not alter medical management. For example, there are no proved effective interventions to reduce mortality in people with a hereditary risk for pancreatic cancer. Some individuals who have already had a colectomy following a diagnosis of colon cancer have little interest in establishing that they inherited a risk for this malignancy.

LIMITATIONS TO GENETIC TESTING TECHNOLOGY

It is imperative that patients and health professionals understand certain limitations and caveats of current genetic testing, including the following considerations:

1. Many genes responsible for HCSs have not yet been identified.
2. The testing technology used in clinical laboratories is not able to detect all of the clinically significant alterations in those genes that have been identified.
3. The testing often identifies gene changes of uncertain clinical significance, i.e., amino acid substitutions that may or may not affect protein function. The affect of these "variants" on cancer risk is often unknown.
4. Genetic test results can provide information only about the probability that an individual will develop certain cancers. There is enormous variability in the

clinical manifestations of HCSs between families and between members of the same family.

5. It is vital that patients understand that even those individuals who do not have a mutation in one of the genes that cause a HCS still have same risk for malignancy as others in the general population.

GENETIC TESTING AND THE FAMILY

Genetic testing is distinguished from other areas of medicine in the extent to which family involvement impacts care of the patient. This is immediately apparent when patients have difficulty providing a complete and accurate family history. Medical issues are not discussed in some families, and the absence of an accessible "family historian" can stymie efforts to gather the necessary information. It is not uncommon for some family members to regard the investigation of genetic cancer risks as "a can of worms." They may be uncooperative or actively hostile toward a relative seeking detailed health information, and they are unlikely to permit the release of necessary medical records over which they have control. Professionals providing genetic counseling for HCSs must be prepared to help patients deal with this issue.

The importance of family involvement is even more pronounced when the patient seeking information is an "at-risk" family member who has not yet manifested clinical features of the suspected syndrome. A negative genetic test result in such an individual is of limited value unless the family history of cancers has already been traced to a gene mutation in a relative who has had cancer or other signs of the syndrome. Otherwise, the patient must be counseled that the family history could be due to a mutation in a different gene (including those that have not yet been discovered), or a mutation that is not identifiable with current technology.

Following testing, there may be issues about communicating results within the family. Occasionally, patients refuse to share information about hereditary risks with relatives, and some affected parents may even balk at telling their own children that they are at a 50% risk of having inherited a HCS. The physician's moral and legal responsibilities in such situations are still under debate. It is best to discuss plans for sharing information within the family prior to initiating genetic testing.

Giardiasis

FRANCES D. GILLIN AND LARS ECKMANN
University of California, San Diego

excystation Emergence of trophozoites from cysts.
trophozoites Metabolically active, proliferating forms of protozoa.

Giardiasis, caused by the protozoan parasite *Giardia lamblia*, is one of the most important waterborne diarrheal diseases, worldwide. Although its life cycle can be reproduced *in vitro* and its small (~12 Mb) genome has been sequenced, neither the basic biology of *G. lamblia* nor the pathophysiology of giardiasis is completely understood.

PARASITE BIOLOGY

Since *Giardia lamblia* neither invades nor secretes any known toxin, its adaptations to survival in hostile environments and ability to differentiate are key virulence factors. The dormant ovoid cyst form of *G. lamblia*, which is responsible for transmission of giardiasis, persists in fresh cold water for weeks and is relatively resistant to common disinfectants. Infection is initiated by ingestion of as few as 10 cysts in fecally contaminated water or occasionally food. Exposure of the quadrinucleate cysts to gastric acid initiates excystation. In the small intestine, the parasite emerges and divides into two binucleate trophozoites that attach to the apical surface of the epithelium. In humans, *G. lamblia* generally colonize below the entrance of the common bile duct. When trophozoites are carried downstream by the flow of intestinal fluid, they differentiate into infectious cysts that are passed in the feces. Trophozoites are ~10 μm long and shaped like a half pear, with an attachment disc on their ventral surface. Trophozoites also use their eight flagella to "swim" in the lumenal fluid and remain in the small intestine. *G. lamblia* lacks many *de novo* biosynthetic pathways and scavenges most of its purines, pyrimidines, amino acids, and lipids from the host. This parasite is amitochondriate, with a microaerophilic metabolism, using glucose and arginine for energy. *Giardia* belongs to one of the earliest lineages to branch from the eukaryotic line of descent, which makes it a valuable model for elucidating the biological innovations associated with the evolutionary appearance of nucleated cells.

EPIDEMIOLOGY, DISEASE, AND TREATMENT

In the United States and other developed countries, hikers and campers, families with children in day care, and travelers are at particular risk for giardiasis. Infections are much more common in most developing countries. In some areas, nearly 100% of children may be infected before the age of 2 years. Both the duration and the severity of giardiasis are highly variable. Approximately half of infected people are asymptomatic and the infection frequently resolves spontaneously within ~2 weeks. However, *G. lamblia* can cause severe and protracted diarrhea, which may lead to villus blunting and malabsorption, resulting in malnutrition and weight loss, especially in children. Importantly, trophozoites do not invade or secrete any known toxin or cause a mucosal inflammatory response. Trophozoites are covered with a dense layer of a cysteine-rich protein that is immunogenic, but also highly variable. Since the genome encodes >150 of these variable surface proteins, they are poor vaccine candidates. Moreover, antigenic variation is likely important for chronicity of infections and susceptibility to re-infection. A crude veterinary vaccine is available for cats, but the relevant antigens are not known. Repeated infections appear to confer some immune protection in humans. In endemic areas, adults are less frequently infected than children or than visiting adults from non-endemic areas. Experimental studies suggest that both B-cell-independent and B-cell-dependent host defenses, especially secretory immunoglobulin A, play important roles in controlling and clearing *G. lamblia*. Treatment with 5-nitroimidazoles, such as metronidazole (Flagyl), is effective in >85% of cases. *G. lamblia* is sensitive to these drugs because of its anaerobic metabolic pathways, which are not present in the host. Metronidazole is activated by

STRUCTURE, GROWTH, AND DEVELOPMENT

Morphology

The enteric nervous system (ENS) has unique structural and functional properties that have led to the concept of a "little brain" in the gut, serving as an independent center of integrative neural activity. It is organized as two ganglionated plexuses, the myenteric plexus and the submucous plexus, which contain no connective tissue or blood vessels but consist exclusively of densely packed neurons, glial cells, and their

Copyright 2004, Elsevier (USA). All rights reserved.

processes. Enteric glial cells have unique ultrastructural features clearly different from satellite cells of the autonomic ganglia and Schwann cells of peripheral nerves. They do not form basal laminae, they ensheathe axons not individually but in groups, they are extensively coupled by gap junctions, and they make numerous synaptoid contacts with vesicle-containing nerve varicosities.

Enteric glial cells are recognized as being similar to central nervous system astrocytes. This is confirmed by their expression of glial fibrillary acidic protein and vimentin, the calcium-binding protein S-100, glutamine synthetase, and Ran-2. Additionally, enteric glial cells transiently express the intermediate filament nestin during development. Primarily, enteric glial cells have been regarded as a relatively homogeneous cell population. Nevertheless, there is evidence to suggest morphological and functional heterogeneity among these cells, even though distinct subsets have not yet been consistently identified in the mature ENS.

Development and Differentiation

Enteric glia, like enteric neurons, develop from multipotential precursor cells in the neural crest. Enteric neurons evolve from vagal neural crest cells colonizing the entire length of the gut in a proximodistal direction and from sacral neural crest cells migrating in a distal–proximal direction, and most enteric glia also originate from these initial waves of crest-derived cells. However, enteric glia may also arise from glial precursors that enter the gut along with the extrinsic innervation later in development.

During the course of ontogeny of the ENS, nestin-immunoreactive neural crest cells emerge and give rise to both enteric glia and neurons. These cells proliferate in response to two neurotrophic factors, glial cell line-derived neurotrophic factor (GDNF; most likely produced by mesenchymal cells) and neurturin, but not to persephin or endothelin-3. Later on, nestin-positive precursors are replaced by separate lineages of neuronal and glial progenitors and the specified progenitors lose nestin, which is replaced by type-specific cytosolic and intermediate filament proteins. At this stage, GDNF acts as a neurotrophic factor and maintains cells in the neuronal lineage, but does not promote the development of glia. The factor required for further glial development may be a neuregulin, such as glial growth factor (GGF). Glial development in the ENS is also promoted by neurotrophin-3 (NT-3), through its high-affinity receptor TrkC, and the neuropoietic cytokines ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF), through the α (CNTFRα) and β subunits (gp130 and LIFRβ) of the tripartite CNTF receptor, respectively. In contrast, neural growth factor (NGF) appears not to affect the development of enteric glia.

Postnatally, fibroblast growth factor and GGF seem to increase the division rate of enteric glia. In addition, high GDNF levels in the adult intestine imply an important role for this neurotrophic factor in the maintenance of the adult ENS. Finally, neurotrophins have been implicated in intestinal inflammation and repair processes and it is conceivable that enteric glia may mediate such effects. The high-affinity neurotrophin receptors (NTRs) TrkA (for NGF) and TrkB (for brain-derived neurotrophic factor and the neurotropins 4 and 5) have been found on enteric glial cells from all sections of the adult human gut, and $p75^{NTR}$ receptor immunoreactivity has been demonstrated on enteric glial cells of adult human and rat gut.

Proliferation

Cultured enteric glial cells have been used in *in vitro* studies to understand the functional properties of these cells. Enteric glial cells proliferate in response to compounds that increase intracellular cyclic adenosine monophosphate (cAMP), such as cholera toxin, dibutyryl cAMP, 8-bromo-cAMP, and forskolin, as well as to laminin and fibronectin, but not to epidermal growth factor. Furthermore, it has been suggested that enteric neurons inhibit the proliferation of enteric glia and Schwann cells and that enteric glial cells may depend to some degree on neuronal signals for terminal differentiation. The molecular nature of these signals is as yet unknown.

Inflammatory mediators appear to modulate the proliferation rate of enteric glial cells. Reactive proliferation of enteric glia is documented in animal models of intestinal inflammation. The identity of the inflammatory mediators is unclear. Nevertheless, evidence from *in vitro* studies suggests that the proinflammatory cytokine interleukin-1β (IL-1β) suppresses enteric glial cell proliferation, in contrast to the immunosuppressive cytokine IL-10.

FUNCTION

Electrophysiological Properties and Neuroglial Interactions

Historically, enteric glia have been viewed as a supportive framework—both structurally and metabolically—of the neuronal elements in the ENS. Evidence for a functional role of enteric glial cells in information transfer is now emerging. Enteric glia have

cell-to-cell coupling, suggesting the formation of enteric glial networks in which neuroligand signal transduction systems are linked to increases in cytosolic Ca^{2+} levels. Enteric glial cells respond to endothelins, vasopressin, adenosine and uridine triphosphate (ATP, UTP), epinephrine, serotonin, histamine, and prostaglandins. The presence of purinoceptors of the P_{2Y2} subtype has been reported, and it has been proposed that enteric glia possess an endothelin (ET_B) receptor linked to phospholipase C as well as intracellular inositol 1,4,5-trisphosphate (IP_3) receptors. IP_3-sensitive Ca^{2+} stores appear to predominate in enteric glia. Depletion of internal Ca^{2+} stores induces capacitative Ca^{2+} entry via a Ca^{2+} channel that is not voltage gated, but may be lanthanum sensitive. Aside from capacitative Ca^{2+} entry, there is evidence from patch-clamp studies that enteric glial cells possess a number of voltage-gated ion channels, including inward-rectifier and delayed-rectifier K^+ channels as well as voltage-activated Na^+ channels. Enteric glia also display large "passive" octanol-sensitive ionic currents, consistent with coupling by gap junctions among these cells.

Enteric Glia and Inflammation

Astrocytes in the central nervous system participate in inflammatory and immune responses. Because of the marked similarities between astrocytes and enteric glial cells, enteric glia are believed also to be involved in inflammatory processes. There is emerging evidence that enteric glia respond to inflammation and are specifically activated in the course of intestinal inflammation. The proliferation rate of enteric glial cells is enhanced in animal models of intestinal inflammation, and there is evidence for the expression of major histocompatibility complex class II (MHC II) antigen on enteric glia in patients with Crohn's disease, which is associated with lymphocytic infiltration of the ENS. This suggests a role for enteric glial cells as antigen-presenting cells that attract immune cells to the ENS. This concept is strengthened by the established capacity of cultured enteric glial cells for phagocytosis and cytokine-inducible MHC II and intercellular adhesion molecule (ICAM-1) expression, which is fully functional for antigen-specific T cell activation. Additionally, enteric glial cells appear to possess functional receptors for IL-1β and IL-6; activation of enteric glial cells by IL-1β via the IL-1 receptor has been shown to stimulate the synthesis and release of IL-6, which displays feedback inhibition of its own secretion. Enteric glial cells appear also to produce IL-1β. Little is presently known about the regulatory mechanisms underlying the production of IL-1β. Evidence suggests that tumor necrosis factor α is not synthesized by enteric glial cells and does not affect cytokine production.

Support for the concept that enteric glial cells produce and are regulated by cytokines is growing. Enteric glial cells appear to possess neurotransmitter receptors, and a preliminary report about stimulated release of IL-6 from enteric glial cells by the neurotransmitter noradrenaline has been published. Thus, enteric glial cells may be an integral part of the inflammatory process in the intestine through the generation of cytokines that regulate the inflammatory response. Simultaneously, enteric glia may serve as an essential link between the nervous and immune systems in the gut by enabling neurotransmitters to modulate inflammation via the release of proinflammatory cytokines from the enteric glia.

A study in adult transgenic mice has implicated enteric glia in maintaining the integrity of bowel function, because ablation of these cells in the small intestine is followed by fulminant jejuno-ileitis and partial degeneration of enteric nerves. This suggests that enteric glia possess factors that are immunosuppressive and antiinflammatory under physiological conditions.

Overall, the cross-talk occurring among the various cell populations in the gut is an area of growing research, and future studies that further examine the role of enteric glia are likely to yield important information in this regard.

Glucose-Dependent Insulinotropic Polypeptide (GIP)

CHI-CHUAN TSENG AND M. MICHAEL WOLFE
Boston University School of Medicine

Glucose-dependent insulinotropic polypeptide (GIP), originally named "gastric inhibitory peptide" for its ability to inhibit acid secretion in dog, is a 42-amino-acid polypeptide and is structurally related to the secretin family of gastrointestinal regulatory polypeptides. GIP is expressed in cells of the upper small intestine and has been shown to be released into the circulation after ingestion of carbohydrate and fat. The full range of biological activity of GIP has yet to be completely elucidated.

STRUCTURE

Glucose-dependent insulinotropic polypeptide (GIP) was first isolated by Brown *et al.* from porcine small intestine in 1969 and was originally named "gastric inhibitory peptide" on the basis of its ability to inhibit acid secretion in dog. Its primary structure was first described in 1971 and revised in 1981. GIP contains 42 amino acid residues and is structurally related to the secretin family of gastrointestinal regulatory polypeptides, which includes secretin, glucagon, glucagon-like peptides (GLP-1 and GLP-2), vasoactive intestinal peptide (VIP), peptide histidine isoleucine, growth hormone-releasing factor, and pituitary adenylate cyclase-activating polypeptide. The amino acid sequences of porcine, human, bovine and rat GIP peptides are shown in Fig. 1.

The human GIP gene, which is located on chromosome 17q, spans approximately 10 kb; the rat GIP gene is slightly smaller, spanning approximately 8.2 kb (Fig. 2). Immediately upstream of the GIP gene is a promoter believed to control tissue-specific and glucose-regulated expression of GIP mRNA. Both the human and rat GIP promoters contain a TATA-box, located 28 and 27 bp upstream of the putative transcriptional start site, respectively. The GIP promoter also contains consensus sequences for activator protein-1 and the cyclic AMP (cAMP)-responsive element, and these elements may be involved in the regulation of GIP gene expression by exogenous factors such as glucose and lipids.

Sequence analysis of the GIP cDNA clones revealed a 459 bp open reading frame encoding a 153-amino-acid polypeptide in the human cDNA and a 432 bp open reading frame encoding a 144-amino-acid polypeptide in the rat cDNA (Fig. 3). The predicted amino acid sequences indicate that both human and rat GIP are derived by proteolytic processing of a preprohormone. Recently, GIP(3–42) was purified from the upper part of the porcine intestine and was shown to have antibacterial activity. It is presumed that this peptide is also derived by proteolytic processing of prepro-GIP.

LOCALIZATION AND DEVELOPMENT

salivary gland. Ultrastructural studies of human IRGIP cells have demonstrated a characteristic appearance of the K cell: intracellular secretory granules having a small electron-dense core surrounded by a concentric electron-lucent halo. In the dog, however, IRGIP cells identified in the duodenum contained uniformly electron-dense secretory granules consistent with the cell type recognized as the I cell of the endocrine cell classification.

During fetal development, immunoreactive GIP cells appeared during the 14th week of gestation in humans, initially in the duodenal region and then emerging distally with age. An ontogenic study in rats reported that GIP mRNA was present between days 18 and 20 of embryonic development, and mRNA levels markedly increased between days 3 and 5 of postnatal life, followed by a gradual increase toward adult levels. GIP transcripts in the submandibular gland, however, were not detected until day 10 postnatally.

METABOLISM

The kidney is the major site of GIP clearance. Several recent studies have demonstrated that intact GIP(1−42) was hydrolyzed into GIP(3−42) by a ubiquitous enzyme dipeptidyl peptidase IV by cleavage at the penultimate alanine residue. This observation was significant since GIP(3−42) was previously shown to be biologically inactive, yet likely immunoreactive with most GIP antisera. Using a specific GIP antiserum against the N-terminus of the intact GIP, GIP(3−42) was found to account for $73.8 \pm 2.9\%$ of total GIP measured in healthy individuals during the fasting state. An hour after a mixed meal, GIP(1−42) and GIP(3−42) constitute $35.7 \pm 4.2\%$ and $58.1 \pm 2.7\%$, respectively, of total immunoreactive GIP detected in the serum. It was concluded that dipeptidyl peptidase IV is the primary enzyme responsible for GIP inactivation and that the true biological half-life for GIP is more likely approximately 2−7 min. Interestingly, the half-life of GIP appears to be shorter in the diabetic than in the normal individuals, a mechanism that may partly account for the diminished GIP effect observed in many diabetic patients.

GIP RECEPTOR

The GIP receptor is a member of the secretin−VIP family of G-protein-coupled receptors with seven

transmembrane-spanning domains. The gene encoding the human GIP receptor (GIPR) spans approximately 13.8 kb and has been assigned to chromosome bands 19q13.2−q13.3. The human GIPR gene consists of 14 exons, with 13 containing protein-coding sequences and one, exon 1, containing 5′-untranslated sequences. The rat GIPR gene is approximately 10.2 kb in length and contains an additional intronic sequence, resulting in 15 exons. When spliced, these exons produce mature transcripts that contain a 1389 bp open reading frame (ORF), encoding a 466-amino-acid protein, and a 1365 bp ORF encoding a 455 bp protein in humans and rats, respectively. Northern analysis has demonstrated GIPR transcripts of approximately 5.5 kb in human and rat insulinoma cell lines. In addition, GIPR transcripts that are 3.8 kb in length have been detected in rat pancreatic islets and a hamster islet tumor cell line (HIT-T15). RNA encoding the GIPR has been identified not only in the rat pancreas and stomach, but also in adipose tissue, heart, pituitary, adrenal cortex, cerebral cortex, bone, hippocampus, and olfactory bulb. *In situ* hybridization has also detected GIPR-specific transcripts in some major blood vessels and within some of the cells lining bronchioles in the lung of rat embryos. The wide- spread distribution of GIP receptor suggests much broader physiological function than has been reported previously.

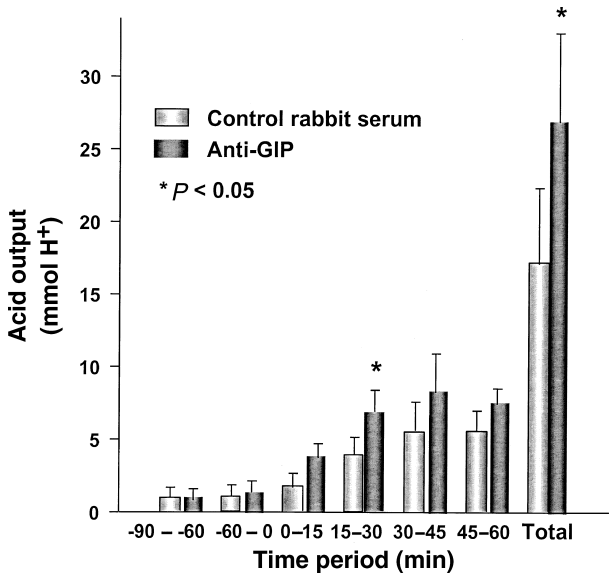

FIGURE 4 Gastric acid secretion compared before and after the intravenous infusion of control rabbit serum or anti-GIP antiserum in dogs. A 10% peptone meal was administered at time 0 minutes. No differences were detected in basal acid output, however the 60-minute meal-stimulated gastric acid secretory response after the infusion of control serum (17.2 ± 5.3 mmol H^+) was significantly less than after the infusion of the GIP antiserum (27.2 ± 6.1 mmol H^+). Data from Greeley, G. (1999). "Gastrointestinal Endocrinology." With permission from Humana Press.

BIOLOGICAL FUNCTIONS

GIP as Enterogastrone

Earlier observation had demonstrated that gastric acid secretion and emptying could be inhibited by the intravenous infusion of a crude extract from small intestinal mucosa. The substance in the extract was later named "enterogastrone," representing a hormone located in the mucosa of the proximal small intestine that was released into the circulation upon the ingestion of fat. Although the full spectrum of biological activity of GIP has yet to be completely elucidated, GIP appears to fulfill the requirements of an enterogastrone. Purified GIP was shown to be a potent inhibitor of gastric acid and pepsin secretion in dogs with denervated pouches. These effects were, however, much attenuated in the intact, innervated stomach, suggesting that cholinergic innervation might antagonize the inhibitory properties of GIP in the stomach. Using a different approach, Wolfe *et al*. infused GIP antiserum into conscious dogs prepared with gastric fistulas. With the binding of 98% of plasma GIP, peptone meal-stimulated gastric acid output increased from 17.2 to 27.2 mmol/h (Fig. 4) and the integrated gastrin response increased from 2.27 to 3.71 ng · min/ml. Moreover, recent studies have demonstrated that GIP stimulated somatostatin release from the isolated perfused rat stomach and inhibited carbachol-stimulated gastrin release. These results suggest that GIP inhibition of rat antral gastrin cells appears to be mediated by the local release of antral somatostatin. Therefore, although the precise physiological relationship between GIP and gastric function has not been determined, it is possible that the effects are species-specific and that GIP may act synergistically with other candidate enterogastrones to inhibit antral gastrin release and acid secretion under physiological conditions.

GIP as Incretin

The existence of a chemical stimulant of the endocrine pancreas had been suggested earlier and the term "incretin" was proposed as the insulin-stimulatory substance released from small intestine following food. Although several gastrointestinal regulatory peptides have been proposed as incretins, only GIP and GLP-1 appear to fulfill the requirements to be considered

physiological stimulants of postprandial insulin release. Many recent studies have demonstrated that, when administered in physiological doses and in the presence of glucose, GIP is a potent stimulator of insulin release by pancreatic islet beta cells. Subsequent studies have also demonstrated the insulinotropic properties of GIP in several experimental models, including the isolated perfused pancreas, isolated pancreatic islet preparations, and *in vivo*. GIP was found to increase intracellular cAMP levels and calcium influx that paralleled the stimulation of insulin release. Furthermore, GIP-stimulated insulin release appeared to be dependent on serum glucose concentration in both the human and rat, with a concentration of 4.4– 5.5 m*M* essential for its insulinotropic action. The observed glucose-dependency of GIP-stimulated insulin secretion appeared to provide an important safeguard against hypoglycemia by preventing the inappropriate stimulation of insulin release during a high-fat, low-carbohydrate meal.

GIP Stimulates GLP-1 Secretion

GLP-1 is a product of intestinal posttranslational processing of preproglucagon and is synthesized in endocrine L cells of the distal small intestine and colon. In humans, GLP-1 infusion has been found to increase plasma insulin concentrations and decrease glucose levels and it has thus been proposed as one of the incretins. Despite all the available data, controversy exists regarding the relative physiological importance of GIP and GLP-1 in stimulating insulin secretion. Recently, studies have demonstrated that GIP stimulated GLP-1 release *in vitro* in rat mucosal cells, but similar results have not been observed in human studies. However, using immunohistochemical studies, immunoreactive GIP and GLP-1 cells were found to be adjacent to each other in the human small intestine, suggesting the existence of a paracrine interaction between K and L cells in this area.

GIP in Adipose Tissue

As stated above, the finding that the GIP receptor is widely distributed in peripheral organs suggests that GIP may have functions in addition to the well-documented enterogastrone and insulinotropic actions. GIP receptor mRNA is expressed in adipose tissue and GIP has been shown to increase lipoprotein lipase activity in a concentration-dependent manner in cultured 3T3-L1 preadipocytes and in explants of rat adipose tissue, suggesting that GIP may play a role in the clearance of chylomicron triglyceride after feeding. However, exogenous porcine GIP and endogenous GIP released by a test meal was without effect on the elimination rate of intravenously injected soy oil in human.

GIP also appears to have action on lipid metabolism within adipocytes. GIP has been reported to stimulate fatty acid synthesis in adipose tissue and to enhance insulin-stimulated incorporation of fatty acids into triglycerides in rat epididymal fat pads. In addition, rat adipocytes incubated with GIP developed increased insulin receptor affinity and showed an increased sensitivity of insulin-stimulated glucose transport. Although still controversial, these results suggest that GIP may play a role in fat metabolism.

GIP in Brain

Although GIP mRNA has not been detected in the brain, GIP receptor mRNA was identified in many regions of the brain, including the olfactory bulb, cerebral cortex, hippocampus, the mammillary bodies, and part of the inferior colliculus. Pharmacological doses of GIP injected into the third ventricle resulted in lower plasma levels of follicle-stimulating hormone without altering levels of luteinizing hormone. GIP also stimulated growth hormone secretion, but was without effect on prolactin and thyroid-stimulating hormone. It remains to be determined whether circulating GIP can gain access to areas in the brain where the receptor is located.

Miscellaneous GIP Biological Properties

In addition to the above putative biological properties of GIP, other actions have been reported in sites where the receptor appears to be present. In the gastrointestinal tract, GIP has been observed to lower esophageal sphincter pressure, to decrease motility of the small intestine, and to reduce intestinal water and electrolyte transport. Receptor mRNA was also detected in the endothelium of major blood vessels where GIP has been reported to increase mesenteric and portal blood flow. Moreover, specific binding sites for GIP have been detected in skeletal muscle and bone, suggesting that GIP may play a role in exercise-induced improvement of peripheral glucose utilization and the function of osteoblasts. Finally, recent studies have shown that GIP may function physiologically as a growth factor for insulin-producing islet beta cells.

REGULATION OF EXPRESSION

The release of GIP into the circulation has been demonstrated primarily after the ingestion of two major nutrient stimuli, carbohydrate and fat. However, the release of GIP in response to oral carbohydrates differs in both magnitude and timing from that following fat

ingestion. Following oral glucose, GIP release is rapid, preceding insulin release, and reaches a peak in peripheral venous blood in approximately 15–30 min, returning to basal values by 3 h in the human and dog. In the rat, plasma GIP levels following a glucose meal do not increase significantly until 60 min and the increment found in rats is much smaller in magnitude when compared to human and dogs. Moreover, only glucose, galactose, and sucrose stimulated GIP release into the circulation, whereas no effect was observed in response to small intestinal perfusion with fructose, mannose, or lactose.

Intralumenal lipid also provides a potent stimulus for the release of GIP into the circulation in humans, dogs, and rats. However, after the ingestion of 100 ml of a triglyceride suspension, the peripheral blood GIP response does not reach a peak until 120–150 min and does not return to baseline by 3 h. In addition to the prolonged response, the amount of GIP released in response to fat is greater than that which follows glucose ingestion. These differences may be due, at least in part, to the effects of lipid-containing meals on gastric emptying. Furthermore, long-chain, but not medium-chain, fatty acids have been found to stimulate GIP release.

In addition to glucose- and fat-stimulated GIP release, some studies have reported the release of GIP after the administration of protein and specific amino acids. An amino acid mixture containing arginine, histidine, isoleucine, leucine, lysine, and threonine provided a potent stimulus for both GIP and insulin release in humans. In contrast, a mixture known to stimulate cholecystokinin release, containing methionine, phenylalanine, tryptophan, and valine, produced only small increases in serum GIP and insulin concentrations. Following intragastric infusion of 10% peptone, a 10-fold increase in serum GIP concentrations was observed in dogs within 15 min. However, the release of GIP was not seen in rats until 120 min after ingestion of a peptone meal. This increment in rats was attenuated by omeprazole, suggesting that protein stimulated GIP release by enhancing gastric acid secretion. Furthermore, some investigators have failed to detect an increase in GIP release in humans after the ingestion of protein meals consisting of cod or steak. These different responses to protein meals may thus be due to interspecies variation.

Prior to the release of any peptide, several intracellular events must occur, among them the stimulation or inhibition of expression of the gene encoding that protein. Because hormonal gene expression can be regulated at several different steps along the biosynthetic pathway, nutrient-regulated GIP gene expression has recently been examined in rats. In animals that ingested

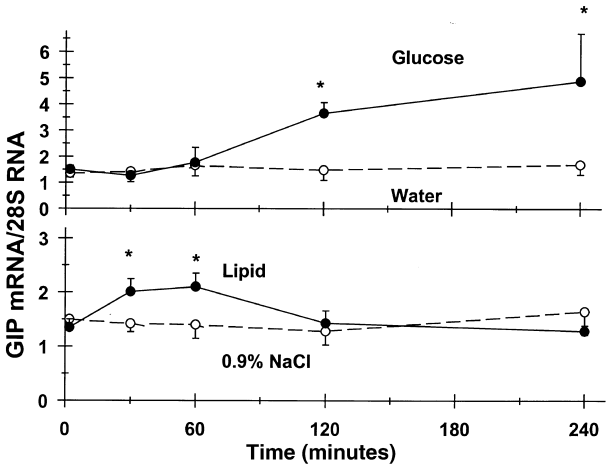

FIGURE 5 Steady state levels of duodenal GIP mRNA in glucose- (top) and Lipomul-fed (bottom) rats. GIP mRNA concentrations are compared to water-fed rats and are expressed as the mean (± SE) ratio of GIP mRNA to 28S ribosomal RNA to correct for gel loading. Each time point consists of 4–6 rats for each group. *$P < 0.05$. Data from Greeley, G. (1999). "Gastrointestinal Endocrinology." With permission from Humana Press.

a 10% glucose solution orally, duodenal GIP mRNA increased steadily over a 4 h period, at which time a fourfold increase in GIP mRNA levels in the small intestine was detected (Fig. 5). In contrast to the effects of glucose, duodenal GIP mRNA following intestinal perfusion with a 20% lipid emulsion was increased, but to a lesser degree when compared with oral glucose ingestion. Moreover, whereas an increase in duodenal GIP mRNA occurred primarily during the latter portion of the meal, the increase in lipid-stimulated GIP gene expression occurred at earlier time points, between 30 and 60 min after the perfusion, and GIP mRNA levels appeared to decline thereafter (Fig. 5). These studies indicate that both glucose- and lipid-containing meals increase GIP gene expression at the pretranslational level. In contrast to glucose and lipid, peptone infusion increased duodenal and plasma GIP concentrations, but failed to induce a significant change in duodenal GIP mRNA levels, suggesting that peptone-stimulated GIP expression might occur only at the posttranslational phase.

CONTRIBUTION TO DISEASES

The precise contribution of GIP to diabetes mellitus is unclear as no definite and consistent abnormalities in GIP release in diabetic patients have been found. Although newly diagnosed type I diabetic patients have been reported to have decreased circulating concentrations of GIP, enhanced and normal GIP release into the

circulation has also been reported in patients with type 2 diabetes mellitus. Furthermore, studies in patients with type 2 diabetes have demonstrated that although the incretin activity of GLP-1 is normal, the insulinotropic properties of GIP appear to be greatly diminished. Although the mechanisms remain unknown, a decrease in GIP receptor number on the pancreatic islet beta cells, a shorter GIP half-life, and chronic desensitization of the GIP receptor due to elevated serum GIP levels might account for impaired insulin secretion seen in diabetic patients.

Recently, corticotropin-independent, food-dependent nodular adrenal hyperplasia has been identified as a rare cause of Cushing's syndrome. In these patients, the serum cortisol levels were significantly elevated after the ingestion of glucose or a mixed meal, and elevated postprandial cortisol levels were not suppressed by a large dose of dexamethasone. Further investigation has demonstrated aberrant expression of the GIP receptor on the steroid-producing adrenal tumors and the infusion of GIP significantly increased plasma cortisol levels. It was concluded that this type of nodular adrenal hyperplasia and Cushing's syndrome may be food-dependent and may result from abnormal responsiveness of GIP receptors on the adrenal cells to the physiological secretion of GIP. Whether GIP plays any significant role in regulating adrenal gland secretion under physiological conditions is currently unknown.

Although GIP is one of the candidate enterogastrones, no evidence has suggested that GIP plays a role in the pathogenesis of duodenal ulcer, as no significant changes in serum GIP levels were detected in a group of duodenal ulcer patients. Furthermore, fasting and food-stimulated GIP levels were significantly elevated in duodenal ulcer patients, indicating that hyposecretion of GIP did not account for hypersecretion of gastric acid seen in this group of patients.

gluconeogenesis Formation of new glucose from noncarbohydrate substrates, including various amino acids, lactate, pyruvate, and glycerol.

glycogen Complex, hydrated polymer of glucose with a very large molecular weight (ranging over several million Daltons), consisting of many glucose molecules joined together to form a compact, highly branched spherical structure with a large number of exposed terminal glucose molecules that are accessible to the enzymes involved in glycogen breakdown (glycogenolysis).

glycogenolysis Intracellular breakdown of glycogen to glucose.

glycogen storage diseases (glycogenoses) Several inherited diseases caused by abnormalities of the enzymes that regulate glycogen synthesis and degradation.

Glucose in excess of cellular energy needs is stored in both liver and muscle as glycogen. The formation of glycogen (glycogenesis) enables storage of glucose without the osmotic consequences of free glucose molecules. Defects in the enzymatic reactions involved in converting glucose to glycogen result in various types of glycogen storage diseases (glycogenoses). Hypoglycemia is the primary manifestation of the hepatic glycogenoses; weakness and muscle cramps are the predominant features of the muscle glycogenoses.

INTRODUCTION

The average well-fed man on a diet rich in carbohydrate stores about 70 g of glycogen in his liver and 200 g in his muscles. The liver is freely permeable to glucose, which is rapidly phosphorylated by glucokinase to form glucose-6-phosphate, which is then converted to glucose-1-phosphate, the starting point for glycogen synthesis (Fig. 1). Hepatic glycogen synthase catalyzes the formation of α-1,4-linkages that elongate the chains of glucose molecules. A branching enzyme leads to formation of α-1,6-linkages at branch points, on average, every 10 glucose units along the chain. In the intervals between meals and during the overnight fast, a cascade of enzymatic reactions activates hepatic glycogen phosphorylase, the rate-limiting enzyme in glycogenolysis, which removes glucose from the outer branches of glycogen, leading, ultimately, to the formation of glucose-6-phosphate. Glucose-6-phosphatase catalyzes the terminal reaction of glycogenolysis and gluconeogenesis, the hydrolysis of glucose-6-phosphate, allowing glucose to be released from the liver into the systemic circulation, a process that is critically important for the maintenance of glucose homeostasis. Although glycogen storage diseases involve both the

muscles and the liver, only the glycogenoses with hepatic involvement are discussed in this article.

GLYCOGEN STORAGE DISEASE TYPE 0

Glycogen storage disease type 0 (GSD0) is caused by a deficiency of hepatic glycogen synthase, leading to a marked decrease in glycogen stores. The inability to store glucose as glycogen causes postprandial hyperglycemia, and increased conversion of dietary glucose to lactate resulting in postprandial hyperlactatemia.

Clinical Features

Individuals with GSD0 are usually asymptomatic early in infancy. Fasting ketotic hypoglycemia develops on cessation of nighttime feeding, and weaning from overnight feeds is difficult. During gastrointestinal illness or periods of poor feeding for any reason, children may become lethargic; hypoglycemia usually is an incidental finding. Childhood growth may be mildly delayed, but most children continue to develop normally. The physical examination is usually normal and there is no hepatomegaly. Hyperglycemia and hyperlactatemia occur after meals, particularly after breakfast, and may be confused with early diabetes.

Epidemiology

GSD0 is inherited in an autosomal recessive manner. It is caused by mutations in the *GYS2* gene located on chromosome 12p12.2. Only 18 cases have been described in the literature, but there is evidence that this disease may be underdiagnosed. GSD0 affects both genders equally and cases from Eastern Europe, Western Europe, North America, and South America have been described.

Diagnosis

Frequent measurements of blood glucose, lactate, and ketones in both the fed and fasting states demonstrate the unique biochemical pattern of postprandial hyperglycemia and hyperlactatemia alternating with fasting ketotic hypoglycemia. Despite the decrease in hepatic glycogen content, the glycemic response to glucagon is variable. A liver biopsy shows hepatocytes that contain only small amounts of glycogen (approximately 0.5% of wet liver weight) and moderate steatosis. The diagnosis can now be made noninvasively by mutational analysis.

Treatment

The goal of treatment is to prevent hypoglycemia. Fasting must be avoided. Frequent high-protein meals and snacks are given every 3–4 hours during the day. Uncooked cornstarch (0.5–1 g/kg) at bedtime prevents overnight hypoglycemia. Because surplus glucose cannot be stored as glycogen and is converted to lactic acid, the diet should contain an increased amount of protein to provide substrate for gluconeogenesis and decreased carbohydrate to minimize postprandial hyperglycemia and hyperlactatemia.

GLYCOGEN STORAGE DISEASE TYPE I

Glycogen storage disease type I (GSDI), also known as Von Gierke disease, is caused by deficient glucose-6-phosphatase activity. Glucose-6-phosphatase is a multicomponent enzyme system located in the membrane of the endoplasmic reticulum; the system consists of the enzyme, a calcium-binding protein, and three proteins that facilitate transport of glucose-6-phosphate (T1), phosphate (T2), and glucose (T3) across the endoplasmic reticulum membrane. More than 80% of patients with GSDI have mutations that cause deficient catalytic activity of the glucose-6-phosphatase system (type Ia GSD). Mutations in the *G6PT1* gene cause deficiency of the glucose-6-phosphate transporter (type Ib GSD), which also results in inability to convert glucose-6-phosphate to glucose.

Clinical Features

Symptomatic hypoglycemia may occur soon after birth, but most children do not present with symptoms until 3–6 months of age, when they begin to sleep through the night, or when an intercurrent illness disrupts the normal pattern of frequent feeding. GSDI is occasionally diagnosed in an asymptomatic infant after hepatomegaly and a protuberant abdomen are detected on a routine physical examination. It is more usual, however, for affected infants to present with tachypnea, seizures, lethargy, developmental delay, or failure to thrive. Impaired production of glucose via glycogenolysis and gluconeogenesis causes severe hypoglycemia and increased hepatic production of lactate, triglycerides, and uric acid. Activation of glucose counterregulation as a result of hypoglycemia increases the plasma levels of glucagon, epinephrine, and cortisol and can rapidly lead to severe lactic acidosis. Surgical stress, intercurrent illness, and administration of pharmacologic doses of glucocorticoids can, similarly, cause lactic acidosis without hypoglycemia. There is no effect on social and cognitive development unless the infant suffers cerebral damage from recurrent severe hypoglycemia.

Long-term complications may include hepatic adenomas, focal segmental glomerulosclerosis, renal tubular dysfunction, nephrocalcinosis, nephrolithiasis, gout, anemia, and osteoporosis. Poor metabolic control contributes to the pathogenesis of these complications. More than 60% of patients with GSDI develop hepatic adenomas, which are usually first detected during adolescence (occasionally seen in childhood) and may cause serious morbidity. Adenomas may remain stable or gradually enlarge over time. They may, however, undergo malignant transformation into hepatocellular carcinoma, or may hemorrhage into the abdomen, causing fatal hemoperitoneum. The serum alkaline phosphatase concentration and erythrocyte sedimentation rate are often increased in patients with adenomas. Ultrasonography is the preferred method for screening. When malignancy is suspected because of a change in the sonographic appearance, magnetic resonance imaging provides greater definition. Serum α-fetoprotein is normal in patients with adenomas, but may be increased in some cases of hepatocellular carcinoma. Large hepatic adenomas (>7 cm in diameter) have been associated with an unremitting, iron-resistant anemia, and a peptide (hepcidin) that blocks intestinal absorption of iron and macrophage recycling of iron is inappropriately expressed in the adenomas. In addition to all of these clinical features, patients with type Ib GSD have neutropenia, recurrent bacterial infections, and may develop inflammatory bowel disease.

Epidemiology

GSDI is inherited in an autosomal recessive manner. It is caused by mutations in the *G6PC* gene located on chromosome 17q21. More than 70 mutations have been identified worldwide. The overall incidence is estimated to be 1 in 200,000 births and the highest incidence appears to be in Ashkenazi Jews.

Diagnosis

The simplest means of determining the probable enzymatic defect in a child suspected of having a glycogenosis is to obtain serial blood measurements of metabolites (glucose, lactate, and ketones) during a fast of 3–4 hours duration, performed under close observation. In a child with GSDI, fasting rapidly leads to hypoglycemia and progressive lactic acidosis. Administration of glucagon (30 μg/kg) fails to elicit a glycemic response and may exacerbate the acidosis.

A liver biopsy and assay of hepatic glucose-6-phosphatase activity has, until recently, been the primary method of confirming the diagnosis. Differentiation between the types of GSDI requires an analysis of glucose-6-phosphatase activity in both intact and fully disrupted microsomes. In type Ib GSD, glucose-6-phosphatase activity is normal when the assay is performed on previously frozen tissue (freezing disrupts the microsomal membrane). The diagnosis can now be confirmed by mutational analysis.

Treatment

Treatment consists of providing a continuous dietary source of glucose to prevent blood glucose from falling below the threshold for glucose counterregulation (approximately 70 mg/dl). In infants, continuous glucose can be provided with frequent (every 2–3 hours) feeds during the day and continuous intragastric feeds at night via a nasogastric or gastrostomy tube. From about 6–12 months of age, uncooked cornstarch can be used as an alternative method of glucose delivery. Uncooked cornstarch is slowly absorbed into the circulation and allows the interval between feeds to be increased. The amount of cornstarch and the interval between feeds have to be individualized based on results of blood glucose monitoring and periodic metabolic evaluations. An estimate of glucose requirements can be obtained by calculating the basal glucose production rate using the following formula: $y = 0.0014x^3 - 0.214x^2 + 10.411x - 9.084$, where y = milligrams of glucose/minute and x = body weight (kilograms). If the patient has to fast for any reason or if gastrointestinal illness does not allow adequate intake of glucose, intravenous glucose must be administered at 125–150% of the estimated glucose production rate to ensure euglycemia and to minimize lactic acidosis.

Foods that contain galactose and fructose must be restricted because these sugars cannot be converted to glucose and large quantities may exacerbate the biochemical derangements. Oral citrate supplementation may prevent renal calcification in patients with hypercalciuria and hypocitraturia. If optimal dietary management fails to lower serum uric acid and triglycerides to acceptable levels, treatment with allopurinol and gemfibrozil, respectively, is indicated. Neutropenia in type Ib GSD responds well to granulocyte colony-stimulating factor (G-CSF) therapy, which is also efficacious for inflammatory bowel disease.

GLYCOGEN STORAGE DISEASE TYPE III

Glycogen storage disease type III (GSDIII), also known as Cori disease or Forbes disease, is caused by deficiency of glycogen debrancher enzyme (GDE). Release of glucose from glycogen stores requires the sequential

actions of both glycogen phosphorylase and GDE. After phosphorylase has acted on the outer branches of glycogen, GDE hydrolyzes the branch points. Lack of GDE activity causes glycogenolysis to stop when the outermost branch points are reached, resulting in the accumulation of an abnormal form of glycogen (limit dextrin) in affected tissues. The two main subtypes are defined by the location of the enzyme deficiency. Type IIIa GSD accounts for 85% patients in the United States, and results from lack of GDE activity in both liver and muscle. Only the liver is affected in type IIIb.

Clinical Features

Patients with hepatic involvement have hepatomegaly and ketotic hypoglycemia. In infancy and early childhood it may be indistinguishable from children with GSDI. Because the outer segments of glycogen are accessible and gluconeogenesis can occur normally, the hypoglycemia typically improves with age. In type IIIA, muscle weakness is usually minimal in childhood. Clinically significant myopathy affecting principally the large proximal muscles of the shoulders and hips usually becomes prominent in adulthood. Biochemical abnormalities include increases in aspartate transaminase (AST), alanine transaminase (ALT), and creatine kinase concentrations, and hyperlipidemia. Long-term complications include short stature, cardiomyopathy, and hepatic adenomas in 25% of patients.

Epidemiology

The incidence of GSDIII is about 1 in 100,000 live births and is unusually frequent in Israeli Jews of North African descent (prevalence, 1 in 5400; carrier prevalence, 1 in 35). GSDIII is inherited in an autosomal recessive manner and is caused by mutations in the debrancher gene on chromosome 1p21.

Diagnosis

Fasting causes ketotic hypoglycemia without the hyperlactatemia characteristic of GSDI. Glucagon does not elicit a glycemic response when given after an overnight fast, but does elicit a glycemic response when given 2 hours after a carbohydrate-rich meal. A definitive diagnosis is obtained by demonstrating abnormal glycogen (limit dextrin with short outer branches) in liver and/or muscle and deficient debranching enzyme activity. Definitive subtyping of GSDIII requires biopsies of both liver and muscle, because a normal serum creatine kinase concentration does not rule out muscle involvement. Measurement of enzyme activity in skin fibroblasts or lymphocytes can be used to screen for GSDIII, but results may not be definitive and cannot be used for subtyping.

Treatment

As in GSDI, the goal is to provide a continuous source of glucose to maintain blood glucose above 70 mg/dl. After infancy, uncooked cornstarch (1.75 g/kg at 6-hour intervals) can be used to maintain normoglycemia. Cornstarch has been shown to improve growth and ameliorate the biochemical abnormalities. Milk products and fruit should not be restricted because fructose and galactose can be normally converted to glucose. Amino acids can be used as a substrate for gluconeogenesis, and there is some evidence that a high-protein diet may be beneficial.

GLYCOGEN STORAGE DISEASE TYPE IV

Glycogen storage disease type IV (GSDIV), also known as amylopectinosis or Anderson disease, is caused by deficient branching enzyme (amylo-1,4 → 1,6-transglucosidase) activity, which causes accumulation in the liver of an abnormal unbranched glycogen molecule with long outer branches, resembling amylopectin. The abnormal glycogen acts as a foreign body that induces cirrhosis.

Clinical Features

GSDIV typically presents in early infancy with hepatosplenomegaly and failure to thrive. Because nonbranched glycogen is available for glycogenolysis, hypoglycemia is unusual in GSDIV until late in the disease, when cirrhosis is advanced. The usual clinical course is progressive liver cirrhosis with portal hypertension, esophageal varices, and ascites, culminating in death from liver failure by 5 years of age. Accumulation of amylopectin-like polysaccharide in cardiac muscle can result in a fatal cardiomyopathy. A childhood-onset variant presents as myopathy or cardiomyopathy, and a milder adult-onset variant may present with central and peripheral nervous system involvement resulting from accumulation of unbranched glycogen in neuronal tissue (polyglucosan body disease).

Epidemiology

GSDIV is inherited as an autosomal recessive trait and accounts for about 3% of all cases of GSD. Mutations in one glycogen-branching enzyme (GBE) gene, located on chromosome 3p14, are responsible for both the hepatic and the neuromuscular forms of the disease. All

three forms of GSDIV are caused by mutations in the same gene; significant retention of GBE activity accounts for mild disease.

Diagnosis

The diagnosis of GSDIV is established by demonstrating abnormal glycogen (an amylopectin-like abnormal polysaccharide with long outer chains) that stains with periodic acid Schiff reagent but is partially resistant to diastase digestion. Branching enzyme is deficient in liver, muscle, leukocytes, erythrocytes, and fibroblasts. In adult polyglucosan body disease, the branching enzyme deficiency can be detected only in leukocytes or in a nerve biopsy.

Treatment

There is no specific treatment for GSDIV. Transplantation has been an effective treatment for progressive liver failure.

GLYCOGEN STORAGE DISEASE TYPES VI AND IX

Glycogen storage disease types VI and IX [glycogen phosphorylase deficiency (Hers disease) and phosphorylase kinase deficiency, respectively] are considered together because both impair activity of liver phosphorylase, which catalyzes the rate-limiting step in glycogenolysis. GSDVI is caused by deficiency of glycogen phosphorylase, whereas GSDIX is caused by deficiency of phosphorylase b kinase, which results in failure to activate hepatic phosphorylase.

Clinical Features

Presentation is usually with hepatomegaly and varying degrees of growth retardation. Prolonged fasting or strenuous physical exercise can cause ketotic hypoglycemia. Mild hyperlipidemia and elevations in serum transaminase concentrations are common. Lactic acid and uric acid concentrations are normal and metabolic acidosis is rare. Motor development may be delayed as a consequence of muscular hypotonia and weakness. Uncommon clinical phenotypes have been described, including proximal renal tubular acidosis, neurologic abnormalities, and cirrhosis. A rare severe cardiac-specific phosphorylase kinase variant that can lead to cardiac failure has been reported.

Epidemiology

GSDVI is rare except in the Mennonite community (estimated disease frequency 1 in 1000 in that population). It is inherited as an autosomal recessive trait. *PYGL*, the gene encoding glycogen phosphorylase, is located on chromosome 14q21–q22. GSDIX is inherited either as an X-linked or an autosomal recessive trait, occurs in approximately 1 in 100,000 births, and accounts for approximately 25% of all patients with GSD.

Diagnosis

Glycogen phosphorylase deficiency can be diagnosed by assaying activity of the enzyme in leukocytes and erythrocytes. A definitive diagnosis requires demonstration of the enzyme defect in a liver biopsy. Phosphorylase b kinase can also be assayed in leukocytes and erythrocytes. Because the enzyme has several isoenzymes, the diagnosis can be missed without studies of liver and muscle. Definitive diagnosis of phosphorylase b kinase deficiency, therefore, requires demonstration of the enzyme defect in affected tissues. Subtyping of the disease requires molecular genetic analyses. Mutation analysis is likely to become the standard method for diagnosing both GSDVI and the X-linked variant of GSDIX. It is unlikely, however, to be able to rule-out all forms of GSDIX, because multiple genes are involved in synthesizing the phosphorylase kinase protein.

Treatment

Most patients do not require specific treatment. They should routinely have a bedtime snack and avoid prolonged fasting. In the unusual patient with nocturnal hypoglycemia and ketosis, uncooked cornstarch (2 g/kg) at bedtime prevents hypoglycemia and ketosis. These disorders have an excellent prognosis.

lumenal surveillance peptides Molecules that are constantly present within the gut lumen; their predominant role is to stimulate repair at sites of injury, acting in a "surveillance" fashion.

mucosal integrity peptides Molecules that are constitutively expressed in the mucosa and which function to maintain normal mucosal integrity.

rapid response peptides Molecules produced rapidly at sites of injury and which function to stimulate the repair process.

redundancy State that occurs when two or more factors have similar overlapping functions; removal of one of the factors therefore has much less effect on the system than if it was the sole controlling agent.

restitution The process by which surviving cells at the edge of a wound migrate across the denuded area to reestablish epithelial continuity. This process is not dependent on cell proliferation.

Growth factors are generally considered to be peptides that act via specific receptors, triggering intracellular secondary messengers, resulting in cell proliferation. However, it is important to appreciate that when complex interactions are considered, such as the control of growth and differentiation of gut cells, ascribing somewhat arbitrarily an individual function to a molecule, e.g., to consider "epidermal growth factor" simply a stimulant of proliferation, can be misleading as it is now clear that such factors have multiple effects. For example, although they are often considered separately, the distinctions between cytokines and growth factors are sometimes blurred as the "cytokine" interleukin-8 has been shown to stimulate the migration of human colonic epithelial cells, a process normally associated with "growth factors," and peptides normally considered to be growth factors can influence immunological function. Similarly, molecules such as glutamine or butyrate, which have been generally considered simple energy providers, and vitamins, such as vitamins A and D, which at one time were thought to have limited biological functions, are now known to influence multiple other activities of the cell, such as development, differentiation, and proliferation. To complicate matters even further, peptides that stimulate repair are usually thought of as growth factors. Although this is true in the majority of cases, certain peptides appear to stimulate the repair process without influencing proliferation, the trefoil peptides being a notable example. These peptides are therefore not growth factors as such but may, nevertheless, play an important physiological role and offer potential as a therapeutic strategy. This article therefore focuses on peptide factors that influence gut proliferation and/or repair.

INTRODUCTION

Gut Mucosal Integrity

The gastrointestinal tract possesses the remarkable ability to remain intact despite being constantly bathed in acid and proteolytic enzymes that can digest virtually any form of food that is eaten. When a superficial mucosal injury occurs, such as following direct physical trauma or ingestion of noxious agents such as aspirin or alcohol, the gastrointestinal tract is rapidly healed. The

 Copyright 2004, Elsevier (USA). All rights reserved.

gut therefore possesses powerful mucosal defense and repair mechanisms. These mechanisms include a high rate of cellular turnover (second only to the hematopoietic system), an efficient mucosal blood flow, a continuous adherent mucus layer (which, in combination with gastric bicarbonate secretion, allows the formation of a pH gradient so that the apical surface of gastric epithelial cells is at a neutral pH, despite gastric juice having a pH of 2–3), and the presence of regulatory peptides that can directly stimulate repair and also influence all of the other protective factors.

Ulceration occurs when this balance is disrupted due to additional aggressive factors [mainly *Helicobacter pylori* colonization or ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs)], decreased mucosal defense such as an abnormal mucus layer or reduced production of growth regulatory peptides, or more likely, when there is a combination of the two. This idea would explain why only a minority of patients colonized with *H. pylori* go on to develop ulceration, a finding that cannot be explained at present by differences in the toxigenicity of *H. pylori* strains alone. It is also important to note that aggressive factors and defense mechanisms are not independent since a weakened mucosal defense might be due, in part, to a hyperimmune response from the host damaging the mucosa, a bystander effect, thereby reducing the production of growth regulatory peptides.

Mechanisms of Healing

When an injury occurs, the healing process can be considered in three phases. There is an initial rapid response involving the migration of surviving cells from the wound edge to cover the denuded area. This begins to occur within the first hour following injury and is termed restitution. This is followed by a much slower increase in proliferation and differentiation that only begins 1 to 2 days after the injury has occurred. An additional factor that is often overlooked is the final stage of remodeling, in which the mucosa slowly re-establishes an essentially normal-looking mucosa. Failure to achieve this final stage can leave a weakened mucosal defense against further damage and emphasizes the importance of the quality of healing.

FUNCTIONS OF PEPTIDES IN MUCOSAL INTEGRITY

There are at least 30 different peptides produced within the gut that are involved in mucosal integrity and repair. Although there have been many papers examining the effect of individual peptides on gastrointestinal function, there are little data regarding their function as part of an integrated defense mechanism *in vivo*. Different aspects of their pathophysiological role can therefore be inferred from considering them in isolation, belonging to broad groups based on their overall role in maintaining gut growth or in stimulating repair, and by examining the distribution of their sites of production compared with their sites of action (based on receptor distribution). It is also important to remember that modulation of tissue mass is not simply dependent on the rate of proliferation, but is dependent on the equilibrium established among cell production, migration, and loss (including apoptosis). Peptide growth factors can influence all of these aspects; for example, epidermal growth factor (EGF) stimulates cell proliferation and migration and also influences crypt fission, a recently identified mechanism by which new crypts are produced. Other peptides have also been shown to influence the rate of programmed cell death (apoptosis) within the gut, acting, for example, via the Fas/Fas ligand (FasL) signaling system. Fas is a member of the tumor necrosis factor α/nerve growth factor receptor family and is expressed in various cells including gastrointestinal mucosal cells. Binding of its ligand, FasL, triggers apoptosis.

CONSIDERATION OF REPRESENTATIVE INDIVIDUAL GROWTH FACTORS

EGF Receptor Ligand Family

This group of polypeptides, with the common property of binding to the EGF receptor (also known as the c-erb-1 receptor), includes EGF itself, transforming growth factor-α (TGF-α), amphiregulin, betacellulin, and heparin-binding EGF. Factors that probably also bind to this receptor but are less well identified include mammary-derived growth factor II and human milk growth factor III (which might be the same molecule as EGF). EGF receptor activation requires receptor–ligand interaction followed by dimerization with a subsequent intracellular signaling cascade involving pathways such as tyrosine kinase activity. The realization that heterodimerization with other members of the erb receptor family may also occur adds to the complexity of the situation and is an area that is poorly understood.

Epidermal Growth Factor

EGF is a 53-amino-acid peptide produced by the adult salivary glands and the Brunner's glands of the duodenum. Although there is no doubt that systemically administered EGF has multiple effects on

TABLE I Actions of the Growth Factor EGF

Action	Effect	*Possible* secondary message
Proliferation	↑	
Acid secretion	↑	Protein kinase C, cyclic AMP
Bicarbonate	↑	Prostaglandins
NaCl and glucose uptake	↑	**Brush border area, Na^+–glucose co-transporter, lipids**
Chloride secretion	↑/↓	Phosphatidylinositol 3-kinase
Amylase secretion—pancreas	↑&↓	Cyclic AMP, phospholipase C
Mucus secretion	↑	Prostaglandins
Gastrointestinal blood flow	↑	β-adrenergic, nitric oxide, prostaglandins
Smooth muscle contraction longit	↑	Prostaglandins
Smooth muscle contraction circular	↑	(densensitizes) not prostaglandins
Gastric emptying	↓	
Restitution	↑	Cell migration, prostaglandins
Permeability	↑	
Muscosal protection	↑	**Proliferation, polyamines, mucus, trefoil peptides**

Note. Adapted from Uribe *et al*. (1997).

gastrointestinal and other structures (Table I), there is continuing controversy regarding the physiological role of lumenal EGF. One reason for this controversy is that EGF, along with other ingested products, is susceptible to digestion. When EGF_{1-53} comes into contact with adult acidic gastric juice, it is rapidly digested to an EGF_{1-49} form that only has 25% of the biological activity of the intact EGF molecule. Once EGF enters the small intestine, it is susceptible to further proteolytic digestion under fasting conditions, but may be preserved in the presence of ingested food proteins. Lumenal concentrations of EGF (and other peptide growth factors) are therefore not just modulated only by the amount of production and secretion but are also highly dependent on the intralumenal milieu, particularly with regard to pH and proteolytic activity.

Most recent studies examining the distribution of the EGF receptor in the normal adult human gastrointestinal tract have found it to be present only on basolateral membranes and not on the apical (lumenal) surfaces. The distribution of the EGF receptors might, however, vary between species; for example, autoradiographic studies have been reported to show apical receptors in the pig intestine. If EGF receptors are distributed only on the basolateral membranes of the normal adult human gut, the EGF present within the intestinal lumen is unlikely to exert any biological activity except at sites of injury. Evidence in favor of this role for EGF includes the finding that rats that have had their salivary glands removed do not develop spontaneous ulcers or atrophy of the gut, but do develop increased ulceration and diminished repair if artificial ulcers are induced. This has led to the suggestion that EGF acts as a "lumenal surveillance peptide" in the adult gut, having little activity under basal (nondamaged) conditions but being readily available to stimulate the repair process at sites of injury. It is important to note, however, that lumenal EGF might gain access to basolateral receptors in the immature neonate gut because of its increased permeability.

Transforming Growth Factor-α

TGF-α is a 50-amino-acid molecule that is present in the mucosa throughout the gastrointestinal tract. Systemic administration of TGF-α stimulates gastrointestinal growth and repair, inhibits acid secretion, stimulates mucosal restitution after injury, and increases gastric mucin levels.

Within the small intestine and colon, TGF-α expression occurs mainly in the upper (nonproliferative) zones, which suggests that its major physiological role may be to influence differentiation and cell migration rather than cell proliferation. TGF-α may therefore play a complementary role with TGF-α to control the balance between proliferation and differentiation in the intestinal epithelium. Up-regulation of TGF-α expression has been shown to occur in the gastrointestinal mucosa at sites of injury as well as in the liver following partial hepatectomy, supporting a role for TGF-α in mucosal growth and repair. Further evidence for this role comes from research on mice that have had the TGF-α gene "knocked out" using homologous recombination. They have a relatively normal phenotype under control conditions but an increased sensitivity to colonic, although not small intestinal, injury. These findings support the role of TGF-α in maintaining epithelial continuity but suggest that the relative importance of peptides such as this might vary from one region of the gut to another.

Taken together, most studies suggest that the major physiological role of TGF-α is to act as a "mucosal integrity peptide" maintaining normal epithelial function in the nondamaged mucosa.

The Transforming Growth Factor-β Family

This family of molecules is structurally distinct from TGF-β and, in most systems, actually inhibits proliferation. There are at least five different isoforms of TGF-β and their major site of expression in the normal gastrointestinal tract is in the superficial zones where they may function to inhibit proliferation once the cells have left the crypt region. TGF-β has many diverse functions, which include being a potent chemoattractant for neutrophils and stimulating epithelial cell migration at sites of wounds. It is therefore likely to be a key player in stimulating restitution.

Insulin-like Growth Factors and Their Binding Proteins

Insulin-like growth factor-I (IGF-I) and IGF-II promote cell proliferation and differentiation. They are similar in structure to pro-insulin and it is possible that they also exert insulin-like effects at high concentrations. The liver is a major site of IGF synthesis. IGF-I is known to promote protein accretion; i.e., it is an anabolic agent and is at least partly responsible for mediating the growth-promoting activity of growth hormone. IGF-II also has anabolic activity and has been shown to reduce the catabolic state in starved animals.

Most of the biological activity of IGF is dependent on it being in a free form rather than being bound to one of its binding proteins. The physiological relevance of growth regulatory factors such as these can therefore not be understood without also considering their relevant binding factors. Six IGF-binding proteins (IGFBPs) have been identified and cloned. It was initially thought that their main function was to act as carrier proteins, reducing the proteolytic digestion of IGF and limiting its biological activity. Additional roles for IGFBPs have been suggested as a result of the fact that the different IGFBPs show distinct patterns of distribution in different tissues and their levels are altered in response to hormone or nutrient status. Examples include the findings that administration of dexamethasone to rats increases hepatic production of IGFBP-1 and that malnutrition of neonatal rats resulted in reduced serum IGF-I and IGF-II but caused an elevation in serum IGFBP-2. The detailed functions of the IGFBPs are unclear although it is probable that one of the roles of secreted or soluble IGFBP is to inhibit IGF-mediated proliferation or amino acid uptake by limiting the availability of free IGF to bind to its receptors. Conversely, cell surface/matrix-associated IGFBPs may potentiate the actions of IGF by increasing local concentrations of IGF-I and IGF-II next to their receptors.

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) is an acid-stable molecule that was originally identified from platelets but is also synthesized and secreted by macrophages. It consists of two disulfide-linked polypeptides: chain A (14 kDa) and chain B (17 kDa). The dimer therefore exists in three isoforms (AA, AB, and BB), which bind to tyrosine kinase-type receptors. PDGF is a potent mitogen for fibroblasts and arterial smooth muscle cells and oral administration of exogenous PDGF has been shown to facilitate ulcer healing in animals.

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF) is a homodimeric 34 to 42 kDa heparin-binding glycoprotein with potent angiogenic, mitogenic, and vascular permeability-enhancing factors and it is related to PDGF. Specific receptors for VEGF have been identified on the apical membranes of the human colonic cell line Caco-2 and also the human cell line H-4. Although VEGF bound to these cell lines, it did not induce a proliferative response. The pathophysiological role of VEGF is therefore unclear although its angiogenic activity may play an important role in the healing of conditions such as peptic ulceration. In addition, there is currently interest in the use of anti-angiogenic factors, such as blockers of VEGF, for the treatment of malignant disorders.

Hepatocyte Growth Factor

Hepatocyte growth factor (HGF), one of the heparin-binding growth factors, is a potent mitogen for gastric cells *in vitro* and also acts as a morphogen. Expression of both the HGF gene and its receptor, c-*met*, is increased after induction of injury in various animal models. The timing of the response varies according to the method used but suggests that this signaling system may well have relevance in both the early and late phases of ulcer repair. HGF mRNA is located in stromal cells between the regenerative glands and in the arterial vessels in the submucosa and *met* mRNA is located in the epithelial cells of the regenerative glands. This system therefore provides an example of epithelial–mesenchymal cross talk (Table II) and is

TABLE II Production versus Receptor Distribution

Peptide	Source of peptide	Receptor distribution/effects
Transforming growth factor-α	Epithelial cells	c-erb-B1 receptor on epithelial cells
Transforming growth factor-β	Epithelial cells	Suppresses proliferation of enterocytes, stimulates restitution
Hepatocyte growth factor	Cells of mesodermal origin, e.g., fibroblasts	c-*met* receptor on epithelial cells
Basic fibroblast growth factor	Fibroblasts, activated macrophages	Fibroblasts and epithelial cells, stimulate restitution and angiogenesis
Trefoil factor family peptides	Mucus cells, epithelial cells at sites of injury	Poorly defined receptor present on epithelial cells, stimulates restitution not proliferation; mucus stabilization

further complicated by the fact that HGF is secreted from stromal fibroblasts as a single-chain, biologically inactive precursor (pro-HGF). This precursor is converted to an active heterodimeric protein by a novel serine protease (HGF activator). This proteolytic process is probably essential for HGF to exert its mitogenic activity. Interestingly, HGF is converted to its active heterodimeric form only in injured tissue, suggesting that selective activation of HGF by the HGF activator is a mechanism by which HGF action is localized to damaged tissues.

HGF has also been implicated in mediating abnormal gastric mucosal growth, resulting in a condition called large-fold gastritis, in some patients whose gastrointestinal tracts are colonized with *H. pylori*. Eradication of *H. pylori* resulted in a reduction in fold thickness and a parallel fall in HGF levels, suggesting that HGF is important in this trophic response. The molecular link between *H. pylori*, HGF, and abnormal mucosal growth may be mediated by the cytokine interleukin-β (IL-β), since administration of an IL-1β antagonist reduces the production of HGF in these patients. This situation therefore provides some insight into the link between the presence of *H. pylori*, cytokine and growth factor production, and abnormal mucosal growth. Similar mechanisms may also come into play to explain the relationship between *H. pylori* colonization and the development of gastric cancer.

Basic Fibroblast Growth Factor

Basic fibroblast growth factor (bFGF) is normally present in the human gastric mucosa and is a potent stimulant of angiogenesis. It accelerates the healing of experimental gastric and duodenal ulcers in rats and in patients with NSAID-associated gastric ulcers. In ulcerated human gastric mucosa, immunoactive bFGF is unregulated in the granulation tissue, endothelial cells, mononuclear cells, and epithelial cells at the ulcer rim. Taken together, it seems likely that this peptide plays an important role in reestablishing mucosal homeostasis following injury.

Keratinocyte Growth Factor

Keratinocyte growth factor (KGF), a member of the fibroblast growth factor family (FGF7), is a potent stimulant of keratinocyte proliferation, binding to a splice variant of FGF receptor 2. KGF has been shown to ameliorate damage in an experimental model of colitis in rats but KGF mRNA expression was not increased after indomethacin- or acetic acid-induced gastric injury in rats and was ineffective in reducing indomethacin-induced gastric damage. Current data are therefore insufficient to judge whether KGF plays an important role in gastric ulcer healing.

Trefoil Peptides

The trefoil motif consists of a unique "three-loop" structure formed by intrachain disulfide bonds. Three members of this family have been identified in humans and various nomenclatures have been used to describe them in the past. The current accepted practice is to term them all as trefoil factor family members 1–3 (TFF1–3). TFF1 (previously pS2) and TFF2 (previously spasmolytic polypeptide) are present mainly in the mucus-producing cells of the stomach; TFF1 is produced by the superficial epithelial cells throughout the stomach and TFF2 is produced by the deeper glandular elements within the gastric antrum. In contrast, TFF3 (previously intestinal trefoil factor) is predominantly produced by goblet cells of the small and large intestine. All three peptides are also produced at sites of injury, such as those that occur with gastric ulceration or Crohn's disease. Recent evidence suggests that the trefoil peptides have two roles in the gastrointestinal tract: (1) under basal conditions, they may play a role in mucus stabilization and (2) when an acute injury occurs, their rapid up-regulation is important

in stimulating the repair process, particularly that of epithelial restitution, acting as an example of a rapid response peptide.

The trefoil peptides possess the unusual property of decreasing injury and stimulating repair by processes independent of proliferation. This aspect seems particularly attractive when considering using them for treating patients because the pro-mitogenic activity of some of the other peptides could potentially stimulate premalignant lesions elsewhere in the body.

Gut Hormones as Growth Factors

The bowel shows a remarkable ability to respond to changes in dietary intake. Cross-circulation experiments support the concept of circulating trophic factors influencing gut growth although the identity of such a factor(s) remains unclear. Gastrin probably plays a role as a trophic factor for mucosal growth within the stomach and there is currently much interest in the role of glucagon-like peptide-2 (GLP-2), as systemic infusion of GLP-2 resulted in a general trophic response within the gut. This has led to the possibility that GLP-2 ligands may be useful in stimulating growth of the bowel in conditions such as short bowel syndrome. In contrast, early enthusiasm for a major trophic role for the gut hormones peptide YY and cholecystokinin within the gastrointestinal tract has diminished due to the absent or weak response in gut growth when recombinant forms of the hormones have been infused.

REDUNDANCY AND COMPLEX INTERACTIONS

Genomic removal of growth factor expression (producing knockout mice) has provided important insights into the pathophysiological role of several peptides. At first sight, the finding that deletion of factors with potent biological activity such as EGF or TGF-α results in an essentially minimal alteration in mucosal homeostasis seems surprising. However, it has subsequently been shown that much more extreme phenotypes can be generated by cross-breeding to produce double or triple knockouts for EGF receptor ligands. When these animals are produced, much more serious phenotypical abnormalities are caused and deletion of the EGF receptor itself results in multiple problems in the gastrointestinal tract and elsewhere, with fatal consequences. The most likely explanation for these findings is that there is redundancy within the system, allowing mucosal homeostasis to be maintained even if an individual peptide is lost for whatever reason. A further important finding from these studies is that the phenotypes resulting from such experiments are often strain dependent. The fact that major variations can occur within a single species therefore requires that caution be exercised in extrapolating findings from mice to humans.

The cooperative effects of peptides involved in the healing process can be mediated via distinct receptors (e.g., trefoil peptides and EGF) or by the same receptor (e.g., EGF and TGF-α, which both bind to the EGF or c-erb-B1 receptor). In addition, a number of growth factors, such as EGF, are monomeric in solution yet have been shown to activate their cognate receptors by inducing dimerization. It is therefore important to realize that, *in vivo*, EGF may signal to the cell through the formation of receptor homodimers (where two c-erb-B1 receptors link together) or through the formation of heterodimers (where one c-erb-B1 receptor binds to another activated member of the c-erb-B receptor family, such as c-erb-B4, which binds heregulin). This ability to form heterodimers increases markedly the repertoire of ligand–receptor interactions and is an area that can be overlooked if the effects of adding a single growth factor to cell lines *in vitro* are being examined.

A much greater understanding of the physiological roles of peptides can be achieved by considering the epithelium not in isolation but as part of an integrated cross-talking mechanism involving the epithelium and its underlying mesenchyme (see Table II). Control of growth and differentiation of a cell is influenced by factors secreted into the local microenvironment and may be mediated in a paracrine (cell to cell) manner or indirectly by influencing the extracellular matrix composition. A further example of potential cross talk between various systems is demonstrated by the relationship between EGF and trefoil peptides. In the normal mucosa, lumenal EGF is unable to reach its receptor because of its basolateral distribution. However, at sites of injury, EGF can bind to its receptor and, in addition to direct proliferative stimulation, may induce expression of trefoil peptide production (as at least one member of the family has an EGF-responsive enhancer region) as well as that of its own receptor. When produced, the trefoil peptides can act in a synergistic manner with EGF to stimulate the repair process.

CLINICAL APPLICATIONS OF GROWTH FACTORS

General Considerations

Advances in recombinant peptide technology now allow virtually pure peptide to be produced at moderate

cost. This removes the concern of contamination with infectious agents (as seen in some patients treated with purified growth hormone who develop Creutzfeldt–Jakob disease) and the development of antibodies to purified peptides from other species (as seen with porcine insulin). The most widely prescribed recombinant peptide used by gastroenterologists is probably interferon-α for the treatment of infectious liver disease. The use of growth factors for hollow organ gastroenterology is, however, at a much earlier stage. One of the major areas of concern regarding the use of peptides such as EGF in the clinical setting is the worry that systemic administration of growth factors may act to promote tumor growth elsewhere in the body. Oral, as opposed to systemic, administration of growth factors provides one possible approach to this problem. However, for EGF and the trefoil peptides, the oral doses required to treat gastrointestinal damage may be up to 1000 times greater than when the peptide is given systemically, making oral therapy economically unrealistic. Stabilizing molecules against digestion in the small intestine is likely to be more difficult due to the many different proteolytic enzymes produced by the pancreas. Possible strategies include administering the peptide along with nonspecific serine protease inhibitors or administering the peptide in a site-specific release formulation to overcome these problems.

Specific Disease Considerations

Recombinant peptides are unlikely to be of value for the treatment of esophagitis or peptic ulceration due to the high efficacy of acid suppressants and *H. pylori* eradication regimens. There are, however, a number of serious gastrointestinal pathologies for which novel therapies might prove useful. Some examples are given below.

Short Bowel Syndrome

Patients usually acquire this condition as a result of massive intestinal resection for vascular insufficiency or following repeated operations for inflammatory bowel disease. Current therapeutic options consist of long-term parenteral (intravenous) feeding or, in a few selected cases, small bowel transplantation. However, both of these options are associated with high cost and morbidity. Systemic administration of individual growth factors such as EGF has been shown to stimulate bowel growth in animal models of short bowel syndrome and parenteral administration of trophic gut hormones such as GLP-II also show promise. Clinical trials are ongoing.

Chemotherapy-Induced Mucositis

In recent years, high-dose chemotherapy protocols are being increasingly used in an attempt to improve cancer cure rates. As a result of this escalation in dosing, toxic side effects on the bone marrow or gastrointestinal tract can be the factor limiting the dose or duration of treatment. The breakdown in mucosal integrity may range from oral stomatitis to massive intestinal ulceration. Strategies to protect these tissues and encourage their recovery may therefore facilitate the use of higher dosage with greater potential for cure. Several peptide growth factors, such as EGF, KGF, and TGF-β, are currently under examination, although it is important to realize that the great initial promise seen in animal models has yet to be confirmed in clinical trials. For example, in a phase I clinical study of patients undergoing chemotherapy, EGF had only a minor beneficial effect in reducing mouth ulceration. If peptides with growth stimulatory or inhibitory effects are to be used, the timing of administration is likely to be critical; growth-arresting factors might protect bone marrow or gut from the damaging effects of chemotherapy (which tends to affect areas with the highest cell turnover) if given prior to chemotherapy. In contrast, growth-stimulating factors might "rescue" the recovery of injured areas if administered following chemotherapy. This latter approach is already being used clinically as colony-stimulating growth factor is used to stimulate bone marrow recovery following chemotherapy.

Inflammatory Bowel Disease and Necrotizing Enterocolitis

The etiology of ulcerative colitis and Crohn's disease is unknown and current treatment of these severe, incapacitating conditions therefore must be on an empiric basis. Several peptide growth factors are at various stages of investigation. These include EGF, PDGF, TGF-α, IGF-I, KGF, and trefoil peptides. Most are still at a very early (animal model) stage and are unlikely to be in standard clinical usage for many years although a preliminary report of the use of EGF in the treatment of patients with left-sided colitis seems encouraging and provides proof of concept.

Necrotizing enterocolitis is a severe life-threatening illness of young children that causes severe ulceration of the small and large bowel. Its etiology is unclear and initial treatment consists of general supportive measures consisting of fluid replacement and antibiotic therapy, although intestinal resection is often required. A recent case report indicated that a continuous infusion of EGF had a remarkable restorative effect on gut histology and larger clinical trials are ongoing.

Liver Disease

The use of growth factors in the area of hepatology is at an early stage but may be of value in stimulating hepatic regeneration following major surgical resections or for reducing injury and stimulating repair of liver function following exposure to hepatotoxins. For example, EGF has been shown to reduce the amount of hepatotoxicity induced by the toxin carbon tetrachloride in rats. The mechanisms underlying this protective effect are unclear but may be related to the induction of free-radical scavengers as well as growth stimulatory effects.

Multiple-Organ Failure

Multiple-organ failure (MOF) is a severe, life-threatening condition that usually occurs as a result of major trauma, burns, or fulminant infections. Whatever the initiating event, once established, MOF has a high mortality (up to 80%). The pathophysiological mechanisms underlying this condition are unclear although important contributory factors probably include hypoxia, increased intestinal permeability, bacterial translocation, endotoxemia, and uncontrolled systemic inflammatory responses. Several factors, including EGF, are currently under examination as potential therapeutic agents to prevent or reduce the severity of this condition.

SUMMARY

It is now clear that multiple peptides are involved in maintaining gut mucosal homeostasis and in stimulating the repair process. Important information has been obtained by considering the individual factors in isolation but additional insight can be obtained by considering them as belonging to broad groups dependent on their pathophysiological role. Knockout mice studies have confirmed the importance of many of these peptides but also demonstrated that there is redundancy in the system. The advent of recombinant peptide technology offers the potential to use one or several (to elicit synergistic responses) peptides to treat a variety of gastrointestinal conditions. It is important to note, however, that although cell culture and animal models have shown proof of concept, the process of translating their use to standard clinical practice is still at a relatively early stage.

Growth Hormone

DOUGLAS W. WILMORE
Brigham and Women's Hospital and Harvard Medical School

acromegaly State of increased growth in adults due to the oversecretion of GH. The patient is unusually tall, with an enlarged jaw, and large hands and feet. Because this is most commonly related to a pituitary tumor, with tumor enlargement the patient experiences headaches and often visual disturbances.

binding proteins Large molecules that circulate in the bloodstream and attach to smaller molecules such as hormones. These proteins tend to prolong the life of the bound hormones by keeping them in the bloodstream.

endocrine Secretion of a hormone from a gland and transportation of the hormone in the bloodstream to distant sites, where the hormone exerts its action.

insulin resistance Glucose uptake, primarily by adipose tissue and skeletal muscle, is enhanced by the hormone insulin. A resistant state occurs when the same quantity of insulin fails to cause normal uptake of glucose by these tissues.

paracrine Secretion of a hormone from a cell, with the hormonal effect exerted on an adjacent cell.

pituitary gland Small endocrine organ located at the base of the brain; governs growth, metabolism, and reproduction through the secretion of a variety of hormones.

Growth hormone, a protein composed of 191 amino acids, is secreted by the somatotroph cells of the anterior pituitary gland. In children, this hormone is responsible for linear growth and enhancement of lean body mass through the stimulation of protein synthesis. In adults, growth hormone is directly or indirectly responsible for normalization of body composition, improved skeletal muscle and cardiac function, and maintenance of normal serum lipids. In all age groups, the hormone appears to have an effect on the central nervous system, improving cognitive function and life quality.

INTRODUCTION

Growth hormone (GH) elaboration increases in the first 10 years of life, achieves its maximum secretory levels at the time of puberty, and then secretion and blood levels gradually decrease with age. Deficiencies of GH in children result in stunted growth, and excesses due to pituitary tumors result in acromegaly (or gigantism in a child). More subtle are deficiencies that occur with aging, and these have only recently being diagnosed and reversed by exogenous administration of the hormone.

ENDOCRINOLOGY

GH, like some other pituitary hormones, is released from the somatotroph cells of the anterior pituitary gland in a pulsatile or episodic manner, with the greatest pulses coming at night. Secretion of GH is controlled by two antagonistic systems, growth hormone-releasing hormone (GHRH) and somatostatin. GHRH has a marked stimulatory effect whereas somatostatin, which is released from neurons in the median eminence of the brain, inhibits GH secretion. Both of these controlling factors are secreted into the hypophyseal portal system and transported to the anterior pituitary gland, where their interaction with the somatotroph cells accounts for the quantity of hormone secreted.

When GH is released into the bloodstream, about 50% of the hormone is attached to a binding protein. It is transported to various tissues, where it binds to two receptors, leading to homodimerization, which generates a biological response. Signal transduction then proceeds via tyrosine phosphorylation of Janus kinase (JAK) proteins, a common step for substances stimulating cells via the cytokine receptor superfamily, which includes the GH receptor. Once the target cell is stimulated, there are a variety of responses, but the most apparent is the generation of a second hormone, insulin-like growth factor-1 (IGF-1). Although this substance can be synthesized and secreted by multiple cell types, the greatest expression occurs in the liver. Here elaboration is clearly under GH control, and IGF-1 is released into the bloodstream and effects other tissues. In addition to the elaboration of IGF-1, GH also induces the synthesis of binding proteins, the most prominent one being insulin-like growth factor binding protein-3 (IGFBP-3). This binding protein greatly prolongs the half-life of IGF-1, and thus hormonal binding and transport within the bloodstream are regulatory steps in controlling anabolic action (Table I).

TABLE I Comparison of GH, IGF-1, and Insulin

Parameter	GH	IGF-1	Insulin
Molecular mass (Daltons)	22,000	7649	5734
Structure	Folded chain with disulfide bridges	One chain	Two chains
Origin	Anterior pituitary gland	Mostly liver; all tissues	Pancreatic beta cells
Secretion	Pulsatile	Constant, slow release	Pulsatile
Circulating form	About 50% bound	Mainly bound	Free
Production rate	0.2–1 mg/day in adults	10 mg/day	2 mg/day
Half-life	6–20 minutes	12–15 hours	10 minutes

IGF-1 actions are mediated via its receptor, although it can also be bound to the insulin receptor, but at a much lower affinity. IGF-1 stimulates cell proliferation and differentiation. In addition, it can cause hypoglycemia, stimulate protein synthesis, and enhance wound healing. IGF-1, although having a longer half-life than GH, is responsive to dietary perturbations. With fasting or reduction in carbohydrate ingestion, IGF-1 levels decrease, and then return to normal with refeeding. Thus, there appears to be an important regulatory interaction between substrate availability and this anabolic growth factor—e.g., if no nutrients are available, there is no need for a hormone to stimulate cell growth. In addition, IGF-1 elaboration is attenuated during states of selective nutrient deficiency, such as lack of zinc and manganese, and during diseases associated with inflammation. The interactions between GH and IGF-1 are shown in Fig. 1.

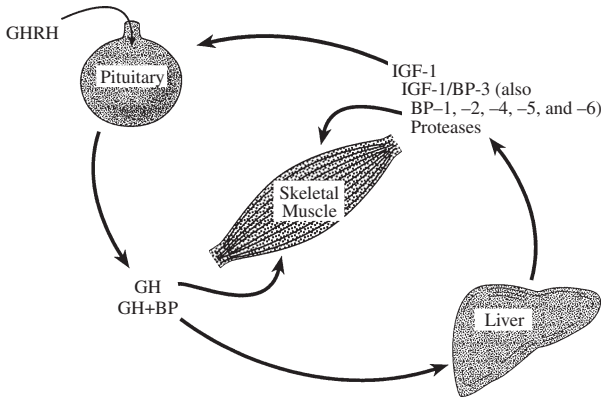

FIGURE 1 Growth hormone (GH) is secreted by the pituitary gland following stimulation by growth hormone-releasing hormone (GHRH). GH travels in the bloodstream, either in the free state or loosely bound to a binding protein (BP). It attaches to cell surface receptors and stimulates changes in metabolism. In the liver, it stimulates the production of insulin-like growth factor-1 (IGF-1) and its binding proteins. During disease states, there is also release of proteases that cleave IGF-1 from BP-3, and this reduces IGF-1 activity. Both GH and IGF-1 have mechanisms that control feedback to the brain, regulating GH elaboration.

PHYSIOLOGY

GH and IGF-1 (the latter working through both endocrine and paracrine mechanisms) work alone or in concert to exert a variety of metabolic effects on an organism (Fig. 2). IGF-1 causes hypoglycemia by decreasing glucose production and enhancing peripheral glucose clearance. In contrast, GH causes insulin resistance, thereby counteracting this undesirable effect of IGF-1. In addition to this antiinsulin effect, GH causes sodium and water retention (probably the most common side effect associated with the administration of GH) and stimulates the mobilization and utilization of adipose tissue. In the whole organism, this results in the loss of body fat and a lowering of blood lipids. This lipolytic effect is countered in part by the actions of IGF-1. Both hormones have pronounced effects on protein synthesis and epiphyseal (bone) growth. GH causes growth of all organs, and studies in both animals and humans have documented that excess GH treatment results in visceromegaly, with enlargement of the liver, kidneys, spleen, and gastrointestinal tract.

The net effect of GH, in conjunction with the secretion of IGF-1, is to produce a marked anabolic state. GH administered to animals or humans accelerates or normalizes growth. This is most easily observed in young children, but changes also occur in the adult. There is enhanced bone growth, a greater lean body mass (characterized by more muscle), and less fat (Fig. 3). If biochemical tests are performed, treated subjects are more resistant to insulin (more diabetic-like) and have lower lipid levels. Performance of cognitive and physical tasks is improved, especially when compared to GH-deficient subjects.

PATHOLOGIC CONDITIONS

GH Deficiency

Children

Congenital growth hormone deficiency can occur as a result of some type of anatomic developmental

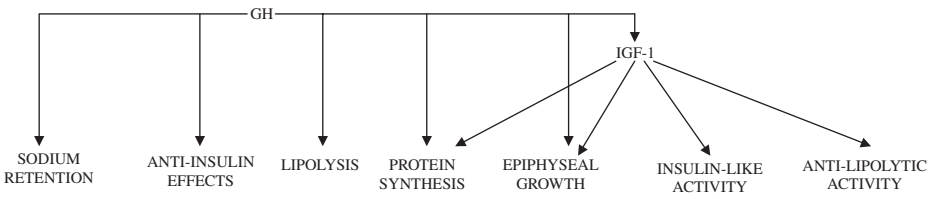

FIGURE 2 Multiple effects of growth hormone (GH) and insulin-like growth factor-1 (IGF-1).

abnormality or is associated with a genetic defect. Children may also acquire a growth hormone-deficient state as a result of radiation for tumors of the central nervous system or associated with resection of hypothalamic, pituitary, or other tumors in the adjacent areas of the brain. Trauma to the area and some infiltrating diseases have also been associated with the deficiency state.

Relative GH deficiency has been described in conjunction with chronic renal failure in children who fail to grow, and in those who receive steroid therapy as immunosuppressive therapy following organ transplantation. Turner's syndrome, a congenital abnormality in girls, is associated with short stature and is responsive to GH therapy.

Adults

The great majority of adults with GH deficiency have diseases associated with the pituitary gland (tumors, adenomas, infarction, or infiltrative diseases), most of which are treated surgically and/or with irradiation. However, GH deficiency is now being recognized in older adults, and when diagnosed, is often treated by replacement therapy.

GH Excess

GH excess is associated with pituitary tumors that secrete excessive amounts of GH. The result is enhanced growth (referred to as gigantism in the child or acromegaly in the adult). Such tumors are also associated with headaches, visual disturbances, abnormal sweating, and, eventually, weakness and fatigue. There is gradual and unexplained swelling of the feet and hands and thickening of the lips and tongue. Removal of the tumor (almost always a pituitary adenoma) necessitates GH replacement, but often resolves many of the unpleasant symptoms.

Further observations of the effects of human growth hormone in elderly hyposomatomedinemic men. *In* "Growth Hormone Replacement Therapy in Adults: Pros and Cons" (Z. Laron and O. Butenandt, eds.). Freund Publishing House, London.

GH THERAPY

GH was the first hormone to be produced by recombinant DNA technology and has been abundantly available for clinical use and study since the mid-1980s. Before that time, GH was extracted from pituitary glands obtained from cadavers, and only a limited quantity of GH was available for therapeutic and investigative use.

Testing for Deficiency

GH is rapidly secreted in response to hypoglycemia (rapidly falling blood glucose). Therefore, one standard test is to administer a small dose of insulin to induce hypoglycemia, and then draw serial blood samples for GH determination. An increase of less than 10 μg/liter from baseline is considered diagnostic of deficiency in children. In adults, the increase must be $<3-5$ μg/liter to diagnose the deficiency state (the value used depends on the method of blood testing). Other stimulation tests are available [e.g., administration of L-dihydroxyphenylalanine (L-DOPA), arginine, and GHRH] and similar guidelines are generally followed if these alternate stimulatory tests are used.

Results in Children

In cases of classic growth hormone deficiency, the administration of GH has resulted in a marked increase in linear growth (Fig. 4) that continues until puberty. In one study, GH-deficient children treated for an average of 8 years had a final height of 171.6 cm (5 ft. 7 in., boys) and 158.5 cm (5 ft. 2 in., girls). The average dose of GH given to children is 0.3 mg/kg/week. This is injected subcutaneously daily or every other day in divided doses. The recommended GH doses for children with renal failure and for Turner's syndrome are slightly higher (0.35 and 0.375 mg/kg/week, respectively) due to the resistance states associated with these disorders.

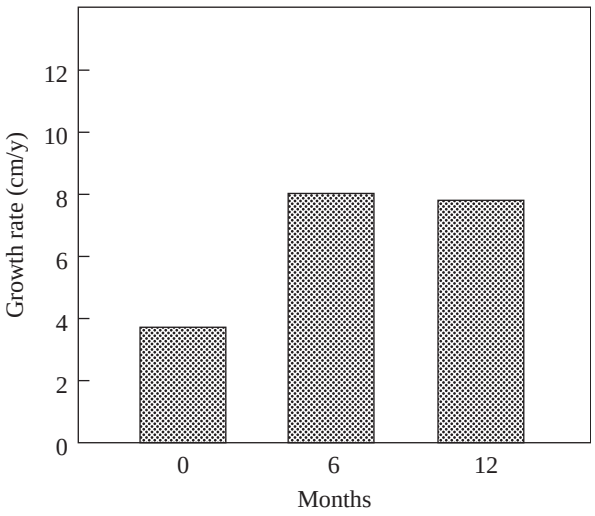

FIGURE 4 The growth rate in GH-deficient children after 6 and 12 months of treatment. Reproduced with permission from Takano, K., Shizume, K., Hizuka, N., *et al.* (1987). Therapeutic benefit of the treatment of GH-deficient children with growth hormone. *In* "Growth Hormone—Basic and Clinical Aspects" (O. Isaksson *et al.*, eds.). Elsevier Science Publ., New York.

Results in Adults

In adult individuals who have documented GH deficiency due to pituitary diseases or associated with aging, replacement doses range from 3 to 25 μg/kg/day (about 0.3−2 mg/day for the average adult). However, a recent consensus conference suggests that the starting dose should be 0.15−0.3 mg/day regardless of body weight. The dose is then adjusted to administer adequate quantities of GH so that IGF-1 levels are elevated to the midnormal range.

The responses to this therapy have been dramatic, especially when compared to the deficient state. In one study, treatment for 26 weeks resulted in a 13% decrease in subcutaneous fat mass and a 30% decrease in intra-abdominal fat mass. Muscle mass and strength were also characteristically increased.

Quality-of-life studies, which include energy levels, mood, and measures of emotional liability, all show general improvement with GH replacement. Long-term outcome studies are lacking, and it is not known at this time if GH therapy is associated with a reduction in cardiovascular risk or with an enhancement in cancer risk. Data from followup studies of patients receiving GH replacement therapy following excision of brain (pituitary) tumors show that, to date, concerns about GH stimulating tumor growth or recurrence are unfounded. Longer term studies of large groups of individuals are needed, however, to answer this question.

Other Uses

GH has been administered to small groups of patients with catabolic conditions, including respiratory failure, burn injury, recovery from surgical procedures, congestive heart failure, liver transplantation, and renal failure. These diseases process are associated with the accelerated breakdown of body tissues, particularly skeletal muscle, and this results in weakness, malnutrition, and poor wound healing, all of which prolong recovery. It is hoped that GH therapy will enhance protein synthesis and thus limit mortality, morbidity, and convalescence time.

The most consistent benefit of high-dose short-term GH therapy has been observed in children following thermal injury. Herndon and associates have shown that such therapy has accelerated wound healing and reduced hospitalization by approximately 2 weeks (Table II). In another large randomized trial in critically ill adults, high-dose growth hormone was associated with increased mortality. This observation has not been made in other studies, but enthusiasm for treatment of the critically ill has been tempered and few trials evaluating GH in this group are ongoing.

TABLE II GH Therapy in Thermally Injured Children

Factor	Control	GH
Wound healing rate (days/% burn)	0.8 ± 0.1	0.54 ± 0.04*
Length of hospitalization	46 ± 6	32 ± 4*

*$p < 0.05$

The anabolic effects of GH have also been utilized to support patients with HIV infection and associated wasting. Studies in such populations show that such GH therapy is effective in supporting lean tissue (muscle mass) during associated catabolic states.

TABLE III Side Effects of GH

Weight gain	Headaches
Dependent edema	Benign intracranial hypertension
Sensation of tightness	Hyperglycemia
Carpal tunnel syndrome	Hyperphosphatemia
Arthralgia	Cardiomegaly
Myalgia	Cardiac arrhythmias
Hypertension	

Side Effects of GH

The most common side effects of GH administration are fluid retention, swelling of the hands and feet, and the occurrence of joint pain and myalgesias. Hyperglycemia may also occur, especially in an individual prone to having diabetes. Other side effects are listed in Table III.

cyclic GMP Intracellular signaling molecule that is produced by the cell surface receptors for guanylin and uroguanylin in target cells. Responsible for mediating cellular responses to these peptide hormones.

epithelial cell balance Physiological process that controls the birth and death rates of cells to maintain the morphology and function of epithelia in organs of the body.

guanylin/uroguanylin Small peptide hormones produced in the intestine, where they act locally to regulate intestinal functions, including the secretion of electrolytes and fluid into the intestinal lumen.

intestine–kidney endocrine axis Hormonal connection between the intestine and kidney formed by enteric guanylin and/or uroguanylin peptides that are secreted into the bloodstream following the ingestion of dietary sodium chloride (i.e., table salt).

Guanylin and uroguanylin are small, heat-stable peptides that are produced throughout the body, but are most abundant in the intestinal tract, where they are secreted locally to regulate epithelial cell functions through the intracellular second-messenger molecule, cyclic 3′5′-guanosine monophosphate (cyclic GMP). Apical plasma membranes of epithelial cells lining the intestinal lumen express high levels of a guanylin/uroguanylin receptor. When the receptor is activated by uroguanylin/guanylin binding to an extracellular portion of this signaling molecule, cyclic GMP is produced to regulate cellular functions. Certain strains of enteric bacteria produce heat-stable enterotoxin peptides that are molecular mimics of uroguanylin. The toxin peptides secreted by some enteric microbes produce an unregulated stimulation of uroguanylin/guanylin receptors, causing a cholera-like disease, often called "traveler's" diarrhea. The high incidence of this disorder in people in developing nations may be linked to the markedly lower incidence of colon cancer found in the developing world, attributed to a protective effect of the guanylin peptide family of cyclic GMP-regulating hormones, as well as to their molecular mimics.

INTRODUCTION

Guanylin and uroguanylin, peptide hormones that are produced in all tissues of placental (i.e., eutherian) mammals, are found most abundantly within epithelial cells of the gastrointestinal tract. In a representative metatherian mammal, the opossum, and in some species of bony fish, three different guanylin-like peptides have also been identified. The biologically active forms of guanylin peptides are highly conserved throughout vertebrate evolution. Most of the guanylin peptides are 15–16 amino acids long and contain two intramolecular disulfide bonds formed between specific cysteine pairs, which provide for a heat- and acid-stable molecule that is biologically active (Fig. 1). Enteric bacteria produce heat-stable toxin (ST) peptides, which serve as molecular mimics of uroguanylin and induce a cholera-like form of diarrhea. The ST peptides secreted by diarrhea-inducing strains of *Escherichia coli*, *Vibrio cholerae*, and *Yersinia enterocolitica* have variable structures, but all of these ST molecules contain a highly conserved core peptide region consisting of 13 residues with three disulfide bonds that are essential for full biological activity. This bioactivity domain of ST peptides is most closely related to a similar region within the biologically active forms of uroguanylin. Bacterial ST peptides have a greater affinity for the intestinal receptors compared to that of uroguanylin, which contributes to the toxicity of STs *in vivo* (Fig. 1). Piscine (i.e., fugu) forms of uroguanylin and bioactive ST peptides secreted by enterotoxigenic strains of bacteria have the closest sequence similarity. A novel bioactive peptide, lymphoguanylin, has been identified in the opossum, and this peptide has only three cysteine residues and one intramolecular disulfide (Fig. 1).

In the intestinal tract, locally secreted guanylin and uroguanylin peptides participate in regulating the physiological process of fluid secretion during digestion. Biological actions have also been demonstrated in the kidney, as demonstrated by increases in urinary sodium chloride (salt), potassium, and water excretion following administration of either guanylin or uroguanylin. Because guanylin and uroguanylin were discovered only 10 years ago, it is likely that other physiological roles will be elucidated for these peptide hormones in the future. The widespread distribution of guanylin/uroguanylin-producing tissues and the broad distribution of their cognate cyclic GMP-producing receptor,

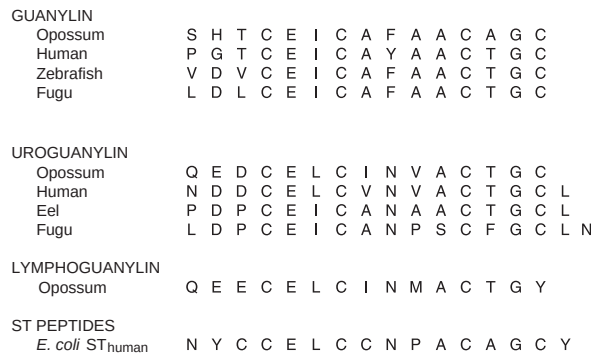

FIGURE 1 Primary structures of guanylin peptides. Amino acids are abbreviated using the single-letter code. Disulfide bonds connect the first to third and second to fourth cysteines in the linear peptide chain of guanylin and uroguanylin. Fugu (puffer fish) and zebrafish peptide sequences were derived from genome sequencing projects; other peptide sequences have been previously published. Heat-stable toxin (ST) peptides also have a third disulfide bond connecting their unique cysteine residues. *Escherichia coli* ST has three additional amino acids (i.e., NSS) on the N terminus, forming a 19-residue peptide.

clearly suggest that these peptide hormones influence cell and organ function throughout the body.

CELLULAR MECHANISM OF GUANYLIN AND UROGUANYLIN ACTION

Uroguanylin and guanylin bind to and activate a specific cell surface receptor that has an intrinsic catalytic activity that produces the intracellular second messenger, cyclic GMP. These receptor enzymes, guanylate cyclases, are localized to plasma membranes of various cells in the body. Thus, guanylin and uroguanylin bind to a receptor guanylate cyclase (R-GC) found on the surface of target cells and regulate cellular functions by stimulating the enzymatic portion of R-GCs to produce cyclic GMP from guanosine triphosphate (GTP). Cyclic GMP inside the cell then binds to specific receptor proteins, which can be either cyclic GMP-dependent protein kinases, cyclic GMP-regulated ion channels, or cyclic GMP-modulated phosphodiesterases.

One physiological mechanism that has been relatively well studied involves the robust stimulation of intestinal fluid and electrolyte secretion produced by guanylin, uroguanylin, and ST peptides mediated by intracellular cyclic GMP. In this example, cyclic GMP binds to and activates one or more protein kinases in certain specialized cells within the intestinal epithelium that are capable of secreting chloride and/or bicarbonate anions. Activated protein kinases catalyze the transfer of phosphate from adenosine triphosphate (ATP) to serine residues on the cystic fibrosis transmembrane conductance regulator (CFTR) protein, which is intimately involved in controlling the secretion of chloride and bicarbonate anions into the intestinal lumen. Phosphorylated CFTR is also associated with a reduction in the intestinal absorption of sodium into the body. The net physiological effect of either guanylin or uroguanylin is the stimulation of intestinal secretions containing the electrolytes sodium, chloride, and bicarbonate. The resulting fluid secretion permits the digestion and absorption of nutrients and other dietary factors.

REGULATION OF SODIUM CHLORIDE HOMEOSTASIS

Both guanylin and uroguanylin are produced in the intestine and then are released into the bloodstream when sodium chloride (salt) is ingested in food and drink. Secretion of these peptides into the bloodstream forms a novel endocrine axis linking the intestine with the kidney via guanylin and/or uroguanylin hormones. A fundamental response to the ingestion of salt in our diets is a marked increase in the excretion of urinary sodium chloride, which helps balance renal salt excretion and dietary salt intake, thus maintaining salt homeostasis in the body. Guanylin peptides stimulate the excretion of sodium, chloride, and potassium in the urine and also increase urinary volume. Kidney tubules express the R-GC type of receptor, but renal tubular cells also appear to have another form of receptor and signal transduction pathway that may be independent of R-GC and cyclic GMP. In fact, kidney cell responses to the peptides appear to be, at least in part, mediated by a G-protein-coupled receptor and pertussis toxin-sensitive mechanism of signaling. This novel signaling mechanism appears to regulate potassium channel activities in kidney cells and therefore may contribute to the observed effects of guanylin and uroguanylin to markedly increase urinary potassium excretion. High-salt diets also enhance the expression of both guanylin and uroguanylin messenger RNA transcripts in the intestine and lead to increases in the urinary excretion of uroguanylin. Both findings are consistent with a novel physiological role for guanylin peptides as regulators of salt balance in the body.

UROGUANYLIN, GUANYLIN, AND COLON CANCER

Tumors begin in the colorectal epithelium as small benign adenomas (polyps), which slowly grow over the course of many years. Many adenomas arise in the colonic mucosa secondary to mutations in the

adenomatous polyposis coli (APC) gene. Adenoma cells can acquire additional gene mutations that accumulate over time and culminate in the formation of malignant adenocarcinomas that may spread to other organs. In both polyp and adenocarcinoma cells, the expression of guanylin and uroguanylin genes is turned off, resulting in a hormone-deficient state within the tumors. However, the R-GC form of receptor for these peptides continues to be expressed at normal levels. In a mouse model of human colon cancer, the oral administration of uroguanylin had a profound effect of reducing both the number and the size of tumors that appeared within the intestinal tract, thus markedly reducing tumor burden. Moreover, when human colon cancer cells were treated with uroguanylin or related peptides, the cells responded by undergoing programmed cell death (apoptosis). Other agents that elevate intracellular cyclic GMP levels also elicit apoptosis of colon cancer cells. Based on these new findings, it may be postulated that a primary physiological role of the guanylin peptides is to regulate epithelial cell turnover by influencing cellular lifetimes. In this manner, guanylin and uroguanylin can participate in the complex cellular mechanisms that regulate birth and death rates of the epithelial cells that populate the intestinal mucosa in order to maintain both the morphology and the function of the intestinal epithelium.

The antitumor actions of uroguanylin in both animal and cell models of colon cancer have stimulated additional investigations of this peptide hormone for potential use in the prevention and/or therapy of colon cancer. In addition, chemical analogues of uroguanylin-like peptides have been synthesized; the analogues contain a radioactive atom that can be detected at the surface of the body using the noninvasive imaging method of single photon-emitting computed tomography (SPECT). Preclinical studies have demonstrated that these uroguanylin-like agents can be used to locate colon adenocarcinomas that have spread to other organs in the body. This diagnostic approach is very promising for the early detection of metastatic forms of colon tumors because the tumor cells have very high levels of uroguanylin/guanylin receptors. The radioactive forms of these uroguanylin-like peptides bind to cell surface receptors, and the macromolecular complexes are then internalized and concentrated within the tumors. SPECT imaging can then be used to detect and locate one or more secondary colorectal tumors that have spread to other organs. It is clear that discovery of the guanylin family of cyclic GMP-regulating peptides has provided new insights into colon tumor biology per se. Moreover, the uroguanylin-like peptides offer new therapeutic approaches to prevent, detect, or treat colon cancer.

H2-Receptor Antagonists

MITCHELL L. SCHUBERT
Virginia Commonwealth University's Medical College of Virginia and McGuire Veterans Affairs Medical Center, Richmond

erosion A shallow ulcer confined to the mucosal layer.
gastric H^+,K^+-ATPase An ATP-hydrolyzing enzyme responsible for catalyzing the exchange of lumenal K^+ for cytoplasmic H^+ by parietal cells, bringing about gastric lumenal acidification.
gastroesophageal reflux Backflow of acidic gastric contents into the esophagus, producing a spectrum of clinical symptoms and manifestations ranging from mild episodic heartburn and regurgitation without macroscopic esophagitis to chronic inflammation and ulceration; severe cases may involve stricture and hemorrhage.
gynecomastia Excessive development of the male mammary glands.
Helicobacter pylori A gram-negative urease-producing bacterium that causes an active chronic gastritis and is an important etiological factor in the development of gastric and duodenal ulcers.
nonsteroidal anti-inflammatory drugs Medications that reduce inflammation by inhibiting the enzymatic activity of cyclooxygenase, a key enzyme in the biosynthetic pathway leading to the formation of prostaglandins. Examples include aspirin, ibuprofen, naproxen, and diclofenac.
peptic ulcer A loss of tissue, extending through the mucosa into the submucosa, in the esophagus, stomach, or duodenum, due to acidic gastric secretions.
pharmacokinetics The disposition of drugs within the body in relation to their absorption, distribution, metabolism, and elimination.

Histamine receptors have been classified into four major subclasses: H1, H2, H3, and H4. H1 receptors are widely distributed and mediate the actions of histamine in the allergic response and as a bronchial constrictor. H2 receptors are present primarily in the stomach, where they regulate gastric acid secretion, and to a lesser extent in the heart, central nervous system, reproductive system, and on lymphocytes. Histamine-2 (H2)-receptor antagonists are drugs that competitively block the ability of histamine to interact with H2-receptors. H3-receptors were originally identified as inhibitory autoreceptors on histamine-containing nerve terminals in the central nervous system. In the stomach, H3-receptors augment acid secretion by suppressing somatostatin secretion. In the antrum, suppression of somatostatin leads to stimulation of gastrin, the main hormonal stimulant of acid secretion, whereas in the fundus, it leads to stimulation of histamine and acid secretion. Most recently, an H4-receptor has been identified in intestine, spleen, thymus, and immune cells. The H4-receptor shares 40% homology and overlapping pharmacology with the H3 receptor; its physiologic function is not known. This article focuses on the role of blocking H2 receptors in the stomach. The identification of the H2 receptor on the basolateral membrane of the parietal cell by Black in 1972 and the subsequent development of safe and effective H2-receptor antagonists have revolutionized the treatment of gastrointestinal acid-related disorders.

INTRODUCTION

Until the development of histamine-2 (H2)-receptor antagonists, the only treatments available for patients with acid-related disorders were bed rest, bland diets, milk drips, antacids, and surgery. Ulcers and ulcer pain

Copyright 2004, Elsevier (USA). All rights reserved.

recurred and complications such as bleeding, perforation, and obstruction were frequent. Surgery, mainly vagotomy (to denervate the acid-producing area of the stomach) with antrectomy (to remove the hormone gastrin), became the "gold standard" for the treatment of recurrent, recalcitrant, or complicated disease. Unfortunately, surgery proved not to be definitive (1–10% recurrence rate) and produced its own set of problems, including gastric stasis, bile reflux gastritis and esophagitis, and gastric remnant carcinoma.

The introduction of cimetidine, the first commercially available H2-receptor antagonist, and the subsequent introduction of ranitidine, famotidine, nizatidine, and roxatidine revolutionized the management of acid-related diseases and improved the quality of life for a large number of patients. For the first time, peptic ulcer disease and gastroesophageal reflux disease could be treated and prevented pharmacologically.

MECHANISM OF ACTION

The main secretagogues active at the level of the parietal cell are acetylcholine, histamine, and gastrin (Fig. 1). Acetylcholine, released from intramural postganglionic nerve terminals, binds to parietal cell muscarinic subtype 3 (M3) receptors that are coupled to an increase in intracellular calcium. Histamine, released from enterochromaffin-like (ECL) cells, which reside in the basal half of the oxyntic gland in the vicinity of parietal cells, binds to parietal cell H2 receptors that are coupled to an increase in intracellular concentrations of adenosine 3′,5′-cyclic monophosphate (cAMP). Histamine-containing ECL cells are the predominant endocrine/paracrine cell type in the oxyntic mucosa and constitute 65–75% of the endocrine cells in rat and 30–35% of the endocrine cells in humans. Gastrin, released from antral G cells in the distal stomach, travels through the bloodstream to activate cholecystokinin subtype 2 (CCK_2; previously termed CCK-B) receptors present on both parietal and ECL cells that are coupled to an increase in intracellular calcium. The increase in parietal cell levels of cAMP and calcium synergistically activates the parietal cell proton pump, an H^+,K^+-ATPase, that catalyzes the exchange of lumenal K^+ for cytoplasmic H^+ and is responsible for gastric lumenal acidification (Fig. 1).

Gastrin, the main stimulant for acid secretion during ingestion of a meal, activates the parietal cell directly and, more importantly, indirectly by increasing the production and release of histamine from ECL cells (Fig. 1). In H2-receptor-deficient mice, gastrin is an ineffective secretagogue, confirming the notion that, although CCK_2 receptors are present on the parietal cell, gastrin stimulates acid secretion primarily by binding to CCK_2 receptors on ECL cells that are coupled to histamine release.

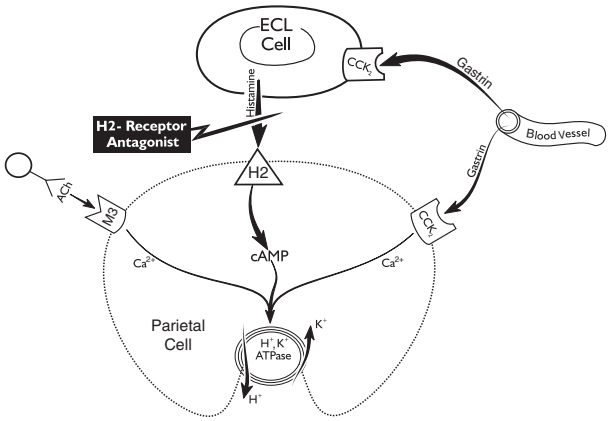

FIGURE 1 Model illustrating the action of the main secretagogues at the level of the parietal cell, the transduction pathways to which they are coupled, and the site of action of H2-receptor antagonists. Acetylcholine (ACh), released from intramural neurons, binds to M3 receptors that are coupled to an increase in intracellular calcium (Ca^{2+}). Histamine, released from enterochromaffin-like (ECL) cells, binds to H2 receptors that are coupled to an increase in cellular adenosine 3′,5′-cyclic monophosphate (cAMP). Gastrin, released from G cells in the antrum into the bloodstream, binds to CCK_2 receptors on the parietal cell that are coupled to an increase in Ca^{2+} and more importantly binds to CCK_2 receptors on ECL cells that are coupled to the release of histamine. The two transduction pathways in the parietal cell, i.e., cAMP and Ca^{2+}, converge on and activate the H^+,K^+-ATPase, the hydrogen pump of the parietal cell. H2-receptor antagonists competitively block the H2 receptor on the parietal cell, thus blocking both histamine-driven acid secretion and that elicited by gastrin, whose action is mediated primarily by the release of histamine from ECL cells.

The structure of H2-receptor antagonists is patterned after that of histamine (Fig. 2). The initial compounds (e.g., cimetidine) share histamine's imidazole ring. Subsequent compounds (ranitidine, famotidine, and nizatidine) use other five-membered rings (i.e., furan and thiazole rings). Roxatidine, which is available in Europe, differs from previous compounds in that the five-membered ring has been replaced with a phenyl ring. Unlike the other H2-receptor antagonists, roxatidine is a prodrug that is rapidly metabolized to yield the active compound.

H2-receptor antagonists competitively and selectively inhibit the binding of histamine to H2 receptors on the basolateral membrane of the parietal cell, thereby reducing intracellular concentrations of the signaling molecule cAMP and, as a result, the secretion of acid by the parietal cell. As discussed above, the H2-receptor

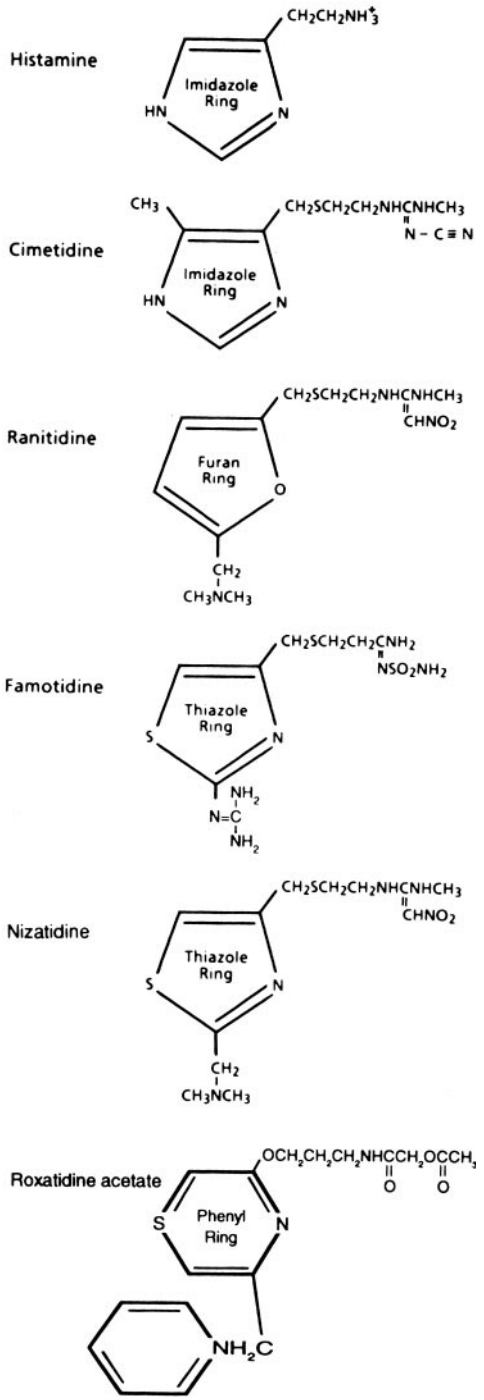

FIGURE 2 Chemical structure of histamine and H2-receptor antagonists.

antagonists are effective at blocking both histamine-driven acid secretion and that elicited by gastrin, whose action is mediated primarily by the release of histamine from ECL cells. The relative potencies of the H2-receptor antagonists clinically available are as follows: famotidine > ranitidine = nizatidine = roxatidine > cimetidine (Table I).

PHARMACOKINETICS

The absorption of H2-receptor antagonists from the gastrointestinal tract varies considerably; their mean bioavailability after oral administration is as follows (Table I): famotidine 45%, ranitidine 50%, cimetidine 60%, nizatidine 95%, and roxatidine 95%. Peak plasma concentrations occur 1–3.5 h after oral administration, although wide interindividual variations are observed. Concomitant administration of antacids or sucralfate may decrease the absorption of H2-receptor antagonists by up to 30%.

The H2-receptor antagonists are widely distributed throughout the body, with a mean volume of distribution of 1.5 liter/kg (Table I). Protein binding is low, in the range of 8% for roxatidine to 30% for nizatidine. Although all the H2-receptor antagonists cross the blood–brain barrier, cimetidine achieves the highest cerebrospinal fluid levels. All cross the placenta and are secreted into breast milk.

After oral administration, cimetidine, ranitidine, and famotidine are extensively metabolized by the liver. By contrast, 65% of nizatidine or roxatidine is excreted unchanged in the urine. Nizatidine produces an active metabolite, *N*-2-monodesmethylnizatidine, which exhibits 60% of the H2-receptor-blocking activities of the parent compound. After intravenous administration, 65–85% of each H2-receptor antagonist is excreted unchanged in the urine.

The elimination half-life varies considerably, averaging 1.5 h for cimetidine, ranitidine, and nizatidine; 4 h for famotidine; and up to 6 h for roxatidine (Table I). Because the half-life of H2-receptor antagonists is increased up to 10-fold in patients with renal insufficiency, it has been suggested that one-half the therapeutic dose be given to patients with creatinine clearances below 30 ml/min. No dosing adjustment is required for patients with hepatic dysfunction.

EFFICACY

Although a number of factors may contribute to the pathogenesis of peptic ulcer disease and reflux esophagitis, gastric acid secretion plays a pivotal role and reduction in acid secretion is the cornerstone of treatment for these diseases. Maximal healing rates for peptic ulcer are achieved when intralumenal pH is maintained at or above 3 for 16 h out of a 24 h period. In contrast, optimal healing of reflux esophagitis requires greater acid inhibition, a target pH at or above 4 for 16 h out

TABLE I Comparison of H_2-Receptor Antagonists

Characteristic	Cimetidine	Ranitidine	Famotidine	Nizatidine	Roxatidine
Absorption					
Bioavailability (%)	30–80	39–88	40–50	75–100	95
Time to peak concentration (h)	1–2	1–3	1–3.5	1–3	1–3
Distribution					
Volume (liter/kg)	0.8–2.1	1.0–1.9	1.1–1.3	1.2–1.6	0.9–1.9
Protein binding (%)	20	15	16	30	8
Elimination					
Serum half-life (h)	1.5–2.5	1.6–3.1	2.5–4.0	1.1–2.0	2.0–6.0
Relative potency	1	4–10	20–50	4–10	4–6

of a 24 h period. Treatment for as little as 2–7 days with H2-receptor antagonists may induce tachyphylaxis, i.e., progressive loss of efficacy, with time. The precise mechanism is not known.

Duodenal and Gastric Ulcers

Approximately 60–80% of duodenal and gastric ulcers can be healed by 4-week treatment and 80–90% by 6- to 8-week treatment with therapeutic doses of any of the H2-receptor antagonists. Ulcers can be successfully treated with either a twice-a-day dose or a single bedtime dose (cimetidine, 800 mg; ranitidine, 300 mg; famotidine, 20 mg; nizatidine, 300 mg; or roxatidine, 150 mg). Once healed, however, cure is not permanent and 80% of patients will have a relapse of their ulcer within 1 year. Maintenance therapy with one-half the standard therapeutic dose administered at bedtime (i.e., cimetidine, 400 mg; ranitidine, 150 mg; famotidine, 10 mg; nizatidine 150 mg; or roxatidine, 75 mg) can decrease the 1-year relapse rate to 10–20%.

In the vast majority of cases, duodenal and gastric ulcers are associated with either *Helicobacter pylori* infection of the stomach or the use of nonsteroidal anti-inflammatory drugs (NSAIDs); Zollinger-Ellison syndrome caused by a gastrin-secreting tumor (gastrinoma) is a rare cause of peptic ulcer disease. In patients infected with *H. pylori*, additional therapy aimed at eradicating the bacteria may accelerate the rate of ulcer healing over that achieved using an H2-receptor antagonist alone and prevents ulcer relapse. Ranitidine bismuth citrate, 400 mg twice a day for 4 weeks, in conjunction with clarithromycin, is an approved regimen for eradication of the bacteria.

NSAID-induced ulcers can be effectively treated with H2-receptor antagonists, especially if the NSAID can be discontinued. If the NSAID must be continued, H2-receptor antagonists achieve only a 50% healing rate at 8 weeks. For the prevention of NSAID-induced ulcers in high-risk patients, concomitant administration of H2-receptor antagonists is effective in preventing duodenal but not gastric ulcers.

Zollinger-Ellison syndrome is characterized by marked gastric acid hypersecretion. H2-receptor antagonists have been used successfully to control acid secretion but high and frequent dosing is required (e.g., ranitidine: 2700 mg per day in divided doses every 4–6 h) and this condition is now most often treated with proton pump inhibitors.

Reflux Esophagitis

Reflux esophagitis manifests as a spectrum of endoscopic and pathologic stages ranging in severity from reflux symptoms without evidence of esophageal damage to erosive and ulcerative esophagitis. Over-the-counter formulations of H2-receptor antagonists provide at best partial relief, with complete relief occurring in only 15% of patients. In patients with erosive or ulcerative esophagitis, standard doses of H2-receptor antagonists provide complete symptom relief and mucosal healing in only approximately 50–75% of patients at 8 weeks. Because healing of erosive esophagitis requires greater acid suppression than that required to heal duodenal or gastric ulcers, ranitidine 150 mg qid or comparable doses of another H2-receptor antagonist are recommended. After complete healing, symptomatic recurrences occur in 80% of patients. In contrast to duodenal and gastric ulcer, maintenance therapy to prevent recurrence requires the use of the same dose required to achieve healing.

Prophylaxis of Stress-Related Gastric Hemorrhage

Patients admitted to intensive care units, particularly those with respiratory failure, coagulopathy, extensive burns, head injuries, or extensive trauma, are at increased risk for stress-related gastric mucosal damage

and subsequent upper gastrointestinal bleeding. Despite controversy regarding the precise role of acid in the development of stress-related gastric damage, data show a strong relationship between mucosal damage, bleeding, and low pH. H2-receptor antagonists, administered continuously intravenously, are effective in preventing stress ulcer and stress ulcer bleeding.

Adjuvant Treatment of Cancer

H2-receptor antagonists, in particular, cimetidine, have been shown to improve the survival of patients with colorectal cancer, melanoma, and renal cell cancer. It has been proposed that cimetidine enhances the host immune response by increasing the cytotoxic activity of mononuclear cells and tumor-infiltrating lymphocytes and prevents cancer metastasis by inhibiting cancer cell adhesion to endothelial cells via down-regulation of the cell surface expression of E-selectin, a ligand on endothelial cells that binds tumor antigens.

ADVERSE EFFECTS

The H2-receptor antagonists are generally well tolerated with adverse effects observed in 1.5% of treated patients compared with 1.2% of placebo patients.

Central Nervous System

Cimetidine and ranitidine, but perhaps not nizatidine, cross the blood–brain barrier and may interact with H2 receptors present in the brain. A variety of central nervous system (CNS) side effects, ranging from headache, dizziness, anxiety, somnolence, and depression, to confusion and delirium, have been reported. It should be noted, however, that the overall frequency of CNS effects is very low, less than 0.2%. Advanced age and renal dysfunction may predispose to CNS side effects.

Endocrine

Cimetidine possesses weak anti-androgenic activity and may rarely cause gynecomastia, hyperprolactinemia, and impotence. Gynecomastia has been observed in up to 4% of patients with Zollinger-Ellison syndrome who were treated for prolonged periods with high doses of cimetidine. Prolactin levels may rise acutely but usually return to normal with continued use. Sperm counts may be depressed, but usually remain within normal limits. Although ranitidine, famotidine, and nizatidine do not possess anti-androgenic activity, nevertheless they may rarely cause gynecomastia.

Renal

Cimetidine has rarely (1 in 100,000 patients exposed) been associated with an idiosyncratic hypersensitivity interstitial nephritis, which may manifest as fever, rash, arthralgia, polymyositis, eosinophilia, and sterile pyuria. Renal function usually returns to normal once cimetidine is stopped. Cimetidine, but none of the other H2-receptor antagonists, has been reported to increase serum creatinine concentrations as a result of competition for renal tubular excretion between cimetidine and creatinine.

Hematologic

Thrombocytopenia, anemia, and leukopenia have been reported only rarely. In most circumstances, patients had serious underlying disease and/or were taking multiple drugs, making it difficult to establish a direct cause and effect. H2 receptors are present on the cell surface of suppressor T lymphocytes and H2-receptor antagonists have been reported to have mild immune-modulating effects; they have induced tumor regression in several studies and may cause false-negative immediate skin tests.

Pregnancy and Breast-Feeding

The H2-receptor antagonists cross the placenta and are also distributed in breast milk. Although data in humans are limited, these drugs have been assigned to Food and Drug Administration Pregnancy Category B and should be used in pregnancy only if clearly needed. Because of the potential for adverse reactions in nursing infants, caution should be exercised in administering these drugs to nursing mothers.

Other Effects

H2 receptors have been identified in the human atria and rare cases of dysrhythmia and atrioventricular conduction defects have been reported. Asymptomatic elevations in hepatic transaminases may occur. Studies suggest that cimetidine delays gastric emptying, whereas ranitidine and nizatidine accelerate it.

DRUG INTERACTIONS

Interference with Drug Absorption

H2-receptor antagonists may interfere with the absorption of other drugs or themselves by altering gastric emptying, binding directly to another drug, or altering intragastric pH. Cimetidine has been reported to delay gastric emptying, whereas ranitidine and

nizatidine accelerate it. Antacids and sucralfate bind to and inhibit the absorption of H2-receptor antagonists by 10–25%. Certain drugs that are weak bases, such as the antifungal medications ketoconazole and itraconazole, require an acid environment for optimal absorption. As the pH rises in response to H2-receptor antagonists, the absorption of these drugs decreases.

Cytochrome P450 Interactions

The liver is a major site for drug biotransformation. Many drugs are lipophilic and require conversion in the liver to more polar, aqueous-soluble compounds for elimination in bile or urine. Cytochrome P450, or the mixed-function oxidative microsomal enzyme system, refers to a group of heme-containing hepatic enzymes that catalyze the oxidative biotransformation of lipophilic substrates to more polar hydrophilic compounds. Cytochrome P450 is defined by its maximal absorption of light at 450 nm. Multiple different cytochrome P450 enzymes are expressed in a given individual and differences among individuals in their capacity to metabolize drugs may reflect genetically determined differences in the expression of these enzymes.

Imidazole-containing drugs, such as cimetidine, are capable of inhibiting the catalytic activity of one or more cytochrome P450 enzymes, in particular, CYP1A2 and CYP2C19. Ranitidine, which lacks the imidazole ring, interacts 5- to 10-fold less. Less information is available regarding the other H2-receptor antagonists, but they do not appear to have any significant interaction. Although cimetidine has the potential to interfere with the hepatic metabolism of many therapeutic drugs, only a few are of potential clinical significance because of their narrow therapeutic ranges: theophylline, warfarin, quinidine, phenytoin, cyclosporin, and tricyclic antidepressants. The clinical importance of these interactions depends on (1) how often cimetidine is taken, (2) the initial serum concentration of the therapeutic drug, (3) the individual susceptibility of the patient to the interaction, and (4) the individual sensitivity of the patient to the therapeutic drug.

Warfarin exists as a mixture of *S* and *R* isomers; (*S*)-warfarin is five times more potent as a vitamin K antagonist than (*R*)-warfarin. Cimetidine inhibits the metabolic clearance of the *R* isomer only; thus, it causes only a slight prolongation of the prothrombin time.

Many cardiac anti-arrhythmics, such as quinidine, lidocaine, and flecainide, are metabolized by cytochrome P450 and elevated levels may occur during co-administration with cimetidine. The elimination half-life of beta-blockers, such as propranolol and metoprolol, but not atenolol and nadolol, which are primarily cleared through the kidney, may be prolonged by cimetidine. Cimetidine may augment the blood pressure-lowering effect of nifedipine and the delay in atrioventricular conduction induced by verapamil.

Despite the potential for adverse interactions between cimetidine and various drugs metabolized by cytochrome P450, the reality is that serious complications only very rarely occur. Most problems can be avoided by monitoring the plasma levels of a drug with a narrow therapeutic window or by administering the H2-receptor antagonist in a single nighttime dose.

Interference with Drug Elimination

Cimetidine can interfere with the renal clearance of creatinine as well as cationic drugs that undergo active renal proximal tubular secretion. By competing for the transport mechanism, cimetidine may impair the elimination of procainamide and cyclosporin.

Alcohol Dehydrogenase Interaction

A portion of ingested alcohol is metabolized in the stomach by the enzyme alcohol dehydrogenase. Cimetidine, ranitidine, and nizatidine have been reported to inhibit gastric alcohol dehydrogenase. In addition, ranitidine and nizatidine have been reported to accelerate gastric emptying, thus shortening the exposure of alcohol to gastric alcohol dehydrogenase. Since the initial reports that cimetidine, ranitidine, and nizatidine, but not famotidine, increase blood alcohol levels, the validity of these findings and the clinical implications have been the subject of considerable controversy.

Halitosis

KEN YAEGAKI
University of British Columbia, Vancouver

halitosis Abnormally foul or fetid breath/oral malodor or simply bad breath.
organoleptic measurement and score Scoring odor intensity by smelling a patient's breath. Observation conditions must ensure that breath air is not diluted with room air.
volatile sulfide compounds Compounds such as hydrogen sulfide, methyl mercaptan, and dimethyl sulfide that are the main cause of halitosis and that are produced from sulfur-containing amino acids by bacterial putrefaction.

Most cases (approximately 90%) of halitosis originate within the oral cavity. Oral bacteria degrade sulfur-containing amino acids to volatile sulfide compounds (VSCs). Numerous compounds exist in human breath, but only VSCs correlate well with organoleptic score. Approximately 10% of halitosis cases are related to conditions outside the mouth. In general, people are not able to assess their own malodor accurately and 30–90% of the patients visiting oral malodor clinics do not in fact exhibit bad breath.

INTRODUCTION

Halitosis can be classified into three main categories (Table I): genuine halitosis, pseudo-halitosis, and halitophobia. Genuine halitosis is subclassified as physiologic halitosis and pathologic halitosis. Physiologic halitosis is caused by physiologic factors, such as tongue coating. Pathologic halitosis is further subdivided into oral pathologic halitosis and extraoral pathologic halitosis. The principal causes of oral pathologic halitosis are periodontal conditions and progressive dental caries. Pseudo-halitosis and halitophobia are psychological phenomena in which patients complain of the presence of halitosis, but others do not perceive their breath to be offensive. Improvement in the condition of pseudo-halitosis can be obtained by explanation of examination results and simple treatment measures. In contrast, halitophobic patients cannot believe, despite evidence to the contrary, that they do not have halitosis. Halitophobic patients are thus considered to suffer from a social phobia.

TABLE I Classification of Halitosis

Genuine halitosis
Physiologic halitosis
Pathologic halitosis
Oral pathologic halitosis
Extraoral pathologic halitosis
Pseudo-halitosis
Halitophobia

EXTRAORAL PATHOLOGIC HALITOSIS

Gastrointestinal diseases, especially stomach conditions, are popularly believed to cause halitosis. Since the esophagus is collapsed, this does not happen unless function of the esophagus is abnormal. It has been demonstrated that gastric *Helicobacter pylori* infection may cause halitosis. Pyloric stenosis and extrinsic duodenal obstruction can also cause halitosis. Since malodorous compounds, such as volatile sulfide compounds (VSCs), are absorbed from the intestines into the bloodstream, the compounds diffuse into lung air. However, as thiols, such as H_2S and CH_3SH, immediately react irreversibly with blood components, only dimethyl sulfide is transported from the blood into the air in the lung.. Therefore, although hydrogen sulfide, methyl mercaptan, and ethanethiol are found in the breath of patients with liver conditions, *fetor hepaticus* is probably principally caused by dimethyl sulfide. Furthermore, C-2–C-4 aliphatic acids and lomonene have also been suggested as components of *fetor hepaticus*. Some metabolic disorders can result in halitosis. Trimethylaminuria causes a fishy odor in urine, sweat, and breath because an oxidative enzyme that converts trimethylamine to trimethylamineoxide is lacking. In patients with high blood cholesterol, isoprene with specific malodor can be detected in the breath utilizing a simple laboratory device. Diabetes elevates the acetone level in breath and is generally believed to be the most plausible reason for halitosis. However, acetone itself does not produce a fetid malodor; the foul breath of diabetics may be linked to their periodontal condition or other infections. Diabetes is an indirect rather than a direct reason for halitosis. Nasal, sinus, or pharyngeal conditions have also been assumed to be

 Copyright 2004, Elsevier (USA). All rights reserved.

frequent reasons for halitosis, but in fact this is seldom the case. Conditions of the bronchi and the lung, however, can cause halitosis. Aniline, *o*-toluidine, *n*-propanol, and methylethylketone have been found in the breath of patients with lung carcinoma. Some medications cause halitosis. Sulfur-containing drugs, such as cysteine, cysteamine, or disulfiram, result in foul breath. Psychopharmacologic, antirheumatic, or antihypertensive drugs also causes halitosis. Anticholinergics, antidepressants, analgesics, and numerous other drugs that suppress salivation may cause halitosis as they suppress the natural cleansing action of saliva in the mouth.

PHYSIOLOGIC HALITOSIS

The majority of halitosis cases are physiologic and evidence-based treatments of halitosis are necessary. To carry out a rational treatment, the halitosis must be classified and appropriate treatment needs (TN) determined. The TN for physiologic halitosis comprise instructions by the clinicians on oral hygiene and tooth brushing. The most important oral hygiene procedure is tongue cleaning. Physiological halitosis mainly originates from the dorso-posterior region of the tongue when covered with a coating containing desquamated epithelial cells, blood cells, and bacteria. Approximately 60% of total VSCs are produced from such tongue coatings. Tongue brushing has been found to be more effective and safer in reducing oral malodor than tongue scraping. A tongue brush with very soft and tiny bristles or a toothbrush for infants is recommended to clean the tongue. The clinician should instruct the patient that brushing must always be performed from the terminal sulcus to the front of the tongue to avoid brushing the tongue tonsil.

DISCRIMINATIVE DIAGNOSIS OF EXTRAORAL PATHOLOGIC HALITOSIS FROM OTHER HALITOSIS

To perform organoleptic measurements, a translucent tube (1 in. diameter, 4 in. length) is inserted through a privacy screen (a translucent tube is inserted at the center). The patient is asked to close his or her mouth and breathe normally through the nose for 1 min and then exhale his or her breath into the tube. For the first 1–2 s, the judge smells the patient's breath for oral malodor and gives a score (Table II). Then, the patient is instructed to brush the tongue and to rinse the mouth with 0.75–1.50% H_2O_2 or 0.12–0.20% chlorhexidine mouthwash. After these procedures that markedly reduce oral malodor are performed, organoleptic measurement is carried out again for odors originating in the lung.

TABLE II Organoleptic Score Scale

Category	Description
0: Absence of odor	Odor cannot be detected
1: Questionable odor	Odor is detectable, although the examiner could not recognize it as malodor
2: Slight malodor	Odor is deemed to exceed the threshold of malodor recognition
3: Moderate malodor	Malodor is definitely detected
4: Strong malodor	Strong malodor is detected, but can be tolerated by examiner
5: Severe malodor	Overwhelming malodor is detected and cannot be tolerated by examiner (examiner instinctively averts the nose)

Hamartomatous Polyposis Syndromes

SHERRY C. HUANG AND JOHN M. CARETHERS
University of California, San Diego

bone morphogenetic protein receptor type 1A Mutated receptor in some patients with juvenile polyposis syndrome.

hamartoma Mature but disorganized normal tissue indigenous to the site of origin.

phosphatase and tensin homologue Tumor suppressor gene on chromosome 10; mutated in patients with Cowden disease and in some patients with juvenile polyposis syndrome and Bannayan–Riley–Ruvalcaba syndrome.

serine/threonine kinase 11 Gene that is mutated in patients with Peutz–Jeghers syndrome.

Hamartomatous polyposis syndromes are a group of clinically distinct disorders in which the predominant feature is multiple hamartomatous polyps in the gastrointestinal tract. These syndromes are transmitted in an autosomal dominant fashion to offspring, but sporadic forms do exist. Despite the nondysplastic histologic characteristics of the polyps, each hamartomatous polyposis syndrome carries specific cancer risks at different organ sites. Several mutated genes have recently been identified in the different polyposis syndromes. These genes may provide clues to the pathogenesis of the polyps and may play an important role in classifying the hamartomatous polyposis syndromes prior to cancer formation. Pathways involved in the hamartomatous syndromes include those of vascular endothelial growth factor, the transforming growth factor-β superfamily, and antagonizing the effects of Akt/protein kinase B.

INTRODUCTION

The autosomal dominant inherited hamartomatous polyposis syndromes consist of juvenile polyposis syndrome (JPS), Bannayan–Riley–Ruvalcaba syndrome (BRRS), Cowden syndrome (CS), Peutz–Jeghers syndrome (PJS), and hereditary mixed polyposis syndrome. Recently, these syndromes have been associated with germ-line mutations in certain tumor suppressor genes, but there remains some overlap in manifestations of a mutated phenotype. Because organ-specific cancer risks in each syndrome are different (see Table I), it is important to arrive at a molecular basis for classifying these syndromes. For instance, patients with JPS are predisposed to colorectal cancers with a 4- to 12-fold increase in incidence. Although in BRRS the risk for colorectal carcinoma is not known, carcinoma of the breast, endometrium, and thyroid has been well described in CS. As such, medical and surgical treatments of these syndromes differ based on the different disease phenotypes and subsequent malignant potential. Genotyping these syndromes has been important in classifying these diseases prior to cancer formation.

PEUTZ–JEGHERS SYNDROME

Patients with Peutz–Jeghers syndrome have associated characteristic mucocutaneous pigmentary spots along with intestinal hamartomatous polyps. Classically, pigmentary macules (1–5 mm) are often found in the perioral region and cross the vermilion border. The PJS polyps are distinct from those seen in the other hamartomatous polyposis syndromes in that the polyps demonstrate an arborizing pattern of growth of the muscularis mucosae, with extension into branching fronds of the polyp. These benign glands within the polyp are often surrounded by smooth muscle, which extends into the submucosa or muscularis propria (pseudoinvasion).

The incidence of PJS has been described as 1 in 120,000 births and occurs in all races and skin types. On biopsy, the mucocutaneous pigmentary macules are characterized by increased melanocytes at the epidermal–dermal junction. No malignant transformation has been ascribed to the hyperpigmentation associated with PJS. Young patients with PJS often present with symptoms of the small intestine (intussusception and abdominal pain), where the polyps occur most frequently. As the PJS patient ages, the morbidity shifts to malignancy. Patients with PJS have a 15-fold elevated relative risk for developing cancer, with 93% of patients developing cancer by age 64. The major sites of cancer are small intestine, stomach, pancreas, colon, esophagus, ovary, lung, uterus, and breast.

The genetic cause of PJS has been well described by many groups and appears to be a germ-line mutation in

TABLE I Cancer Risks and Screening in Hamartomatous Polyposis Syndromes

Syndrome	Cancer	Risk	Screening recommendations
Juvenile polyposis syndrome	Colon	Up to 68%	Initial colonoscopy in early teens (12–15 years) in asymptomatic patients; interval determined by symptoms, but every 3 years thereafter
	Gastric, duodenal	Rare	Upper GI endoscopy every 3 years to manage symptoms of polyps
Cowden syndrome	Colon	Minimal	As needed to manage symptoms of polyposis
	Thyroid	3–10%	Annual thyroid exam, start in teens
	Breast	25–50%	Breast exam, start at 25 years; annual mammograms, start at age 30
Peutz–Jeghers syndrome	Colon	35–40%	Initial colonoscopy in early teens in asymptomatic patients; interval determined by symptoms, but every 3 years thereafter
	Pancreas	35%	Endoscopic or abdominal ultrasound every year, start at age 30
	Stomach	25–30%	Upper GI endoscopy every 2 years, start at age 10
	Small bowel	10–15%	Annual hemoglobin; small bowel barium study every 2 years, start at age 10
	Esophagus	Rare	None
	Breast	50–60%	Annual breast exam; mammography every 2–3 years, start at age 25
	Ovarian	20%	Annual pap smear, annual pelvic ultrasound, start at age 20
	Uterine/cervical	8–10%	Annual pelvic exam, annual pelvic or vaginal ultrasound, start at age 20
	Testes	10%	Annual testicular exam, start at age 10; testicular ultrasound if feminizing features occur

the *STK11/LKB1* gene, located on chromosome 19p13.3. The protein product of *STK11/LKB1* is a tumor suppressor found in a variety of adult and fetal tissues. Genetic analysis of PJS polyps demonstrates that both alleles of *STK11/LKB1* are inactivated in most polyps. In adenomatous tissues or adenocarcinomas from patients with PJS, additional genetic lesions appear, suggesting the *STK11/LKB* may play a "gatekeeper" role for the development of malignancy in patients with PJS. Diagnosis is based on the finding of typical melanin pigment spots and characteristic gastrointestinal (GI) polyps. Management involves screening to prevent benign and malignant complications.

COWDEN SYNDROME

Cowden syndrome occurs in 1 of 200,000 individuals and is autosomal dominantly inherited. It is characterized by multiple hamartomatous polyps in the colon and throughout the GI tract. Juvenile-like polyps that contain neural elements are the most common, but a number of other polyps may occur, including lipomas, inflammatory polyps, ganglioneuromas, and lymphoid hyperplasia. The hallmark of CS is facial trichilemmomas, which most commonly occur around the mouth, nose, and eyes.

Two-thirds of patients with CS have thyroid adenomas and goiters, and as many as three-fourths will have fibrocystic breast disease and fibroadenomas. Excess risk of GI cancers has not yet been described, although the two most common cancers that develop in patients with CS are thyroid cancer (10%) and breast cancers (as many as 50% of patients). The genetic cause of CS has been well described. It arises from mutations of the *phosphatase and tensin homologue* (*PTEN*) gene on chromosome 10q23, which encodes a 403-amino-acid dually specific phosphatase. Other benign soft tissue and visceral tumors have been described, including hemangiomas, lipomas, lymphangiomas, neurofibromas, uterine leiomyomas, and meningiomas. Up to 85% of patients who meet the diagnostic criteria of CS have a mutation of the *PTEN* gene. Management centers on cancer surveillance and prevention.

BANNAYAN–RILEY–RUVALCABA SYNDROME

Bannayan–Riley–Ruvalcaba syndrome is also known as Bannayan–Zonana syndrome, Ruvalcaba–Myhre–Smith syndrome, and Riley–Smith syndrome. BRRS is a rare congenital syndrome with features of intestinal juvenile polyps, macrocephaly, subcutaneous and visceral lipomas and hemangiomas, cognitive and motor developmental delay, lipid storage myopathy, Hashimoto thyroiditis, and pigmentary spotting of the penis in males. The prevalence of BRRS is unknown. Approximately half of the patients with BRRS have evidence of germ-line mutations in *PTEN*, the same mutated gene that is associated with CS. BRRS and

CS have been described in the same family, suggesting that the two syndromes might be allelic. Analysis of patients with BRRS and CS for germ-line *PTEN* mutations indicates a similar mutational pattern. Some BRRS patients do not have germ-line mutations in *PTEN*. Rather, they have gross chromosome deletions or rearrangements involving the *PTEN* locus on chromosome 10, making the patient haploinsufficient. CS and BRRS are sometimes referred to as the *PTEN* hamartoma tumor syndrome (PHTS).

JUVENILE POLYPOSIS SYNDROME

Juvenile polyposis syndrome is a disease in which 10 or more juvenile polyps are found in the gastrointestinal tract without evidence of the extraintestinal manifestations that categorize the patient in the other hamartomatous polyposis syndromes. Juvenile polyps are hamartomas, which are mature but disorganized tissues indigenous to the anatomical site of origin. The cystic, inflammatory, nonneoplastic histological appearance of juvenile polyps initially led most clinicians to feel there was no risk of malignant transformation, but the association between cancer and JPS is well described. Several cases describing the presence of atypical, hyperplastic, or adenomatous and adenocarcinomatous changes have been reported in the literature, representing a potential progression of the histology toward cancer. The dysplasia has been described as presenting in two forms: the coexistence of adenomatous changes in a juvenile polyp, and coexisting adenomas lacking features of juvenile polyps found in patients with JPS.

Patients with JPS are predisposed to gastrointestinal malignancies, with a 16% risk of developing colorectal carcinoma in young patients and a cumulative risk of 68% by 60 years of life. It is noteworthy that the mean age at presentation is 34 years (range 15–59 years) and that the clinical outcome is usually poor, with a high percentage of poorly differentiated or mucinous cancers. It is possible that the cancer risk in this group is even higher given the large number of colectomies performed to treat unmanageable symptoms. Also associated with JPS are pancreatic, gastric, and duodenal cancers.

The *PTEN* gene has been implicated in a minority of patient with JPS, whereas approximately half of the patients with JPS have germ-line mutations in the *SMAD4* gene located on chromosome 18q21.1. This gene encodes a key intracellular signal transducer and transcriptional regulator for the transforming growth factor-β superfamily of ligands and receptors. Another one-quarter to one-half of JPS patients have mutations in the bone morphogenetic protein receptor type 1A (BMPR1A), a receptor for the bone morphogenetic protein ligand, which is upstream in the SMAD4 signaling cascade.

Management of JPS involves treatment of secondary symptoms arising from the polyposis (bleeding, malabsorption). Surveillance for cancer formation is critical.

Haustra

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

taenia coli Three strips of longitudinal smooth muscle spaced equidistantly around the circumference of the colon.

Haustra appear as a prominent morphologic feature when the colon is viewed radiographically after instillation of barium contrast media in humans (Fig. 1). Haustra appear as sacculations that are separated from one another by constrictions of the colonic circular muscle coat; they are repeated more or less uniformly along the length of colon. The haustra are not permanently fixed structures, and sometimes appear to migrate along the length of the colon. At other times, they may be absent. In their absence (e.g., in certain disease states), the colonic wall appears on radiographs to have a smooth profile.

ANATOMY AND PHYSIOLOGY

The circular muscle coat of the ascending, transverse, and descending segments of the colon is overlaid on the surface with three thin strips of longitudinal muscle that are about 6 mm wide and spaced equidistantly around the circumference. These three strips of longitudinal muscle are the epiploic taenia, libera taenia, and mesocolic taenia; as a group, these strips are called the taenia coli. When the taenia coli reach the rectosigmoid region of the large intestine, they merge to envelop the entire circumference of the bowel. An

earlier interpretation assumed that the taenia coli are shorter than the length of the colon and that this produces circumferential wall distortion, giving the sacculated appearance of haustra. Later discoveries of the role of the enteric nervous system in the control of the colonic musculature caused this concept to become outmoded.

A segmental pattern of colonic motility programmed by the enteric nervous system now accounts for the ultraslow forward movement of feces in the colon. The motility pattern is called "haustration." Ringlike contractions of the circular muscle divide the colon into chambers, in which contraction of the autogenic smooth muscle is maintained in a state of inhibition by ongoing activity of inhibitory motor neurons. The ringlike constrictions reflect autogenic muscle contractions in segments in which the inhibitory motor innervation has been inactivated by integrative functions in the colon's enteric neural network.

The neurally programmed haustrations are dynamic in that they form and reform at different sites. The most common pattern in the fasting individual is for the contracting segment to propel the contents in both directions into relaxed receiving segments. This mixes and compresses the semiliquid feces in the haustral pockets and probably facilitates absorption of water with minimal forward propulsion. Net forward propulsion occurs when sequential migration of the haustra occurs along the length of bowel. The contents of one haustral pocket are propelled into the next region, where a second pocket is formed, and from there to the next segment, where the same events occur. This results in slow forward progression and is believed to be a mechanism for compacting the feces in storage.

HAUSTRA AS MARKERS OF DISEASE STATES

The radiographic appearance of abnormal haustrations has been reported for patients diagnosed with irritable bowel syndrome. Major hallmarks of irritable bowel syndrome are abdominal pain and disordered defecation that cannot be ascribed to an organic or nonneurogenic disorder. Modern investigative methods now implicate neuropathy in the brain–gut axis as a factor in the etiology of the syndrome. Neuropathic alterations, especially in the neural networks of the enteric nervous system, are expected to underlie a motility component of the "irritable colon."

Variabilities in the shape, size, and spacing of colonic haustrations are reported for some cases of irritable bowel syndrome. One of the striking variations is a complete absence of haustra coincident with exaggerated narrowing of the colonic lumen that produces an appearance of shortening. The appearance of shortening, narrowing, and lack of haustration may also be observed in patients with advanced ulcerative colitis.

Helicobacter pylori

ZHANNAT Z. NURGALIEVA*, KAREN J. GOODMAN†, AND DAVID Y. GRAHAM*,‡
*Baylor College of Medicine, †University of Texas, and ‡VA Medical Center, Houston

B-cell gastric lymphoma A monoclonal proliferation of cancerous B cells that have infiltrated the gastric glands.

CagA A protein produced by the cag pathogenicity island of *Helicobacter pylori* and encoded by cytotoxin-associated gene A. The protein induces the production of CagA antibodies and the $CagA^+$ strain of *H. pylori* is responsible for a more severe inflammatory response in the host than that produced by $CagA^-$ strains. $CagA^+$ strains are associated with a higher likelihood of peptic ulcer, atrophic changes in stomach, intestinal metaplasia, and gastric cancer.

***cag* pathogenicity island (*cag* PAI)** A group of approximately 40 genes present in the genomes of some *Helicobacter pylori* strains. Strains with the *cag* PAI cause more inflammation and the presence of this pathogenicity island is associated with an increased risk of developing gastric cancer or peptic ulcer disease.

gram-negative A characteristic that refers to bacteria that do not retain the violet stain used in Gram's method and therefore appear pink instead of blue after being stained.

gastritis Inflammation of the mucous membrane of the stomach.

outer inflammatory protein A An outer inflammatory protein of *Helicobacter pylori* that is involved in mucosal inflammation. The protein is considered a virulence factor of the bacterium and its presence is associated with increased mucosal inflammation.

salvage therapy Antimicrobial regimens designed to be used after failure of first-line therapies.

ulcer A break in the lining of the stomach, duodenum, or esophagus where hydrochloric acid and pepsin are present. Ulcers formed in the stomach are known as gastric or stomach ulcers and ulcers formed in the first part of the small intestine are known as duodenal ulcers.

urease An enzyme that breaks down urea to form ammonia and carbon dioxide.

***Helicobacter pylori* is a transmissible bacterial infection of the gastric mucosal surface. The infection results in progressive mucosal damage with eventual impairment of gastric function. *H. pylori* infection is now established as the most common cause of gastritis and is etiologically related to gastric ulcer disease, duodenal ulcer disease, primary gastric B-cell lymphoma, and gastric adenocarcinoma. This unique bacterium, which resides in the acidic environment of the human stomach, was identified in 1982. Since that time, extensive research by health scientists has resulted in considerable knowledge regarding its role in disease. There has also been success in developing simple methods to identify the infection and antibiotic regimens for its eradication. Nonetheless, there are still many avenues to explore with regard to the nature of the bacterium and its interactions with the host. Victory over *H. pylori* cannot be declared until it can be effectively prevented from causing human disease. Current gaps in knowledge regarding the natural history of the infection, its mode of transmission, pathogenic mechanisms, cofactors involved in disease pathways, and how to induce immunity present obstacles to prevention.**

MICROBIOLOGICAL PROPERTIES

Helicobacter pylori belongs to a family of gram-negative, spiral-shaped bacteria. It measures $0.6 \times 3.5\,\mu m$ in size. It is highly motile due to the presence of unipolar flagella that allow the organism to swim with a darting motion through the thick mucus lining the stomach cavity. The bacterium is microaerophilic and growth *in vitro* requires an enriched selective medium and an atmosphere with reduced oxygen and increased CO_2 concentrations. The optimum temperature for growth is 37°C. Growth on agar plates typically appears within 3 to 4 days as tiny, smooth, and translucent colonies of *H. pylori*. Initial growth may require a longer time and culture plates are typically kept for 2 weeks to improve the sensitivity of this method to diagnose infection.

BACTERIAL VIRULENCE FACTORS

Important characteristics of the bacterium that allow colonization of the gastric mucosa include motility, urease production, and the ability to adhere to the surface cells lining the stomach cavity. Motility allows the bacterium to escape the highly acidic surroundings in the stomach lumen and reach the more alkaline surface cells of the gastric mucosa. Urease produced by the bacterium hydrolyzes urea to liberate ammonia, which neutralizes gastric acid and provides a suitable microenvironment for *H. pylori* while protecting it from the acid in the stomach.

Colonization by the bacterium and production of toxins induce the production of pro-inflammatory

 Copyright 2004, Elsevier (USA). All rights reserved.

factors (cytokines) by the host. Evidence suggests that the severity of the host's inflammatory response is related to the presence of certain bacterial genetic factors including the presence of the *cag* pathogenicity island and the outer inflammatory protein, OipA. In Asia, more than 90% of *H. pylori* strains possess the *cag* pathogenicity island. In developed Western countries, the proportion is somewhat lower but is generally 60% or more. The presence of this pathogenicity island is associated with more aggressive clinical outcomes of *H. pylori* infection, including duodenal ulcer and gastric cancer. However, *H. pylori* strains lacking both the *cag* pathogenicity island and OipA have been found in patients with peptic ulcer and with gastric cancer, and therefore, there is no currently identifiable "safe" *H. pylori* infection.

NATURAL HISTORY

Acute *H. pylori* infection has been observed in a few cases of experimental and accidental inoculation as well as in prospective studies, especially in Japan. In these cases, *H. pylori* colonization led to inflammation of the gastric mucosa and transient reduction in the ability of the stomach to make acid (hypochlorhydria) accompanied by a broad spectrum of symptoms. Two voluntary inoculations produced distinct outcomes. The first resulted in gastritis accompanied by acute dyspeptic symptoms and detectable *H. pylori* on histologic examination of biopsies; the infection appeared to be eliminated spontaneously by 14 days. A 1-week course of tinidazole was also taken. No antibody response was detected. The second experimental inoculation resulted in a persistent infection, which resisted a series of trials using single antibiotics. In this case, anti-*H. pylori* immunoglobulin M (IgM) levels rose and fell within weeks following acute infection; IgG became detectable when IgM levels fell. Acute infection is recognized by the presence of new-onset upper gastrointestinal symptoms and either the characteristic histologic features or the presence of positive histology or urea breath test (see below) and negative serum IgG antibody levels. Several studies have followed IgG levels after *H. pylori* colonization is eliminated; titers generally decline following elimination, often reaching seronegative levels within 1 or 2 years. The immune response to *H. pylori* does not appear to confer immunity, given that previously infected individuals are susceptible to re-infection. Furthermore, co-infection with multiple strains, though uncommon, has been reported. Because spontaneous elimination is rarely observed when adults with preexisting *H. pylori* infection are followed over time, it has been assumed that infection generally persists once acquired. However, this assumption overlooks observations that suggest that exposure to *H. pylori* may sometimes result in brief, self-limiting infection, particularly in young children. Given that infection is not generally detected at onset, the proportion of acute infections that persist is not known. Furthermore, cases of infection detected in epidemiologic studies will tend to be persistent, particularly when measurement of antibodies is used for detection. Therefore, most of what is known about the epidemiology of *H. pylori* infection relates to persistent infection; little is known about the epidemiology of acute *H. pylori* infection.

EPIDEMIOLOGY

Acquisition of *H. pylori* infection typically occurs in childhood and in Western countries it is likely to result commonly from intrafamilial spread. Age, socioeconomic conditions (in particular, the stage of economic development of the geographic region, residential crowding, education level, and belonging to a socially marginalized group), and migration from a high-prevalence region are major determinants of the prevalence of the infection. Children from higher social strata in developed nations typically acquire the infection at a rate of less than 1% per year, except perhaps during early childhood, whereas in developing countries, the rate of acquisition among young children may exceed 10% per year. The prevalence of *H. pylori* infection in adults is believed to reflect the rate of acquisition when they were children and thus the social and economic conditions of their families during that time period. In developing countries, widespread acquisition of the infection occurs early in life, such that by adolescence or earlier, the prevalence is often in the range of 80–90% and remains constant across adult birth cohorts. In developed countries, the average rate of acquisition appears to have fallen as standards of living have improved. This change manifests in an increase in prevalence with age, which is believed to represent a progressive fall in acquisition in successive birth cohorts, rather than continued acquisition of infection during adulthood. Longitudinal studies in developed countries have shown that the prevalence of infection is declining in all age groups. It has been suggested that this apparent change in the epidemiology of *H. pylori* infection is possibly related to the widespread use of antibiotics for other infections.

TRANSMISSION

Because *H. pylori* is not easily isolated from extragastric secretions, the usual portals of entry and exit to and

from the human host are not known with certainty. Perinatal transmission from mother to infant does not appear to occur readily and blood-borne transmission is implausible. Iatrogenic transmission by gastroenterological procedures has been documented, but other specific modes of transmission have been neither confirmed definitively nor ruled out.

Given that residential crowding is a major risk factor for infection and that the infection clusters within families, person-to-person transmission is likely, although the relative importance of fecal–oral, oral–oral, and gastric–oral (for example, through vomitus) pathways is not clear. Studies from a number of areas, especially Andean Latin America and Kazakhstan, have suggested a role for waterborne transmission. Contradictory findings have been reported from other parts of the world, although investigators from various regions have reported the detection of *H. pylori* in water using molecular techniques such as polymerase chain reaction. The major route of transmission may well vary among populations, with the organism being opportunistic in the sense that any route that allows access to the stomach may lead to infection. Evidence consistent with each of these routes has been reported.

Studies in rural Andean children under 10 years of age suggest that *H. pylori* infection is most readily transmitted among siblings who are close in age, whereas researchers in Germany, where the average family size is smaller, believe that parent-to-child transmission may be more important. Studies of the *H. pylori* strains recovered from family members have generally shown them to be similar or identical to the strain from one of the parents, often the mother. Recently, *H. pylori* has been isolated from vomitus as well as from natural and cathartic stools, suggesting that transmission may be enhanced during episodes of acute gastroenteritis.

Studies investigating the possibility of zoonotic transmission have also had conflicting findings and recent data suggest that it is more likely that animals in close contact with humans may acquire human *H. pylori* strains rather than animals being a reservoir for human infection.

EFFECTS ON THE STOMACH

The stomach serves as a chamber for milling, disinfecting, and delivering components of ingested substances to the small intestine for absorption. Acid and pepsin secreted in the stomach help to denature proteins and prevent potential pathogens from colonizing the mucosa. The stomach can be divided into three major areas: one area, the body or corpus, where cells secrete acid, and two areas, the cardia and the antrum, the most proximal and distal parts of the stomach, respectively, which do not make acid. The corpus, the largest area of the stomach, contains glands that make acid and pepsin. The antrum contains endocrine cells that produce gastrin (G cells) and somatostatin (D cells), which help to control acid secretion in the corpus.

H. pylori-induced inflammation in the antrum can produce an imbalance between gastrin and somatostatin secretion, leading to a dysregulation of acid secretion, which tends to produce more acid for longer time periods. In contrast, inflammation in the corpus can inhibit acid-secreting cells. Therefore, the physiologic response to *H. pylori* infection depends on the site and severity of the inflammation. When the infection is primarily in the antrum (antral predominant gastritis), the individual tends to make excessive amounts of acid and is at increased risk of duodenal ulcer disease. Severe corpus gastritis is associated with low-level acid secretion and degeneration of the normal glandular architecture of the stomach, leading to gastric atrophy. Patients with severe corpus gastritis are at increased risk of gastric ulcer and gastric cancer.

H. PYLORI-ASSOCIATED DISEASES

Gastritis

Almost all *H. pylori*-infected individuals develop inflammation of the lining of the stomach (gastritis) (Fig. 1). Typically, this inflammation does not cause symptoms; thus, the infection has a long latent period. Acute infection may be accompanied by nonspecific transient abdominal pain, nausea, and vomiting. Chronic infection is characterized by infiltration of inflammatory cells within the gastric mucosa. Eradication of *H. pylori* generally results in healing of the gastric mucosa with reduction or disappearance of the inflammation followed by a normalization of gastric secretion. In some individuals, persistent *H. pylori* gastritis leads to a loss of the glandular components of the gastric mucosa, a process known as atrophy. In such cases, *H. pylori*-induced gastritis damages gastric structure and function, leading to reduced acid secretion (hypochlorhydria or achlorhydria), with consequences such as increased enteric infection or reduced absorption of iron and vitamin B12.

Peptic Ulcer Disease

The lifetime risk of developing peptic ulcer among *H. pylori*-infected individuals is approximately 1 in 6. Peptic ulcer disease is a chronic disease that can spontaneously heal and recur. The cure of *H. pylori* infection leads to healing of active ulcers and prevention of ulcer recurrence. Thus, discovery of effective

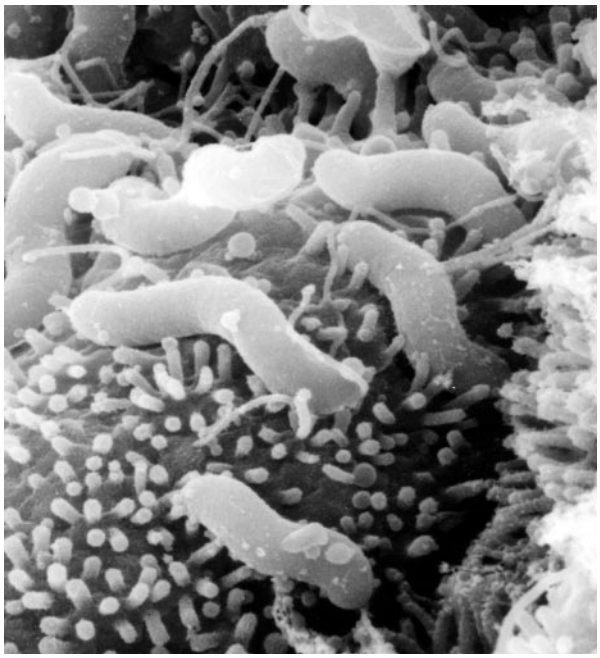

FIGURE 1 Scanning electron microscopic photograph of *Helicobacter pylori* attached to the lining of the human stomach. Courtesy of Professor Tatsuo Yamamoto, Niigata, Japan.

methods to treat *H. pylori* infection resulted in changing a major chronic disease into a curable condition.

Gastric Cancer

The World Health Organization's International Agency for Research on Cancer classified *H. pylori* as a definite carcinogen in 1994. Gastric cancer was known to be associated with atrophic gastritis before the discovery of its association with *H. pylori*. The idea that chronic *H. pylori*-induced gastritis could lead to cancer fit coherently into previous theories regarding the role of chronic inflammation in gastric carcinogenesis. The lifetime risk of gastric adenocarcinoma varies greatly across populations (e.g., 1−3% in the United States and 11−12% in Japan). However, not all populations with a high prevalence of *H. pylori* infection have a high rate of gastric cancer; the type of associated gastritis is the best predictor of the outcome. In the United States, where gastric cancer rates are lower, antral predominant gastritis and superficial gastritis without atrophy are the most common types. In contrast, in Japan, where gastric cancer rates are higher, *H. pylori*-associated gastritis is typically atrophic. The different cancer risks associated with *H. pylori* infection across populations most likely reflect differences in the distributions of cofactors, such as dietary patterns involved in carcinogenesis, as well as differences in the virulence of the dominant *H. pylori* strains. Current knowledge suggests that widespread prevention of *H. pylori* infection will yield dramatic declines in gastric cancer rates.

B-Cell Gastric Lymphoma

Continuous lymphoid infiltration of gastric mucosa can lead to the development of tumors, called mucosa-associated-lymphoid tissue lymphomas (MALT lymphomas), that arise in the lymphoid tissues of the stomach. MALT lymphomas associated with *H. pylori* infection are monoclonal proliferations of cancerous B cells that have infiltrated the gastric glands. The malignancy is typically low-grade. Eradication of *H. pylori* infection, if instituted early, leads to the remission of MALT lymphomas in most cases.

DIAGNOSIS

Patients with a potentially curable clinical manifestation of *H. pylori* should be tested. This group includes those patients with known peptic ulcer disease or low-grade gastric MALT lymphoma. Most clinicians agree that testing patients with dyspepsia is worthwhile because that population includes many patients with peptic ulcer disease. The controversy concerns how to target patients with latent *H. pylori* infection in order to prevent a clinical manifestation. Current recommendations by the Maastrich consensus conference also target those with a known increased risk of a clinical manifestation and include those with a family history of gastric cancer or peptic ulcer. Long-term use of drugs that suppress gastric acid secretion is now thought to promote the progression of *H. pylori* gastritis. Thus, many experts recommend testing patients for whom long-term antisecretory therapy is planned (e.g., those with gastroesophageal reflux disease). Cost-effectiveness research in the United States has shown that a population-based test and treat approach may be a worthwhile disease prevention effort, but the potential adverse effects associated with such an approach have not yet been adequately evaluated.

Active or current *H. pylori* infection can be diagnosed noninvasively using a urea breath test or a stool antigen test. If endoscopy is needed, it is possible to identify the infection in biopsies of the gastric mucosa by histology, rapid urease test, or culture. Current infection or past exposure to *H. pylori* can be diagnosed by detecting antibodies in blood or urine.

Testing for Active *H. pylori* Infection

Urea Breath Testing

The urea breath test is a noninvasive method that detects *H. pylori* urease activity. The organism produces

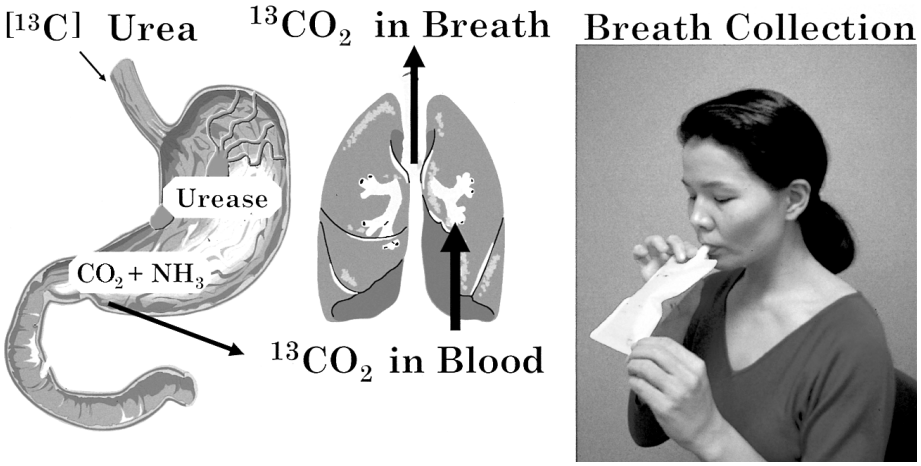

FIGURE 2 Urea breath test. This test is based on the measurement of labeled carbon dioxide produced by the enzyme urease. The steps include ingestion of labeled urea, hydrolysis of the urea into labeled CO_2, collection of a breath sample, and measurement of enrichment of the level of labeled CO_2.

the enzyme urease, which splits urea into carbon dioxide and ammonia. If one administers urea labeled with the nonradioactive carbon isotope, ^{13}C, or the radioactive isotope, ^{14}C, one can take breath samples before and after administering the labeled urea and determine whether urease is present in the stomach (Fig. 2) by measuring the excess labeled carbon in the expired breath using isotope-ratio spectrometry. Urea breath testing is considered the most accurate of the noninvasive methods for detecting active *H. pylori* infection. The use of drugs that temporarily reduce the number of *H. pylori* in the stomach can cause false-negative results. Thus, it is important to withhold proton pump inhibitors, antibiotics, and bismuth for at least 1 week prior to testing.

Stool Antigen Testing

The stool antigen test is based on the detection of *H. pylori* antigens in the stool. These antigens are detected using an enzyme immunoassay. Stool antigen testing is subject to the same limitations as the urea breath test, with the added need to refrigerate or freeze stool specimens that cannot be tested immediately. For initial diagnosis, it is comparable in accuracy to the urea breath test. It is less accurate when used to confirm successful eradication. Reliability is increased if testing is delayed until 6 to 8 weeks after treatment.

Histology

Biopsy of the gastric mucosa is easily and safely performed during examination of the stomach by endoscopy. Examination of the stained tissue under the microscope reveals both infiltration of the mucosa with inflammatory cells and the presence of the bacterium (Fig. 3). The accuracy is improved if special stains that target the bacteria are used. Biopsy-based methods (histology, culture, and rapid urease test) share the limitation that biopsy sampling may miss colonized areas of the stomach because the colonization may be patchy.

Culture

H. pylori can be cultured from gastric mucosal biopsies. Culture is not routinely available, but is particularly valuable for patients with treatment-resistant infections as one can test the recovered organism for susceptibility to different antibiotics and thus choose a therapy with an increased likelihood of success.

Rapid Urease Tests

The urea breath test detects one of the split products of ingested urea (labeled CO_2) and the rapid urease test detects the other product (ammonia). A biopsy of gastric tissue is placed into a medium containing urea and a pH indicator. When the bacterial urease splits the urea, the liberated ammonia will increase the pH; this is recognized by a color change in the test indicator. Rapid urease tests are fast, inexpensive, and easy to perform. A limitation is that this method requires a high density of bacteria in the specimen. Negative results could mean that the level of bacteria in the specimen obtained is low.

Testing for Current *H. pylori* or Past Exposure to the Infection

Antibody Testing

Detection of antibodies against *H. pylori* is widely used to check the infection status. A variety of serum,

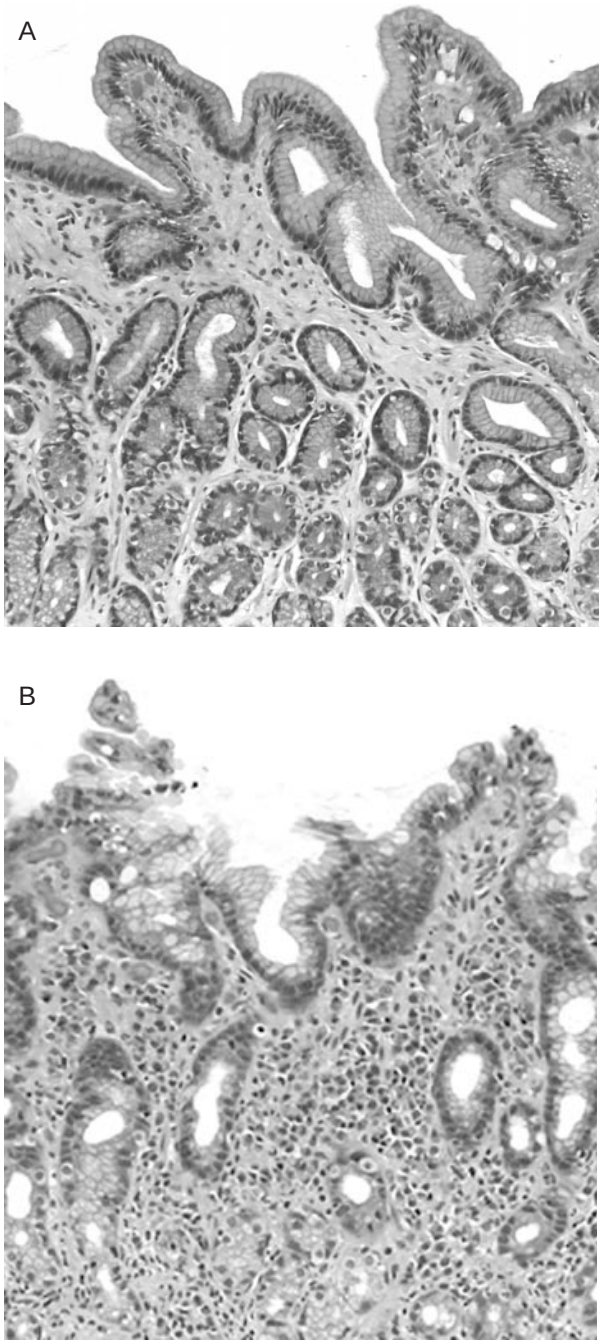

FIGURE 3 Photomicrographs of infected and normal stomachs. (A) A normal gastric mucosa essentially devoid of inflammatory cells. (B) Gastric mucosa with an inflammatory infiltrate made up of acute and chronic inflammatory cells.

whole-blood, and urine tests are available for use in the laboratory and in the office. The primary limitation is that antibody tests cannot distinguish a past history of the infection from an active infection. Antibody testing is useful for screening of patients with a high pretest probability of an active *H. pylori* infection, such as a patient with a peptic ulcer. The antibody level falls slowly after eradication of the infection and thus cannot be used to confirm successful therapy.

TREATMENT

The stomach is actually a very hostile place for antibiotics to work, as the contents are acidic and vary in volume. Nonetheless, successful combination therapies have been discovered. In general, therapy consists of a drug to inhibit acid secretion and two or more drugs to kill the bacterium. Two or more antibiotics are needed to prevent the development of antibiotic resistance. The antibiotics most widely used for anti-*H. pylori* therapy include clarithromycin, amoxicillin, metronidazole, tetracycline, and furazolidone. Clarithromycin is a member of the macrolide group of antibiotics that bind specifically to bacterial ribosomes and lead to bacterial death by disrupting protein synthesis. This drug is resistant to the acidic environment of the stomach, but is much more effective when acid secretion is suppressed. Amoxicillin is an acid-stable semisynthetic penicillin that is also a mainstay of *H. pylori* therapy and also requires suppression of acid secretion. Metronidazole is a pro-drug from the nitroimidazole group, which does not require inhibition of acid secretion. Tetracycline hydrochloride and oxytetracycline are both effective and neither requires inhibition of acid secretion. Bismuth salts including the bismuth subsalicylate and the colloid suspension of bismuth citrate are also commonly used. These drugs are thought to act topically in the stomach; they have the advantage of not requiring drugs to reduce acid secretion and not generating bacterial resistance.

Treatment Regimens

The most effective therapies are triple or quadruple therapies (based on the number of drugs used). Triple therapies typically consist of a combination of clarithromycin, amoxicillin, or metronidazole given twice a day along with a drug to reduce acid secretion. A commonly used triple or quadruple therapy consists of a bismuth salt, metronidazole, and either tetracycline or amoxicillin, with the optional addition of an antisecretory drug. The antisecretory drugs used are either histamine-2 receptor antagonists or proton pump inhibitors, with the latter being more effective for pH control (Table I). Rescue or salvage therapy is the name given to regimens designed to be used after failure of first-line therapies; such failures reflect the possibility of bacterial resistance to one or more of the drugs included in the

TABLE I Recommended Antibiotic Treatment Regimens for *Helicobacter pylori* Infection

Triple therapy
Proton pump inhibitor two times daily
Clarithromycin 500 mg two times daily
and
Amoxicillin 1000 mg two times daily
or
Metronidazole 500 mg two times daily
Quadruple therapy
Proton pump inhibitor two times daily
Bismuth four times daily
Tetracycline 500 mg four times daily
Metronidazole 500 mg three times daily

regimen. The growing problem of antibiotic resistance requires modification of the treatment approach in such cases. Culture of the organism and testing for antibiotic resistance are recommended so that a more effective new therapy can be selected.

Good compliance with the treatment regimen is considered critical for success. In general, therapies of longer duration (10 or 14 days) are more effective than those of shorter duration (7 days). Other predictors of treatment success include the prevalence of *H. pylori* strains in the local population that are resistant to antibiotics used in the treatment regimen and also the prevalence of *H. pylori* infection in children in the local population, which is an indicator of current levels of transmission. Currently, there is a need for more effective therapies in populations where antibiotic resistance and transmission levels are high.

Confirmation of Successful Therapy

Because overall current therapy for *H. pylori* is effective in only approximately 70% of cases, it is important to test for the presence of *H. pylori* posttherapy and confirm that the infection was cured. The availability of noninvasive diagnostic methods such as the urea breath test or stool antigen test enhances the feasibility of posttherapy testing and eliminates the need for posttherapy endoscopy to confirm cure of the infection. Avoiding endoscopy to verify elimination of *H. pylori* is particularly important in settings where the invasive procedure may serve as a source of re-infection. Testing should be withheld until after approximately 4 weeks of therapy cessation. With the stool antigen test, the waiting period should be longer, 6–8 weeks. The proton pump inhibitors should be stopped at least 1 week prior to testing.

PROSPECTS FOR PREVENTION

Prevention of *H. pylori* infection will require identification of the weak links in the chain of transmission that are amenable to modifications in behavior or in household sanitation. The prevalence of *H. pylori* infection "naturally" falls in association with improved standards of living, sanitation, and household hygiene. Thus, *H. pylori* infection is one of a whole host of infectious diseases that will decline and disappear as standards of living improve. For the short term, there is considerable interest in development of a vaccine to prevent infection. Work in experimental animals has provided proof of principle, but early human trials have been disappointing. As humans are the major reservoir of infection, cure of *H. pylori* infection reduces the pool of potential "transmitters." Studies are under way in developing countries to observe whether elimination of the infection in a village will lead to long-term eradication of the infection and whether it is necessary to treat the entire family of infected children to prevent re-infection. Clearly, there is still much work to be done.

parasitic nematodes make up a relatively small proportion of the total, various species have evolved to exploit almost all plants and animals (vertebrate and invertebrate). Dozens of nematode species parasitize humans and many rank among the most common infections known. In addition, parasitized persons frequently harbor more than one species simultaneously. Many species of parasitic nematodes inhabit the human gastrointestinal tract and others reside in tissues (the latter are collectively known as filarial nematodes). The major species of nematodes infecting humans are listed in Table I.

Parasitic nematodes are nonsegmented roundworms of the phylum Nematoda. They possess an outer covering, or cuticle, that is chemically complex in structure and serves to protect the worm from attack (e.g., by host antibodies or digestive enzymes). The cuticle is shed each time the nematode molts during development. A muscle layer under the cuticle allows for active movement of larval and adult forms. Nematodes have a complete digestive system, with a mouth (also known as a buccal cavity), muscular esophagus, intestine, and anus. The buccal cavity of hookworms contains teeth (*Ancylostoma* species) or cutting plates (*Necator americanus*) that the worms use to attach to and lacerate intestinal mucosal tissue. Following copulation with the male, females of most intestinal nematode species produce eggs that are voided from the host in the feces. Nematode eggs hatch to release larvae following their release into the external environment (hookworms) or on ingestion by the host (pinworms, whipworms, *Ascaris lumbricoides*). An exception is *Strongyloides stercoralis*, whose eggs hatch in the host intestine immediately after being released from the female. Females of other nematode species (e.g., *Trichinella spiralis*, the tissue-dwelling filariae) are viviparous, giving birth directly to larvae. All nematode larvae undergo four molts as they develop to adults. Nematode larvae that are infectious to humans have generally undergone their first two molts in the soil (e.g., hookworms) or in an insect vector (filaria). *S. stercoralis* is unique among parasitic nematodes in that it may undergo all four molts outside the host and exist as a free-living and sexually reproducing adult. Adult parasitic nematodes vary considerably in size, from 1 cm or smaller in length (e.g., pinworms, hookworms, *S. stercoralis*) to over 1 m (*Dracunculus medinensis*). Intermediate between these extremes is the giant roundworm *A. lumbricoides*, whose size (10–30 cm) and general appearance are quite similar to those of an earthworm. Male nematodes are generally smaller than females of the same species.

Nematode infections are generally acquired through three routes: by ingestion, by skin penetration, or through the bite of an insect vector (see Table I). Several intestinal nematode species infect through the oral route, by direct ingestion of eggs (pinworms, whipworms, *A. lumbricoides*), larvae (*Ancylostoma* species hookworms), or raw/undercooked meats contaminated with larvae (*Tr. spiralis*). Intestinal nematodes (all hookworm species, *S. stercoralis*) may also infect via penetration of host skin by third-stage larvae (percutaneous infection). By contrast, the tissue-dwelling filarial nematodes are typically spread by insect vectors such as mosquitoes (lymphatic filariae) or biting flies (*Onchocerca volvulus*, *Loa loa*). A notable exception is the tissue-dwelling guinea worm (*D. medinensis*), which is spread by drinking water contaminated with the intermediate host (a copepod, or "water flea"), which may harbor infectious larvae.

The degree of pathology caused by nematodes is dependent on many variables, such as the particular species present, parasite burden, and various host factors such as immune status. Light infections with intestinal nematodes generally cause little pathology and the host is typically unaware of their presence. At higher burdens, intestinal nematodes may cause clinical disease through various mechanisms, such as irritation (pinworms, whipworms, *S. stercoralis*, and *Tr. spiralis*), physical obstruction and/or perforation of the gastrointestinal tract (*A. lumbricoides*), or laceration of the intestinal mucosa with subsequent blood-feeding (hookworms). Intestinal nematode infections may lead to nutritional deficiencies that are especially harmful to children; heavily parasitized children may suffer serious, often irreversible physical and cognitive developmental delay. The larval stages of certain intestinal nematodes (hookworms, *S. stercoralis*, and *A. lumbricoides*) may also cause pathology as they migrate through the skin and/or pulmonary system prior to taking up residence in the gastrointestinal tract. Adult filarial worms often cause pathology in the tissues they inhabit, which include the skin (*L. loa*, *O. volvulus*), the lymphatics (*Brugia malayi*, *Wuchereria bancrofti*), the eye (*L. loa*, *O. volvulus*), or subcutaneous tissues (*D. medinensis*).

TREMATODES

Trematodes, also known as flukes, are parasitic nonsegmented flatworms belonging to the class Trematoda in the phylum Platyhelminthes. The major species infecting humans are listed in Table I. There are no free-living trematodes and all species parasitic to humans require at least one intermediate host, typically a snail, to complete their life cycle. Some species also require a second intermediate host, such as a fish (*Clonorchis sinensis*) or crab (*Paragonimus westermani*). Trematodes

TABLE I Major Helminth Species Infecting Humans

Species	Intermediate host or vector	Infectious stage; Mode of infection	Major target organ(s)	Major clinical features[a]
Nematodes				
Ascaris lumbricoides (giant roundworm)	None	Egg; ingestion	Small intestine	Diarrhea, malnutrition, intestinal obstruction
			Hepatobiliary system	Biliary obstruction
Dracunculus medinensis (guinea worm)	Copepod	Larva; ingestion of infected copepod in drinking water	Subcutaneous tissues of lower extremities	Cutaneous ulcers, secondary bacterial infections
Enterobius vermicularis (pinworm)	None	Egg; ingestion/inhalation	Colon, rectum, anus	Anal itching, behavioral disturbances, appendicitis
Hookworms[b]				
Ancylostoma duodenale	None	Larva; percutaneous or oral	Small intestine	Anemia, malnutrition, growth delay of children
Ancylostoma ceylanicum	None	Larva; percutaneous or oral	Small intestine	Anemia, malnutrition, growth delay of children
Necator americanus	None	Larva; percutaneous	Small intestine	Anemia, malnutrition, growth delay of children
Loa loa	Mango fly	Larva; bite of fly	Subcutaneous tissues	Angioedema (Calabar swelling), adults in the eye
Lymphatic Filariae				
Brugia malayi	Mosquito	Larva; bite of mosquito	Lymphatic vessels	Lymphadenitis, lymphedema (elephantiasis)
Wuchereria bancrofti	Mosquito	Larva; bite of mosquito	Lymphatic vessels	Lymphadenitis, lymphedema (elephantiasis)
Onchocerca volvulus ("river blindness")	Blackfly	Larva; bite of fly	Subcutaneous tissues	Adults: subcutaneous nodules Microfilarial larvae: dermatitis, ocular lesions
Strongyloides stercoralis (threadworm)	None	Larva; percutaneous	Small intestine	Diarrhea, malnutrition, growth delay of children
Trichinella spiralis	Pigs, cattle, etc.	Larva; ingestion of raw or undercooked meat	Small intestine	Adults in intestine, diarrhea, abdominal pain
			Muscle, brain	Larvae: cysts cause damage to tissues and organs
Trichuris trichiura (whipworm)	None	Egg; ingestion	Colon, rectum	Dysentery, prolapsed rectum
Trematodes				
Clonorchis sinensis (Chinese liver fluke)	1st: snail[c]; 2nd: fish	Metacercaria; ingestion of contaminated raw fish	Liver (bile ducts)	Liver enlargement, cholangitis (bile duct inflammation), gallstones, pancreatitis
Fasciola hepatica (sheep liver fluke)	Snail	Metacercaria; ingestion of contaminated plants	Liver	Liver damage and enlargement, bile obstruction, secondary bacterial infection

continues

TABLE I Major Helminth Species Infecting Humans (*continued*)

Species	Intermediate host or vector	Infectious stage; Mode of infection	Major target organ(s)	Major clinical features[a]
Fasciolopsis buski (giant intestinal fluke)	Snail	Metacercaria; ingestion of contaminated plants	Small intestine	Ulceration, diarrhea, malnutrition, intestinal obstruction
Paragonimus westermani (lung fluke)	1st: snail[c]; 2nd: crab	Metacercaria; ingestion of contaminated raw crabs	Lung	Cough, shortness of breath, bloody sputum, lung abscesses
			Central nervous system	Seizures, visual disturbances, headache, weakness
Schistosomes (blood flukes)				
Schistosoma mansoni	Snail	Cercaria; percutaneous	Liver	Egg-induced fibrosis leads to hepatosplenomegaly
Schistosoma japonicum	Snail	Cercaria; percutaneous	Liver	Egg-induced fibrosis leads to hepatosplenomegaly
Schistosoma haematobium	Snail	Cercaria; percutaneous	Bladder	Egg-induced fibrosis leads to hematuria, dysuria
Cestodes				
Diphyllobothrium latum (broad fish tapeworm)	1st: copepod; 2nd/3rd: fish	Plerocercoid larva; ingestion of contaminated raw fish	Small intestine	Abdominal pain, diarrhea vitamin B12 deficiency leading to anemia
Echinococcus granulosus (hydatid tapeworm)	Dog[d]; sheep	Egg (from dog feces); ingestion	Liver, lungs, brain, bone marrow	Organ damage by hydatid cysts, potentially fatal anaphylaxis following rupture of cyst
Hymenolepis nana (dwarf tapeworm)	None	Egg; ingestion	Small intestine	Nausea, vomiting, diarrhea
	Flea	Cysticercoid; ingestion of flea		
Taenia saginata (beef tapeworm)	Cow	Cysticercus; ingestion of raw or undercooked beef	Small intestine	Abdominal pain, nausea, vomiting, diarrhea
Taenia solium (pork tapeworm)	Pig	Cysticercus; ingestion of raw or undercooked pork	Small intestine	Adult: abdominal pain, nausea, vomiting, diarrhea
	None	Egg (from human feces); ingestion	Brain, eye, muscle	"Cysticercosis": cysterci cause organ damage leading to seizures, hydrocephalus, visual disturbances

[a] Caused by adult worms, unless otherwise noted.

[b] The dog and cat hookworms *A. caninum, A. braziliense*, and *Uncinaria stenocephala* cannot complete their life cycles in humans but larvae may cause cutaneous larval migrans (creeping eruption of the skin). Juvenile *A. caninum* may also cause eosinophilic enteritis.

[c] The snail is a source of cercariae, which encyst in the second intermediate host.

[d] The dog is the definitive host and is infected by consuming infected sheep.

possess a cellular epithelial covering, or tegument, that protects the parasite from host immune factors and serves as an absorptive surface for the acquisition of nutrients. A muscle layer under the tegument allows for movement within the host. Trematodes have oral and ventral suckers, which they employ for attachment and migration. The digestive system originates at the oral sucker and contains a pharynx, an esophagus, and a bifurcated intestine. There is no anus; thus, waste products must be regurgitated following digestion. Aside from the schistosome species, which have separate sexes, trematodes are hermaphroditic (having both male and female reproductive organs). Reproduction of the hermaphroditic trematodes may occur through self-fertilization (*C. sinensis*, *Fasciola hepatica*, *Fasciolopsis buski*) or cross-fertilization between two worms (*P. westermani*). The largest of the major hermaphroditic trematode species is *Fasciola hepatica* (approximately 35 mm by 15 mm) and the smallest is *P. westermani* (10 mm by 5 mm). Adult schistosomes have a somewhat greater length to width ratio, with males measuring approximately 10 mm by 1 mm and females 15 mm by 0.2 mm. Schistosomes also exhibit marked sexual dimorphism. Males have a prominent longitudinal groove, or gynecophoral canal, that cradles the female as they copulate.

The hermaphroditic trematode infections are acquired orally through ingestion of the infectious metacercarial stage. The metacercariae are found encysted on water plants (*Fasciola hepatica*, *Fasciolopsis buski*), in fish (*C. sinensis*), or in crabs (*P. westermani*). Following ingestion, the metacercaria hatches in the small intestine to release a larva. The schistosome infectious stage is the cercaria, which is released from the intermediate snail host in great numbers on exposure to sunlight. Schistosome cercariae have a forked tail and are highly motile; unlike hermaphroditic metacercariae, they actively seek out the host and penetrate intact skin. Trematode eggs are typically voided from the host in the feces; they may also be passed in the urine (*Schistosoma haematobium*) or in the sputum (*P. westermani*). After exiting the host, eggs produced by trematodes hatch on contact with fresh water, releasing a ciliated free-swimming form known as a miracidium. The miracidium seeks out and penetrates the intermediate snail host, where it develops into a structure called a sporocyst that undergoes asexual reproduction, eventually giving rise to thousands of cercariae. As discussed above, schistosome cercariae are directly infectious to humans, whereas those of the hermaphroditic trematodes encyst on plants, fish, or crustaceans to become metacercariae, which are then consumed by the host.

As is the case for nematodes, trematode-induced pathology in humans is dependent on many variables, such as the infecting species, parasite burden, and host factors. The major clinical features of trematode infections are summarized in Table I. Schistosomes are unique among parasitic helminths in that their eggs are the primary cause of clinical disease, whereas adults residing in the veins cause little, if any, pathology. Many (perhaps half) of the eggs produced by *Schistosoma mansoni* and *Schistosoma japonicum* fail to penetrate the intestinal wall to be excreted and are instead carried via the portal circulation into the liver. Once lodged in hepatic tissues, the eggs induce a hypersensitive immune reaction that in chronic cases leads to fibrosis (scarring) around the portal triads of the liver (also known as "pipe stem" fibrosis). In contrast to the schistosomes, pathology associated with the hermaphroditic trematodes is primarily caused by the adult flukes at the site of infection. For example, *Fasciola hepatica* causes trauma to the liver as it burrows through tissue while migrating to the bile ducts, where in heavy infections the parasites may cause bile obstruction. Bile duct pathology may also be caused by *C. sinensis*. Other organs affected by trematodes include the small intestine (*Fasciolopsis buski*) and the lung (*P. westermani*). Furthermore, *Paragonimus* flukes may aberrantly migrate to the central nervous system, causing seizures and other serious neurological symptoms.

CESTODES

Cestodes, also known as tapeworms, are parasitic segmented flatworms belonging to the class Cestoidea in the phylum Platyhelminthes. The major species infecting humans are listed in Table I. All cestode species parasitic to humans (excepting the dwarf tapeworm, *Hymenolepis nana*) require at least one intermediate host to complete their life cycles. Like trematodes, cestodes possess a protective tegument. As cestodes do not have a gut, all nutrient acquisition occurs through the tegument using specialized submicroscopic structures known as microtriches (similar to microvilli). The basic structure of an adult tapeworm consists of a scolex (head), a neck, and the strobila, which is a chain of segments individually known as proglottids. The scolex serves to attach the tapeworm to the host intestinal tissue; in most species, it is outfitted with four suckers, and spines may also be present. The proglottids grow from the neck of the tapeworm; there may be as few as 3 (*Echinococcus granulosus*, a diminutive 5 mm in length) or as many as 4000 (*Diphyllobothrium latum*, which may reach an astounding 15 m). As the proglottids mature, they develop male and female sex organs,

with cross-fertilization generally occurring between adjacent segments. After mating, the proglottids become gravid with hundreds to thousands of eggs and detach from the tapeworm, passing out of the host in the feces. In *Taenia* species tapeworms, the eggs may then be consumed by an intermediate host (e.g., a pig or cow), where they hatch, releasing a structure called the oncosphere, which penetrates the tissues and develops into a cysticercus. Consumption of cysticerci-contaminated meat (in raw or undercooked form) by the definitive human host allows the larval tapeworm to be released in the intestine, where it develops into the adult parasite, measuring up to 10 m in length. *D. latum* are acquired by humans through the ingestion of an infected fish, which in many cases is the *third* intermediate host (the first being a copepod, which is ingested by a minnow, which in turn is ingested by a larger fish). *H. nana* tapeworms are unique in that adult infections may result from the ingestion of the intermediate host (in this case, a flea or beetle) or more commonly through direct consumption of eggs derived from human feces. Eggs of *E. granulosus* and *Taenia solium* may also be infectious to humans, leading to severe pathology (see below).

The vast majority of adult tapeworm infections cause little, if any, clinical disease, although passage of proglottids (which are often capable of caterpillar-like movement outside the host) may be quite distressing. Much more serious disease is associated with ingestion of the eggs of *E. granulosus* or *T. solium*, in effect making the human an "accidental" intermediate host for disseminated larval cysts. In the case of *E. granulosus*, ingestion of eggs shed in the feces of dogs (the definitive host) leads to large fluid-filled "hydatid" cysts in the liver, lungs, brain, and bone marrow. *T. solium* eggs are acquired from the feces of humans infected with adult tapeworms. The cysticerci (cysts) associated with *T. solium* are somewhat smaller than those of *Echinococcus* but are more likely to localize to the brain; neurocysticercosis may cause various neurological symptoms such as seizures, hydrocephalus, and visual disturbances. *T. solium* cysticerci may also cause damage to the eye and skeletal muscle.

Hemobilia

SUMITA VERMA AND MICHEL MENDLER
University of Southern California, Los Angeles

endoscopic retrograde cholangiopancreaticography A procedure in which a fiber-optic endoscope is inserted into the duodenum and dye is injected via the ampulla of Vater to visualize the biliary and pancreatic ducts.

hemobilia Bleeding into the intra- or extrahepatic biliary system.

percutaneous transhepatic cholangiography Procedure during which a needle is inserted into the liver via the skin and into a bile duct. Then dye is injected, outlining the biliary system. Through the needle a catheter can be placed to drain the biliary tract, which is known as percutaneous transhepatic biliary drainage.

transarterial embolization Catheterization of the hepatic artery via the femoral artery and using various modalities to selectively embolize the bleeding vessel.

Hemobilia occurs when there is a communication between a vessel of the splanchnic circulation and the intrahepatic or extrahepatic biliary system. It is a rare entity, but nonetheless is an important differential diagnosis of gastrointestinal bleeding. It may occur in a variety of settings and its clinical course may vary from absence of symptoms to life-threatening hemorrhage.

INTRODUCTION

"I believe that if the liver is injured by a contusion, it may lead to blood leaving the body by way of vomit or the stool; for there is no doubt that the biliary duct takes unto itself (to the great good of the patient) some of the blood issuing into the liver and leads it down to the intestines; from there it is either impelled upwards through reverse peristalsis or downwards the usual way." This is the first description of hemobilia found in the medical literature and it appeared in Francis Glisson's *Anatomia Hepatis* in 1694. It was based on the clinical course of a young nobleman who had a stab injury in the right upper quadrant and died following upper gastrointestinal bleeding and on postmortem was found to have significant liver injury. In 1777, Antoine Portal recognized the first antemortem case of hemobilia. Subsequently, Quincke described the classical clinical triad of hemobilia: right upper quadrant pain, jaundice, and upper gastrointestinal tract bleeding. However, it was not until 1948 that Philip Sandblom coined the word hemobilia, while describing a few cases of traumatic hemorrhage through the biliary tract. The first successful operation for hemobilia was carried out in 1903 by Kehr when he identified and ligated an aneurysm of the right hepatic artery that had ruptured into the gallbladder neck. The first successful hepatic resection for hemobilia was reported in 1957. Finally, in 1976 Walters and colleagues used transarterial embolization (TAE) for the management of hemobilia.

ETIOLOGY AND PATHOGENESIS

Three reviews on this topic, by Sandblom, Yoshida *et al.*, and Green *et al.*, provide detailed descriptions of the various etiologies of this condition as well as the changing trends in prevalence over the past three decades (Table I). In the earliest review reported by Sandblom, the commonest cause for hemobilia was accidental trauma (mostly road traffic accidents). In contrast, the most recent series suggests that iatrogenic trauma is the most frequent cause. This is mostly due to the

TABLE I Causes of Hemobilia

Cause	Sandblom (1973) ($n = 545$)	Yoshida *et al.* (1987) ($n = 103$)	Green *et al.* (2001) ($n = 222$)
Iatrogenic trauma	15%	40%	66%
Accidental trauma	33%	19%	6%
Inflammation	28%	9.7%	6.3%
Gallbladder disease	11%	8.7%	5.8%
Vascular	7%	14.6%	9%
Tumors	5%	6.8%	5%
Others	1%	—	—

TABLE II Iatrogenic Risk of Hemobilia

Procedure	Risk of hemobilia
Percutaneous liver biopsy	0.006–1%
Laproscopic cholecystectomy	0.5%
Stenting of biliary stricture	2–10%
Percutaneous transhepatic cholangiography	4–10%
Stenting of biliary stricture	5–10%
Percutaneous transhepatic biliary drainage	3–14%

dramatic increase in the number of percutaneous liver procedures. The risk is related to the size of the needle used. Table II summarizes the incidence of hemobilia after various procedures. Although percutaneous liver biopsy (PLB) is the commonest procedure associated with hemobilia, the overall risk is extremely low (Table I). Ultrasound-guided biopsies or use of the transjugular route does not reduce the risk. In a review of 25 cases of post-PLB-related hemobilia, 10 of the 25 patients had more than one needle pass, raising the possibility that multiple passes is a significant risk factor. Percutaneous transhepatic cholangiography (PTC) also carries risk of hemobilia because of the close relationship between the bile ducts and the blood vessels. If indeed hemobilia does result after PTC, clots may form in the bile ducts and this may cause diagnostic problems as the clots can often be mistaken for stones. If percutaneous biliary drainage is performed, the risk of hemobilia can be even greater (Table II). Other iatrogenic causes include gallbladder surgery. This can result in damage to the hepatic artery due to sutures or dissection, which may result in an arteriobilary fistula or a false aneurysm that erodes into the biliary system. The vessel most often damaged is the hepatic artery or one of its branches, especially the right artery when it lies anterior to the common bile duct. The risk is increased by intraoperative explorations of the bile ducts. In 20% of ducts explored for retained stones following cholecystectomy, a clot rather than a stone was found to be the cause of the filling defect seen on the operating cholangiogram. Despite some initial concerns, there is no evidence to suggest that the incidence of hemobilia is higher after laparoscopic cholecystectomy than after conventional open cholecystectomy.

The other major cause of hemobilia remains accidental trauma (although the number of cases has declined dramatically over the years). This usually follows blunt trauma in over 80% of cases, although it can also occur after abdominal stab injuries and gunshot wounds. Approximately 2% of liver injuries result in hemobilia. The commonest extrahepatic cause is laceration or bruising of the hepatic artery at the porta hepatis. This then leads to hemobilia by one of two mechanisms: intrahepatic hematoma or arteriobiliary fistula. In the former, a cavity filled with blood and bile develops inside the liver, which enlarges, and eventually blood is evacuated into the biliary system and the gastrointestinal tract. The fact that bile retards wound healing further facilitates this mechanism. The second mechanism is by formation of a false aneurysm, which ruptures directly into a bile duct. Such aneurysms develop especially on the branches of the hepatic artery in the hilar or juxtahilar region.

Less frequent but noteworthy causes of hemobilia include gallbladder disease, cholelithiasis (erosion of the cystic artery by an impacted stone), acalculous cholecystitis, and carcinoma. Liver tumors, both primary (hepatocellular cancer, cholangiocarcinomas) and metastatic deposits, can also result in hemobilia, as can true (mycotic) aneurysms of the hepatic artery. Finally, in Asian countries such as China and Korea, hemobilia is a frequent and serious complication of ascariasis and hydatid infection.

The anatomic origin of hemobilia has been studied in detail by many investigators, including Sandblom, Yoshida *et al.*, and Merrell *et al.* Their findings are strikingly consistent. In over 50% of cases the blood originates from the liver, in approximately 20% of cases it originates from the extrahepatic ducts, in 9% of cases it originates from the gallbladder, and in approximately 2% of cases it originates from the pancreas. The bleeding is usually arterial in origin; a venobiliary communication is exceptional (the latter can occur in patients with portal hypertension especially after a transjugular portosystemic shunt placement). The fate of the blood in the bile tract varies. In cases of severe bleeding, the blood directly passes to the gastrointestinal tract and manifests as hematemesis or melena. If the hemorrhage is slow, clots can form as blood and bile do not mix due to differences in specific gravities and surface tension. Since bile is thrombolytic, if bile flow is ensured, the clots are lysed. However, in the presence of impaired bile flow, the clots persist and cause biliary obstruction, which could lead to the development of cholangitis, cholecystitis, and pancreatitis. In addition, clots that remain in the bile ducts could serve as a nidus for subsequent stone formation.

CLINICAL PRESENTATION

The clinical manifestations are protean, related to the rate of blood loss and etiology of hemobilia. Fortunately, the frequency of major hemobilia is considerably less than that of minor hemobilia. Quincke first described the classical triad of symptoms of hemobilia: right upper

quadrant pain, jaundice, and hematemesis. However, all three symptoms are present in only 22% of patients (especially if the etiology is traumatic) (Fig. 1). In approximately one-third of patients, the only symptom is gastrointestinal bleeding, and hemobilia must be remembered as an important differential diagnosis. Bleeding may be scanty or profuse, prolonged or brief, and continuous or intermittent. If bleeding is significant, it may mimic a lower gastrointestinal bleed. Slow blood loss with anemia is unusual, but three decades ago fecal occult blood testing was a diagnostic test for gallstone-induced biliary colic. In addition, patients may present with cholangitis or pancreatitis. It is important to remember that after accidental injury, there may be a delay before patients develop symptoms. The onset of bleeding may be delayed for 4 days to 5 months (average 4 weeks). Rarely the bleeding may be recurrent, with episodes of abdominal pain relieved by gastrointestinal bleeding. In contrast, after iatrogenic trauma, hemobilia manifests soon after the procedure (mean of 5 days after PLB).

Hemobilia occurs more frequently in men, except that bleeding caused by gallstones occurs more commonly in women. The age distribution is fairly uniform, from 10 to 70 years of age, with accidental trauma occurring within the first four decades and iatrogenic trauma being concentrated in the fifth to sixth decade. Laboratory tests may be normal or reveal anemia, moderate to marked elevations in serum alkaline phosphatase, and mild to moderate elevations in serum bilirubin and transaminases.

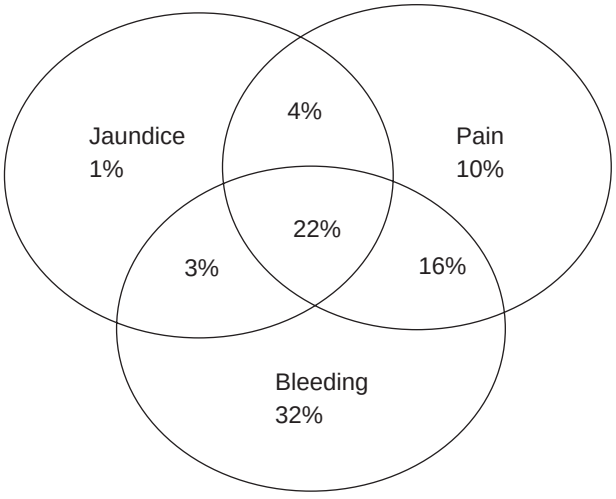

FIGURE 1 Presentation of symptoms in 121 patients with hemobilia. Reprinted from Green *et al.* (2001), with permission from Blackwell Synergy.

INVESTIGATIONS

Early diagnosis is important because the mortality is directly proportional to the delay in controlling the hemorrhage. The definitive diagnosis is established by angiography, which is the investigation of choice, though most patients usually undergo an endoscopy and/or an imaging modality beforehand. The exact sequence of investigations must be individualized depending upon the severity and etiology of the bleeding. In cases of non-life-threatening hemobilia, a diagnostic endoscopy may be reasonable followed by conservative management. Although only 12% of cases are initially diagnosed with endoscopy, it may confirm the diagnosis in an additional 30% of cases and help exclude other causes of gastrointestinal bleeding. In cases of suspected traumatic liver injury, a computerized tomography (CT) scan is useful. Although it cannot demonstrate the actual site of bleeding, and the CT grade of a liver injury alone is not a good predictor of development of hemobilia in the future, it may provide indirect evidence of hemobilia by demonstrating cavitating lesions, aneurysms, and pseudo-aneurysms. Ultrasound is probably less sensitive than a CT scan, as immediately after a bleed into the biliary tract, there may be high echogenicity similar to that of the liver, so that the bile ducts may not be seen. Cholangiography is useful if there is percutaneous access or if an ERCP has been performed. Blood may be seen oozing from the ampulla of Vater and contrast studies may show filling defects in the bile ducts. These defects may be string-like or spherical and impossible to differentiate from stones. In addition, parasitic infections of the biliary tree may be confirmed.

Angiography is the gold standard in most cases of significant bleeding. Selective arteriography of the celiac axis and the superior mesenteric artery is the ideal procedure. In addition to providing information about the exact site of bleeding, it may reveal aneurysms (both true and false) and damage to the hilar arteries. Occasionally an arteriobiliary fistula is diagnosed. In the rare case where there is a high index of suspicion for hemobilia and all investigations including angiography are normal, there may be a role for ^{99m}Tc-RBC scanning.

TREATMENT

Management depends entirely on the severity of bleeding. If the bleeding is not significant, a conservative approach is ideal. In cases of severe bleeding, the aim is to stop the bleeding and prevent/relieve biliary obstruction. Transarterial embolization is now the treatment of choice to stop bleeding in hemobilia. Embolic

occlusion is achieved by various means: balloons, microcoils, gelfoam, or cyanoacrylate. The success rate of TAE varies between 80 and 100%. It has a lower morbidity and mortality than surgery. The most serious complication of TAE is ischemia or infarction of the liver (uncommon due to dual blood supply of the liver) and inadvertent embolization of unintended organs such as the gallbladder and the pancreas. Less serious side effects include pain, fever, bacteremia, and transaminitis. As much as possible, the TAE should be superselective both to reduce the risk of ischemic liver injury and to prevent recurrent bleeding that might develop from collateral vascular channels.

If there is evidence of biliary obstruction, then drainage must be ensured either via an ERCP or through the percutaneous route. Surgery is indicated if TAE fails, for cholecystitis, for hepatic cavitating lesions, and occasionally for biliary drainage. During surgery, the aim is to ligate the offending bleeding vessel, and when this is not possible, nonselective ligation of the right or left hepatic artery and/or arterial reconstruction must be performed. If the bleeding persists, more drastic measures, such as resection of the affected liver segment or partial hepatectomy, are indicated. Other adjunctive modalities used in the management of hemobilia include pharmacological agents such as vasopressin and somatostatin.

In a recent review of 171 cases of hemobilia between 1996 and 1999, Green *et al*. reported that a conservative approach (including correcting coagulopathy and adequate drainage) successfully controlled bleeding in 43% of cases of hemobilia, TAE controlled bleeding in 36% of cases, and surgery was required in 22% of cases (including cholecystectomy in 12% and hepatic artery ligation in 2% of patients in whom TAE was unsuccessful).

PROGNOSIS

In Sandblom's initial review of hemobilia in 1972, the overall mortality was 25%, but by the late 1980s the mortality rate had been reduced by half. From 1996 to 1999, only five deaths were reported from hemobilia. This reduction in mortality rate over the past 30 years is due to multiple factors: heightened awareness, an increasing number of cases of mild hemobilia due to iatrogenic causes, and finally increasing use of and refinement in the technique of TAE.

CONCLUSIONS

Hemobilia is the phenomenon of bleeding into the biliary tree, which in two-thirds of cases is related to iatrogenic trauma, notably percutaneous liver procedures. The classical clinical presentation is with right upper abdominal pain, jaundice, and gastrointestinal bleeding. Diagnosis is established by angiography and TAE is the treatment of choice, being successful in 80–100% of the cases. Both increasing awareness of this condition and refinement in TAE techniques have contributed to the dramatic decline in the mortality resulting from this condition over the past three decades.

Hemorrhage

DOUGLAS W. WILMORE
Brigham and Women's Hospital and Harvard University

coagulation The natural process by which blood clots to reduce or prevent bleeding.
endoscopy The process of examining the lining of the intestinal tract using a flexible device that can easily be inserted into the mouth or anus and which allows magnification and viewing of the lumen.
hemorrhage The loss of blood from blood vessels.
sclerotherapy The injection of a highly irritating substance into a blood vessel, which causes a clot to form.
sympathetic nervous system A portion of the nervous system that responds automatically to stresses on the body, such as exercise, temperature changes, and hemorrhage.
vasoconstriction The process of blood vessels closing down or constricting, to limit the amount of blood flowing through them.

Hemorrhage or bleeding is the loss of blood from blood vessels that constitute the vascular compartment. The vascular compartment is made up of arteries, veins, capillaries, and the heart, and the size of this space is approximately 7–8% of the individual's body weight (in kilograms). Thus, a 70 kg male would have approximately 5–5.5 liters of blood in the body (70 kg $\times$ 0.07 = $\sim$5.0 liters and 70 kg $\times$ 0.08 = $\sim$5.5 liters). Blood is composed of plasma, red blood cells, and white cells or leukocytes. The blood plasma (the liquid phase of blood) carries coagulation factors that facilitate blood clotting mechanisms. The red blood cells, or erythrocytes, constitute 30–45% of the blood volume and primarily carry oxygen from the lungs to tissues of the body. During acute hemorrhage, all blood components are lost in equal proportions, but during a slow occult bleed, the plasma component is rapidly replaced by the body and the primary deficit is the red blood cells.

PHYSIOLOGY

Blood Pressure

The circulating blood is propelled by the pumping action of the heart. The force of the heart and the resistance created by small arterial vessels, called arterioles, combine to cause pressure within the arterial tree (which is measured as blood pressure). This head of pressure ensures perfusion of vital organs, such as the brain and kidneys, and of the coronary arteries of the heart. As bleeding occurs, the pressure within the vascular compartment is initially maintained as the volume of blood flowing through large capacitance veins is reduced. These vessels include the superior and inferior vena cava, the pulmonary veins, and the large veins draining the extremities. With additional loss of blood, blood pressure falls, oxygen delivery to vital organs is impaired, and tissue damage or cell death may occur. This stage of bleeding is referred to as hemorrhagic shock.

Response to Bleeding

During the initial phases of acute blood loss, little initial change in blood pressure occurs. In fact, a healthy individual can generally withstand loss of 20–25% of his or her blood volume (1.0–1.5 liters) without experiencing significant symptoms (Table I). With greater degrees of acute hemorrhage, neurohormonal reflex responses are activated, in an attempt to maintain blood pressure and ensure tissue perfusion. These responses include activation of the sympathetic nervous system, which stimulates vasoconstriction of peripheral vessels and activation of the pituitary gland. This last response results in the elaboration of hormones that enhance contraction of the smooth muscles of the vascular tree, thus enhancing vasoconstriction, and stimulating salt and water retention by the kidney. The elaboration of the stress hormone epinephrine from the adrenal gland stimulates, among other things, the heart, causing tachycardia and increasing its pumping action. All of the autonomic responses reflect the body's attempt to maintain blood volume and support blood pressure, which reflects perfusion of vital tissue.

Signs Related to the Extent of Blood Loss

As acute hemorrhage progresses, the blood pressure falls and tissue perfusion diminishes. The skin becomes cool and clammy. Little urine is formed, reflecting diminished renal perfusion, and the patient may become quite confused and agitated as the oxygen supplied to the brain is reduced. Rapid restoration of blood pressure

	Low urine output	Low urine output
	Postural hypotension	Hypotension
	Confusion	Mental status changes

is essential at this point in order to prevent permanent organ damage or death.

Treatment

The treatment of hemorrhage is twofold: (1) stop the bleeding at its site and (2) replace the blood that has been lost. Direct pressure on a superficial vessel or a large vessel in extremity is an efficient method to employ while the patient is being transported to a medical facility for definitive treatment. A variation of this theme is followed by many emergency medical units who apply special inflatable pressure pants to the lower torso in patients with injuries to and blood loss from the lower extremities. In contrast, internal bleeding represents much more of a diagnostic and therapeutic challenge, as discussed below.

Replacement of the lost blood requires insertion of an intravenous line, usually in a vein in the extremity, followed by the immediate administration of an appropriate volume of a salt-containing intravenous solution. This solution serves as a plasma mimic and can be readily stored at room temperature in ambulances and emergency rooms. Blood pressure and urine volume are monitored to ensure adequacy of therapy. If a large volume of blood is lost, the patient's blood type is determined at the hospital and type-specific red blood cells (or occasionally whole blood or blood components, such as platelets or fresh plasma) are administered to ensure the adequacy of the oxygen-carrying capacity of the blood or to enhance coagulation mechanisms. With stabilization, further diagnostic and therapeutic methods are pursued so that a definitive treatment plan to permanently arrest the hemorrhage can be followed.

CAUSES OF HEMORRHAGE

Trauma

One obvious cause of hemorrhage is tissue injury. Falls, scrapes, and other accidents, particularly those that occur while traveling in high-speed automobiles, account for a variety of traumatic injuries associated with bleeding. The hemorrhage may be external and quite apparent or may be internal, such as that associated with a fracture of a long bone, which results in bleeding into the surrounding soft tissue. Internal bleeding may also occur in the thoracic or abdominal cavity. With blunt abdominal injury (as occurs following a fall or seat belt injury), organs such as the liver or spleen may be damaged, causing intra-abdominal hemorrhage. To aid diagnosis, a small tube is inserted into the abdomen and sterile fluid is injected and then withdrawn. The fluid is then examined for red blood cells and if they are present, bleeding has occurred. In addition to this technique of peritoneal gavage, modern scanning techniques are utilized to determine sites of tissue injury and to plan therapy.

Other causes of intracavitary hemorrhage are associated with penetrating injuries, such as those that occur when an individual falls on a pipe or rod. More common are the injuries sustained during altercations involving knives or guns. These injuries frequently require surgical exploration to stay the bleeding and repair damaged tissue.

Upper Gastrointestinal Tract Hemorrhage

Patients frequently present with bloody vomitus, which is a reflection of disease in the upper gastrointestinal tract. Fortunately, in approximately 80% of patients who present with this type of bleeding, the hemorrhage is self-limiting and diagnostic measures can proceed in a nonemergency fashion after appropriate supportive therapy has been provided. In the remaining patients, combined emergency approaches involve the gastroenterologist, who performs endoscopy, the radiologist, who performs additional diagnostic studies (and on occasion can embolize bleeding vessels), and the surgeon, who may be called upon to perform a life-saving operation.

The causes of upper gastrointestinal hemorrhage include esophageal variceal bleeding, peptic ulcer disease, tears of the lower esophagus secondary to severe

TABLE II Causes of Gastrointestinal Bleeding

Other	25

vomiting (an entity called Mallory–Weiss syndrome), vascular malformations, erosive gastrointestinal mucosal lesions (caused by alcohol and drugs such as aspirin), and tumors (Table II). Many of these localized lesions can be diagnosed and treated by endoscopy and electrical coagulation or sclerotherapy, and other lesions (including tears and tumors) require operative repair.

Lower Gastrointestinal Hemorrhage

Patients frequently present with blood in their stools. Alternatively, a physician may detect a low red blood cell count and diagnose slow occult bleeding from the colon. Diagnosis of lower gastrointestinal bleeding is more difficult than the detection of upper intestinal bleeding because of the presence of fecal material in the colon, which requires removal before endoscopic and radiographic testing can satisfactorily be performed.

The causes of bleeding from the lower gastrointestinal tract are multiple and include diverticulosis, vascular anomalies, inflammatory or immune lesions of the lower tract, such as Crohn's disease or ulcerative colitis, benign or malignant tumors, or congenital anomalies, such as a Meckel's diverticulum (Table II). If bleeding is rapid, blood replacement therapy must be provided and diagnostic measures initiated. Endoscopy and arteriographic studies are the most frequent examinations performed and on occasion, in the unstable patient, emergency operative intervention is required. If no source of bleeding is discovered, a radionucleotide scan, barium studies, or combined operative and endoscopic investigations are the next usual diagnostic steps.

With slower occult bleeding, bowel preparation with the use of laxatives, enemas, and liquid diets greatly facilitates diagnostic studies of the colon and rectum. Bleeding also occurs from external hemorrhoids and anal fissures, which can be treated by local means.

Other Sites of Hemorrhage

Hemorrhage also occurs from other organs, such as the bladder, uterus, and lungs, as well as into the brain. Appropriate diagnostic studies are necessary to determine appropriate therapy for bleeding from these organs. Although hemorrhage from these or other sites is usually associated with local tissue injury or disease, patients who have abnormalities of blood coagulation mechanisms also present with episodes of bleeding from these and other organs. This is particularly true in individuals taking anticoagulant drugs (aspirin, heparin, or coumadin) or those with inherited abnormalities in coagulation.

Hemorrhoids

SARA HUGHES JAVID AND STEPHEN JOHN FERZOCO
Brigham and Women's Hospital, Boston

external hemorrhoids Those hemorrhoids that originate below the dentate line.

hemorrhoid Symptomatic and pathologic, downward displacement of normal vascular tissue of the anal canal.

internal hemorrhoids Those hemorrhoids that originate above the dentate line. Differentiated as first through fourth degree: first degree, slide below the dentate line on straining; second degree, prolapse through the anus on straining but reduce spontaneously; third degree, prolapse through the anus on straining and require manual replacement into the anal canal; fourth degree, prolapse is not manually reducible.

Hemorrhoids constitute a condition that has been recognized and treated for over 4000 years. The word "hemorrhoid" is derived from the Greek adjective "haimorrhoides," which means bleeding . Hemorrhoids originate in the anal canal as cushions of submucosal vascular tissue that can undergo pathologic changes, producing symptoms. Hemorrhoids can be classified by their location relative to the dentate line, the junction between the rectal mucosa and the specialized epithelium of the anal canal (anoderm). Hemorrhoids that originate below the level of the dentate line are classified as external hemorrhoids, and those that originate above the dentate line are termed internal hemorrhoids. Internal hemorrhoids can be further described as stage I, II, III, or IV.

INTRODUCTION

Hemorrhoids are one of the most common anorectal complaints brought to physicians. Symptomatic hemorrhoids affect approximately 42 per 1000 persons, or 10.6 million persons per year in the United States. Of those, only 2.5 million people present to a physician for treatment. The incidence of hemorrhoids appears to peak in middle age and declines after the age of 65. An equal distribution of hemorrhoid disease is observed between the sexes.

Hemorrhoids are composed of submucosal cushions of vascular tissue found in the left lateral, right anterior, and right posterior positions of the anal wall that are devoid of muscle. Each cushion has a venous and arterial supply, as well as multiple small arteriovenous anastomoses between the two. The blood supply is derived from the superior rectal artery arising from the inferior mesenteric artery, the middle rectal arteries arising from the internal iliac arteries, and the inferior rectal arteries arising from the pudendal arteries. The venous drainage is to the portal venous system above the dentate line and to the systemic circulation below the dentate line.

The function of the hemorrhoidal cushions is to aid in anal continence. The pathologic, downward displacement of these cushions is probably caused by factors such as constipation, prolonged straining, pregnancy, aging, and increased intraabdominal pressure. This displacement is thought to result in the distension of cushion venules, which causes symptomatic hemorrhoids.

Treatment of symptomatic hemorrhoids typically begins with conservative measures, including the moderation of diet. If unsuccessful, however, more aggressive nonoperative therapies can be utilized for both external and internal hemorrhoids. Operative strategies are indicated in circumstances of nonoperative treatment failure or on presentation with acute thrombosis or prolapse of hemorrhoids.

The various clinical presentations and diagnosis of external and internal hemorrhoids are addressed in the following discussions. In addition, available therapeutic options for patients are reviewed and compared. Last, the various complications that may ensue as a result of hemorrhoid therapy are discussed.

CLINICAL PRESENTATION AND DIAGNOSIS

The most common complaint of patients suffering from hemorrhoids is painless rectal bleeding or bright red blood associated with bowel movements. Patients may also present complaining of a "bulge" from the anus, mucus discharge, or a feeling of incomplete evacuation. Pain results when hemorrhoids undergo thrombosis, incarceration, or acute prolapse with edema. As a general rule, internal hemorrhoids are typically nonpainful and present characteristically with rectal bleeding. External hemorrhoids are more apt to present as a mass protruding from the anus or irritation with constipation, but may also cause bleeding.

 Copyright 2004, Elsevier (USA). All rights reserved.

Examination of the patient using proper positioning and instruments is essential to diagnose hemorrhoids. The patient should be placed in the left lateral or prone jackknife position or in a modified left lateral (Sims') position. Inspection, palpation, digital rectal examination, and anoscopy should be performed on all patients. Internal hemorrhoids cannot be palpated, but prolapse can best be observed if the patient is asked to strain on the toilet. Anoscopy also permits clear visualization of the internal hemorrhoidal cushions. In addition, either a flexible sigmoidoscopy or a rigid procotosigmoidoscopy should be done to exclude coexisting colorectal pathology. A colonoscopy is indicated for those patients over age 40 or those patients with additional symptoms or a positive family history. Alternative etiologies for the patient's symptoms should be excluded, such as anal fissure, abscess, fistula, polyps, malignancy, inflammatory bowel disease, skin tags, anal warts, or rectal prolapse.

NONOPERATIVE MANAGEMENT

A multitude of treatment options for hemorrhoids exists, many of which have been in existence for thousands of years. These modalities include ligation, cautery, surgical excision, and possibly even the intervention of St. Fiacre, the patron saint of hemorrhoid sufferers. Treatment is reserved for symptomatic hemorrhoids only, and amelioration of these symptoms and cure are the aims to be sought. With the exception of fiber agents, hemorrhoid therapies work by fixing the anal cushions to their normal physiologic sites.

The first-line treatment of hemorrhoid disease usually begins with bulking agents (e.g., psyllium or methylcellulose) and increased water intake. These dietary modifications are thought to alleviate symptoms by softening bowel movements and reducing strain on defecation. One controlled trial has compared fiber (psyllium) with placebo in 52 patients with symptomatic hemorrhoids. These patients experienced a significant 36% reduction in bleeding when compared with placebo. Pain with defecation was also reduced. Warm sitz baths (60°C) are another effective local treatment used to alleviate symptomatic hemorrhoids. Topical creams, ointments, or foams have been shown to have minimal efficacy in randomized clinical trials (RCTs), but may reduce symptoms by exerting a local anesthetic effect.

If bleeding or other symptoms persist, other more aggressive therapies are utilized. The most commonly used nonsurgical method for treatment of first-, second-, and third-degree internal hemorrhoids is rubber band ligation (RBL). In this technique, a hemorrhoid ligator (e.g., McGown or McGivney ligator) is used to apply a rubber band to the base of the hemorrhoid cushion. This leads to strangulation, small ulcer formation, and the eventual fixation of the tissue to the underlying sphincter. For this procedure, the patient should be placed in the prone jackknife position. Typically, one band is placed on each hemorrhoid bundle, and the largest is banded first. Banding in close approximation to the dentate line or internal sphincter should be avoided. Following the procedure, patients may resume normal activities, but should be made aware of potential complications, including pain, thrombosis, delayed bleeding, or infection.

Infrared photocoagulation (IRC) is an alternative treatment for first- and second-degree hemorrhoids. Through the application of heat via infrared radiation, the hemorrhoid cushion becomes inflamed and scars, leading to its fixation. The infrared coagulator is applied three or four times near the apex of the hemorrhoid. Patients should be aware of the possible complications of pain or fissure due to inappropriate positioning of the coagulator at the dentate line.

The oldest technique in use is injection sclerotherapy, in which a sclerosing material (e.g., phenol, 5% in cottonseed oil) is injected into the submucosa above the hemorrhoid, resulting in fibrosis and fixation of the cushion. This technique is rarely used today due to high rates of stricture formation and other complications.

Although the efficacy of these techniques has never been compared to placebo in a controlled trial, there have been several small RCTs comparing them to one another. Ultimately, none has been proved superior to the others. However, one meta-analysis of five randomized trials revealed that RBL and IRC had similar efficacy rates, but sclerotherapy was inferior. Although patients with RBL had fewer symptomatic recurrences, they also experienced a fivefold greater incidence of pain compared to patients who had IRC. Therefore, the choice between RBL and IRC should be individualized based on patient and provider preference.

OPERATIVE MANAGEMENT

Surgical treatment of hemorrhoids should be reserved for those patients for whom nonoperative management fails or in cases of acute emergency. Only 5–10% of patients with symptomatic hemorrhoids require surgery. Although it has been shown in one meta-analysis comparing hemorrhoidectomy with RBL that hemorrhoidectomy was more effective, it was also associated with a significantly greater risk of complications, postprocedure pain, and cost. The most common indication for hemorrhoidectomy is the frequent, symptomatic prolapse of internal hemorrhoids leading to pain and/or anal seepage. Other indications include

difficulties in anal hygiene secondary to prolapsing internal or external hemorrhoids, or acute prolapse, thrombosis, or strangulation of hemorrhoids. Several options are available for excisional hemorrhoidectomy, including Milligan–Morgan hemorrhoidectomy, Ferguson closed hemorrhoidectomy, and Whitehead hemorrhoidectomy.

Each hemorrhoidectomy procedure is performed with the patient in the prone jackknife position with buttocks taped laterally. In the Milligan–Morgan hemorrhoidectomy, first described in 1937, the entire involved hemorrhoid complex is ligated at its base and the distal anoderm and skin are left open to heal by secondary intention. Although proved a safe and efficacious method, one obvious disadvantage to this technique is discomfort from the open wound.

In the closed Ferguson hemorrhoidectomy, an hourglass-shaped incision is made encompassing the entire hemorrhoidal complex, taking care to preserve the anal sphincters. In this technique, the entire wound is closed primarily, and the anoderm between hemorrhoid pedicles is preserved. The Whitehead hemorrhoidectomy is more technically demanding because, in addition to removing hemorrhoidal tissue, the prolapsed dentate line must be relocated to its proper position. This technique is less frequently performed because some studies have shown high complication rates of mucosal ectropion and anal stricture.

A newer technique currently used is the circular stapled hemorrhoidectomy. This procedure can be used for patients with all grades of internal hemorrhoids, but is best reserved for patients with grade III or IV hemorrhoids. It is not applicable to patients with external hemorrhoids. First, a pursestring suture is placed 4–6 cm above the dentate line, above the enlarged internal hemorrhoids. A 31-mm stapler is then used to perform a circumferential mucosectomy at this position, leading to the repositioning and fixation of the prolapsed anoderm on closure of the defect. Thus, the hemorrhoidal cushions are preserved and returned to their physiologic location. Although there are no data yet documenting the long-term results of stapled hemorrhoidectomy, preliminary studies of this approach show a decreased frequency of postprocedure pain, shorter recovery time, and similar complication rates compared to other types of hemorrhoidectomy.

Other forms of hemorrhoidectomy, such as laser hemorrhoidectomy, not only add to cost and cause increased pain, but also provide no advantage over traditional hemorrhoidectomy approaches. Anal stretch and lateral sphincterotomy methods have also been abandoned for the treatment of hemorrhoids due to the high associated risk of anal incontinence.

COMPLICATIONS OF MANAGEMENT

Pain is the most frequent complication of hemorrhoid surgery. The key to avoiding this complication lies in the usage of a combination of oral and intravenous narcotics as well as local analgesics such as bupivacaine in the perianal incision. Nonsteroidal antiinflammatory medications, including ketorolac, have also been shown effective in managing pain caused by hemorrhoidectomy. In addition, preoperative and postoperative lactulose, perioperative metronidazole, glyceryl trinitrate ointment, and warm sitz baths are all used to reduce pain.

Postoperative bleeding occurs in approximately 1% of patients within the first 24 hours of treatment, at which time it typically represents a technical failure of the procedure. Bleeding may also occur 1–2 weeks postoperatively in 0.5–4.0% of cases due to separation of the ligated pedicle before sufficient thrombosis has occurred. Bleeding at this time can be quite severe, and may require either suture ligation or tamponade by anal packing.

Urinary retention is another problem that occurs in 1–52% of patients after hemorrhoidectomy. This is best prevented by limiting fluid administration to 250 ml perioperatively, avoiding the use of spinal anesthesia or anal packing, and by the liberal use of aggressive analgesia.

Henoch–Schönlein Purpura

SALAHUDDIN KAZI
University of Texas Southwestern Medical Center, Dallas

immunoglobulin A nephropathy Immune-complex-mediated glomerulonephritis defined immunohistologically by the presence of glomerular immunoglobulin A.

palpable purpura Visible and often palpable discrete cutaneous hemorrhage, typically in dependent areas. It is occasionally confluent and extensive.

Henoch–Schönlein purpura is a small-vessel vasculitis with the classic clinical tetrad of purpura, arthritis, abdominal pain, and glomerulonephritis. Histologically, it is characterized by the deposition of immunoglobulin A in and around blood vessels, including the glomeruli of the kidneys. It is primarily a disease of children but also occurs in adolescents and adults.

EPIDEMIOLOGY

Henoch–Schönlein purpura (HSP) has a worldwide prevalence in children of 1.5/1000 and an annual incidence of 135/million. In children with familial Mediterranean fever, the prevalence is 130/1000. Upper respiratory tract infection precedes onset of HSP in children in up to 50% of cases. Girls and boys are affected equally, with a median age of onset of 4 years. In adults, the annual incidence is much lower and is estimated to be 1.2/million, but this may be an underestimation.

ETIOLOGY AND PATHOGENESIS

HSP is characterized by the deposition of immunoglobulin A (IgA)-containing immune complexes in the tissues. The glomerular lesion is identical to that of IgA nephropathy, a disease with which it likely shares a common etiology. The disease often follows an upper respiratory infection and occurs more commonly in the winter months, suggesting that infection triggers an autoimmune response. Most patients will have elevated serum levels of IgA. Of the two isotypes of IgA (IgA1 and IgA2), IgA1 is exclusively associated with IgA nephropathy, suggesting that selective increase in IgA1 production and/or clearance plays an important role in pathogenesis of this disorder. Once IgA immune complexes are deposited, immune-mediated inflammation ensues.

CLINICAL FEATURES

Cutaneous

The hallmark of HSP is the acute onset of palpable purpura of the legs. Purpura may be extensive and confluent and may involve the buttocks, trunk, and upper extremities. There may be associated edema.

Musculoskeletal

Arthritis is the second commonest feature of HSP. It is typically acute and usually involves the large joints of the legs. Arthritis may occasionally precede cutaneous disease. The arthritis is not associated with serious sequelae.

Renal

Renal involvement is very common in HSP, but is frequently asymptomatic. The incidence of renal disease increases in HSP with the patient's age. Overt disease occurs in less than 50% of children, usually within 4 weeks of the onset of systemic symptoms. When the kidneys are involved, hematuria is universal, whereas proteinuria and renal insufficiency are less common. The combination of hematuria and proteinuria is a marker for progressive renal insufficiency. The prognosis is excellent, with less than 1% of children progressing to end-stage renal disease; however, more than 10% of adults with HSP progress to end-stage renal disease.

Gastrointestinal

The majority of children with HSP have gastrointestinal symptoms and signs. These include colicky abdominal pain, nausea, vomiting, and gastrointestinal bleeding. These symptoms typically develop within 8 days of the first sign of rash. Endoscopy reveals hemorrhagic and erosive lesions, typically of the duodenum, although erosions have been documented in other regions of the gastrointestinal tract. Histology of mucosal biopsies may reveal IgA deposition. Clinically obvious gastrointestinal bleeding occurs in 25% of patients, whereas occult blood loss is present in 50%. Intussusception is a rare complication of HSP.

 Copyright 2004, Elsevier (USA). All rights reserved.

Pancreatitis and protein-losing enteropathy have been reported.

Other

Acute scrotal swelling has been reported in children. Central nervous system involvement is very rare. Asymptomatic pulmonary involvement is common, but overt pulmonary hemorrhage is rare.

DIAGNOSIS

The diagnosis of HSP in children is usually obvious, based on the classic tetrad of cutaneous, musculoskeletal, renal, and gastrointestinal symptoms. In adults, other disorders that can cause similar symptoms and signs include systemic lupus erythematosus, Wegener's granulomatosis, antiglomerular basement membrane (GBM) disease, and drug-induced cutaneous leukocytoclastic vasculitis. Skin biopsy, although often not needed for diagnosis of HSP, will show a leukocytoclastic vasculitis of the postcapillary venules. IgA deposition in vessels can be demonstrated in most cases. An elevated serum IgA is present in 50% of patients. Renal biopsy is generally reserved for patients with overt renal disease. Renal histopathology ranges from minimal change to severe crescentic glomerulonephritis. IgA deposition in the glomeruli can usually be demonstrated.

THERAPY AND PROGNOSIS

HSP is a self-limited disease in the majority of cases, especially in children, with complete recovery occurring in 90% of cases. Recurrences are common, occurring in one-third of cases. Therapy is largely supportive and consists of adequate hydration and the use of nonsteroidal antiinflammatory drugs to relieve painful edema and arthritis. Corticosteroids can hasten resolution of purpura and are also widely used to treat abdominal symptoms. Treatment for renal disease is indicated only in patients with marked proteinuria and/or renal insufficiency. There are few data regarding the efficacy of aggressive immunosuppression in advanced renal disease. Azathioprine, cyclophosphamide, and plasmapheresis have all been employed in patients with severe renal disease. Renal disease is more common and more extensive in adults. Renal transplantation may be performed in patients that progress to end-stage renal disease.

Hepatic Adenomas

ANNE M. LARSON
University of Washington, Seattle

glycogen storage diseases Disorders secondary to defects in any of the proteins involved in the synthesis or degradation of glycogen, leading to storage of quantitatively or qualitative abnormal glycogen.

oral contraceptive An oral agent containing estrogen or estrogen and progesterone and used in the prevention of pregnancy.

Hepatic adenomas were virtually unknown prior to 1960. They are benign liver cell tumors resulting from the proliferation of hepatocytes that are otherwise histologically normal or near normal. In the older literature, they are often referred to as "benign hepatoma."

EPIDEMIOLOGY

Hepatic adenomas (HA) are more often seen in women (9 : 1), predominantly of childbearing age. Prior to the introduction of oral contraceptives (OCPs) in the late 1950s, HA were rarely seen. The incidence began increasing in about 1960, with the highest risk in older women (> 30 years) who had taken high-dose OCPs for 5 years or more. In the United States, the reported incidence is 1−1.3 per million in non-OCP users and 30−40 per 100,000 in long-term OCP users. There has been some decrease in incidence with the reduction of estrogen dosing in oral contraceptives.

HA have also been associated with the glycogen storage diseases (GSDs). They are seen in 52% of those with GSD type I and 25% of patients with GSD type II. In this setting, the lesions are more likely to be multiple, occur before the age of 20 years, and are more common in males (2 : 1). Malignant transformation is common at a mean age of 23 years.

Other less common associations include the use of anabolic or androgenic steroids, diabetes mellitus, pregnancy, familial adenomatous polyposis, carbamazepine, and severe combined immunodeficiency. Rarely, they can occur sporadically in patients without risk factors.

ETIOLOGY AND PATHOGENESIS

The true etiology of HA development is uncertain. Although it is postulated that they are responsive to hormonal influences, not all HA show evidence of estrogen receptors. In patients with GSD, it is postulated that there is a glucagon/insulin imbalance with glycogen overload and possible proto-oncogene activation. Diabetics may have a mechanism similar to GSD.

CLINICAL PRESENTATION

Most patients are young women (mean age 34 years) with a history of OCP use (>90%). Although patients may be asymptomatic (5−10%), many present with right upper quadrant pain or discomfort (50%) and some with an abdominal mass (25−35%). Pain may be chronic or intermittent. Approximately 25−40% will present with "classic" symptoms of severe acute abdominal pain and hemoperitoneum with subsequent hypotension followed by shock (mortality rate of 6%). The lesions are usually single, but can be multiple in 10−20% of cases. Rarely are there more than 5 in number. In the setting of GSD, multiple adenomas are more common. At the time of presentation, HA are usually > 5 cm. Hepatic laboratory studies are normal unless hemorrhage occurs. Rarely, the alkaline phosphatase and gamma-glutamyl transpeptidase (GGT) can be slightly elevated.

HISTOPATHOLOGY

Grossly, HA are large, bulging, well-circumscribed tan-yellow tumors, often 5 cm and up to 30 cm in size. There are large blood vessels traversing the surface and there is no true capsule. Central necrosis or hemorrhage may be seen and they always occur within liver parenchyma with normal architecture. Microscopically, the cells closely resemble normal hepatocytes with the hallmark feature of cells arranged in plates two to three cells thick separated by sinusoids. The cells are larger than normal hepatocytes and contain excess glycogen and fat. There is a well-defined reticulin framework, but no portal tracts or bile ducts. Bile plugs in distended canaliculi may be seen. Dilated sinusoids with thin-walled capillaries may be present and the tumor is perfused solely by the peripheral arterial feeding vessels.

 Copyright 2004, Elsevier (USA). All rights reserved.

DIAGNOSIS

The differential diagnosis includes normal liver, other liver tumors [focal nodular hyperplasia (FNH), fibrolamellar hepatocellular carcinoma, hepatocellular carcinoma], and the regenerating nodules of cirrhosis. Imaging studies all reveal a well-demarcated lesion, but are generally nonspecific. Ultrasound shows a smooth or nodular lesion with variable echogenicity. Doppler shows venous signals; however, ultrasound is not able to reliably distinguish HA from other lesions. On a noncontrast computed tomography image, the lesions are either hypo- or isodense with the surrounding liver. Irregular vascular enhancement occurs after contrast injection. The central portion of the lesion remains hypodense if hemorrhage is present and can be difficult to distinguish from FNH. On delayed images, HA is hypodense. On magnetic resonance imaging, HA shows a low signal to slightly hyperintense image on T1 with a well-defined low-intensity capsule. The tumors heterogeneously enhance on T2 images and may be difficult to distinguish from hepatocellular carcinoma.

Nuclear scintigraphy is rarely diagnostic; however, compared with normal liver, there is decreased uptake of 99m-Tc-sulcur colloid. This may be helpful differentiating HA from FNH. With angiographic evaluation, HA have a wide variety of appearances and the tumors may appear either hypovascular or hypervascular. Blood flow is from the periphery to the center with a homogenous blush during venous phase. Angiography can help distinguish hepatocellular carcinoma or focal nodular hyperplasia from HA. Definitive diagnosis, however, requires liver biopsy. This carries a small risk of bleeding and may not be diagnostic if the biopsy specimen is too small.

TREATMENT/MANAGEMENT

Management of HA is straightforward. Patients should avoid estrogens. The adenomas may decrease in size or disappear ($<20\%$). Women should be counseled to avoid pregnancy due to the increased risk of HA growth and rupture. Surgical resection, by either enucleation or resection, is the recommendation of choice, due to the risk of rupture, necrosis, and malignant transformation. Elective surgical mortality is less than 1%; however, if the surgery is performed urgently following rupture, mortality increases to 5–8%. If HA is OCP-related, an observation period is recommended to see if disappearance occurs or to "down-size" the lesion prior to surgery. No lesion >5 cm should be expectantly followed. If smaller lesions are followed, serial scans and α-fetoprotein (AFP) measurements are required. Liver transplantation should be considered if HA are found in association with type I glycogen storage disease or if the disease is multifocal or diffuse (particularly with increasing AFP).

PROGNOSIS

Prognosis is not well established. HA may improve after discontinuation of oral contraceptives (20%). Adenomas may also evolve into malignant tumors and most case reports are associated with OCP use. The risk is higher when associated with anabolic and androgenic steroids or GSD. HA may recur; therefore, postoperative surveillance with ultrasound every 2 years is recommended.

Hepatic Circulation

VIJAY SHAH
Mayo Clinic

autoregulation Process by which vascular inflow is regulated to maintain total liver blood flow at a relatively constant level.

space of Disse Virtual space located between the sinusoidal endothelial lining and the parenchymal hepatocyte population.

Under normal physiologic conditions, the liver functions as a low-resistance system, thereby enabling the accommodation of large volumes of portal blood in the absence of significant changes in pressure. Liver cells, which are predominantly responsible for function of the hepatic circulation, include endothelial cells within the sinusoids, portal venules, hepatic arteries, and hepatic venules, and contractile cells, which include hepatic stellate cells and vascular smooth muscle cells. Pathologic perturbations can impair the function of the hepatic circulation through the actions of specific vascular mediators, most notably, nitric oxide, endothelin, and perhaps carbon monoxide. In liver cirrhosis, hepatic vascular compliance is lost and portal pressure increases in response to small changes in venous inflow, due predominantly to mechanical factors as well as through imbalances in vascular factors, culminating in hepatic vascular constriction. Other clinically relevant insults such as ischemia–reperfusion, alcohol, and endotoxin impair hepatic vascular function in the absence of structural changes, probably through the production of injurious cytokines from Kupffer cells.

CELLULAR ANATOMY

Introduction

Hepatic vascular regulation occurs through the dynamic interplay of the vascular endothelium, which is uniquely situated to transduce bloodborne and mechanical stimuli onto its underlying contractile cells. However, in contradistinction to blood flow regulation in other regional vascular beds, the cells that are responsible for these hemodynamic signaling functions in liver maintain unique phenotypes (Table I).

TABLE I Major Sinusoidal Liver Cells

Cell type	Putative function
Sinusoidal endothelial cell	Vasoregulation

	Contractility/relaxation
Kupffer cell	Phagocytosis
	Cytokine production
	Vasoregulation
	Immune functions

Liver Endothelial Cell

The liver endothelial cell encompasses distinct phenotypes determined by cell location. The hepatic macrocirculation is composed of cells that maintain a phenotype similar to that of endothelial cells throughout other regional vascular beds. However, within the liver sinusoids, which make up a microcirculatory unit that provides an anastomosis between the portal venous and hepatic venous circulation, the sinusoidal endothelial cells contain fenestrae (Fig. 1). Fenestrae in these cells are grouped into sieve plates, and these pores, in conjunction with the lack of a basement membrane, facilitate the transport of macromolecules from the vascular channels to the space of Disse, the potential space located between the abluminal portion of the endothelial cell and the adjacent hepatocytes, and within which Kupffer cells and hepatic stellate cells reside. These fenestrae are dynamic structures; their diameter is modulated by pharmacologic agents as well as through pathophysiological insults.

Hepatic Stellate Cells

Hepatic stellate cells are postulated to be a contractile cell within the sinusoid, functioning as a liver-specific pericyte, akin to the mesangial cell in the kidney. These cells serve the function of vitamin A storage under physiologic situations. However, on activation, which occurs in response to a variety of antagonistic stimuli and perhaps even in normal circumstances, these cells develop a contractile phenotype and

maintain a function equivalent to a smooth muscle effector cell. In support of this concept, hepatic stellate cells have been demonstrated to possess a variety of smooth muscle cell phenotypic characteristics on activation, *in vitro* and *in vivo*, including the ability to relax in response to endothelium-derived vasodilators, most notably nitric oxide (NO).

Kupffer Cells

Kupffer cells, as members of the reticuloendothelial system, function as resident macrophages. Although their vasoregulatory function is not prominent, these cells may influence hepatic hemodynamics in certain circumstances, perhaps through the endotoxin-dependent production of potentially vasoactive cytokines such as tumor necrosis factor.

VASOREGULATORY SIGNALING SYSTEMS

Vasoregulatory signaling within the liver occurs predominantly through paracrine mechanisms, but also, in part, through neurohumoral mechanisms. Paracrine signaling occurs through the endothelium-derived production of vasoactive mediators (Table II), which act abluminally on underlying contractile cells and thereby promote alterations in vascular diameter and perfusion. Over the past few decades, several key paracrine vasoregulatory signaling systems have been identified and characterized, including nitric oxide, endothelin (ET), and carbon monoxide (CO). Relevant neurohumoral pathways include the renin–angiotensin system as well as the sympathetic adrenergic modulator norepinephrine.

Nitric Oxide

NO is produced by the heme-binding P450-like NO synthase (NOS) enzyme family, including the endothelial, neuronal, and inducible isoforms of NOS (eNOS, nNOS, and iNOS, respectively). eNOS appears to be the most relevant isoform in the maintenance of normal hepatic vascular function, and a number of experimental studies utilizing pharmacologic and molecular approaches have established the important role of this enzyme in hepatic vasodilation. eNOS-derived NO acts in a paracrine manner on adjacent contractile cells, where it produces relaxation through a cyclic

TABLE II Major Vascular Mediators in Liver

guanosine monophosphate (cGMP)-dependent signaling pathway (Fig. 2). Shear stress, caused by the frictional force of blood within the vascular channels, is one of the most potent physiologic stimuli of NO production through eNOS. The roles of nNOS and iNOS in regulation of vascular function in liver remain less defined.

Endothelin

In normal circumstances, endothelin is also synthesized and released by liver endothelial cells in response to distinct stimuli. The G protein-coupled ET-1 receptors are located on most liver cell populations. Interestingly, it appears that ligand binding with the ET-A receptor on contractile liver cells promotes hepatic constriction, whereas ligand binding on the ET-B receptor localized to liver endothelial cells can paradoxically promote vasodilation in an NO-dependent mechanism (Fig. 3). Based on studies examining portal pressure and sinusoidal diameter in response to endothelin infusion into the portal vein, the predominant action of endothelin is to constrict veins and sinusoids within the hepatic vasculature.

Carbon Monoxide

CO may also function to maintain sinusoidal tone in a relaxed state, analogous to NO, although the potency of activation of downstream guanylate cyclase by CO is very low as compared to NO. CO is synthesized by a family of enzymes termed heme oxygenases (HOs). HO-2, which is abundantly expressed in liver endothelium, appears to be responsible for basal CO production.

Neurohumoral Regulation

Both the sympathetic adrenergic agonist, norepinephrine, and the renin-dependent vasoconstrictor, angiotensin, have some vasoreactivity in the liver. The hepatic vasculature is richly innervated with sympathetic adrenergic nerves and infusion of norepinephrine results in hepatic constriction. Angiotensin also has a constrictive effect in experimental models as well as a direct contractile effect on isolated hepatic stellate cells in culture.

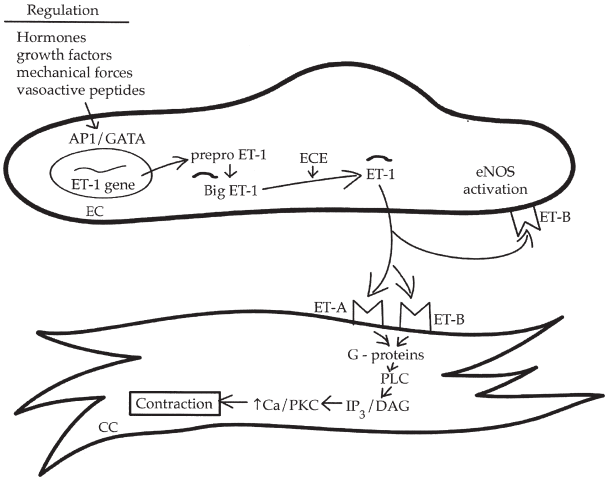

FIGURE 3 The endothelin (ET) signaling pathway. Regulation of ET-1 production occurs at the transcriptional level in response to mechanical forces, hormones, growth factors, and vasoactive peptides such as prostacyclin. Although ET-1 can paradoxically stimulate endothelial nitric oxide synthase (eNOS) activation through ligand binding on the ET-B receptor of endothelial cells (EC), the predominating action of ET-1 occurs on abluminal contractile cells through the ET-A and ET-B receptors, culminating in contraction. ECE, Endothelin-converting enzyme; PLC, phospholipase C; CC, contractile cell; DAG, diacylglycerol; IP_3, inositol trisphosphate; PKC, protein kinase C. PHYSIOLOGY OF THE HEPATIC CIRCULATION

Introduction

The hepatic vascular bed is a low-pressure system that is able to accommodate a large volume of blood; indeed, total hepatic blood flow constitutes nearly 30% of total cardiac output. The liver receives a dual blood supply (Fig. 4) from the portal vein as well as the hepatic artery, similar to the pulmonary system, which is perfused by the pulmonary artery as well as the bronchial artery. Portal venous blood comprises approximately 70–90% of total hepatic blood flow and is derived from the mesenteric venous circulation, including the digestive tract, spleen, and pancreas. Portal blood flow is determined primarily by the rate and volume of blood in the mesenteric vessels, which is, in turn, determined by dilation and constriction of the mesenteric arterioles. Hepatic arterial blood flow is derived from the celiac plexus.

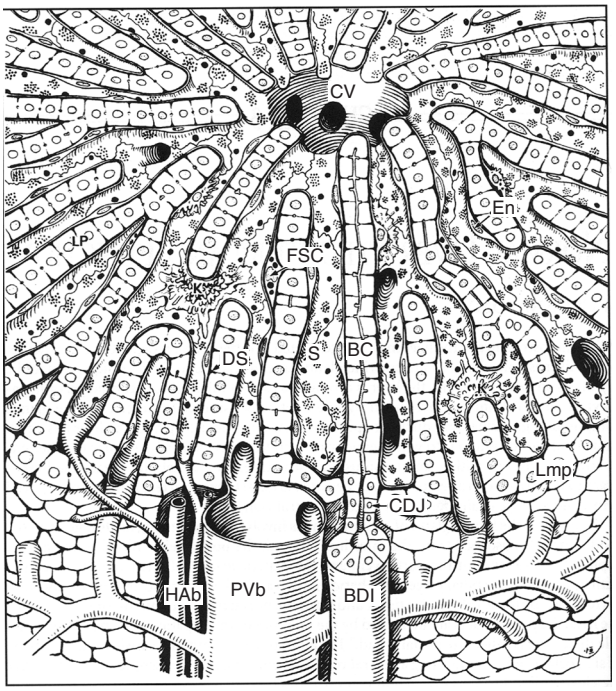

FIGURE 4 Vascular architecture of the liver. Blood flow enters the liver via the portal vein (PVb) as well as the hepatic artery (HAb). While portal blood enters directly into the sinusoids (S), hepatic arterial blood perfuses into distinct anatomic locations prior to reentering the sinusoids. Sinusoidal blood leaves the liver via the central veins (CV). Sinusoidal endothelial cells (En) form the fenestrated sinusoidal wall. Kupffer cells (K) are located within the sinusoids, whereas hepatic stellate cells, also termed fat-storing cells (FSC), lie within the space of Disse (DS), adjacent to the single layer of hepatocytes (liver plate; LP). Bile canaliculi (BC) drain bile into interlobular bile ducts (BDI) via the caniliculoductular junction (CDJ) in the opposite direction to flow in the vascular channels. Reproduced with permission from Motta, P., Muto M., and Fujita, T. (1978). "The Liver. An Atlas of Scanning Electron Microscopy," pp. 129. Igaku-Shoin Medical Publishers, Inc.

Sinusoidal Flow Regulation

Although the sinusoids are a high-compliance system, hepatic perfusion and pressure regulation are regulated, in part, through events within the hepatic sinusoids, although probably in conjunction with pre- and postsinusoidal sites, depending on the specific circumstance. Under normal physiologic circumstances, sinusoidal flow regulation occurs, in part, through the recruitment and dropout of individual sinusoidal vessels. The traditional paradigm of endothelium-dependent regulation of smooth muscle tone in sinusoids remains an area of investigation. For example, although the sinusoidal endothelial cells can produce vasoactive agents, the lack of a traditional underlying smooth muscle puts into question the precise mechanism of sinusoidal channel tone modulation. In this regard, the hepatic stellate cell may function as a sinusoidal effector cell. However, its contractile function in normal physiologic conditions remains circumspect, and the lack of contractile mechanisms in normal sinusoid has led some to believe that the site of maximal resistance within the normal liver may lie distal to the sinusoid. For example, terminal hepatic venules do possess a modest smooth muscle contractile layer and may serve as a resistance site.

Hepatic Artery and Autoregulation

Under normal physiologic conditions, the hepatic artery supplies only 10–25% of total hepatic blood flow, with the remainder of hepatic blood flow derived from the portal venous system. Although a portion of the hepatic arterial flow does eventually coalesce with portal venous blood within the hepatic sinusoids, the hepatic artery maintains a unique anatomical distribution pattern that is distinct from that of the portal vein. The major sites of primary hepatic arterial flow appear to include the peribiliary plexus, the vasa vasorum of hepatic veins, the portal tract interstitium, and Glisson's capsule, although the distribution does vary among species. Although there may be bypass tracts directly to the hepatic veins, much of the hepatic arterial flow from these sites does eventually reanastamose with portal vein derived blood within the parenchymal sinusoids, thereby providing highly oxygenated arterial blood to the hepatocytes in conjunction with the poorly

oxygenated portal venous blood. Interestingly, the high-pressure hepatic arterial flow does not contribute significantly to the overall portal pressure, although the mechanism of sinusoidal decompression of high-pressure arterial flow remains unclear. Although impairment of hepatic arterial flow has limited untoward effects on the liver under normal physiologic conditions, conditions associated with diminished portal vein flow, such as portal vein thrombosis and liver cirrhosis, result in a significant dependence on hepatic arterial flow to maintain hepatic parenchymal perfusion. Another interesting characteristic of hepatic arterial flow is its propensity to supply tumors with perfusion, a characteristic that is exploited for selective therapeutics through approaches such as hepatic artery chemoembolization of hepatoma. Another important function of the hepatic arterial blood flow is to maintain constant total hepatic blood flow through a process termed autoregulation. This requires compensatory adjustment of hepatic arterial flow in response to changes in portal blood flow. Maintenance of total hepatic blood flow at a constant level is important to maintain normal portal pressure, as well as to maintain the homeostatic balance of xenobiotics and endogenous peptides cleared within the liver. Adenosine concentration in the space of Mall is thought to mediate hepatic blood flow autoregulation through a mechanism termed the hepatic arterial buffer response.

PATHOPHYSIOLOGY OF HEPATIC CIRCULATION

Hepatic Circulation in Liver Cirrhosis

Important changes occur in the hepatic circulation in liver cirrhosis; the changes culminate in an increase in intrahepatic vascular resistance, an important component in the development of portal hypertension and its clinical sequelae. Much of the increase in intrahepatic resistance occurs through restrictive factors caused by architectural remodeling of the parenchyma and vascular channels. For example, deposition of collagen within the space of Disse and the development of regenerative nodules both likely account for a significant portion of the increase in intrahepatic resistance that occurs in cirrhosis. However, a smaller, yet important, component of the increase in intrahepatic resistance occurs through the dysfunction of hepatic vasoregulatory cells and ensuing development of hepatic vasoconstriction. Indeed, cumulative experimental evidence from independent groups has demonstrated an imbalance of vasoactive factors in liver cirrhosis, which is characterized by enhanced production of the constrictor endothelin and diminished production of the vasodilator NO. In addition to phenotypic defects in the endothelial cell production of these molecules, evidence also suggests that the effector cell mediating hepatic constriction may be the activation and enhanced contractility of the hepatic stellate cell. Elucidation of the complex regulatory mechanisms that mediate NO and ET-1 signaling in hepatic vasoregulatory cells may provide opportunities for future experimental therapeutics for treatment of cirrhosis.

Hepatic Circulation in Ischemia–Reperfusion

Clinical scenarios such as orthotopic liver transplantation are often associated with the pathophysiologic syndrome of ischemia–reperfusion, which causes parenchymal liver injury, in part, through hepatic microcirculatory dysfunction. Although the duration of ischemia plays a role in this process, the reperfusion process appears to be a particularly injurious event in the ensuing microcirculatory injury process. Reperfusion injury causes microcirculatory dysfunction through different mechanisms, including an imbalance of vasoactive agents, which promotes sinusoidal constriction and an increased production of reactive oxygen species, which alters the oxidant/antioxidant status of the vasculature in a detrimental way.

Hepatic Circulation in Response to Endotoxin

Clinical conditions such as alcoholic liver disease and sepsis syndrome are associated with hepatic vascular dysfunction. Alcoholic liver disease results in the development of increased intrahepatic resistance, often in the absence of appreciable fibrosis. Sepsis syndrome is commonly associated with liver enzyme abnormalities with changes in the hepatic microcirculation. Hepatic circulatory dysfunction in these syndromes may have a common mechanistic link, because both are associated with elevated endotoxin delivery to the portal vein. Portal venous endotoxin stimulates Kupffer cells in the sinusoids to produce tumor necrosis factor, an inflammatory cytokine, which, in turn, causes circulatory disturbances, including sinusoidal vasoconstriction, leukocyte adherence to vascular channels, and an ensuing reduction in sinusoidal perfusion. These mechanisms may be relevant to the syndromes of alcoholic liver injury and sepsis.

asterixis Motor disturbance consisting in the failure to actively maintain posture or position; usually elicited by dorsiflexion of the patient's hand with the patient's arms outstretched and fingers separated.
confusional syndrome Disturbed orientation in regard to time, place, or person, sometimes accompanied by disordered consciousness.

Hepatic encephalopathy can be defined as a potentially reversible disturbance in central nervous system function secondary to hepatic insufficiency or portal–systemic shunting. This broad definition reflects a spectrum of neurologic manifestations, ranging from subtle alterations in neuropsychological tests to appearance of deep coma, brain edema, and intracranial hypertension. The significance of the development of hepatic encephalopathy in a patient with liver disease cannot be underemphasized. A first episode in a patient with cirrhosis carries a poor prognosis and should prompt consideration of liver transplantation. Development of hepatic encephalopathy in a patient with acute liver failure marks the transition to a life-threatening disease; in this condition, the degree of hepatic encephalopathy is a strong predictor of outcome and an important criterion for performing liver transplantation.

CLASSIFICATION

The nomenclature of hepatic encephalopathy (HE) has been a source of confusion, with some terms implying different meanings to different investigators. A new classification of HE takes into account both the type of hepatic abnormality and the duration/characteristics of HE symptoms, categorizing HE in groups and subgroups:

a. Encephalopathy associated with acute liver failure (type A, for acute).
b. Encephalopathy associated with portal–systemic bypass and no intrinsic hepatocellular disease (type B, for Br-pass).
c. Encephalopathy associated with cirrhosis and portal hypertension and/or portal–systemic shunts (type C, for cirrhosis).

We can divide type C further into:

c.1. Episodic HE. Subdivided into precipitated and spontaneous, depending on the presence of precipitating factors. "Recurrent encephalopathy" refers to the occurrence of at least two episodes of episodic HE within 1 year.

c. Encephalopathy associated with cirrhosis and portal hypertension and/or portal–systemic shunts (type C, for cirrhosis).

We can divide type C further into:

c.1. Episodic HE. Subdivided into precipitated and spontaneous, depending on the presence of precipitating factors. "Recurrent encephalopathy" refers to the occurrence of at least two episodes of episodic HE within 1 year.

Copyright 2004, Elsevier (USA). All rights reserved.

c.2. Persistent HE. Includes cognitive deficits that impact negatively on social and occupational functioning, and is subdivided into mild and severe. Treatment-dependent persistent HE is a subgroup in which overt symptoms develop promptly after discontinuing medication.

c.3. Minimal HE. Refers to abnormalities of cognition, affection/emotion, behavior, or bioregulation that are not usually detected by regular clinical examination; diagnosis requires specific neuropsychological and neurophysiological tests.

PATHOGENESIS

A common pathogenic notion is that HE is caused by substances that are efficiently metabolized by the liver. In liver disease as well as in portal-systemic shunting, these substances gain access to the systemic circulation. Increased brain exposure to these substances leads to a disturbance of normal neurotransmission and results in the clinical symptoms that are characteristic of HE.

Neuropathology

With the exception of brain edema in acute liver failure (ALF), no major anatomical alterations are found in the brains of patients in hepatic coma. However, ultrastructural studies point to the astrocyte as the main cell affected in HE. A distinctive morphologic alteration of astrocytes—Alzheimer type II astrocytosis—has been described in the HE of chronic liver disease, with cells exhibiting enlarged nuclei, peripheral margination of chromatin, prominent nucleoli, and excessive accumulation of glycogen. These morphological changes, however, are not specific to HE. In addition, selective swelling of astrocytes is a consistent finding in patients and experimental models of ALF and HE. It is noteworthy that the magnetization transfer ratio, a nuclear magnetic resonance index that reflects the water content of the tissues, is altered in patients with chronic liver disease and returns to normal after performance of liver transplantation, suggesting that low-grade brain edema may be present in the HE of chronic liver disease.

Putative Toxins

Ammonia has been viewed as the most important factor in the genesis of HE. Ammonia is detoxified in the brain through binding to glutamate, resulting in the formation of glutamine. This reaction is catalyzed by the astrocytic enzyme glutamine synthetase. An increase in brain glutamine is a consistent finding in patients and experimental models of HE. Because glutamine is an organic osmolyte, its accumulation may play a major role in astrocyte swelling. In recent years, abnormalities in the normal concentrations of brain organic osmolytes have become evident in HE, suggesting underlying disturbances in cell volume homeostasis.

Increased availability of natural benzodiazepines, which are agonist ligands of the γ-aminobutyric acid (GABA) receptor complex, has been also proposed as the cause of HE. Even though several lines of evidence point to an increased GABA-ergic tone in HE, the presence of such natural benzodiazepines has not been totally confirmed. Other compounds, such as manganese, aromatic amino acids, mercaptans, phenols, or short-chain fatty acids, have also been associated with the development of HE. Hypermanganesemia has been related to parkinsonian manifestations. The altered ratio between aromatic amino acids and branched-chain amino acids in plasma of patients with liver failure, in favor of the former, has been postulated to result in the synthesis of false neurotransmitters. This hypothesis, however, is still far from proven.

Altered Neurotransmission

Multiple neurotransmitter systems have been found to be altered in patients with HE. It is convenient to remember at this point that normal neurotransmission is highly dependent on adequate astrocyte function, and there is a linkage between astrocytic alterations and disturbed neurotransmission. Glutamate is the main excitatory neurotransmitter of the brain and the system for which most abnormalities have been shown, including decreases in total brain glutamate, increases in extracellular glutamate, and decreases in astrocytic glutamate transporters and receptors. Alterations in the GABA system, such as increased GABA-ergic tone, activation of the peripheral-type benzodiazepine receptors, and increased neurosteroids, have been also described. Increased metabolism of serotonin, decreases in dopamine (DOPA) receptors and increased degradation of DOPA, and increases in endogenous opioids and histamine receptors are alterations in other neurotransmitter systems that have been also described in HE.

CLINICAL PRESENTATION

Episode of Hepatic Encephalopathy

An acute confusional syndrome includes an impaired mental state, neuromuscular abnormalities, fetor hepaticus, and hyperventilation. The symptoms appear abruptly and develop over a period of hours

to days, with oscillation of severity over time being an important clinical feature. Initial subtle symptoms, such as changes of personality or disturbances of sleep, may progress to inappropriate behavior, confusion, stupor, and coma if no therapeutic interventions are initiated. Asterixis is very characteristic of mild and moderate stages of HE. However, asterixis is not exclusive of HE and disappears as HE progresses to coma.

Once an episode of HE has developed, relapses are common. The patients usually respond well to treatment, with reestablishment of cognitive function. Careful neurologic and neuropsychological examinations between episodes may, however, reveal abnormalities.

The clinical manifestations of an episode of HE occurring in chronic liver disease are similar, though not identical, to those seen in ALF. An episode of HE in cirrhosis is characterized by a more insidious presentation, with fluctuations of mental state; a precipitating factor is commonly identified and patients usually respond to treatment, with reversal to normal mental status within hours or few days. In contrast, HE in ALF is more progressive and less fluctuating; its evolution follows closely that of the underlying liver disease, patients respond poorly to usual treatments, and brain edema and intracranial hypertension may develop.

Persistent Hepatic Encephalopathy

Manifestations that do not reverse after adequate treatment are considered to be severe when daily activities are impaired. The most extreme manifestations include, severe parkinsonism and myelopathy, in combination with other neurologic manifestations such as ataxia, dysarthria, gait abnormalities, or tremor. This stage of the disease is rarely seen nowdays due to the availability of liver transplantation and the small number of patients that undergo surgical portal–systemic shunting.

DIAGNOSIS

Clinical history and physical examination are the most valuable tools to make the diagnosis. A history of chronic liver disease or the presence of altered liver function tests in a patient with the described symptoms and signs strongly suggests HE. However, the diagnosis of HE is a diagnosis of exclusion. Other diagnostic possibilities to exclude are intracranial occupying lesions, cerebrovascular events, infectious diseases, or other metabolic disorders. Asterixis can also be seen in patients with uremia, hypercapnia, phenytoin intoxication, or hypomagnesemia. Detailed physical examination, searching for signs of cirrhosis, and determination of plasma ammonia or performance of specific neurophysiological or neuroimaging techniques may be useful to make a positive diagnosis.

Grading of HE

Grading of HE is necessary to assess the evolution of the condition and the response to treatment. The two most useful and recommended methods of grading HE are based on clinical findings. The West Haven criteria are a semiquantitative classification that groups HE in four stages, covering the whole spectrum of HE except minimal HE. Thus, stage I includes trivial lack of awareness, euphoria, anxiety, shortened attention span, and impairment of skills such as addition or subtraction; stage II is characterized by lethargy, time disorientation, obvious personality change, and inappropriate behavior; stage III includes somnolence to semistupor but responsiveness to stimuli, confusion, gross disorientation, and bizarre behavior; and stage IV is coma and no response to noxious stimuli.

The Glasgow coma scale, initially developed for patients with neurotrauma, is less subject to observer variability, but its use has not been validated in metabolic encephalopathies. It measures the response to eye opening, verbal behavior, and motor responsiveness, and quantifies neurologic impairment in a continuous numerical scale. It is mainly useful for evaluation of advanced stages of HE.

The portal–systemic encephalopathy index, which combines assessment of mental state, arterial ammonia, electroencephalography, number connection test, and estimation of degree of asterixis, is another method that has been extensively used to grade HE. However, a consensus has been recently reached indicating that it is not adequate for clinical followup evaluation and it is not recommended for clinical trials.

Neuropsychological Tests

Neuropsychological testing plays a primary role in the diagnosis of minimal HE and in the assessment of cognitive function in patients with chronic HE. The tests are very sensitive, but may be influenced by multiple factors such as age, educational background, or repeated learning. An adequate degree of arousal is necessary for administration of these tests. The psycometric hepatic encephalopathy score (PHES) is a standardized test battery that includes number connection tests A and B and the line-tracing, the serial-dotting, and the digit-symbol tests. Its use was endorsed by a recent consensus, due to its ability to discriminate minimal HE from stage I HE.

Neurophysiological Tests

Electroencephalogram shows characteristic changes in patients with HE, including replacement of the normal background waves of 9 to 12 cycles/second by progressively slower waves and the appearance of high-voltage, low-frequency triphasic waves. The latter have been described, however, in other forms of metabolic encephalopathies. External recording of the integrated electrical response to visual, auditory, or somatosensory stimuli is the basis of the use of evoked potentials. The recordings reflect the function of the cerebral cortex and neuronal networks that are involved in each corresponding pathway. They are considered more sensitive than the conventional electroencephalogram for the diagnosis of mild forms of HE.

Neuroimaging

Computed X-ray tomography plays an important role in the differential diagnosis of the patient with acute neurological symptoms. Brain atrophy is commonly seen in the setting of HE, but no specific abnormalities of HE are observed. In patients with ALF, computed X-ray tomography is not sensitive enough for early detection of brain edema.

Magnetic resonance imaging of the brain of patients with cirrhosis characteristically shows hyperresonant globus pallidus on T1-weighted images. These images are thought to be secondary to deposition of manganese in basal ganglia. Magnetic resonance spectroscopy allows the *in vivo* measurement of common chemicals in the human brain. The characteristic pattern of patients with HE and cirrhosis in the proton spectra consists of an increase in the glutamine/glutamate peak coupled with a decrease in the myo-inositol and choline signals.

TREATMENT

Multiple therapeutic modalities have been used for the treatment of HE. However, their efficacy has been seldom assessed in well-designed clinical trials.

General Measures

The mental status of the patient with HE may change rapidly and, thus, special attention by the nursing staff and specific measures to avoid body harm are required. For patients in stage III or IV of HE, prophylactic tracheal intubation should be considered, especially in the setting of ALF. An adequate hydration and nutritional state should be maintained during the period of altered mental state. Identification and removal of precipitating factors is a mainstay of treatment in HE. Diagnosis of infection is particularly important. Gastrointestinal hemorrhage, renal and electrolyte abnormalities, use of psychoactive medications, constipation, or excessive dietary protein intake are also common precipitants. Adequate treatment for each of these factors, if present, should be promptly instituted.

Reduction of Nitrogenous Load from the Gut

Current consensus exists that prolonged periods of dietary protein restriction should be avoided. Patients should receive the maximum tolerable protein intake, preferably from vegetable and dairy sources rather than animal protein, due to their high fiber content and favorable calorie-to-nitrogen ratio, respectively.

Colonic cleansing lowers blood ammonia levels in cirrhosis. Nonabsorbable disaccharides, such as lactulose and lactitol, remain the first-line pharmacological treatment of HE. In addition to their cathartic effect, they produce acidification of the colon, which favors nonionic diffusion of ammonia into the lumen and increases fecal nitrogen excretion. Therapy is aimed at obtaining two or three soft bowel movements a day. When nonabsorbable disaccharides are taken for prolonged periods, abdominal cramping and flatulence are common, and hypernatremia can result from excessive diarrhea. Lactitol and lactulose enemas have been also shown effective, though the quality of data from all clinical trials with these agents is questionable.

Antibiotics are also a therapeutic alternative. They can reduce ammonia-producing bacteria in the colon. Neomycin, the most commonly used agent, may have actions at the level of the intestinal mucosa, in addition to its antibacterial effect. It is poorly absorbed in the intestinal tract, but oto- and nephrotoxicity may occasionally develop. Metronidazole, which affects a bacterial population different from that targeted by neomycin, can also improve HE. Dosing should be done with care. Other poorly absorbable antibiotics, such as vancomycin or rifaximin, have also shown beneficial effects.

Improvement of Extraintestinal Elimination of Ammonia

Several agents have been used to enhance the metabolism of ammonia in splanchnic and peripheral tissues, with questionable efficacy. Patients with cirrhosis are frequently zinc deficient; zinc is a cofactor in all enzymes of the urea cycle, thus administration of zinc acetate to improve ureagenesis may be specially

indicated in patients with associated malnutrition. Administration of ornithine-aspartate provides substrates for the urea cycle in the liver as well as for the synthesis of glutamine via transamination, which is especially relevant in the muscle. Preliminary experiences in acute and chronic HE have been encouraging.

Counteracting Abnormalities of Central Neurotransmission

Intravenous administration of flumazenil is effective in improving mental state in a limited group of patients with cirrhosis and HE, being particularly helpful if benzodiazepine ingestion is suspected. However, an oral preparation is not available and long-term administration has not been evaluated. Bromocriptine has been used to correct abnormalities of dopaminergic neurotransmission, but at the present time, it is indicated only for the treatment of chronic encephalopathy unresponsive to other therapy. Administration of intravenous and oral solutions of branched-chain amino acids has been evaluated in several clinical trials. However, there is no clear benefit with respect to conventional therapy, and administration of these solutions should be reserved to patients with intolerance to dietary protein.

Manipulation of Splanchnic Circulation

In HE caused by congenital portal–systemic shunts and in those patients with severe HE after placement of a transjugular intrahepatic portosystemic stent shunt, occlusion or reduction of the shunt via surgery or via interventional radiology should be considered. This may be also an option in selected patients with cirrhosis and large spontaneous portal–systemic shunts, if they present with recurrent episodes of HE without precipitating factors.

Hepatic Granulomas

STACEY R. VLAHAKIS
Mayo Clinic and Foundation

caseating granuloma Aggregation of granulofibrillar necrotic material, and sometimes eosinophilic granules.
fibrin-ring granuloma Tissue mass with a central cavity surrounded by a ring of fibrin and epitheloid macrophages.
lipogranuloma Tissue mass containing lipid vacuoles surrounded by macrophages, lymphocytes, and collagen fibers.
noncaseating granuloma Aggregation of epitheloid macrophages, lymphocytes, and multinucleated giant cells.

Granulomas of the liver can be found in a variety of diseases; up to 10–15% of liver biopsy specimens describe granulomas on pathological review. The presence of a granuloma signifies chronic inflammation of the liver parenchyma in reaction to a foreign agent. The inciting agent induces a cell-mediated immune response that stimulates and attracts macrophages and T cells. The macrophages transform into epitheloid cells and accumulate, forming the granuloma.

INTRODUCTION

Histologically, there are four types of granulomas; categorizing a granuloma by type can at times aid in defining the cause of the inflammation that produced the granuloma. Noncaseating granulomas, the most common type found in liver biopsies, are found in a variety of disease states, including sarcoidosis, vasculitis, primary biliary cirrhosis (PBC), and infectious diseases. Caseating granulomas are commonly found in association with mycobacterial or fungal infections. Lipogranulomas are frequently associated with fatty liver or mineral oil ingestion. Fibrin-ring granulomas result from a number of infectious diseases, such as Q fever, or hepatitis A.

CAUSES OF HEPATIC GRANULOMAS

In over half the cases of identified hepatic granulomas, the patient experiences nonspecific clinical symptoms such as fever, weight loss, anorexia, or laboratory evidence of inflammation. Hepatomegaly is reported in about half the cases. Splenomegaly is rare, as is jaundice, which occurs only when associated with bile duct injury. Radiologic imaging of the liver is usually nonspecific, but at times granulomas can coalesce into small nodules that may be detectable by computer tomography (CT) scan or ultrasound. Therefore, a liver biopsy is needed to conclusively establish the presence of hepatic granulomas.

A comprehensive list of potential causes of hepatic granulomas is given in Table I. Essentially, the causes can be separated into five categories: systemic diseases, infectious diseases, malignancies, reactions to chemicals and drugs, and idiopathic.

Sarcoidosis is the most common systemic disease to cause hepatic granulomas, accounting for up to 30% in some case series. Most patients are asymptomatic; for those who have constitutional symptoms, corticosteroid therapy may improve symptoms, but improvement in liver size or liver tests varies. Liver diseases such as PBC, primary sclerosing cholangitis (PSC), and steatosis can be associated with granulomas, but their presence has variable prognostic significance.

Infectious diseases comprise the most diverse causes of hepatic granulomas. Many types of infectious organisms, including mycobacteria, bacteria, fungi, treponemes, rickettsia, viruses, metazoa, and protozoa, can result in hepatic granulomas. Many of these infectious agents are intracellular and cause an inflammatory response in the liver that results in granuloma formation. The most common infectious cause of hepatic granulomas worldwide is *Mycobacteria tuberculosis*. This usually occurs with the miliary form of tuberculosis, and can be associated with caseating necrosis. Throughout the developing world, secondary syphilis and schistosomiasis represent other common infectious diseases causing hepatic granulomas.

Hodgkin's lymphoma is the most common malignant disease associated with hepatic granulomas, which can occur in up to 20% of affected patients. Granulomas, however, are not indicative of malignant involvement of the liver. Chemical exposures, hypersensitivity drug reactions, steatosis, cholestasis, and hepatitis can also result in hepatic granulomas. Idiopathic granulomatous hepatitis, originally described

TABLE I Causes of Hepatic Granulomas

Cause	Disease/example
Systemic diseases	Sarcoidosis, Wegner's granulomatosis, temporal arteritis, polymyalgia rheumatica, erythema nodosum, allergic granulomatosis, Crohn's disease, ulcerative colitis, idiopathic hypogammaglobulinemia, chronic granulomatous disease, systemic lupus erythematosus Liver diseases: primary biliary cirrhosis, primary sclerosing cholangitis, hypersensitivity cholangitis, steatosis
Infectious diseases	Mycobacteria: tuberculosis, *Mycobacterium avium intracellulare*, atypical mycobacteria, leprosy Bacteria: brucellosis, tularemia, yersinosis, actinomycosis, *Bartonella henslae* (cat-scratch disease), listeriosis, meliodosis, *Tropheryma whippelii* (Whipple's disease), typhoid, *Rickettsia, Coxiella burnetti* (Q fever), boutonneuse fever, *Treponema* (syphilis) Fungi: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, candidiasis, aspergillosis Viruses: Epstein–Barr virus, cytomegalovirus, hepatitis C virus, hepatitis A virus, Coxsackie Metazoa: schistosomiasis, larva migrans viscerale, fascioliasis Protozoa: leishmaniasis, toxoplasmosis
Malignancy	Hodgkin's lymphoma, non-Hodgkin's lymphoma, carcinoma
Chemicals/drugs	Hypersensitivity drug reaction, sulfonamides, isoniazid, allopurinol, beryllium, throrotrast, copper sulfate
Idiopathic	Idiopathic granulomatous hepatitis

to cause noncaseating granulomas associated with constitutional symptoms and no extrahepatic involvement, may respond to steroids and has a very favorable prognosis.

DIAGNOSTIC APPROACH

Once hepatic granulomas have been confirmed by pathologic review, the diagnosis can be established using a combination of clinical and laboratory data. The remainder of the biopsy specimen should be evaluated for signs of malignancy or other liver disease, such as PBC, PSC, or steatosis. Polymerase chain reaction (PCR) can be performed to isolate infections involving mycobacteria, *Tropheryma whippelii*, *Bartonella henslae*, Epstein–Barr virus (EBV), or cytomegalovirus (CMV). In addition, gram stains, fungal stains, and cultures from the biopsy and serum can be used to determine bacterial, mycobacterial, and fungal etiologies. The patient should also be questioned about drug history and chemical exposures and should be examined for signs of extrahepatic involvement that may suggest diseases such as systemic lupus, sarcoidosis, lymphoma, or inflammatory bowel disease. Laboratory tests and serologies should be performed to screen for liver diseases and for infectious agents. If no cause is found for the hepatic granuloma, the patient should be reevaluated 3 months later. The treatment of hepatic granulomas is directed at the cause of the liver inflammation.

Hepatitis A

JOHN J. POTERUCHA
Mayo Clinic

fecal–oral transmission Acquisition of an infection by ingestion of fecally contaminated material that contains the infectious agent.
parenteral transmission Acquisition of an infection by exchange of the infectious agent via blood or blood-contaminated body fluids.
prodrome Symptoms indicating the onset of a disease.

Hepatitis A virus is an RNA virus that is a frequent cause of acute hepatitis. The virus is generally spread by person-to-person contact although transmission from contaminated food and water also occurs. The disease is characterized by liver inflammation with increases in liver enzymes and often jaundice. Children with an acute infection have less severe disease manifestations than do adults with acute hepatitis A. Supportive care results in resolution in most patients. A safe and effective vaccine has been developed and is recommended for certain individuals at high risk for the disease or its complications.

INTRODUCTION

Hepatitis A virus (HAV) is the most frequent viral cause of acute hepatitis in the United States. The U. S. Centers for Disease Control and Prevention estimates that hepatitis A causes 180,000 acute infections per year. The average cost per acute hepatitis A case ranges from $1817 to $2459. Because HAV does not cause chronic liver disease and only rarely results in death from acute liver disease, there has been less emphasis in the literature on hepatitis A than on hepatitis B or C. However, HAV causes large outbreaks due to person-to-person spread and may result in fulminant hepatic failure.

VIROLOGY

HAV is a single-stranded RNA virus that is a member of the genus Hepatovirus of the family *Picornaviridae* ("small RNA virus"). HAV is 27 nm and is a spherical, nonenveloped virus with a capsid consisting of 32 subunits. The positive-stranded RNA is approximately 7.5 kb in length and includes a 5′-untranslated segment, a single open reading frame encoding a polyprotein of 2227 amino acids, and a 3′ noncoding region with a poly(A) terminus. The polyprotein is cleaved by a 3C proteinase into 11 structural and nonstructural proteins. Although different HAV strains can be determined using molecular techniques, there are no significant antigenic differences and thus there is only one viral serotype. Infection with one strain or vaccination imparts immunity to all strains of the virus. The ability to detect different viral genotypes can be useful epidemiologically to investigate outbreaks of hepatitis A.

Humans and certain nonhuman primates are the only natural hosts of HAV, although only humans seem to develop significant hepatitis. HAV is usually transmitted by the fecal–oral route. It is postulated that the virus is absorbed in the small intestine, passes via the portal vein to the liver, and is taken up by the hepatocyte. HAV replicates in the hepatocyte cytoplasm where antigen is detected 1 week after inoculation. Virions are then secreted into the bile canaliculus or released into the systemic circulation. Virus may also replicate in the crypt cells of the small intestine, which helps account for the large amount of virus present in feces within a few weeks after exposure. Viremia occurs although HAV concentrations are much lower in blood than in feces. Viral concentrations in blood tend to be highest in the prodromal and early clinical phases of the illness. Although the amount of virus in the feces decreases dramatically soon after the onset of the clinical illness, viral antigen can be found in the stool as long as 2 weeks after the onset of symptoms. Reverse transcription–polymerase chain reaction can detect viral RNA as long as 2 months after the onset of clinical symptoms although the significance of this finding in terms of transmission is not clear.

HAV likely induces hepatocyte injury by an immune mechanism rather than by a cytopathic effect. Large quantities of virus are produced in the liver before the onset of clinical evidence of hepatitis, and HAV in cell culture is not associated with hepatocyte damage. Virus-specific cytotoxic T cells have been identified and these cells secrete cytokines that likely are involved in the inflammatory response and in the resolution of the infection.

 Copyright 2004, Elsevier (USA). All rights reserved.

EPIDEMIOLOGY AND TRANSMISSION

Hepatitis A is a robust virus and the ability to persist in a variety of unfavorable environments allows the virus to have a high attack rate, with up to 90% of those exposed becoming infected. HAV is largely transmitted by person-to-person contact although outbreaks due to ingestion of contaminated food or water also occur. Close living quarters, such as day-care centers, institutions for the disabled, and military institutions, enhance the spread of the virus. The secondary household attack rate is approximately 20%. Because of fecal–oral transmission and lack of clinical symptoms of hepatitis A, children are most likely to spread the infection and numerous outbreaks of hepatitis A in day-care centers have been reported. A short duration of the viremia and the relatively low concentration of HAV in blood help make parenteral transmission of hepatitis A unusual although there have been reported outbreaks in intravenous drug users and recipients of contaminated blood products.

Risk factors for hepatitis A acquisition in the United States are personal contact with an infected patient (12–26% of infections), day-care contact (11–16%), international travel (4–6%), and recognized food- or water-borne outbreaks (2–3%). During recent outbreaks, up to 10% of reported cases occurred in illegal drug users and homosexual men. No risk factor can be identified in 50% of patients acquiring hepatitis A infection.

The overall prevalence of prior hepatitis A infection is determined by assaying for immunoglobulin G antibody against HAV (IgG anti-HAV). The seroprevalence within a region depends on the age of the patient and on living and sanitation conditions. Countries with lower socioeconomic levels and crowded living conditions, such as Ethiopia, are characterized by high transmission rates of hepatitis A such that over 90% of the population will have IgG anti-HAV by the age of 5 years. In the United States, some of the southwestern states have the highest seroprevalence rates of hepatitis A.

Improvements in sanitation, food handling, and control of water supplies have changed the frequency of IgG anti-HAV prevalence. The most recent data show that approximately one-third of the U. S. population has serologic evidence of a prior hepatitis A infection. The highest prevalence rates, approximately 75%, are seen in those >70 years of age. The higher prevalence of infection in older individuals is likely due to a cohort effect, reflecting the fact that the chance of infection during childhood was greater years ago than it has been more recently.

Food-borne outbreaks of HAV are relatively uncommon but have been reported with frozen strawberries, fresh produce, and seafood. Consumption of raw bivalves, such as oysters and clams, is an especially important source of transmission. HAV can survive for extended periods of time in seawater, with viral nucleic acids being detected months after being experimentally seeded in salt water. Bivalves filter large volumes of seawater, thereby concentrating the amount of ingested virus. In addition, bivalves are often harvested from shallow waters near populated areas where water is more likely to be contaminated by sewage.

DIAGNOSIS

The typical clinical and serologic course of acute hepatitis A is shown in Fig. 1. Because there is only one serotype of hepatitis A, one antibody test is sufficient for diagnosis. IgM anti-HAV has a sensitivity of 100%, a specificity of 99%, and a positive predictive value of 88%. Rarely, IgM anti-HAV may not be measurable early in the disease course and repeat testing is advised if clinical suspicion remains high. IgM anti-HAV usually clears by 4 months although it persists for more than 6 months in 25% of patients. IgG anti-HAV generally appears within a few months after infection and persists for life, offering immunity against further infection.

Aminotransferases are the most sensitive markers of hepatocyte injury in acute hepatitis A, initially becoming abnormal during the prodromal phase. The peak levels of aspartate aminotransferase and alanine aminotransferase are generally 1000–2000 IU/liter and fall approximately 10% per day but can take weeks or even months to return to normal. Bilirubin is often elevated, especially in older children and adults. Bilirubin tends to fall at a rate of approximately 50% per week but can remain elevated for months in patients with a prolonged cholestatic phase. Alkaline phosphatase is normal or only modestly elevated unless the patient enters a prolonged cholestatic phase of the illness.

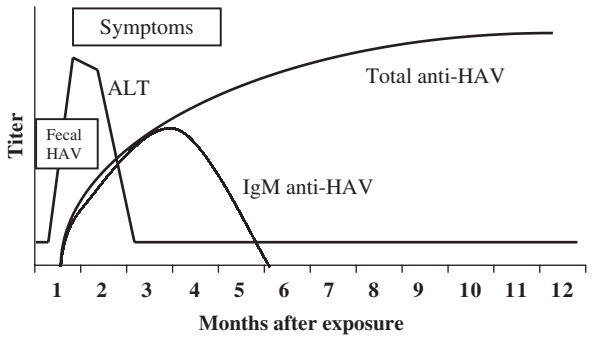

FIGURE 1 Clinical and serologic course of hepatitis A. ALT, alanine aminotransferase.

More severe episodes of hepatitis A are characterized by increases in prothrombin time and decreases in serum albumin and factor V. A mild polyclonal elevation in gamma globulin may be seen, although the elevations are less than would be seen in autoimmune hepatitis. Low-titer autoantibodies are occasionally identified in acute hepatitis A.

Liver biopsy is not necessary for diagnosis and should only rarely be performed in patients with hepatitis A. The typical features of acute hepatitis are hepatocellular degeneration with apoptotic change and variable degrees of portal and lobular inflammation. Histologic findings cannot differentiate between acute hepatitis A and acute hepatitis B. Using *in situ* hybridization techniques, HAV RNA can be detected in hepatocytes, sinusoidal cells, and inflammatory cells. The detection of viral RNA in phagocytic cells suggests that these cells are responsible for clearance of the virus, probably due to the uptake of viral–antibody complexes.

CLINICAL MANIFESTATIONS

The clinical manifestations of hepatitis A are variable, ranging from asymptomatic infection to life-threatening fulminant hepatic failure. Age at acquisition is an important factor in the severity and nature of symptoms of acute hepatitis A (see Fig. 2). Infection with hepatitis A in children less than 6 years of age leads to jaundice in fewer than 10% of cases although most patients have nonspecific symptoms such as fever, arthralgias, and diarrhea. Approximately 50% of individuals between the ages of 6 and 14 years develop jaundice with acute hepatitis A, whereas $>80\%$ of patients greater than 14 years of age develop jaundice. The nonspecific, nonicteric nature of symptoms of acute hepatitis A in children facilitates transmission of the virus because the need to address contacts is not recognized. Because of the decline in acquisition of hepatitis A during childhood, an increasing number of adults are less likely to have immunity and therefore more likely to develop severe disease at the time of infection. Pregnant women acquiring hepatitis A do not have a more severe disease course than other infected patients nor is there an increase in fetal loss.

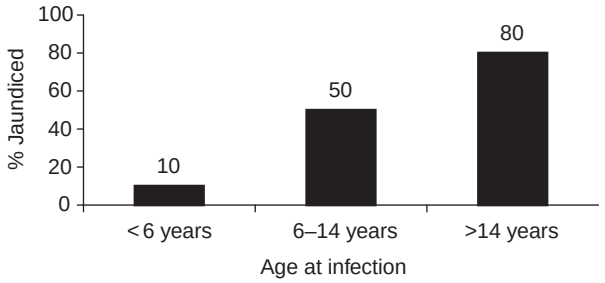

FIGURE 2 Prevalence of jaundice in acute hepatitis A varies with age at infection.

The incubation period of hepatitis A is 15–49 days with a mean of 30 days. There is a 5- to 7-day prodromal period characterized by anorexia, nausea, malaise, and occasionally fever, headache, and abdominal pain. When jaundice occurs, it happens within 2 weeks after the onset of the prodrome and is preceded by dark urine. After jaundice appears, the nonspecific symptoms often subside. The duration of jaundice is generally 5–30 days, with an average bilirubin level of 7 mg/dl. Approximately 10–15% of symptomatic persons have a prolonged illness characterized by either prolonged cholestasis or episodes of relapsing and remitting disease. Prolonged cholestasis can result in jaundice for up to 6 months. Relapsing hepatitis is associated with increases in aminotransferases and reappearance of viral particles in the stool. HAV does not cause chronic hepatitis although acute hepatitis A infection has been reported to precipitate autoimmune hepatitis.

Fulminant hepatitis A, by definition a severe hepatitis with portal systemic encephalopathy, rarely occurs. The frequency is difficult to quantify but it is estimated that the fatality rate of all hepatitis A cases is 1% and most of this mortality is due to fulminant hepatitis A. As might be expected, fatality rates vary with age. Infants and children have a fatality rate of 0.1% and those over 40 years of age have a fatality rate of 1.1%. In a recent U. S. study of fulminant hepatic failure, hepatitis A was the etiology in 7% of cases. The same investigators also suggested that the recovery from fulminant hepatitis A is 69%, significantly higher than previously thought and higher than in patients with fulminant hepatitis B.

Fulminant hepatitis A may be more common in patients who have chronic hepatitis C prior to the acquisition of hepatitis A. One study showed than 7 of 17 (41%) chronic hepatitis C patients acquiring hepatitis A developed fulminant hepatitis compared to 0 of 10 chronic hepatitis B patients developing acute HAV. It is recommended that all patients with chronic liver disease be vaccinated against hepatitis A if not already immune.

Extrahepatic manifestations of acute hepatitis A are unusual. One study reported that hemolysis and acalculous cholecystitis were the most common extrahepatic manifestations. Renal failure, pancreatitis, and manifestations of circulating immune complexes may also be seen.

MANAGEMENT

The large majority of patients with acute hepatitis A have a self-limited infection and therefore specific therapy is not needed. Attention to supportive care, especially hydration, is most important. Bed rest is not necessary although fatigue may limit certain activities. Hospitalization should be reserved for those patients who need intravenous fluids or show signs of developing encephalopathy. Corticosteroids are not beneficial and should generally be avoided. Patients with fulminant hepatic failure should be managed similar to any patient with acute liver failure and occasionally liver transplantation is necessary. The United States Fulminant Hepatitis Study Group data would suggest that most patients with acute hepatitis A resolve and therefore a slightly more conservative approach to liver transplantation than other etiologies of FHF is suggested.

PREVENTION

Because of its mode of transmission, person-to-person spread of HAV is common. Immune globulin is a preparation of concentrated antibodies made from pooled human plasma. Immune globulin provides protection against hepatitis A by passive transfer of antibody. A dose of 0.02 ml/kg provides preexposure protection for up to 3 months; 0.06 ml/kg provides protection for up to 5 months. Recently, IgG anti-HAV titers in immune globulin have decreased due to the declining prevalence in the donor population; however, there has been no definite documentation of declining efficacy. Postexposure immune globulin is useful to prevent infection if used within 2 weeks after exposure. Administration of immune globulin more than 2 weeks after exposure is ineffective. Immune serum globulin should be given to household, sexual, and day-care contacts of infected patients. If a common source food-borne outbreak is identified, immune serum globulin is also recommended for those at risk. Despite being protective, immune globulin administration does not achieve measurable levels of anti-HAV. Simultaneous vaccination with the hepatitis A vaccine is also recommended for individuals requiring immune globulin. One study suggested that the use of the hepatitis A vaccine only was effective in preventing transmission although that has not yet been accepted into clinical practice.

Hepatitis A vaccine became available in 1995 thanks to the use of cell culture techniques. HAVRIX and VAQTA, the two commercially available hepatitis A vaccines, are very effective and probably approximately equivalent in immunogenicity. Both use a formalin-inactivated, laboratory-attenuated strain of HAV and are available in two different formulations, the choice of which depends on age of the vaccinee. Both use a two-dose schedule with the second dose at least 6 months after the initial dose. The vaccines result in protective anti-HAV antibodies (IgG type) in over 90% of adults 1 month after the first dose. Approximately half of vaccinated patients are positive 14 days after the initial dose. The second dose of the vaccine ensures that nearly all patients will have protective levels of antibody. Response rates in children are even higher than in adults. Protective antibody levels seem to persist for at least 8 years after successful vaccination. The most common side effects of HAV vaccine are soreness at the infection site, headache, and malaise. Vaccination is recommended for groups at high risk of hepatitis A acquisition including intravenous drug users, day-care employees, homosexual men, and frequent recipients of blood products. Vaccine is also recommended for those in whom hepatitis A may cause a severe outcome, such as patients with chronic liver disease. Immunogenicity of the vaccine appears to be slightly less in patients with chronic liver disease than in the healthy population and, occasionally, immunity may be lost after liver transplantation. Immunosuppressed patients, such as those who have undergone organ transplantation or who have been infected with human immunodeficiency virus, also have lower immunogenicity with the HAV vaccine.

In large part due to the high response rates to the HAV vaccine, the role of prevaccination testing for anti-HAV has not yet been clarified. Some researchers have suggested that prevaccination testing for individuals at high risk of prior HAV infection is reasonable. Adults for whom prevaccination serologic testing can be considered include adults who were born or lived for a long time in areas with a high endemicity for hepatitis A, persons with a history of infection drug use, and perhaps individuals >40 years old. Because of the high rate of immunogenicity with the hepatitis vaccine, postvaccine testing is not recommended. Booster doses of the vaccine have not yet been recommended because of the long duration of protective antibody after the vaccination series.

Hepatitis B

T. SHAW AND S. A. LOCARNINI
Victorian Infectious Diseases Reference Laboratory, Australia

anti-HBs, anti-HBc, anti-HBe Specific antibodies that are produced in response to their respective antigenic determinants.
hepatitis B core antigen The antigenic specificity associated with the 32 nm diameter core of hepatitis B virus.
hepatitis B e antigen The antigenic determinant that circulates as a soluble protein in serum.
hepatitis B surface antigen The antigenic determinant found on the surface of the hepatitis B virus and on the 22 nm diameter particles and filamentous forms.
hepatitis B virus The 42 nm diameter double-shelled particle, originally known as the Dane particle.
hepatitis B virus DNA The partially double-stranded circular hepatitis B virus genome.
quasispecies Heterogeneous populations of genetic variants of virus found in an infected individual.

Hepatitis B, which may be acute or chronic, is caused by infection with human hepatitis B virus (HBV), a small hepatotropic DNA virus that is distributed worldwide. Infection with HBV occurs mainly as a consequence of exposure to infected blood or body fluids. Up to 5% of cases of chronic hepatitis B progress to fatal liver disease. Effective anti-HBV drugs and vaccines have been developed, but economic and logistical obstacles prevent their use in poor countries where chronic HBV infection is endemic. Elimination of HBV is a long-term goal that will be difficult to achieve unless current paradigms of control are improved or modified.

HISTORY OF DISCOVERY

Epidemic jaundice or infectious icterus has been recognized for at least 2000 years. Outbreaks in the past were probably caused mainly by fecal–oral transmission of hepatitis A virus. Hepatitis transmitted by blood and body fluids was not recognized until the mid 19th century and it was not until the mid 20th century that infectious hepatitis (hepatitis A) and serum hepatitis (hepatitis B and "non-A, non-B" hepatitis) were shown to be caused by different viral agents. Hepatitis B surface antigen (HBsAg) was first discovered in the serum of an Australian aborigine in 1963. It was subsequently found to be associated with acute serum hepatitis in other populations worldwide and shown to be a viral

antigen. In 1970, Dane and colleagues identified virus-like particles that carried HBsAg on their surface in sera from hepatitis patients. Three years later, these "Dane" particles were shown to contain endogenous DNA polymerase activity, confirming their viral nature. Similar viruses were found in other animals during the next decade and have been grouped into a new virus family, the *Hepadnaviridae* (hepatotropic DNA viruses).

TAXONOMY AND CLASSIFICATION

In addition to being found in humans, rodents, and birds, hepatitis B viruses (HBVs) have recently been found in apes and primates. HBVs that infect mammals and birds are classified in separate genera, Orthohepadnavirus and Avihepadnavirus, respectively. All share common features including tissue tropism, restricted host range, virion ultrastructure, genetic organization, and replication strategy. The genome organization and replication strategy of hepadnaviruses are similar to those of retroviruses of animals and caulimoviruses of plants, suggesting a possible ancient evolutionary origin from a common ancestor. Replication of these viruses requires host-cell-mediated transcription and translation of a pregenomic viral RNA, which directs the synthesis of circular double-stranded viral DNA from which viral mRNA is transcribed.

PREVALENCE AND EPIDEMIOLOGY

Approximately 2 billion individuals—approximately one-third of the global population—have serologic evidence of past or present infection with HBV. By the end of the year 2000, nearly 400 million people were chronically infected with HBV according to World Health Organization (WHO) estimates. Chronic HBV infection is associated with a 15–25% chance of development of fatal liver disease, including cirrhosis and hepatocellular carcinoma. HBV-related disease causes approximately 1 million deaths annually. Considering these figures and the availability of safe and effective vaccines, the WHO has recommended that hepatitis B vaccination be incorporated into routine infant and childhood immunization programs in all countries. Chronically and acutely infected individuals are the only sources of HBV for new infections. In most populations, males are more likely to become chronic HBV carriers than females.

Transmission

HBV can be transmitted by sexual contact, percutaneously (for example, from contaminated needles shared by intravenous drug users), by inoculation with contaminated blood or blood products, by transplant of organs from infected donors, and perinatally from infected mothers. Infection of infants of infected mothers *in utero* is rare. Serum HBsAg and HBV DNA are considered reliable indicators of active infection, but the risk of infection from infected carriers is extremely variable because of large differences in HBV replicative activity, which results in enormous differences in viral loads in infected individuals. However, the presence of HBsAg is still regarded as a marker of infectivity irrespective of viral load.

PATHOGENESIS

HBV is not directly cytopathic to hepatocytes in cell culture systems or *in vivo*. Liver damage results mainly from the direct attack of the host's immune system on infected hepatocytes and indirect effects of the immune response on uninfected cells. Although this has been recognized for some time, concepts of the mechanisms responsible have changed radically as a result of recent studies. Noncytocidal effects of pro-oxidative cytokines, in particular, interferons α, β, and γ and tumor necrosis factor α, have been implicated as major contributors to viral clearance, whereas destruction of infected hepatocytes by cytotoxic T cells contributes to both viral clearance and the development of liver disease. Immune complex-mediated responses are believed to be responsible for extrahepatic damage when it occurs.

DIAGNOSIS

Acute and chronic HBV infection can be diagnosed and differentiated by simple serological tests that detect the presence of HBV antigens and antibodies to HBV antigens in blood. Interpretation of the results of these tests is summarized in Table I. Fluctuations in serum HBV DNA, which can be monitored by hybridization or polymerase chain reaction assays, provides a direct measurement of viral replicative activity. Leakage of liver enzymes [usually aminotransferases, in particular, alanine aminotransferase (ALT) and γ-glutamyl transferase] and bilirubin into serum, which can be assayed by biochemical tests, provides surrogate markers of liver damage. Histological examination of liver biopsies may be used to determine the stage and severity of tissue damage. More sophisticated assays may be used to monitor disease progression and response to treatment.

TABLE I Interpretation of Serological Markers in Patients with Viral Hepatitis B

Assay results			
HBsAg	**Anti-HBs**	**Anti-HBc**	**Usual interpretation**
+	−	−	Early acute HBV infection
+	+/−	+	HBV infection, either acute or chronic. Differentiate with IgM anti-HBc; determine amount of replicative activity (infectivity) from HBV DNA assay
−	+	+	Indicates previous infection and immunity to hepatitis B in most cases
−	−	+	Possibilities include: HBV infection in the remote past; "low-level" HBV carrier; "window" between disappearance of HBsAg and appearance of anti-HBs or false-positive or nonspecific reaction. Investigate with IgM anti-HBc and/or challenge with HBsAg vaccine; when present, anti-HBe helps validate the anti-HBc reactivity; assay for HBV DNA by PCR can identify "occult" infection
−	+	−	Vaccine-type response

Acute HBV Infection

In a typical case of acute hepatitis B, HBsAg is first detected 2−3 months after initial infection, which is 1−3 months before the serum ALT starts to rise and 3 to 5 weeks before the onset of symptoms such as dark urine and jaundice. The serum HBsAg reaches a peak concentration during the early acute stage of the illness and then slowly declines to undetectable levels within 4−6 months. Viremia (HBV DNA) is detected during and after the disappearance of HBsAg. Peak levels of HBV DNA exceeding 10^9 genome equivalents per milliliter are found in the late prodromal and early acute phases, reflecting the highly infectious nature of acute HBV infection. Serological markers HBeAg and anti-HBe specific IgM are typically detected after the appearance of HBsAg in blood. High levels of anti-HB-specific IgM are a useful serological test in acute hepatitis B. During early stages of convalescence and before HBsAg disappears, anti-HBe replaces HBeAg, signaling a reduction in viral replication and the beginning of resolution of the disease. Termination of acute HBV infection occurs with the disappearance of HBsAg and the development of anti-HBs.

Chronic HBV Infection

Chronic HBV infection is defined as hepatic necroinflammation due to the persistence of active HBV replication. The WHO defines chronic HBV on the basis of laboratory markers and requires the detection of HBsAg in the patient's serum on two occasions over a 6-month period. Typically, anti-HBc IgM titers are either low or undetectable, whereas anti-HBc IgG titers are high.

NATURAL HISTORY OF INFECTION

The outcome of HBV infection varies enormously. In areas of high endemicity (HBsAg prevalence >8%), HBV infection occurs early in life, usually perinatally, typically remains silent or subclinical, and frequently becomes chronic. In general, chronic infection is only established after maternal transmission of $HBeAg^+$ HBV. Neonates infected from $HBeAg^-$ mothers typically develop acute hepatitis that resolves. Under these conditions, chronic liver disease or liver cancer due to HBV infection appears much later in life and is frequently fatal. By contrast, in areas where the incidence of HBV infection is low (HBsAg prevalence <2%), most primary HBV infections occur in adults as a result of sexual contact or percutaneous infection. Such infections are more likely to be associated with clinically apparent acute hepatitis and less than 10% of cases become chronic. The incubation period from infection to onset of clinically apparent hepatitis is usually between 6 and 24 weeks.

$HBeAg^-$ Chronic Hepatitis B

$HBeAg^-$ chronic hepatitis B occurs as a result of the selection of HBV mutants that are unable to secrete the pre-core protein (HBeAg). It has become the most prevalent form of disease presentation in many parts of the world, particularly in Asian and Mediterranean countries. The most common of several mutations that can cause HBeAg negativity is a guanine to adenine transition at nucleotide position 1896 (G1896A), which creates a TAG stop codon at codon 28 of the pre-core protein. The phase of $HBeAg^-$ chronic hepatitis B

appears to be associated with rapid disease progression, resulting in cirrhosis and hepatocellular carcinoma.

VIRION ULTRASTRUCTURE

The HBV virion is a 42 nm spherical particle within a lipid envelope. The 32 nm diameter nucleocapsid contains the core antigen (HBcAg), the genomic DNA, and viral polymerase. During persistent infection, very high concentrations of incomplete viral forms, mainly aggregates of 22 nm diameter spherical particles and filamentous forms of HBsAg, are found in the blood.

GENOME ORGANIZATION

The HBV genome is a circular, partly double-stranded DNA molecule. The longer minus-sense strand is approximately 3200 nt long and is partly matched by a complementary plus strand, which varies in length from 1700 to 2800 nt. The longer strand is nicked at a point 300 nt from the 5′-end of the shorter strand. Circular conformation is maintained by base pairing between the 5′-ends of the strands, which overlap. The 5′-end of the shorter strand is capped with an oligoribonucleotide and the terminal part of the viral polymerase protein is covalently linked to the 5′-terminus of the longer strand.

Overlapping Reading Frames

HBVs encode only four genes and have evolved a remarkable genetic economy by using gene overlap: the HBV genome is only slightly longer than the longest of its four open reading frames (ORFs). The longest ORF, P, encodes a multifunctional protein that possesses RNase H and RNA- and DNA-dependent DNA polymerase activities as well as the ability to prime reverse transcription and coordinate virion assembly. The envelope (S) gene ORF lies completely within the P gene in a different reading frame and the remaining two genes, C and X, also partially overlap the P gene. Further economy is achieved by the use of alternative starting codons for transcription: the S gene encoded three co-terminal HBs proteins (Pre-S1, Pre-S2, and S). The C gene encodes both HBeAg and HBcAg and the X gene may encode more than one product. Gene overlap undoubtedly places constraints on mutation and evolution rates.

REPLICATION STRATEGY

After attachment and entry into the cell, the virus is uncoated and the viral genome is transported to the nucleus, where it is converted into a supercoiled, covalently closed circular (ccc) molecule, probably by cellular DNA repair enzymes. The supercoiled ccc DNA associates with cellular histones to form a viral minichromosome in the nucleus of infected cells. It is transcribed by cellular RNA polymerase II, producing several unspliced, capped, polyadenylated mRNA species that are translated into viral proteins. Transcription also generates a terminally redundant 3.5 kb pregenomic RNA that is packaged into viral core particles after it is translated to generate the viral polymerase. Within the capsid, the viral polymerase reverse-transcribes the pregenomic RNA, digests the RNA template, and copies the first (minus) DNA strand to regenerate the circular, partially double-stranded viral genome. Virions are enveloped and exported by budding through the endoplasmic reticulum. (See Fig. 1.)

HBV Quasispecies

RNA polymerases and reverse transcriptases are inherently error-prone, which ensures that HBV populations exist *in vivo* as heterogeneous mixtures of variants, termed quasispecies. A variety of selection pressures, including host immune surveillance, antiviral therapies, and virus–cell tropism, can affect quasispecies composition and influence the outcome of infection. A high quasispecies variability allows flexible but unpredictable evolution. Under some conditions, variation may exceed the error threshold beyond which viral survival is impossible, a situation termed “error catastrophe.” Overlap in reading frames of the polymerase, core, Pre-S/S, and X gene products probably places constraints on the number of variants that remain viable. Despite this, several viable variants of HBV that have characteristic mutations affecting the pre-core, core, polymerase, and X peptides have been described. Specific mutations that affect the polymerase may confer resistance to antivirals (see below), but the possible association between particular clinical manifestations and disease outcomes has not been firmly established for mutations that affect the other gene products.

EVOLUTION OF HBV

Until recently, it was generally believed that infection with HBV was restricted to humans, despite evidence for the presence of HBV antigens in other primates. HBVs that infect Old World apes (orangutan, gibbon, gorilla, and chimpanzee) and a New World monkey have been isolated and characterized during the past 5 years. The study of HBV evolution remains difficult because of complications introduced by

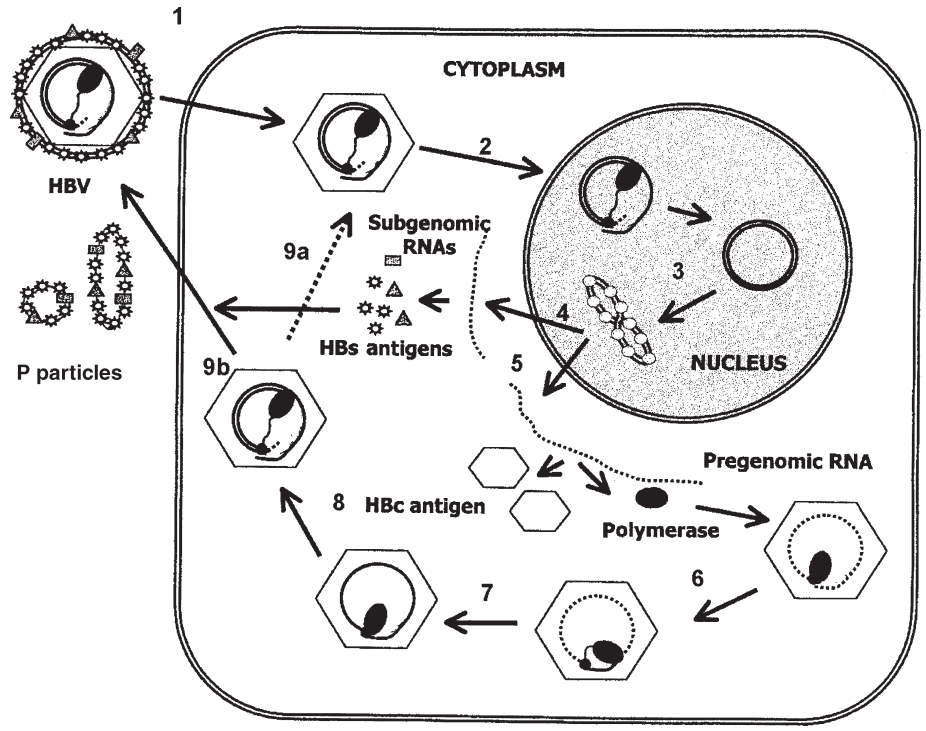

FIGURE 1 Stages in the HBV replication cycle (simplified). (1) Attachment and entry into the host cell followed by uncoating. (2) Transport to the host cell nucleus. (3) Repair of and conversion into a circular double-stranded supercoiled DNA molecule, which assembles a minichromosome. (4) Transcription of viral genes from HBV ccc DNA and export of polyadenylated subgenomic mRNAs and pregenomic RNA to the cytoplasm. (5) Translation of viral RNAs, generating the viral polymerase and structural proteins. (6) Assembly of nucleocapsid particles from core antigen, polymerase, and pregenomic RNA. (7) Covalent attachment of dNTPs to the viral polymerase to form a DNA primer and reverse transcription of the viral pregenome by extension from the DNA primer, generating the first (minus) DNA strand. (8) Degradation of the pregenomic template RNA and synthesis of a partial complementary second DNA strand. There are two alternative fates for mature intracellular nucleocapsids: delivery to the host nucleus and further replication (9a) or acquisition of a viral envelope and secretion from the cell via the endoplasmic reticulum and Golgi apparatus (9b). Aggregates of surface antigens may also be secreted. The translation and fate of nonstructural viral proteins are not shown.

intergenotype recombination, by constraints on nucleotide substitution imposed by gene overlap, and by differential selection pressures affecting different parts of the genome. Phylogenetic analyses provide evidence for a diversion of human genotypes A–E from genotype F and H and hepadnaviruses of apes. Recent analyses have also distinguished distinct patterns of recombination between genotypes A and D and between genotypes B and C and have resulted in a estimated mean nucleotide substitution rate in HBV of 4.2×10^{-5} nt/site/year, which suggests that human and ape HBVs diverged relatively recently. However, the direction, frequency, and sequence of early transmission events that generated different primate HBVs remain controversial.

HBV Genotypes

Eight HBV genotypes (named A–H) have been defined on the basis of nucleotide sequence divergences of >8%. The geographical distributions of genotypes are distinct and each is associated with different disease manifestations. Genotypes A to F occur globally, genotypes B and C predominate in Eastern Asia and Oceania, genotypes E is restricted to West Africa, and genotypes F and H are found in Central and South America, respectively. Genotype G was found in a small percentage of HBV-infected individuals in both France and Georgia (United States); it contains a unique 36 bp insertion in the core gene and two stop codons in the precore region.

Although the latter prevent the translation of HBeAg, HBV/G-infected individuals have all been shown to be $HBeAg^+$ due to co-infection with HBV/A, and HBV/A/G recombinants have also been detected *in vivo*. How co-infection occurs, the significance of recombination, and whether replication of HBV/G requires HBV/A are currently unknown. Phylogenetic trees constructed from either full-length genome sequences or individual gene sequences show that genotype G is clearly separated the other seven genotypes.

Clinical and Epidemiological Significance of Genotypes

Sequence differences between different HBV genotypes may lead to structural differences at the pregenome level, which may in turn affect translation and reverse transcription. There is accumulating evidence to suggest that clinical manifestations of infection, treatment response, and long-term prognosis of infection may all be influenced by genotype. Genotyping has also proved to be useful for tracing routes of transmission. A variety of facile and reliable methods for differentiating between different HBV genotypes have recently been developed.

PREVENTION AND CONTROL

Vaccination

Conventional Vaccines

Current HBV vaccines consist of recombinant HBsAg protein produced in yeast. Intramuscular injection of three successive doses induces protective levels of anti-HBsAg (>10 mIU/ml) in >95% of infants and children and >90% of vaccinated healthy adults, but response rates are lowered by smoking, obesity, diabetes, renal impairment, immune deficiency, and advancing age. Vaccination of all newborn infants is recommended, as is vaccination of previously unimmunized children and adolescents, as well as adults who belong to high-risk groups. High-risk groups include health care workers, injecting drug users, persons with multiple sexual contacts, partners and family members of individuals known to be infected with HBV, long-term residents of institutions, patients with chronic renal failure, recipients of clotting factor concentrates, and travelers intending to stay in regions where HBV is endemic. In high-risk groups, postvaccination testing for the presence of anti-HBs is advisable, but it is regarded as unnecessary for adolescents, children, and infants. A second three-dose course of injections is usually recommended for those who fail to respond to a primary course of vaccination. Up to 50% of nonresponders respond to a single vaccine dose and up to 75% respond to three additional doses. Responders are protected against HBV infection even after HBs antibody titers fall to undetectable levels and, except in hemodialysis patients, revaccination to boost immunity is usually not required.

Safety of Vaccines

HBV vaccines have an outstanding record of safety and efficacy. Since 1982, more than a billion doses of HBV vaccine have been administered worldwide. In countries where routine infant immunization programs have been introduced, their introduction has not been associated with increases in adverse effects and no evidence has been found to substantiate anecdotal reports of associations between HBV vaccination and a variety of syndromes and diseases in adults. Nonfatal anaphylactic reactions have been reported to occur at a frequency of approximately 1 in 600,000 vaccinations and further vaccination is obviously contraindicated in such cases.

National Vaccination Programs

Since 1991, the WHO has recommended that HBV immunization be included in national immunization programs worldwide. By March 2001, 116 countries had followed this recommendation, including most countries in Eastern and Southeast Asia, the Pacific Islands, Australia, North and South America, Western Europe, and the Middle East. Pediatric and childhood immunization programs in countries such as Taiwan, where the chronic infection frequency was previously high (up to 20% HBsAg prevalence), have reduced the childhood carrier frequency to approximately 1% within the past decade. Unfortunately, many low-income countries in sub-Saharan Africa and the Indian subcontinent and newly independent states have been unable to introduce routine HBV vaccination due mainly to cost and the lack of organizational infrastructure needed to introduce routine vaccination.

Vaccines for the Future

Vaccines that can be administered orally or intranasally are the most economically feasible for mass immunization of humans on a global scale, but very few vaccines are currently available for administration by these routes. Now that it is possible to produce genetically engineered crop plants that express biologically active proteins, efforts have been directed at producing edible plants that express HBsAg. Results of pilot experiments that show HbsAg-specific IgG production in laboratory animals and human volunteers following ingestion of transgenic plants that expressed HBsAg

are encouraging and suggest that mass immunization using dietary staples as vectors may become a reality. An alternative and equally ingenious approach involves the use of live attenuated *Salmonella typhimurium* genetically engineered to produce HBsAg as vector. Although this vaccine is only at the developmental stage, strong cellular and relatively insignificant humoral immune responses observed after oral administration of this "enterobacterial" vaccine suggest that it may be useful in some situations in which the conventional recombinant vaccines are ineffective, such as therapeutic immunization of chronic carriers.

Chemotherapy

Problems Associated with HBV Chemotherapy

Development of chemotherapy for HBV has been difficult for a variety of reasons. HBV infection has remained virtually untreatable for most of the >30 years that have passed since it was first identified as a major cause of serum hepatitis. Because the HBV genome does not encode virus-specific enzymes for (deoxy)-nucleoside salvage, its replication depends on host cell enzymes for its supply of DNA precursors. Furthermore, its unusual strategy of replication via an RNA intermediate means that transcription and translation of the RNA intermediate can continue even when reverse transcription and duplication of the resulting DNA transcript are completely blocked. Nucleoside analogues that inhibit the HBV polymerase effectively have no direct effect on the viral minichromosome, which can be removed only by the destruction of infected hepatocytes. Chemotherapeutic strategies that rely solely on inhibitors of the viral polymerase must inevitably be virustatic rather than virucidal, and, not surprisingly, HBV replication invariably resumes following withdrawal of treatment. Prolonged treatment carries disadvantages besides cost and the risk of cumulative toxicity. Antiviral monotherapy (continued exposure to a single drug) selects for mutations that cause drug resistance, typically within 12 months of initiation of treatment.

Currently Approved Drugs

Interferon-α Until very recently, interferon-α was the only drug licensed for use against chronic HBV infection. Although a subgroup of patients with active liver disease (indicated by elevated serum transaminase levels) and low-level viremia respond favorably to interferon treatment, overall response rates are poor. Individuals who belong to certain ethnic groups as well as those who are co-infected with hepatitis delta virus (HDV) or human immunodeficiency virus (HIV) or who are otherwise immunocompromised usually fail to respond. Furthermore, interferon is generally administered by subcutaneous or intramuscular injection, which is inconvenient, and its use is associated with several undesirable side effects. Thus, the need for more efficacious and better-tolerated orally available anti-HBV agents has been evident for some time. Two safe and efficacious new anti-HBV drugs are now available and several more are at advanced stages of clinical development.

Lamivudine Lamivudine, the β-L-[−]enantiomer of 2′,3′-dideoxy-3′-thiacytidine, is an analogue of deoxycytidine. It is activated intracellularly by phosphorylations catalyzed by cellular enzymes. The triphosphate inhibits HBV polymerase activity by terminating newly synthesized viral DNA chains. Originally developed for treatment of HIV infection, lamivudine shows good oral bioavailability and is well tolerated, even when given for long periods. Treatment with lamivudine at the usual dose of 100 mg/day produces a rapid decrease in serum HBV DNA, clearance of HBeAg, improvement in liver histology, and normalization of serum transaminases in many cases. Unfortunately, drug-resistant HBV mutants appear almost invariably during long-term (>12 months) lamivudine treatment (see below) and their appearance is associated with further disease progression.

Adefovir dipivoxil Adefovir dipivoxil is a prodrug for the broad-spectrum antiviral deoxyadenosine monophosphate analogue adefovir (9-[2-phosphonylmethoxyethyl]-adenine). Large-scale phase III clinical trials have shown that treatment with adefovir dipivoxil at a dose of 10 mg/day produces antiviral effects comparable to those of lamivudine. Resistance to adefovir has not been observed during 48-week clinical trials and it is active against lamivudine-resistant HBV mutants. Adefovir dipivoxil has been approved for use as an anti-HBV agent by the Food and Drug Administration in the United States and is expected to gain approval from regulatory authorities in other countries in the near future.

Drug-Resistant HBV and Combination Chemotherapy

As noted above, HBV exhibits a high mutation rate because of the inherently poor copying fidelity of both host RNA polymerase II and the HBVl polymerase, both of which lack proofreading 3′-5′ exonuclease activity. Populations of HBV quasispecies in chronically infected individuals include preexisting variants that are potentially drug-resistant. Initiation of treatment may select for drug-resistant variants ("mutants") that may become the predominant population as treatment

progresses. Lamivudine resistance is usually due to mutations (analogous to those that confer lamivudine resistance in HIV) that cause the methionine in the active site YMDD (tyrosine–methionine–aspartate–aspartate) motif of the viral polymerase to be replaced by isoleucine, valine, or serine. Lamivudine resistance appears to confer cross-resistance to other L-nucleoside analogues, but does not confer cross-resistance to adefovir dipivoxil. Lamivudine-resistant HBV mutants are eclipsed by wild-type virus after drug withdrawal, but can still be detected for at least 12 months, and their transmission can cause acute hepatitis B. Current consensus of opinion predicts that multidrug combination regimes analogous to highly active antiretroviral therapy that have been used to treat HIV infection will be required to avoid development of drug resistance and will most likely be used routinely in the future to control chronic HBV infection. Although a high viral load ensures the preexistence of variants that are potentially resistant to one or two antiviral drugs, it has been shown that the preexistence of variants with the potential for resistance to three or more drugs is unlikely.

FUTURE PROSPECTS

Prophylactic vaccination may ultimately be able to control and perhaps eliminate HBV infection at some time in the distant future. Universal hepatitis B vaccination will require concerted efforts and cooperation between governments, public health authorities, and pharmaceutical companies in many countries. Meanwhile, control of HBV infection in the millions of individuals already infected with HBV will depend on the development of new chemotherapeutic strategies, which will similarly require high-level organization and planning for optimal effect. Continuing advances in the understanding of HBV biology, in drug design, in monitoring disease progression, and in vaccine development should, in principle, make the task of elimination of HBV increasingly easy, provided that economic and political obstacles can be overcome.

Hepatitis C

ANDREA D. BRANCH
Mount Sinai School of Medicine, New York

acute infection First 6 months of hepatitis C virus infection; patients are typically asymptomatic. Serum alanine aminotransferase levels often reach 10 times the upper limit of normal; the course may be self-limiting or may progress to chronic infection.

alanine aminotransferase Enzyme that is released from the liver during times of stress and injury; can be measured in serum and plasma.

chronic infection Hepatitis C viremia that persists for longer than 6 months. The clinical course is highly variable, and the disease spectrum ranges from minimal disease to liver failure and hepatocellular carcinoma.

cryoglobulinemia Most common extrahepatic manifestation of chronic hepatitis C. Cryoglobulins are detected in lab tests based on their precipitation at cold temperatures; symptomatic disease is uncommon (less than 1% of patients) and results from local deposition of immune complexes.

hepatitis C virus genotypes Broad families of hepatitis C viruses that circulate worldwide; some genotypes are more responsive to interferon treatment than others. Depending on the genotyping system, the global population of viruses is divided into 6 or 11 genotypes. Full-length RNA sequences of the members of a genotype are identical to each other at 30% or more of the nucleic acid positions.

interferons Family of naturally occurring peptides with both antiviral and antiproliferative effects; several α interferons (2a, 2b, and a consensus molecule, for example) have been developed as pharmaceutical agents for HCV.

internal ribosome entry site Intricate RNA structure that is located near the beginning of hepatitis C virus RNA; promotes the initiation of viral protein synthesis.

pegylated α interferons Pharmaceutical agents in which the interferon is linked to polyethylene glycol to improve the pharmokinetic profile (half-life) and efficacy.

polymerase chain reaction Process that is used to copy nucleic acids multiple times so that there is sufficient material for analytical detection.

quasispecies Population of hepatitis C viruses present in a particular individual at a particular time. The full-length sequences comprising the quasispecies are identical to each other at a minimum of 90% of the 9600 positions in the viral RNA molecules.

ribavirin Guanosine analogue that has antiviral and immunomodulatory effects; increases the sustained viral response rate of interferon when the combination is used to treat patients with chronic hepatitis C virus.

Hepatitis C virus is primarily transmitted through contaminated blood and is an important cause of liver failure and hepatocellular carcinoma. Acute infection is usually asymptomatic, although clinically significant and protracted disease can occur during this phase, which lasts up to 6 months. Hepatitis C virus is difficult to study. It has no known hosts other than humans and chimpanzees, does not propagate well in culture, and can barely be detected in the liver during chronic infection. Despite these limitations, an effective therapy has been developed, and about 50% of patients who can tolerate treatment are cured of chronic infection.

INTRODUCTION

Hepatitis C virus (HCV) infects about 3% of the world's population. In the United States, it accounts for about 15% of acute viral hepatitis, 60–70% of chronic hepatitis, and up to 50% of cirrhosis and end-stage liver disease. Chronic infection accounts for virtually all of the serious hepatitis C virus-related liver disease and causes an estimated 8000 to 10,000 deaths in the United States annually.

Routes of Transmission and Epidemiology

The routes of HCV transmission are central to HCV epidemiology, liver disease, and virology. Transmission usually occurs as a result of percutaneous or permucosal exposure to contaminated blood or blood products. Because blood exchanges are relatively rare events, HCV has few opportunities to move from one person to another. It has evolved strategies that allow it to elude the immune system and to establish chronic infections that maintain high levels of infectious virus in the blood for years, while causing minimal liver damage, at least in the short term.

HCV does not have an insect vector for transport from one person's bloodstream into another's. It relies on humans. Unsafe medical practices cause HCV epidemics in many parts of the world. Intravenous drug use is largely responsible for the epidemic in the United States. According to Miriam Alter and colleagues, the

 Copyright 2004, Elsevier (USA). All rights reserved.

Centers for Disease Control and Prevention (CDC) estimate that the recreational use of intravenous drugs has transferred HCV to 60–70% of the 3.9 million living Americans (1.8% of the population) who have been infected with HCV. Transfusions account for only about 7% of the transmissions, and sexual activity for about 15%. Infections resulting from sexual activity comprise a relatively small fraction of the total because transmission of HCV between sexual partners in monogamous relationships is very inefficient compared to that of other blood-borne viruses, such as human immunodeficiency virus (HIV) and hepatitis B virus (HBV). The transmission rate is so low that the CDC recommends that couples use their own discretion when deciding whether to use condoms to further reduce the already minimal risk. Vertical transmission from viremic mothers to their babies also occurs at a relatively low rate, about 4–7% per pregnancy. Coinfection with HIV makes transmission more likely. The actual time and mode of vertical transmission are not known. Babies of viremic mothers should be tested for HCV between the ages of 2 and 6 months and again at 18 to 24 months. CDC guidelines for HCV screening of members of high-risk groups are available on their web site.

The number of new cases of HCV in the United States has declined dramatically in recent years, according to CDC estimates. During the period from 1985 to 1989, there were 242,000 acute cases each year; in 1998, there were 40,000 new infections. The change is almost entirely due to a reduction in new HCV infections among recreational intravenous drug users. The introduction of specific screening tests to remove HCV from the blood supply was an important step for clinical medicine, but it had limited impact on the epidemic. Transfusions never accounted for more than 20% of HCV transmissions, at most. Screening for hepatitis B markers, begun in the 1970s, had already eliminated most posttransfusion HCV in the United States before specific tests for this virus became available. The factors leading to the decline in new cases of HCV that took place during the 1990s need to be elucidated so that this information can be used to avoid a repeat of the previous outbreak. Unfortunately, despite the drop in new infections, the burden of HCV disease is projected to climb as individuals exposed in previous decades advance into the later stages of pathology.

Natural History and Antiviral Therapy

The natural history of HCV infection is highly variable. Acute infection is usually asymptomatic and leads to self-limited disease in about 10–50% of patients. Patients who fail to clear the virus during the first 6 months progress to chronic infection. Chronic infection causes only mild inflammation and minimal fibrosis in many patients, but has serious consequences for others. It is estimated that about 20% of patients develop cirrhosis, usually after decades of chronic viremia. Once it arises, cirrhosis can be followed by liver failure and/or hepatocellular carcinoma in a few years. Disease progression is hastened by excessive alcohol consumption. It is more rapid in men than in women, and is faster in both sexes when infection is acquired after the age of 40. Liver damage during chronic infection is thought to be largely immune mediated, although viral cytotoxicity cannot be ruled out with existing data.

It is not clear how HCV eludes the immune system and establishes chronic infection. Viral mutability may play a role. HCV has a high mutation rate and circulates in each patient as a population of closely related sequences called a quasispecies. Sequence diversity and mutation may allow resistant viral variants to emerge faster than the adaptive immune system can cope with them. Hepatotropism may also be a factor. The liver can be chronically infected by several pathogens, suggesting that it is inherently vulnerable to this type of infection.

Antiviral treatment is available for patients with either acute or chronic infection. HCV can be eliminated in a significant percentage of patients with chronic infection by treatment for 6 to 12 months with interferon α (IFNα) and ribavirin. The duration and efficacy of combination therapy are influenced by the genotype of the virus. Genotype 1, the most common genotype in the United States, is relatively resistant; however, in selected populations receiving optimized treatment, almost 50% of patients with genotype 1 virus achieve a sustained viral response. More efficacious and economical treatments with fewer side effects are needed. Several groups are actively seeking a vaccine.

ACUTE INFECTION

Clinical Course and Serology

Primary HCV infection is asymptomatic in the vast majority of cases. Symptoms, when they occur, include right upper quadrant pain, nausea, vomiting, malaise, and fever. Jaundice develops in less than 20% of patients. Some evidence suggests that patients who become jaundiced are more likely to clear the infection, but this observation has not been confirmed in all studies. The innocuous presentation leaves most individuals unaware that they are infected. Because most patients with acute infection do not seek medical

attention, the natural history of this phase of HCV infection remains in question. Much of the available data were obtained from subjects who had a risk factor for exposure to the virus, rather than from the general population.

The first detectable serum marker of acute HCV infection, HCV RNA, initially can be found 7 to 21 days after exposure. HCV antibodies usually become detectable at about 50 days after infection, but may appear as early as 20 days, as late as 6 months, or even later. During the first month, HCV RNA levels often rise rapidly and reach high titers prior to the onset of alanine transaminase (ALT) elevations or symptoms. During the first 6 months, HCV RNA serum levels often fluctuate and may range over several orders of magnitude at various times (see Fig. 1). HCV RNA may become temporarily undetectable in patients who later develop chronic disease. Because of this variability, patients presumed to have cleared the infection should be retested 6 to 12 months later. True clearance of viral RNA is usually followed by a normalization of ALT levels within a few weeks or months and a complete recovery.

The incubation period—the interval between exposure and the elevation of aminotransferases to twice the upper limit of normal—ranges from 2 to 26 weeks, with an average of about 6–7 weeks. In 90% of adult cases, the peak ALT level exceeds 10 times the upper limit of normal, but this peak may be missed in patients who are not monitored at frequent intervals. ALT values may not reach their peak or plateau level until 8–12 weeks after inoculation, or later. The lack of correlation between the timing of the RNA and ALT elevations has been taken as a sign that HCV is not directly cytopathic. This conclusion may be an oversimplification. The processes leading to damage in the HCV-infected liver are not well understood.

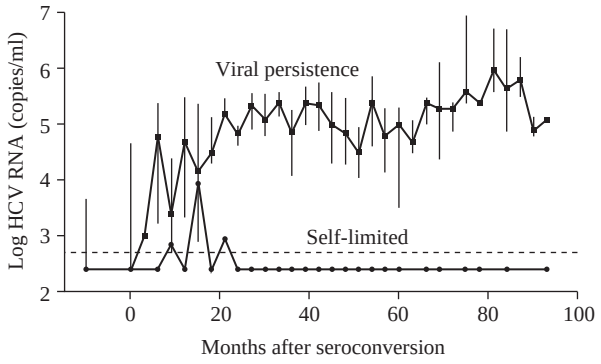

FIGURE 1 Hepatitis C virus (HCV) RNA levels in self-limited versus persistent infection. The median HCV RNA levels for each 3-month interval among 28 individuals with viral persistence and 6 individuals with self-limiting infection are indicated. All members of a group were included if data were available. Vertical lines represent the 25th to the 75th percentile of values for viremic patients. The dashed line indicates the lower limit of the assay (500 copies/ml). Reproduced with permission from Villano *et al.* (1999).

Histology

Acute HCV has histological features that are typical of acute viral hepatitis in general. These features include evidence of liver cell injury and lobular necrosis. During acute infection, inflammation in the portal areas is in proportion to the inflammation throughout the specimen. Inflammatory cells are often present in areas of liver cell necrosis. Thus, during acute infection, inflammation is less concentrated in portal areas than during chronic infection. Studies of acute HCV (non-A, non-B hepatitis) often report eosinophilic degeneration of hepatocytes, intense sinusoidal mononuclear cell infiltration, Kupffer cell activation, hepatocellular fat accumulation (steatosis), and bile duct injury. Because acute HCV is generally asymptomatic and is rarely assessed histologically, these findings may reflect liver pathology that is unusually severe.

Diagnosis of Acute Infection in the Clinical Setting

There are no currently validated methods that allow acute and chronic infection to be distinguished with certainty except in the rare patient who is observed to convert from seronegativity for HCV antibodies and RNA to seropositivity. High levels of serum aminotransferases in a patient with HCV RNA and antibodies may indicate acute infection, but may also indicate exposure to a second hepatitis virus, a toxic drug, or alcohol. Thus far, immunoglobulin M (IgM) responses have not proved to be helpful; similar levels may be present in both acutely and chronically infected patients. Some investigators are exploring anticore IgM as a possible marker of acute infection.

Treatment of Acute Infection

No guidelines are currently available in the United States for the antiviral treatment of patients with acute HCV infection. Several trials of IFNα monotherapy have been conducted. In some series, nearly 100% of the patients eliminated the virus. Further trials are needed to determine the optimal timing, duration, and dose of interferon and to explore the potential benefit of combining interferon and ribavirin for the treatment of acute HCV infection. If there is a window of opportunity during primary infection, combination therapy may

extend its boundaries and reduce the pressure to initiate treatment in patients who would experience spontaneous clearance if given the opportunity.

The successful outcome of interferon monotherapy for the treatment of acute HCV suggests that virtually all genotypes of HCV are inherently sensitive to interferon. Because treatment has oftentimes been delayed for 3 to 4 months, the high rate of viral clearance also indicates that HCV strains remain interferon sensitive and vulnerable to elimination even after they have been given the opportunity to diversify.

As illustrated in Fig. 2, the successful outcome of early interferon treatment indicates that a large percentage of the patients who would otherwise progress to chronic infection can mount an effective defense if they are aided by interferon during the acute phase. Evidently, if the virus is not expunged during this critical period, the patient and the virus adapt to each other and chronicity becomes fully established. The mechanisms of this adaptation are only partially understood. Once chronicity is established, only a minority of patients can clear the virus when treated with interferon monotherapy.

Fulminant HCV

In rare cases, acute HCV has a fulminant presentation. In fulminant hepatitis C infection, HCV RNA titers are very high until late in the clinical course and liver failure rapidly ensues. Because of the compressed time frame, HCV antibodies may not be present at any point.

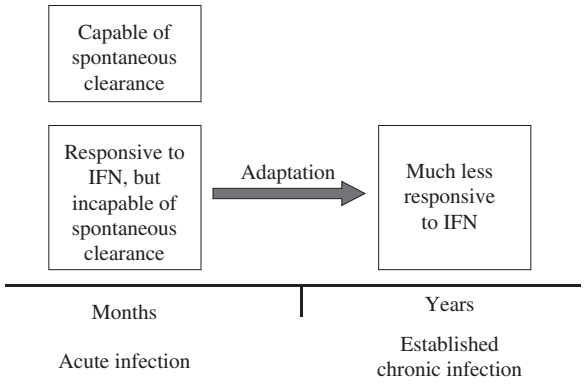

FIGURE 2 The transition to chronic infection. During the acute phase, most individuals have the capacity to clear the virus spontaneously, or in response to interferon (IFN) monotherapy. Later, most viremic patients can no longer clear the infection when treated with interferon alone. The adaptations responsible for this conversion are likely to include modulation of the host responses and changes in the viral quasispecies.

The detection of serum HCV RNA is the earliest and most valuable marker for the diagnosis of fulminant hepatitis C.

THE TRANSITION TO CHRONICITY

ALT Values Fall, but High-Level Viremia Persists

Traditionally, HCV infection has been strictly divided into acute and chronic phases, and a diagnosis of chronic infection has been made when aminotransferases remain elevated for 6 months or more. The persistence of HCV RNA is now the hallmark feature, and the line dividing acute and chronic infection has become blurred by the recognition that spontaneous viral clearance can occur more than 6 months after inoculation (see Fig. 1). The timing of viral clearance is of little clinical significance provided that it occurs before extensive scarring takes place.

In patients who fail to clear the virus, fluctuations of viral load may parallel ALT fluctuations for a time. Later, this temporal association is lost. During established chronic infection, ALT levels are usually much lower than during the peak of acute infection, and may be persistently normal, elevated, or variable. Approximately 30% of patients with chronic hepatitis C have normal ALT levels, and another 40% have ALT levels that are less than twice the upper limit of normal. In contrast to the decline in ALT levels, HCV RNA titers may remain at approximately the same level as during acute infection (see Fig. 1). The large number of persistently viremic patients who have minimal liver damage indicates that HCV quasispecies and the individual patient can become adapted to each other and coexist for decades.

Demographic Factors Associated with Higher and Lower Chronicity Rates

The percentage of acute infections that progress to chronicity ranges from about 50 to 85%, depending on the population. The value most commonly cited for the overall chronicity rate is closer to 85%. The low incidence of symptomatic acute HCV infection in the general population makes it difficult to obtain the prospective data needed to measure this important value directly. In the absence of longitudinal data, the chronicity rate is often calculated from cross-sectional data as follows: the fraction of the subjects positive for both HCV antibodies and HCV RNA (those with chronic infection) is divided by the fraction positive for HCV antibodies (those with chronic infection plus those who

cleared HCV). This approach misses individuals who lack HCV antibodies, including people with self-limited infections who lost antibodies after clearing the infection. Loss of antibodies has been reported in up to 50% of patients with self-limited infections. Thus, the chronicity rate of 75–80% may be an overestimate for the population at large, and is surely an overestimate for certain demographic groups. It is important to delineate the viral and host factors that determine whether acute infection spontaneously clears or progresses to chronicity. This knowledge may provide useful insights for pharmaceutical and vaccine development.

Self-limited infection appears to be more common among the young, females, and Caucasians; however, prospective studies have not yet identified any clinical, serologic, or virologic features that predict the outcome in an individual patient. The survey of the United States population in the National Health and Nutrition Examination Survey (NHANES III) revealed that African-Americans had a chronicity rate of 86%, whereas Caucasians had a chronicity rate of 68%. This disparity is unexplained, but is confirmed by other studies. Its cause may underlie the lower success rate of interferon treatment in African-American patients compared to Caucasians. NHANES III also demonstrated that African-American men had a higher chronicity rate than African-American women (98 versus 70%). Although this survey showed no difference between the men and women of other racial and ethnic groups, several cohort studies reveal that women, especially young women, clear HCV at a relatively high rate. At least 45% of the young healthy women exposed to HCV through contaminated immune globulin had self-limited infection. Youthfulness also favors HCV clearance. Only about 50% of children exposed to HCV while undergoing cardiac surgery had chronic infection when tested as adults, indicating that at least half cleared the infection. Infants born to HCV-infected mothers may clear HCV at a similarly high rate, although more studies are needed to firmly establish the infection frequency in newborns.

Because the incidence of acute HCV infection in the general population is low, the populations enrolled in most cohort studies are composed of individuals at high risk of infection, such as health care workers exposed through needle sticks or other accidents, recipients of blood products, babies of HCV-infected mothers, and recreational users of intravenous drugs. In some cases, the distinctive features of the study population may have an impact on the outcome of HCV infection. Transfusion recipients are often chronically ill, elderly, and immunocompromised; the 80% chronicity rate of these individuals may not be representative of the population as a whole. Similarly, individuals who use intravenous drugs for recreation often have repeated exposure to blood-borne pathogens, including HIV and HBV. Their immune responses to HCV may be distinctive. The special characteristics of the study populations must be considered when drawing general conclusions from the results.

Features of Efficacious Immune Responses

Intense, broad-based, rapid, and enduring cellular immune responses are associated with self-limited infection, whereas, weak, narrow, delayed, and fleeting T cell responses are associated with viral persistence. Humoral immune responses may also play a role in viral clearance; however, this point is controversial. Moreover, the precise characteristics of effective T cell responses are not yet known.

A detailed longitudinal study of individuals exposed through needle stick accidents revealed that HCV infection was controlled only in the single patient who had an early and vigorous CD4+ and CD8+ T cell response that evolved during the course of the infection. In this study, Francis Chisari and colleagues first detected HCV-specific CD8+ T cells in the peripheral blood 7 weeks after infection. Cells were CD38+ (activated) and their appearance coincided with the onset of liver disease. From week 12 onward, the CD8+ T cells became CD38− and began to produce IFNγ for the first time. This change in the CD8+ T cell phenotype coincided with a 5 log drop in the titer of HCV RNA and a precipitous decline in the ALT level. If CD8+ CD38− T cells that produce IFNγ play an important role in viral eradication and if they achieve viral clearance through noncytopathic mechanisms that do not destroy liver cells, as Chisari and colleagues suggest, greater knowledge of these cells may open the door to improved antiviral therapies. This knowledge may also shed light on the immunological mechanisms that allow some chronically infected patients to maintain virus replication at a stable level while experiencing little or no liver damage.

The patient who cleared the virus had an unusually high HCV RNA titer. This high titer was thought to enhance immune responses by providing a robust signal; however, in other studies, low viral titers were a favorable prognostic sign for viral clearance. The predictive value of RNA titer is not clear. Further research is also needed to relate immune responses detected in peripheral blood cells to those occurring in the liver, and to determine whether a single series of events, including the emergence of CD8+ CD38− T cells that produce IFNγ, is required for spontaneous clearance, or if a variety of pathways can lead to resolution.

Viral Strategies to Evade the Immune System and Establish Chronic Infection

Many features of HCV are likely to help it avoid host antiviral defenses. These include (1) a tropism for the liver, which is a large and resilient organ that supports a variety of chronic viruses, (2) the ability to infect lymphocytes, potentially establishing an extrahepatic reservoir that may be resistant to eradication, (3) the production of protein domains, such as the interferon sensitivity-determining region (ISDR), which may dampen innate cellular antiviral defenses and alter cell physiology, and (4) rapid expansion and diversification that outpaces antiviral defenses. Of these escape strategies, rapid expansion and diversification have received the most attention.

A sudden burst of replication during the first weeks of infection may allow the virus to invade a large number of cells and to diversify before the adaptive immune system can bring the infecting strain under control. Diversification creates a mixed population, which may contain escape mutants. Patrizia Farci and colleagues found that diversification and evolution of the HCV population typified patients who progressed to chronicity, whereas relative evolutionary stasis of the viral population occurred in patients who later cleared the infection. The evolutionary stasis observed during self-limited infection may have reflected the immune system's ability to eliminate individual components of the quasispecies before they could generate resistant progeny, or it may have resulted from the absence of selective pressure exerted by the adaptive immune system. The latter circumstance would indicate that broad-spectrum antiviral factors, such as cytokines, e.g., IFNγ, played a major role.

In addition to diversification, other strategies are also important, as indicated by an experiment in which chimpanzees were inoculated with a single pure HCV sequence. Chronic infection developed, but without the accumulation of mutations in the hypervariable region—the domain most strongly associated with escape mutants in people. Although mutations in other regions of the genome did occur, and may have generated escape mutants, it is likely that host factors also contributed to the outcome.

The liver can be chronically infected by a number of pathogens, including HBV, HCV, the delta agent, and the flavivirus, GB virus C (GBV-C)/hepatitis G virus (HGV). Even the hepatotropic viruses that do not establish chronic infections, such as hepatitis A and E viruses (HAV and HEV), persist for weeks or months. Specific features of liver physiology and immunology may contribute to the protracted course of viral infections. The liver contributes to oral tolerance, and it may play a role in other processes involving active down-modulation of immune responses. If mechanisms similar to those leading to oral tolerance became activated during viral infection, the "healthy carrier" state that characterizes many chronically infected HCV patients might result.

CHRONIC INFECTION

The Spectrum of Disease

HCV is a slowly progressive disease. In many patients, liver pathology is limited to mild inflammation and minimal fibrosis. Only about 20% of patients develop cirrhosis, usually after decades of chronic viremia. The major life-threatening consequences of chronic hepatitis C are cirrhosis, complications of end-stage liver disease (portal hypertension and hemorrhage), and hepatocellular carcinoma (HCC). Cirrhosis may develop silently in patients who are unaware of their infection and may not be discovered until overt hepatic decompensation occurs. The likelihood of the development of HCC is estimated to be 1−3% after 30 years of chronic infection. Once cirrhosis is established, liver cancer develops at an annual rate of about 1−4%. Many patients with chronic infection suffer from fatigue and report a seriously diminished quality of life. This problem is most pronounced in patients with cirrhosis. Symptomatic cryoglobulinemia (which is associated with local deposition of immune complexes) and other extrahepatic manifestations occur in a small percentage of patients. Fortunately, many patients escape the serious adverse effects of chronic HCV infection for at least 20 years. It is possible that most will retain adequate liver function indefinitely, but the dearth of long-term natural viral history studies leaves the final outcome in question.

Liver Damage

Much of the serious liver dysfunction in patients with chronic HCV infection is due to the deposition of scar tissue, or fibrosis. Scarring is a generalized response to insults. It is one of the downstream consequences of inflammation and cell injury. Inflammation contributes to liver damage by promoting fibrosis and by causing multiple rounds of cell death, mutation, and cell division—thereby setting the stage for transformation and carcinogenesis. Some investigators believe that all HCV-associated liver injury is indirect and immune mediated, but this point is not settled.

Whatever the driving forces, key variables in the outcome of chronic HCV infection are the extent of

scarring and the rate of scar tissue accumulation. The extent of fibrosis can be accurately determined only by biopsy. Many scoring systems are used to measure fibrosis, including the histology activity index (HAI; Knodell score), the Ishak modification of the HAI score, and the Metavir score. Both the stage of fibrosis and the grade of necroinflammation have prognostic significance; however, unlike scar formation, necroinflammatory activity is not cumulative.

Because liver biopsy is uncomfortable for patients and has a significant morbidity and mortality, efforts are underway to identify a panel of serum markers that might be used in combination with a second modality, such as ultrasound, to measure fibrosis. No noninvasive method is currently available, and liver biopsy remains the gold standard. However, longitudinal studies show that higher ALT levels are associated with a high rate of fibrosis progression, and, conversely, that persistently normal ALT levels are associated with a low rate. Such associations raise hope that in the future noninvasive fibrosis assessment will become possible.

Host Factors Affecting the Fibrosis Progression Rate

All of the important variables that are known to impact the rate of fibrosis progression are characteristics of the patient. HCV genotype, viral load, and the diversity of the quasispecies have not consistently emerged as significant factors (although genotype strongly affects the response to antiviral therapy). Three independent human factors are associated with an increased rate of fibrosis progression: age, alcohol consumption, and male sex. The median time between infection and the development of cirrhosis is estimated to range from a high of 42 years (for abstinent women who were infected before the age of 40) to a low of only 13 years (for men infected after the age of 40 who consume large quantities of alcohol). It is likely that the fibrosis progression rate varies over time in the same individual. Immune responses are generally less vigorous in the elderly, raising concern that the fibrosis progression rate may increase as an individual ages.

It is interesting that two of the factors associated with higher fibrosis progression rates—greater age and male sex—are also associated with increased chronicity rates. This similarity suggests that the inability to clear the virus and the inability to avoid HCV-associated liver damage stem from the same root cause. The cause is likely to be a subtle perturbation, or lesion, in immune responses.

The fibrosis progression rate is accelerated by a number of comorbid conditions. HIV infection, genetic immunodeficiencies, and immunosuppressive drugs have a significant impact. Almost 24% of HCV-infected patients with agammaglobulinemia develop end-stage liver failure within 5 years. Among immunosuppressed liver transplant recipients, the estimated mean time to the development of cirrhosis is only 12 years. Coinfection with hepatitis B virus and other liver pathogens, and diseases such as nonalcoholic steatohepatitis (NASH), may also accelerate fibrosis. To avoid the deleterious effects of coinfection, all patients with chronic HCV should receive vaccines for HAV and HBV unless they are already immune.

Diagnostic Tests for HCV: Detection of Antibodies and HCV RNA

An enzyme immunoassay (EIA) for HCV antibodies is usually the first diagnostic test performed on a patient suspected of having HCV. Commercial assays include epitopes of the nucleocapsid protein (core) and three additional viral proteins (NS3, NS4, and NS5). The specificity of the current EIAs for HCV antibodies is greater than 99%. A second type of antibody test, an immunoblot assay, can be used to confirm EIA results. Recent improvements in EIAs have reduced the need for immunoblot assays in most clinical settings. However, these tests remain useful when used in combination with EIAs during the screening of individuals who have a low risk of HCV infection, such as blood donors. Assays that detect the HCV core antigen have recently been developed and their usefulness is under investigation.

Three types of assays are used to characterize HCV RNA. Qualitative tests establish the presence or absence of HCV RNA in serum and are the most sensitive methods for HCV RNA detection. They are especially valuable when viremia is low. Quantitative tests measure the titer of HCV RNA in serum and are often used to monitor the response to antiviral therapy. When quantitative testing is used for this purpose, all of the measurements should be performed in the same laboratory with the same method. Fortunately, a common system for reporting HCV RNA titers has recently been adopted. Formulas are available for converting the units measured in previous eras to the currently agreed-upon international units (IUs) of HCV RNA.

Genotyping is an additional test that is applied to HCV RNA. This test is performed to identify the type of HCV that infects a particular patient. This information is needed to guide treatment decisions because some genotypes are more sensitive to interferon than others. Genotype is usually determined by amplifying a portion of the HCV RNA with the polymerase chain reaction (PCR) and then analyzing the resulting products.

Available methods reliably distinguish the six major genotypes and many subgenotypes.

Antiviral Treatment for Chronic HCV Infection

Antiviral treatments for HCV have improved dramatically in recent years and now include longer half-life pegylated interferons (peginterferons) that are used in combination with ribavirin. Treatment guidelines continue to evolve. The results of clinical trials should be consulted frequently for updates. The primary goal of antiviral treatment is viral eradication. Several studies show that viral clearance is followed by an improvement in liver histology. Cirrhosis is not completely irreversible, as was once thought. It is hoped that the incidence of HCC will also be reduced by viral clearance, but longer followup is needed to measure this end point and to obtain information about the impact of viral clearance on conditions such as portal hypertension. Some studies suggest that IFN treatment may reduce the rate of disease progression even among patients who remain viremic.

Two forms of pegylated IFNα are currently approved by the Food and Drug Administration. Most protocols use weekly injections of between 0.5 and 1.5 μg/kg of body weight. More research is needed to identify the optimal dose of these new pharmaceuticals. In recent trials, patients with genotype 2 or 3 had a sustained virological response rate of 70–80% when treated with peginterferon and 800 mg/day of ribavirin for 24 weeks. Patients with genotype 1 had a 40–50% sustained response rate after treatment for 48 weeks with weekly peginterferon and daily ribavirin at a dose of 1000 to 1200 mg.

Because of the lower response rate of patients with genotype 1 virus, it is useful to obtain a baseline measurement of the HCV RNA levels in these individuals prior to initiating treatment, and to repeat this test 12 weeks later. If HCV RNA is not detectable, or if the titer has dropped 100-fold or more, treatment should be continued. In the absence of such a drop, a sustained viral response is very improbable. The wisest choice may be to discontinue treatment, or continue with the understanding that a slowing of disease progression is the best result that can be realistically considered as a therapeutic goal.

At the end of treatment, HCV RNA should be measured with the most sensitive test available. A positive HCV RNA test strongly predicts relapse. Negative results should be repeated 24 weeks later, to ensure that the virus has been eradicated. Because of the relatively low success rate (in the case of patients with genotype 1) and the paucity of information about success rates (in the case of patients with genotypes 4, 5, and 6), some investigators feel that it may be advisable for patients with genotypes 1, 4, 5, and 6 who have little evidence of liver injury to be monitored at regular intervals, but to delay therapy until more efficacious treatments become available. Conversely, patients with extensive fibrosis and/or necroinflammatory activity may wish to initiate treatment using current protocols, unless counterindications are involved.

Many patients cannot tolerate current antiviral treatments. The expense and side effects of combination therapy are an impediment to treatment. Moreover, because a wide variety of medical and psychiatric conditions have been exclusion criteria in many of the trials, it is an open question as to what response rates can be achieved in the broad population of chronically infected HCV patients. More than half of all HCV-infected patients would not satisfy the inclusion and exclusion criteria for enrollment in the major peginterferon and ribavirin trials. Fortunately, new pharmaceutical agents may be available soon. These new agents include small-molecule inhibitors of HCV enzymes that are analogous to HIV protease inhibitors. Safety trials of an HCV protease inhibitor are underway.

Liver Transplantation

Liver transplantation replaces a failed or tumorous liver with a graft from a cadaveric or live donor. HCV is the leading indication for liver transplantation in the United States. Reinfection of the graft is virtually universal and immediate. Although some recipients have a favorable course, reinfection often leads to recurrent hepatitis and graft damage. Cirrhosis of the graft occurs in up to 30% of patients within 5 years of transplantation. In recent years, the incidence and severity of recurrent hepatitis C has increased, raising concern that long-term survival rates may be compromised. The factors that may be contributing to this increase in recurrent hepatitis, such as an increase in the average age of liver donors and changes in immunosuppressive drug protocols, are under investigation.

VIROLOGY

HCV RNA and Proteins

Michael Houghton and colleagues first positively identified HCV in 1989. The availability of specific tests for this pathogen soon revealed that HCV is the cause of over 90% of the disease previously known as non-A, non-B (NANB) hepatitis. The HCV-specific tests opened the door to detailed studies of HCV virology and revealed that HCV is in the family Flaviviridae. Yellow fever virus

and GBV-C/HGV are also in this family, although they are rather distant relatives of HCV and are members of another genus. HCV is a positive-sense RNA virus, meaning that both the genomic and the antigenomic strands are composed of RNA, and the RNA that is released from the infectious particle is capable of serving as a messenger RNA once it is reaches a compatible cytoplasm.

The RNA genome of HCV is about 9600 nucleotides in length and has nontranslated regions (NTRs) at both ends (see Fig. 3). Portions of the NTRs form RNA structures that are required for replication, a process that takes place in association with membranous structures in the cytoplasm. An internal ribosome entry site (IRES) mediates the initiation of protein synthesis. This highly conserved region is a target in many HCV RNA detection and quantitation tests, such as the polymerase chain reaction (PCR) assay. The conventional HCV proteins are encoded in the main open reading frame (ORF) of the genomic RNA and are released from a polyprotein precursor while the nascent polyprotein is undergoing synthesis.

The conventional proteins include three structural proteins that are thought to be included in the viral particle: core, and two glycoproteins, E1 and E2. The remaining proteins encoded by the main ORF include two molecules that are not required for HCV RNA replication, p7 and nonstructural protein 2 (NS2); p7 is a small hydrophobic transmembrane protein reported to self-assemble into a pore, and NS2 promotes a metal-dependent self-cleavage reaction that severs the bond

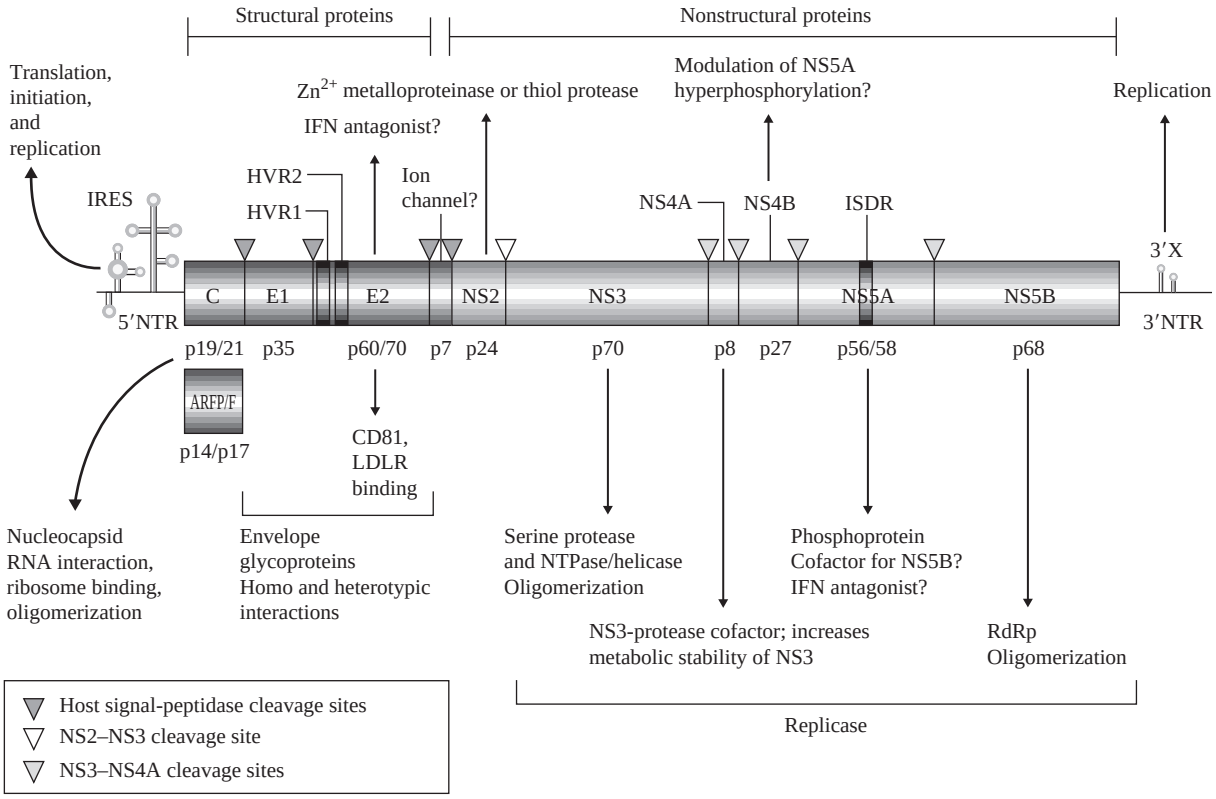

FIGURE 3 Map of the hepatitis C virus (HCV) genome. The boxed area corresponds to the single open reading frame of the HCV genome. The stem–loop structures represent the 5′ and 3′ nontranslated (NTR) regions, including the internal ribosome-entry site (IRES) and 3′X regions. The functions and molecular masses (in kilodaltons) of the gene products after polyprotein processing are shown. Core (C)–E1, E1–E2, E2–p7, and p7–nonstructural protein 2 (NS2) junctions are cleaved by cellular signal peptidases to yield structural proteins. The NS2–NS3 metalloproteinase undergoes autocatalytic cleavage, which releases the mature NS3 serine protease. NS3 cleaves the remainder of the NS polypeptide. The two regions that have extreme sequence variability in E2, known as hypervariable regions 1 and 2 (HVR1 and HVR2), are indicated. A region in NS5A, known as the interferon (IFN) sensitivity-determining region (ISDR), has been linked to the response to IFNα therapy in some strains of HCV. Both NS5A and E2 have been implicated as antagonists of IFN. ARFP/F, Alternative reading-frame protein/frameshift protein; LDLR, low-density lipoprotein receptor; RdRp, RNA-dependent RNA polymerase. Copyright 2002 Macmillan Publishers Ltd.

between itself and NS3. NS3 has a serine proteinase domain at one end, and a helicase domain at the other. It combines with a 54-amino-acid-long membrane protein called NS4a. The NS3–NS4a heterodimeric complex processes the polyprotein, releasing the downstream viral proteins. The function of NS4b is not known, but its membrane associations may aid in the assembly of a multiprotein replication complex. The function of NS5a in viral replication is also unknown; however, this phosphoprotein contains the interferon sensitivity-determining region and confers resistance to IFNα. NS5b is the RNA-dependent RNA polymerase. In addition to the 9100-base-long ORF, genomic HCV RNA has an alternate reading frame (ARF) overlapping the core gene. The ARF gives rise to antigenically active products whose functions are under investigation.

Open Questions

What Is the Form of the Infectious Particle and the Identity of the HCV Receptor?

It is generally accepted that the HCV virion is a flavivirus-like particle with an outer envelope composed of lipids and two viral proteins, E1 and E2. Inside this protective envelope, the HCV core protein forms an inner shell and encases a single full-length copy of HCV genomic RNA. A few electron microscope images of such a particle have been obtained from serum samples of infected patients, although visualization has proved to be unexpectedly difficult. Sedimentation studies indicate that HCV infectivity peaks in serum fractions that are less dense than those that contain traditional flavivirus particles. This unusual sedimentation pattern could be a consequence of particle degradation caused by the centrifugation process, or it could indicate that a portion of the HCV RNA is associated with components of lipoprotein particles, as has been proposed. In keeping with this possibility, the low-density lipoprotein (LDL) receptor mediates the uptake of certain HCV RNA-containing particles—although it is not clear that this pathway can initiate an infectious cycle. CD81 has also been identified as a possible cellular receptor for HCV, and its significance is also under investigation.

Do the Enzymatic Viral Proteins Have Additional Functions?

The proteins encoded by the main ORF are derived from a single polyprotein precursor. Thus, of necessity, they are generated in equimolar amounts. If HCV has a flavivirus-like infectious particle, each virion contains about 500 molecules of the core protein (and one genomic RNA). Every time a virion is produced, 500 molecules of each of the other proteins are also produced. Whereas the virion constituents (core, E1, and E2) are released into the circulation, the other proteins have no export pathway. This design would seem to generate viral enzymes, such as NS5b, in excess of the amount needed for enzymatic activity. If the viral enzymes have additional functions, one may be to provide scaffolding within the replication complex. If these proteins are not all needed for enzymatic activity and scaffolding, their relatively high concentration may position them to interact with cellular constituents.

Does the Core/ARF Region of the HCV Genome Express an Oncogenic Protein?

Epidemiology and natural history studies demonstrate an association between HCV and HCC, but the nature of the association between HCV and HCC remains unexplained at the molecular level. Although HCV may induce HCC primarily by causing chronic inflammation, rather than by producing a frankly oncogenic protein, it appears that chronic inflammation is not solely responsible for HCV-associated HCC. Certain strains of HCV transgenic mice expressing the core/ARF gene develop cancer in the absence of inflammation. Many cell culture studies implicate this segment of the HCV genome in cellular transformation and tumorigenesis. The oncogenic potential of other gene regions is also under investigation. The discoveries that the HCV IRES functions more efficiently during mitosis and that full-length HCV replicons reach higher levels in dividing cells suggest that HCV may replicate more efficiently in cells that are actively dividing and that the virus is under selective pressure to express a protein that promotes cell cycling.

Which Liver Cells Support HCV Replication during Chronic Infection?

Although chronically infected patients often have more than 1 million copies of HCV RNA/ml of blood, detecting HCV proteins and RNA in liver cells is difficult, and the nature of the infected cell is in doubt. As noted previously, experimental systems indicate that dividing cells favor HCV replication; however, this awaits confirmation in human liver specimens. Most data point to a widespread infection of hepatocytes, with each infected cell expressing a very low level of HCV proteins. Based on this model, it is estimated that each cell produces only about 10 to 100 virions per day—such attenuated expression is thought to promote chronicity by confounding the immune system's efforts to identify and destroy infected cells. Ironically, both high-level expression in a very small number of cells and very low-level expression in a large number of cells

would lead to a similar result: a liver in which no signal can be detected in the vast majority of cells, and technical questions about the rare cells emitting a signal. New experimental approaches are needed to resolve this matter and to understand the complex interplay between the virus and the patient that takes place in the HCV-infected liver.

CONCLUSIONS

HCV is a highly unusual pathogen. Its novel characteristics confer advantages and disadvantages from the standpoint of containment and intervention. For example, compared to other viruses that establish chronic infection, HCV has an unprecedented sensitivity to antiviral therapy and can be eradicated in 50% of patients. This sensitivity is clearly an advantage to patients with HCV.

A second novel feature of HCV, the complexity of the core/ARF gene region, is more ambiguous in its clinical implications. The position of this region at the beginning of the main ORF, and its high content of RNA signals, suggest that this domain has regulatory functions. Regulation of viral gene expression could be an advantage to patients if it results in reduced cell damage, but it could be a disadvantage if it promotes chronicity by attenuating viral protein production to the point that the immune system has a difficult time recognizing infected cells.

The nearly total reliance of HCV on direct exposure to contaminated blood for transmission differs from that of other blood-borne viruses, such as HIV and HBV, and has minimized its dissemination into the general United States population. The epidemic is settling into a selected segment of the population: The CDC studies estimate that 70% of new HCV infections occur in individuals who are using intravenous drugs for recreation. This pattern has the potential to allow targeted interventions to be deployed efficiently, but it also has the potential to harm HCV-infected patients by increasing their isolation.

One feature of HCV that is not unusual is its tendency to rise and fall rapidly in the population. The recent decline in new HCV infections provides a window of opportunity: if the reduced incidence can be sustained, the benefits will be great. Pathogens, such as HCV, that cause outbreaks need to be monitored closely. The timely NHANES III study has been extremely valuable; however, it was limited to individuals in households, and missed homeless people and those in institutions. HCV surveillance should continue to have a high priority and should be expanded to include all sectors of society, especially those at high risk of infection.

Many aspects of HCV molecular virology, pathogenesis, and epidemiology have been characterized, but much remains to be learned about this highly unusual virus. The unanswered questions, the expanding burden of HCV-associated liver disease, and the lack of a vaccine combine to make HCV investigation one of the most active research areas in gastroenterology.

predominates in tropical and subtropical areas. With the increased control of HBV achieved in recent years in developed countries, the prevalence of HDV infection has greatly declined in the Western world.

The clinical expression of HDV infections varies from asymptomatic infections to severe forms of acute and chronic liver disorders. Most HDV-infected individuals who develop chronic hepatitis D suffer from a serious and progressive liver disorder. First-line diagnosis is based on the finding of immunoglobulin (IgM and IgG) antibodies to HDV. The ultimate diagnostic gold standard is the detection of HDV RNA in serum or hepatitis D antigen (HDAg) in liver.

The only approved therapy for chronic hepatitis D is interferon α. This, however, cures no more than 15–20% of noncirrhotic forms of the disease. Transplantation offers a safe, therapeutic option for end-stage HDV disease. Provided that prophylaxis with lamivudine and standard hepatitis B immunoglobulins is given, reinfection occurs very rarely.

VIROLOGY

Hepatitis D virus is the only member of the Deltaviridae family. It consists of a negative-stranded RNA virus that depends on HBV for propagation but not for RNA replication. The helper HBV does not share sequence homologies or functional similarities with HDV; the latter shares functional and structural properties with small plant viruses such as viroids and virusoids. There are three major genotypes of HDV.

The virion is a 35- to 37-nm particle consisting of the circular ribonucleic acid (HDV RNA) and delta antigen coated by the HBV surface antigen. The genome is a 1.7-kb single-stranded circular RNA that can fold itself into an unbranched rodlike structure; this folding is caused by base pairing of over 70% of its nucleotides. It has two unique features: transcription by a host RNA polymerase and an autocatalytic capacity (self-cleaving and self-ligation). The autocatalytic RNA segments are functionally similar to the "hammerhead" ribozymes described in plant viruses, but differ structurally, suggesting that the catalytic domain of HDV RNA represents a new and different ribozyme motif.

The HDV encodes a single protein, the delta antigen, from the transcription of a 0.8-kb mRNA. The HDAg consists of two isoforms, the small (S-HDAg, p24) HDAg and the large (L-HDAg, p27) HDAg, derived from a common open reading frame; the isoforms differ by 19 to 20 amino acids at the C terminus. The addition of these amino acids is the consequence of RNA editing at the *amber/W* site. The mRNA contains the open reading frame for the S-HDAg, a 195-amino-acid species that is essential for HDV genome replication. A host cell RNA polymerase that is normally DNA dependent is redirected to act on HDV RNA as template. The S-HDAg p24 promotes HDV replication and is produced by infectious RNA. The L-HDAg p27 inhibits replication and is required for virion assembly. Replication of HDV occurs via the rolling circle model. Circular genomic RNA is transcribed by poly II to yield multimeric linear transcripts of antigenomic sense that undergo autocatalytic cleavage and ligation to produce circular monomeric antigenomic RNA; then, the antigenomic RNA serves as a template for replication of circular genomic RNA by similar transcription and processing.

The host range of HDV infections includes humans, chimpanzees, woodchucks, and ducks carrying the HBV-related hepadnavirus. Though spread of the virus from cell to cell requires the presence of the HBsAg, HDV infection can be initiated by the direct injection of cDNA clones into the liver or by cell transfection.

NATURAL HISTORY

Hepatitis D virus can be acquired by coinfection with HBV or by superinfection of a carrier of HBV. Individuals with antibody to the HBsAg (anti-HBs) in their serum are also protected from HDV. In healthy persons simultaneously coinfected by the two viruses, activation of HDV is dependent on the previous activation of HBV. Usually the underlying HBV infection is self-limited and HDV coinfection resolves. In superinfected HBsAg carriers, the biological effect necessary to support HDV is provided by the HBV colonizing the infected host. Superinfected carriers stand a high risk of becoming chronic HDV carriers; progression to chronicity occurs in over 90% of cases.

The natural history of chronic HDV disease varies. In active double HBV and HDV infections, disease may run a rapidly progressive course, leading to liver failure in less than 2 years. Within the general population, the disease runs a benign nonprogressive course in a minority of the patients (about 15%); in the majority it runs a progressive course, leading to cirrhosis within a few years. Over a median of 6.6 years of follow up, HDV cirrhosis increases twofold the risk for mortality and threefold the risk for hepatocellular carcinoma compared to ordinary HBV cirrhosis, and over a period of 12 years liver cancer has developed in 40% of HDV cirrhotic patients. Patients with chronic hepatitis D may exhibit liver/kidney antibody microsome type 3 (LKM3), which is distinct from LKM1 of autoimmune type 2 hepatitis. LKM3 reacts with uridyl diphosphate (UDP) glucuronyltransferase.

Most HDV infections in endemic areas are contracted in adolescence or early adulthood and present clinically with signs of decompensated cirrhosis in the fourth or fifth decade of life, i.e., one to two decades earlier than patients presenting with HBV or HCV cirrhosis. Of note, the current clinical scenario of HDV disease in the developed world reflects the recent profound decrease in the prevalence of HDV and is different from the clinical spectrum of the disease described in the past. With the control of HBV infection in recent years the number of new HDV infections has markedly declined and the clinical scenario of hepatitis has distinctly changed in the developed world; fresh and florid forms of the disease have become rare and a majority of contemporary HDV cases represent cohorts of patients with long-standing infection, and clinical expression is usually an advanced cirrhosis.

TRANSMISSION AND EPIDEMIOLOGY

Transmission of HDV occurs by the parenteral route, either overtly or covertly, and the same as for HBV transmission. Significant rates of HDV transmission were reported in the past in specific epidemiologic groups, including medical personnel, hemodialysis patients, institutionalized patients, and prisoners, with prevalence rates depending on local hygienic standards and effectiveness of HBV prophylaxis; the control of HBV achieved in recent years in developed countries has also greatly diminished HDV infection in these settings.

Sexual contacts provide HDV transmission, as attested by the prevalence of anti-HDV in prostitutes and in sexual partners of HDV-infected carriers. Transmission of HDV is promoted by household overcrowding; in Italy, cohabitation with a carrier of HDV has been identified as a critical risk factor, and the reduction of family size has been important in determining the decrease of the infection in recent years.

Infection occurs worldwide, but distribution varies. Prevalence variations are in keeping with local prevalence rates of HBV but not dependent on them. The prevalence of HDV infection is very low in North America and Northern Europe. Hepatitis D predominates in several tropical and subtropical countries, where HBV is still hyperendemic. New foci have been identified in the Mato Grosso in Brazil, in Samara, Russia, and among indigenous people of the Amazon basin of Ecuador.

Of the three well-characterized genotypes of HDV, genotype I is predominant and is found in many parts of the world. Genotype II predominates in Taiwan and Japan. Genotype III has so far been found only in the Amazon Basin.

DIAGNOSTIC AND CLINICAL FEATURES

Active HDV infection is diagnosed by the finding in serum or liver of the HDV RNA or of the HDAg. Viremia can be detected with genetic probes that hybridize with complementary HDV RNA; transcription polymerase chain reaction (PCR) can detect in serum 10 to 100 copies of the viral genome.

Attempts to measure HDAg in serum are unrewarding. In immunocompetent patients with chronic hepatitis D, serum HDAg is undetectable by enzyme immunoassay (EIA) or radioimmunoassay (RIA) because these patients have invariably high titers of the homologous antibody, which blocks the antigen in immunocomplexes that are unavailable to the assays. The HDAg can be detected in the liver with immunohistological techniques. Diagnostic screening is performed with indirect antibody markers—the IgM antibody to HDAg (IgM anti-HD), which is measured with μ capture immunoassays, and total antibody to the HDAg (anti-HD), which detects predominantly the IgG antibody and is measured with competitive radioimmunoassays. The IgM anti-HD is the first reaction in primary infection; it persists, progressing to chronicity, and as a rule is detectable in high titers in patients with chronic hepatitis D and represents a surrogate marker of HDV-induced liver damage. The IgG antibodies develop some weeks after primary infection, reaching high titers with progression of infection, and persist in immunocompetent patients with chronic hepatitis D. They do not confer protection and may also be present in HBsAg-negative individuals, representing a serological "scar" of a double HBV/HDV infection that has resolved.

The clinical course of acute HBV/HDV coinfections varies according to the degree of HBV and HDV expression and the interplay between the two viruses, ranging from icteric hepatitis, with full but transient expression of both viruses, to milder anicteric forms associated with diminished HDV expression. Early repression of HBV can inhibit HBsAg synthesis to the extent that this marker is not detectable in serum.

Acute hepatitis D is clinically and histologically indistinguishable from ordinary hepatitis B; distinction requires specific serologic testing. The markers of HBV infection are the HBsAg and IgM anti-HBc; finding the latter is required for diagnosing HBV/HDV coinfection as opposed to superinfection. Coinfection hepatitis is diagnosed from the increase of IgM anti-HD; the IgG antibody also increases but is usually elevated after a delay of several weeks, compared to the IgM antibody.

Severe forms of the illness are accompanied by the full battery of HDV markers, including early HD antigenemia. HDV RNA can be detected in serum very soon during the course of infection and disappears with resolution of disease.

Superinfection results in hepatitis in previously healthy carriers of the HBsAg; it may lead to liver failure in carriers with preexisting chronic hepatitis B. In about 15% of the cases, the chronic disease is a mild portal and periportal hepatitis with no or minimal histological detection of fibrosis. In the other 85% of cases, histology shows extensive inflammation and necrosis with widespread lobular involvement. Disease can be present in HDV carriers with normal liver enzymes; it is often severe in HDV-positive children. Concomitant HIV infection does not appear to modify the course of chronic hepatitis D; these patients may have blunted or absent IgM and IgG anti-HD responses.

PREVENTION AND THERAPY

Vaccination against HBV is safe and efficacious prophylaxis against hepatitis D, because it prevents the helper infection on which HDV thrives. No specific form of prophylaxis is available for the HBsAg carrier at risk of HDV. The only licensed therapy of chronic hepatitis D is interferon α (IFNα), which appears efficacious only in a minority of patients; although 40–70% of treated noncirrhotic patients normalize liver enzymes during therapy, 60–97% of the responders relapse after stopping therapy. Permanent response is shown by the progressive decline of IgM anti-HD and the disappearance of HDV RNA during therapy and by the subsequent seroconversion from HBsAg to anti-HBs.

Doses of 5–9 MU thrice weekly or of 5 MU daily are required and therapy should be prolonged for at least for 12 additional months after normalization of aminotransferases has been achieved. This regimen may cause important side effects, in particular psychiatric alterations. With the recent epidemiologic decline of HBV and HDV infection in Southern Europe and the striking diminution of new cases of both infections, the ratio of cases of long-standing advanced disease over fresh forms of the disease has increased; these forms are more resistant to IFN, and the results of therapy are even less encouraging than reported in clinical trials in the 1980s. Treatment with lamivudine in order to further inhibit and possibly eradicate the underlying HBV infection has been unsuccessful. Combination therapy of IFN with lamivudine is currently being explored; initial results are not promising.

Liver transplantation provides a valid therapeutic option for end-stage HDV disease; dual HBV/HDV infection protects from graft reinfection because in most cases HBV synthesis is repressed by the concomitant HDV infection, so that HDV transplants cannot transmit the HBV necessary to rescue HDV in the liver graft. Combined prophylaxis with lamivudine (pre- and posttransplantation) and standard hepatitis B immunoglobulins posttransplantation have virtually abolished the risk of HDV reinfection in the graft.

Hepatitis E

PIET C. DE GROEN
Mayo Clinic and Foundation

bilirubin A bile pigment formed during the catabolism of heme-containing compounds, primarily hemoglobin.

jaundice Excessive accumulation of bilirubin, as a result of enhanced production or impaired elimination, resulting in yellow discoloration of the skin, sclera, and mucous membranes.

The hepatitis E virus is responsible for major epidemics of enterically transmitted non-A, non-B viral hepatitis in sub-tropical and tropical countries. Similar to hepatitis A, clinical manifestations associated with symptomatic disease are mostly those of mild cholestatic hepatitis, treatment is supportive, and medical emphasis is placed on prevention and development of effective vaccines.

VIRAL AGENT AND DIAGNOSTIC TESTS

The hepatitis E virus, responsible for major epidemics of enterically transmitted non-A, non-B viral hepatitis in subtropical and tropical countries, was cloned in 1990. The virus is currently classified in a separate genus—*Hepatitis E-like viruses*—and consists of a single, plus-strand RNA genome of approximately 7.2 kb without an envelope (Fig. 1). The virus contains at least three open reading frames encoding viral proteins against which antibodies are made on exposure. These antibodies, especially those against the capsid protein derived from the second open reading frame and a small protein of unknown function derived from the third open reading frame, are detected by the current serologic assays. As for hepatitis A, immunoglobulin M (IgM) antibodies and the ratio of IgM/IgG antibodies are markers of acute infection (Fig. 2). IgM antibodies are present in most patients with acute infection as defined by the presence of hepatitis E DNA in serum. Detection of DNA via polymerase chain reaction is used mainly for research purposes. Hepatitis E virus isolates segregate into four major genotypes and at least nine different groups based on full-length sequence comparisons.

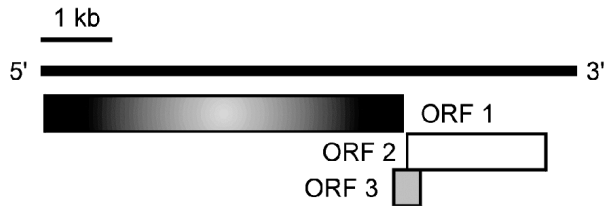

FIGURE 1 Schematic representation of the hepatitis E virus. 5′, 5′-end; 3′, poly(A) tail and 3′-end; ORF, open reading frame.

EPIDEMIOLOGY

Epidemics of symptomatic disease due to hepatitis E virus occur only in tropical or subtropical climates. Endemic areas include Africa (Genotype I), Mexico (Genotype II), and the Middle East and Asia (Genotypes I and IV). Retrospective studies on stored sera from past epidemics of viral, enterically transmitted non-A, non-B hepatitis in Mexico, Africa, Afghanistan, Pakistan, India, Bangladesh, Burma, Nepal, and Borneo have revealed that all were caused by strains of hepatitis E. In addition, hepatitis E was found to be responsible for the hepatitis epidemic of the southern area of Xinjiang, China, in which 120,000 individuals

became infected between September 1986 and April 1988.

Most reports of symptomatic hepatitis E in the United States and Europe describe cases of travelers who acquired the disease in endemic areas, such as Mexico, Africa, or the Far East, and became symptomatic after returning home. However, a small number of cases, mostly asymptomatic, likely are acquired in the United States or Europe. The different genotype (Genotype III) isolated from these cases supports infection from a local source. Sporadic cases have been reported from numerous nonendemic countries, including the United States, Japan, and the Netherlands.

TRANSMISSION

Hepatitis E is transmitted via the fecal–oral route, predominantly via fecally contaminated drinking water supplies. However, preliminary reports also suggest transmission of the hepatitis E virus via blood transfusions. Volunteer studies confirmed the presence of the virus in serum and feces before and during clinical disease. The virus is shed into feces approximately 1 week before symptoms develop. The incubation period varies from 2 to 9 weeks with a mean of approximately 45 days. Swine constitute the main animal reservoir for hepatitis E. Indeed, analyses of hepatitis E genotypes in swine show a close homology for each geographic area with the human genotypes, suggesting that hepatitis E is a zoonosis, with swine as one of its hosts. Other animal sources in Asia and the United States are rodents, in particular, rats.

SYMPTOMS AND SURVIVAL

Hepatitis E predominantly affects young adults (15–40 years old). The symptoms of hepatitis E are similar to those of hepatitis A. Frequently, a prodrome consisting of anorexia, nausea, low-grade fever, and right upper abdominal pain is present 3–7 days before jaundice develops. Aminotransferase levels peak (mostly between 1000 and 2000 U/liter) near the onset of symptoms; bilirubin levels (10–20 mg/dl) peak later. Liver biopsy specimens may show prominent canalicular bile stasis. Jaundice usually resolves after 1–2 weeks. In approximately 10% of cases, the disease is fulminant, especially in pregnant women, in whom mortality rates as high as 20% due to hemorrhagic and thrombotic complications have been reported. The disease may also be fulminant in elderly patients and cause decompensation in patients with chronic liver disease. There is no evidence suggesting that hepatitis E can cause chronic infection.

TREATMENT AND PREVENTION

No specific treatment for symptomatic hepatitis E exists; as for hepatitis A, the disease is self-limited and supportive care is provided as necessary. Prevention is achieved by improving hygienic conditions, e.g., clean drinking water, thereby preventing fecal–oral transmission. Postexposure administration of immune serum globulins from endemic areas has not decreased infection rates during epidemics. However, several experimental vaccines—employing recombinant protein, DNA, or virus-like particles—have been shown to induce protective immunity in animals as well as in human volunteers. A recombinant hepatitis E vaccine is currently in phase III clinical trials.

Hepatocellular Carcinoma (HCC)

CHRISTOPHER D. COSTANZA AND KHALED SELIM
University of California, San Diego

aflatoxin B1 Toxic metabolite produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus,* which contaminate improperly stored peanuts, grain, and rice in hot and humid parts of the world.

ascites Accumulation of fluid that has leaked out of the liver and collected in the abdominal cavity.

Child–Pugh score System that makes use of simple laboratory values (total bilirubin, albumin, and prothrombin time) and clinical examination (ascites and hepatic encephalopathy) to predict which patients with end-stage liver disease will survive a major abdominal surgery; also used to assess the severity of cirrhosis.

chronic liver disease Ongoing injury to the liver lasting at least 6 months.

chronic viral hepatitis Infection with hepatitis B or hepatitis C virus lasting more than 6 months.

cirrhosis Condition involving the liver parenchyma; microscopic assessment demonstrates replacement of normal hepatocytes with fibrosis and regenerative nodules.

cryosurgery Ablative procedure in which subzero liquid nitrogen is injected into the hepatocellular cancer, with a goal of killing the tumor cells.

end-stage liver disease Signs and symptoms of a patient who has decompensated cirrhosis, e.g., ascites, encephalopathy, and esophageal variceal bleeding.

α-fetoprotein Normally produced to a greater degree in fetal life, but also made by malignant hepatocytes in hepatocellular carcinoma; can be elevated in the serum of patients with liver cancer and can be used to screen in patients at risk to develop hepatocellular carcinoma.

fibrolamellar hepatocellular carcinoma Tumor that is considered a histological variant of hepatocellular carcinoma, but has distinctive histological and clinical features. Tumors usually develop in younger, noncirrhotic patients have a more favorable prognosis.

hemochromatosis Inherited disease in which iron overload can affect the liver, heart, pancreas, and skin. Complications of liver involvement include cirrhosis and hepatocellular carcinoma.

hepatic artery chemoembolization Ablative therapy in which the blood supply of the tumor is selectively decreased by embolization to cause tumor cell death. In addition to decreasing the blood supply, a chemotherapeutic agent can be applied directly to the tumor.

hepatic encephalopathy Altered mental status in a patient with end-stage liver disease, ranging from mild confusion to coma; stems from the fact that in a cirrhotic liver, the cells have been replaced with scar tissue and are no longer able to remove toxins from the blood.

hepatitis B DNA virus that infects humans and is transmitted by blood, sex, or childbirth. Some chronically infected patients can progress to cirrhosis and hepatocellular carcinoma.

hepatitis C RNA virus that infects humans and is transmitted primarily through blood. Most patients become chronically infected and some will develop cirrhosis and hepatocellular carcinoma.

hepatocellular carcinoma (hepatoma) Liver cancer.

hepatocyte Normal liver cell.

liver biopsy Procedure in which a needle is placed into the liver and a small portion of the liver is removed for histological examination; most commonly done through the skin as an outpatient procedure.

percutaneous ethanol injection Ablative therapy in which a needle is inserted into the mass and ethanol is injected, with the goal of killing all the tumor cells.

radiofrequency ablation Ablative therapy in which a probe is inserted through the skin into the tumor, with the goal of killing the tumor cells with heat.

surgical resection Treatment that offers best chance of a cure, but is rarely possible because most patients present with symptomatic tumors; the surgery is technically challenging and recurrence rate is high.

transplantation Offers excellent chance for cure if patients are chosen carefully.

Hepatocellular carcinoma (HCC) is a serious health problem and is responsible for as many as 1 million deaths per year worldwide. Major risk factors for HCC are hepatitis B, hepatitis C, cirrhosis of any kind, and exposure to aflatoxin B1. In Africa and Asia, where both the incidence of vertically transmitted hepatitis B and aflatoxin B1 exposure are increased, rates of HCC are nearly 15 times higher than in the United States. If detected early in its course, HCC can be cured with surgical resection, transplantation, and possibly by nonsurgical ablative therapies. Unfortunately, many patients do not have any symptoms from HCC and are diagnosed after the cancer has become advanced and incurable. Most patients who suffer from HCC will die from the tumor. Screening and surveillance strategies to detect HCC at an earlier and more curable stage are being developed and implemented in countries around the world. The effects of such strategies on the natural history of HCC are unknown.

 Copyright 2004, Elsevier (USA). All rights reserved.

Decreasing rates of vertical transmission of hepatitis B, increasing the vaccination rate of hepatitis B, and improving the food storage conditions in areas where aflatoxin B1 flourishes seem to represent the best strategies to decrease the morbidity and mortality associated with HCC.

INTRODUCTION

Hepatocellular carcinoma is the most common primary malignant tumor of the liver, it represents up to 90% of all hepatic malignancies. Worldwide, the incidence of HCC is generally correlated with the prevalence of hepatitis B virus (HBV) infection. The incidence of HCC has risen sharply in Japan and other developed nations, including the United States, possibly due to the "silent" hepatitis C virus (HCV) epidemic. Patients infected with HCV can go several decades without symptoms, but after 20–30 years they can develop symptoms from complications of chronic liver failure, including HCC. HCC occurs predominantly in the setting of chronic liver disease and is most often associated with cirrhosis of the liver. Microscopically, cirrhosis is defined by the destruction and replacement of the normal liver cells by scar or fibrosis. Cirrhosis is caused by a variety of chronic insults to the liver, including HBV, HCV, aflatoxin B1, and alcohol. Once a patient develops cirrhosis, the rate of developing a subsequent HCC is approximately 1–3% per year. HCC is more common in men and the incidence increases with age. HCC is one of the few human cancers for which an underlying etiology, such as HBV or HCV, can be identified in most cases. Surveillance for HCC in high-risk individuals with serum α-fetoprotein (AFP) and ultrasound is being recommended in the United States and other countries. The goal of a surveillance program is to detect small, asymptomatic masses in a group of high-risk patients before the tumor is deemed unresectable. Early diagnosis of HCC is a critical prognostic factor because smaller tumors are generally associated with better outcomes. Several different systems have been used to stage HCC clinically, but, in general, vascular invasion, poor histological differentiation, and large tumors portend a poor prognosis. Surgical resection, transplantation, and ablative therapies are the mainstay of treatment for HCC.

EPIDEMIOLOGY

HCC is the sixth most common cancer in men and eleventh most common cancer in women worldwide. However, because almost every individual who develops liver cancer dies of the disease, HCC is the third most common cause of death in men and the seventh most common in women. HCC accounts for approximately 12,000 deaths per year in the United States and more than 1 million deaths per year worldwide. The epidemiology of HCC differs among geographic regions, ethnic groups, and gender. The prevalence rate of chronic HBV correlates with the incidence of HCC in most geographic regions. Vertical transmission of HBV at birth (from the mother to child) is the major risk in areas with increased incidence of HBV and HCC, such as Southeast Asia, Japan, Korea and sub-Saharan Africa (see Table I for regional incidence rates of HCC). In some parts of the world, HCC is the most common form of internal malignancy and the most common cause of death from cancer. In a given geographical region, different ethnic groups can have markedly varied rates of HCC. For example, in the United States, the incidence of HCC is higher among individuals of East Asian origin, in part because of the increased prevalence of HBV in these patients.

HCC is less common in the majority of developed, Western countries, but appears to be increasing in incidence in these areas. It has been suggested that this increase is due, in part, to the silent epidemic of hepatitis C virus (HCV). Incidence rates are expected to continue to rise for the next 20 years because of HCV. In the US, 50% of all patients who develop HCC will be infected with HCV.

RISK FACTORS

HCC is one of the few human cancers for which at least one risk factor can be identified in most cases. Table II shows the most common risk factors for development of HCC and the relative amount that each factor accounts for in the United States. The most important etiologic factors for HCC are HBV, HCV, cirrhosis, and exposure to aflatoxin B1. Regardless of the etiology, patients with cirrhosis have a fourfold increase in incidence of HCC as compared to patients without cirrhosis. The estimated annual incidence of HCC in patients with cirrhosis is estimated between 3 and 6% per year.

About 85% of the world's cases of HCC occur in the Southeast Asia, eastern Asia, and sub-Saharan Africa.

TABLE I Regional Incidence Rates of Hepatocellular Carcinoma

Region	Age-adjusted incidence
China	60–130/100,000
Taiwan	50–120/100,000
Korea	40–100/100,000
Japan	20–50/100,000
Southern Europe	10–40/100,000
Northern Europe	<5/100,000
United States	<5/100,000

TABLE II Risk Factors for Hepatocellular Carcinoma

Etiology	Percentage of HCC cases caused by, in the United States
Cirrhosis of any kind[a]	
Idiopathic	15–40%
Chronic viral hepatitis	
Hepatitis B	5–10%
Hepatitis D	<1%
Hepatitis C	30–55%
Metabolic disorders	
Hemochromatosis	<1%
α1-Antitrypsin deficiency	<1%
Toxins	
Aflatoxin	<1%

[a] Possible etiologies: anabolic steroids, estrogens, oral contraceptives, and smoking.

HBV is endemic in these regions, with up to 15% of the population being chronically infected. Persistent HBV infection increases the risk of HCC by 100-fold. Men infected at birth with HBV have an estimated lifetime risk equal to 50% for developing HCC.

In HBV infection, random integration into the host genome by a portion of the viral genome contributes to genetic instability by microdeletion or secondary chromosomal rearrangement, increasing the chance for a mutational event. Unlike HBV, HCV is not integrated into the host's genome and the precise mechanism of how HCV leads to HCC is not known, but most likely it is secondary to cirrhosis.

In the United States and Europe, HBV and HCV have equivalent contributions to the incidence rate of HCC. Alcohol-related cirrhosis, alone or in combination with HCV, causes a fair amount of HCC in the United States and Europe. Alcohol acts synergistically with HCV and thus all patients with HCV must be instructed to abstain from alcohol.

Inherited metabolic disorders such as hemochromatosis, tyrosinemia, α1-antitrypsin deficiency, Wilson's disease, and glycogen storage diseases are all associated with a significantly increased risk for development of HCC. Hemochromatosis is a familial disease that is the result of iron overload in various organs, including the liver. In the liver, iron is accumulated in the hepatocytes, causing cellular degeneration and inflammation that can lead to cirrhosis and significant increased risk of developing HCC. Men, for unknown reasons, are at an increased risk for HCC from all conditions in which cirrhosis develops, including chronic HBV infections. In addition to gender, increasing age correlates with incidence of HCC in all geographical and ethnic groups.

Exposure to mycotoxin, aflatoxin B1 (a by-product of the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, which infects grains, rice, and peanuts in hot and humid parts of the world), Thorotrast (a radiographic contrast agent used until the 1950s); C_{17}-alkylated androgenic steroids, and vinyl chloride is another risk factor for the development of HCC.

DIAGNOSIS

Diagnosing HCC at an early stage is critical in determining prognosis. An early diagnosis leaves open the possibility of a surgical cure, via resection or transplantation. Sadly, most patients are diagnosed with HCC after symptoms have developed and the tumor is advanced and incurable.

Clinical Features

Up to 40% of patients with HCC will be asymptomatic at time of diagnosis. When symptoms from HCC are present, it is often difficult to distinguish from symptoms associated with cirrhosis or end-stage liver disease. Patients with both chronic liver disease and HCC often complain of fatigue, jaundice, abdominal pain, and weight loss. On physical exam, many patients will have stigmata of end-stage liver disease such as ascites, peripheral edema, muscle wasting, and jaundice. Other common signs on physical exam are hepatomegaly, splenomegaly, and hepatic bruit, and in some cases a liver mass may be obvious. HCC should be included in the differential diagnosis in any patient with chronic liver disease who experiences sudden worsening of their general condition.

Laboratory Features

Routine laboratory tests for the evaluation of liver function (alanine aminotransferase, aspartate aminotransferase, albumin, prothrombin time, bilirubin, and alkaline phosphate), markers of specific diseases (hepatitis B serologies, hepatitis C antibodies, hemochromatosis, ceruloplasmin, and α1-antitrypsin), and serum α-fetoprotein can be measured in the evaluation for HCC. AFP is an oncofetal antigen; a protein normally expressed in fetal life, but can be reproduced by neoplastic cells, including HCC cells. AFP can be used as a tumor marker and has been shown to be elevated (above 20 mg/ml) in up to 70% of patients diagnosed with HCC. However, AFP utility is limited, because elevations as high as 1000 ng/ml may be seen in patients with very active chronic viral hepatitis without HCC. Although AFP can be produced from other tumors, including undifferentiated teratocarcinoma and embryonal cell

carcinoma, a rising AFP in a patient with cirrhosis is highly suspicious for HCC. AFP can also be used to monitor a response to therapy for HCC and in detecting recurrence of HCC in that patient if AFP was elevated prior to treatment. Some patients with HCC will present with polylcythemia (elevated hemoglobin), hypercalcemia, and hypoglycemia, elevations that are most likely due to tumor-generated hormones.

Liver Biopsy

Preliminary evidence suggests that when performing liver biopsy in a patient with HCC, the needle tracks can become seeded with HCC. The true frequency with which this occurs is unknown, but has been reported as high as 1%. Because of possible malignant seeding as well as other more common complications (bleeding or pneumothorax), some physicians advocate to not perform a needle-biopsy before possible curative surgical therapy; resection, or transplantation. Some examples of indications supporting a liver biopsy include cases in which the diagnosis is not clearly established, when multifocal disease is suspected, and when nonoperative ablative therapy is being considered.

The histological appearance of HCC is of a liver cell cord-like structure, composed of hepatocytes of varying cell differentiation. In some well-differentiated tumors, the cancer cells are so well-differentiated that it is difficult to distinguish tumor cells from normal hepatocytes. On the other extreme, some tumors have cells with severe anaplastic features and only minimal evidence of hepatocellular differentiation. Fibrolamellar hepatocellular carcinoma, usually considered a histological variant of HCC, occurs in a different population and has a better prognosis and deserves special mention. Fibrolamellar HCC usually develops in noncirrhotic livers and does not produce AFP. Fibrolamellar HCC is more common in Caucasian patients and is rarely seen in Asians. The tumors usually grow to a large size without metastasizing and therefore are more amenable to surgical cure at time of presentation.

Radiographic Features

Radiological studies have played an important role in diagnosis and management of HCC for over 20 years. Radiological evaluation is used to identify and characterize the tumor, to direct liver biopsy, and to assess the extent of the disease. Radiological technology has evolved from radioisotope scans of the liver to highly specialized computed tomography (CT) and magnetic resonance imaging (MRI). Ultrasound examination also plays a key role in HCC and has been studied extensively in screening and surveillance populations. Ultrasound has been found to be highly sensitive, 66–84% for lesions less than 3 cm, specific, and less expensive than CT or MRI. Additional benefits of ultrasound include its wide availability, noninvasive nature, and ability to estimate the severity of the underlying liver disease. However, ultrasound is operator dependent and is not as sensitive, specific, or reliable as dual-contrast CT scans and MRI in detecting lesions smaller than 1 cm. Because of this, multiphase contrast-enhancing CT scans and MRI have largely replaced ultrasound for characterizing HCC. The term "triple-phase" CT scan has been coined to describe the very rapid scanning of the liver before contrast injection, during the filling of the hepatic artery, and during filling of the portal vein with contrast. CT scans or MRI scans are particularly useful for patients in whom ultrasound has not been able to accurately define a suspected lesion. Additionally, CT scans can provide volumetric data that can be used to determine the extent of resection in suitable candidates. Using specialized contrast agents can also increase the sensitivity and specificity of the CT and MRI scans. Lipiodol CT scans use lipiodol oil, which is iodized poppy seed oil that selectively enhances the vascular HCC liver nodules. For lesions less than 1 cm, a lipiodol CT scan has a sensitivity of about 70%. Even with the latest and most advanced technology, radiological imaging will not detect a substantial number of small tumor nodules and thus periodic surveillance in high-risk cirrhotic patients is recommended.

SCREENING AND SURVEILLANCE

HCC screening programs for the average-risk patient are not currently recommended in the United States. Surveillance programs for patients at high risk for the development of HCC, such as cirrhotics, are being done in the United States and other nations. Table III shows the suggested guidelines for surveillance for HCC. Serum AFP and radiological imaging, including ultrasound, CT scan, or MRI, are used to screen high-risk individuals. Using AFP alone to screen patients in populations with an increased incidence results in a sensitivity of 80–90%. In areas with a low incidence of HCC, such as the United States, the sensitivity of serum AFP drops to between 50 and 70%. Specificity is constant at 80–90% in both high- and low-incidence populations. In the United States and Western nations, serum AFP and an ultrasound examination are performed every 6 months for high-risk patients. Patients with persistently elevated AFP, or ill-defined lesions on previous imaging, represent a higher risk group of patients, and should be followed more closely with AFP every 3 months and ultrasound, CT scan, or MRI every 3–6 months.

TABLE III Guidelines for Hepatocellular Carcinoma Surveillance

Surveillance is recommended for the following patients
Cirrhosis from any cause
Chronic hepatitis B
Family history of HCC
Previously resected HCC
Chronic liver disease with documented fibrosis
Surveillance is not recommended for the following patients
Healthy patients with no liver disease
Chronic hepatitis C without cirrhosis
Patients who are not candidates for possible treatment options (surgical resection, transplantation, or ablative therapies)

Up to 50% of patients who are diagnosed with HCC are not aware that they had underlying liver disease and therefore would not benefit from a surveillance program. Additionally, for a surveillance program to have an effect and to achieve the modest survival benefit reported from Western tertiary centers, a population must have adequate financial and surgical support. Therefore, it is unlikely that surveillance programs will have a major impact on HCC mortality rates throughout the world. It is more likely that strategies such as universal vaccination against HBV, improved eradication of HBV and HCV with medical treatment, and removal of aflatoxins from the food chain will have a more significant impact on prevention.

STAGING

Once a patient has been diagnosed with HCC, the next step is to determine the stage of the cancer. As in other types of malignancies, the goal of staging in HCC is to stratify the patient based on historical outcomes, to predict mortality, and to then determine the most appropriate treatment modality. There are several different staging systems available, including the pathologic tumor–node–metastasis (pTMN), International Union Against Cancer (UICC), Cancer of the Liver Italian Program (CLIP), Okuda, and Barcelona Clinic Liver Cancer (BCLC) systems. HCC differs from other cancers in that underlying hepatic function and not the biology of the tumor best correlates with survival. Because the pTMN system does not assess the underlying hepatic function, its prognostic value is limited. The Okuda system was the first system to incorporate the biology of the tumor and the status of underlying liver disease. All the clinical staging systems have shortcomings, thus it is necessary to consider many aspects, including performance status and severity of hepatic dysfunction, tumor extent, and comorbid conditions, prior to recommending a treatment strategy.

TREATMENT

Surgical Treatment

Surgical removal of the tumor, via resection or liver transplantation, is the treatment of choice and offers the best chance at a cure. However, less than 20% of patients with HCC will present with a resectable lesion. Patients who present with unresectable HCC have a mean survival time of about 6 months. If a patient has symptoms at the time of diagnosis, the mean survival/doubling time of the tumor is about 3 months. Relative contradictions to surgical resection include extrahepatic tumor, jaundice without obstruction, hepatic encephalopathy, refractory ascites, renal insufficiency, poor hepatic function, multifocal disease, portal vein involvement, and/or portal hypertension. The most common sites for distant metastasis are lungs and bone.

Surgical Resection

For patients with HCC in an otherwise normal liver, i.e., without underlying hepatic dysfunction, resection can be done with low morbidity and mortality ($< 5\%$). Long-term results are also good, with a 5-year survival ranging between 35 and 50%. Patients with a single, small tumor (less than 5 cm), negative resection margins, and an absence of nodal or vasculature involvement have better survival. Partial hepatectomy is the preferred surgical technique for noncirrhotics or patients with mild (Child's A) cirrhosis. Whereas individuals with well-compensated cirrhosis tolerate a partial hepatectomy, patients with Child's B or C cirrhosis do poorly with such a large segment of their liver removed. Therefore, when possible, it is best to preserve as much residual liver mass by using a smaller operation, such as a segmental or nonanatomical resection, in patients with severe liver dysfunction. Hepatic resection is most often done for curative purposes, but other indications for resection include ruptured HCC, mass effect, paraneoplastic symptom relief, and for diagnostic purposes. The most common reported complications following resection include bile leaks, bleeding, and liver failure. Tumor recurrence in the residual liver occurs in approximately 50–70% of patients, either in a *de novo* or a metachronous lesion.

Liver Transplantation

Liver transplantation is an appealing surgical approach to HCC because it removes the cancer and

results in the widest possible resection margin, removing the remaining liver, while simultaneously restoring hepatic function. Transplantation is the treatment of choice for patients with small HCC and advanced cirrhosis (Child–Pugh score B or C). Since 1983, the National Institutes of Health has endorsed liver transplant for selected patients with HCC. Transplantation is contraindicated if there is extrahepatic spread of the tumor, if a single tumor is greater than 5 cm, or if there are more than three tumors and one of them is greater than 3 cm in diameter. Several series have found similar survival rates in patients with HCC compared with those without HCC as long as the aforementioned guidelines were followed. Historically, patients with HCC have done poorly while waiting on the transplant list, because the rate of tumor progression is about 70% per year. Recently, to allocate organs and give a higher priority to patients with HCC, the Model for End-Stage Liver Disease (MELD) system has been implemented in the United States. Whether this improves the outcomes of patients with HCC on the waiting list remains to be seen. Other solutions to this problem may include living donor transplantation, split-liver techniques, and accepting marginal donor organs for patients with HCC. Living donation eliminates the waiting period and may be the preferred treatment strategy for patients with HCC. However, it is a relatively new strategy and the long-term survival analysis is not yet available. Although there is little evidence to suggest that preoperative or neoadjuvant ablative therapy improves survival, it is generally recommended to retard tumor growth and metastatic spread.

Ablative Therapy

Tumors that are not amenable to surgical resection, either because the tumors are multiple or inaccessible or there is severe hepatic dysfunction, can be treated with one of several ablative techniques. The first nonsurgical ablative technique was ethanol injection, which is relatively safe and effective and is still widely used. Cryosurgery, radiofrequency ablation, hepatic arterial embolization, and chemoembolization are additional ablative therapies that can be used on nonresectable tumors.

Percutaneous Ethanol Injection

In percutaneous ethanol injection (PEI), using ultrasound for guidance, the tumor is injected with ethanol, with a goal of achieving complete tumor necrosis. Most tumors require multiple injections on separate days. PEI is used to treat tumors less than 5 cm in diameter in patients with three nodules, each less than 3 cm. Contraindications to PEI include the presence of ascites, coagulopathy, and/or obstructive jaundice. Results vary with the size of the tumor, with an 80% response rate for tumors less than 3 cm. The advantages of PEI are that it is minimally invasive, simple, safe, low cost, and quite efficacious.

Cryosurgery

Cryosurgery is an operative procedure in which subzero liquid nitrogen is administered directly into the tumor. It can be done in conjunction with hepatic resection, especially when the tumor is discovered in the contralateral lobe. Survival rates are comparable to resection but randomized clinical trials are lacking.

Radiofrequency Ablation

A relatively new technique, radiofrequency ablation (RFA), uses a heat-generating probe to destroy the tumor cells. The probe can be introduced through the skin, laparoscopically, or via an open operation. The long-term results for RFA patient survival has not been assessed. Short-term results appear to be similar to those for PEI, but fewer applications are needed. Complications include tumor seeding of the tract in 3–12% of the cases. Most physicians reserve this technique for nonresectable lesions.

Hepatic Artery Chemoembolization

Most HCC tumors receive all their blood supply from the hepatic artery, whereas the normal liver receives most of its blood supply (60–70%) from the portal vein. The goal of hepatic artery chemoembolization (HAC) is to reduce blood supply selectively to the tumor, causing induced hypoxic death of tumor cells. The procedure consists of doing an angiogram and identifying the specific artery that is supplying the tumor with blood. Next, an emulsion of lipiodol, gelatin sponges, and a chemotherapeutic agent is infused into the tumor. Randomized trials have failed to show any survival benefit of HAC versus no treatment. HAC is a palliative approach when surgery and other percutaneous ablative therapy are contraindicated. Complications include infection, abscess, liver failure, and death.

CONCLUSION

HCC is a major worldwide health issue and appears to be increasing in developed Western countries. Hepatitis B, hepatitis C, cirrhosis, and exposure to aflatoxin B1 are the major risk factors for development of HCC. If diagnosed earlier, smaller tumors are more amenable to

potentially curative management, including surgical resection, liver transplantation, and possibly ablation. Unfortunately, despite screening directed at high-risk populations, 80% of patients present with advanced HCC that cannot be resected or cured. Prevention of HCC with HBV vaccination programs and medical treatment of HCV and HBV may have an impact on HCC outcomes in the future.

allograft Transplantation of cells from the same species with differences in major histocompatibility complex antigens.

mature hepatocyte Parenchymal epithelial liver cell expressing liver genes expected in fully differentiated cells.

progenitor cell Cell with the capacity to replicate extensively, exhibit patterns of gene expression found in immature cells, and differentiate into mature cells.

stem cell Cell with the capacity to produce differentiated cells of more than one lineage or multiple lineages without losing the capacity for self-renewal.

xenograft Transplantation of cells from a different species with incompatible major histocompatibility complex antigens.

The term "hepatocyte" refers to parenchymal liver cells, which exhibit a variety of synthetic, metabolic, and detoxification functions necessary for sustaining life. Loss of an adequate functioning mass of hepatocytes leads to liver failure, which may occur suddenly (acute liver failure) or gradually over months or years following the onset of progressive liver disease (chronic liver failure). Liver failure is characterized by global abnormalities in hepatic function leading to or associated with perturbation of brain function (hepatic encephalopathy), kidney function (hepatorenal syndrome), sepsis, multiorgan failure, and eventually death. Deficiency or loss of specific gene function may lead to other types of liver diseases or affliction of distant organs without hepatic injury. Consideration of cell therapy is appropriate for liver failure, as well as numerous genetic and metabolic diseases. Moreover, hepatocytes possess the machinery to express many therapeutic genes, which makes the liver an attractive

allograft Transplantation of cells from the same species with differences in major histocompatibility complex antigens.

mature hepatocyte Parenchymal epithelial liver cell expressing liver genes expected in fully differentiated cells.

progenitor cell Cell with the capacity to replicate extensively, exhibit patterns of gene expression found in immature cells, and differentiate into mature cells.

stem cell Cell with the capacity to produce differentiated cells of more than one lineage or multiple lineages without losing the capacity for self-renewal.

xenograft Transplantation of cells from a different species with incompatible major histocompatibility complex antigens.

The term "hepatocyte" refers to parenchymal liver cells, which exhibit a variety of synthetic, metabolic, and detoxification functions necessary for sustaining life. Loss of an adequate functioning mass of hepatocytes leads to liver failure, which may occur suddenly (acute liver failure) or gradually over months or years following the onset of progressive liver disease (chronic liver failure). Liver failure is characterized by global abnormalities in hepatic function leading to or associated with perturbation of brain function (hepatic encephalopathy), kidney function (hepatorenal syndrome), sepsis, multiorgan failure, and eventually death. Deficiency or loss of specific gene function may lead to other types of liver diseases or affliction of distant organs without hepatic injury. Consideration of cell therapy is appropriate for liver failure, as well as numerous genetic and metabolic diseases. Moreover, hepatocytes possess the machinery to express many therapeutic genes, which makes the liver an attractive

Copyright 2004, Elsevier (USA). All rights reserved.

target for gene therapy. Also, hepatocytes can be used to produce bioartificial liver-assist devices to support patients with liver failure. Hepatocytes constitute the most abundant type of liver cell (~60%). Other types of liver cells include bile duct cells; hepatic stellate cells, which are present in the space of Disse, juxtaposed between hepatocytes and liver sinusoids; endothelial cells, which line the liver sinusoids; fibroblasts; pit cells; and Kupffer cells. The function of the liver as a cohesive unit depends on cross talk among various cell types through release of cytokines, chemicals, and signaling molecules capable of modulating cell function. Each of these cell types may impact liver function in health and disease.

ONTOGENIC CONSIDERATIONS

The human liver originates from the foregut endoderm after 4 weeks of pregnancy and develops rapidly. The structure of the liver assumes an adult form during the subsequent several weeks with production of bile by 14 weeks, indicating establishment of hepatobiliary function. The development of hepatocytes requires "specification" of embryonic cells along the hepatic lineage, which occurs with the activation of master transcription factor switches regulating gene expression, e.g., hepatocyte nuclear factor-3, as well as "differentiation" of specified cells into mature hepatocytes under regulation by additional sets of genes. The liver stroma originates from primitive cardiac mesoderm and the development of endothelial cells is critical for hepatocytes at this stage. During fetal development, hepatocytes express some genes, e.g., α-fetoprotein, which is replaced after birth by abundant expression of the albumin gene. Also, fetal hepatoblasts express both hepatic and biliary genes and may differentiate along either of these cell lineages. In contrast, the prevalence of progenitor cells in the adult liver declines markedly, although in certain circumstances, progenitor cells can reappear in the adult liver.

RELATIONSHIP WITH STEM/PROGENITOR CELLS

To sustain an adult organ, cell losses arising from normal "wear and tear" must be balanced by equivalent replacement of healthy cells. The normal adult liver is characterized by extremely limited rates of cell losses. However, in response to trauma or surgical resection, hepatocytes replicate and restore the liver mass. This property places the liver among the few organs in the body with the capacity to regenerate itself. Studies established that in appropriate circumstances hepatocytes divide indefinitely and repopulate the liver multiple times. On the other hand, the life span of individual hepatocytes may be limited by the ability of cells to maintain normal chromosomal lengths. In animals lacking telomerase, an essential protein required for reconstituting the ends of chromosomes during cell division, hepatocytes become more susceptible to injury and liver disease. In situations where hepatocytes are unable to proliferate, additional types of liver cells, designated "oval cells," may appear. Oval cells originally referred to poorly differentiated epithelial cells arising after exposure to cancer-inducing chemicals. However, oval cells also arise during liver regeneration following hepatotoxicity with chemicals, hepatitis virus infection, and acute liver failure. Cells similar to oval cells have been isolated from the pancreas, which in common with the liver arises from the foregut endoderm. Oval cells may produce hepatocytes, bile duct cells, and other cell types. Similarly, hepatocytes may be derived from hematopoietic stem cells, occasionally in the normal liver but much more frequently in the diseased liver. It is noteworthy that the fetal liver is a major site for the production of hematopoietic cells. This function is no longer necessary in adults, although hematopoiesis may be encountered in the adult liver during some diseases. Further examples of stem cell plasticity have been encountered in cells from other sources, e.g., multipotent adult progenitor cells of mesenchymal origin, with the capacity to differentiate into hepatocytes. Also, differentiation of pluripotential embryonic stem cells into mature hepatocytes is under active investigation. These considerations of liver renewal are relevant for understanding pathophysiological mechanisms and for identifying suitable types of cells for accomplishing cell therapy since the supply of donor livers for transplantation is very limited.

PRINCIPLES OF CELL ISOLATION AND CULTURE

The ability to isolate primary hepatocytes offers a variety of cell culture-based methods to elucidate biological mechanisms, to develop novel drugs, to establish drug metabolism and toxicity, and to advance cell therapy and other applications. The standard procedures employed to dissociate liver cells require the use of enzymes, e.g., collagenase, to perfuse the entire liver or portions of the liver, followed by mechanical dispersion of cells and separation of various liver cell types through gravity, by inert gradients using cell density, and by the use of fluorescence-activated cell sorting or magnetic cell sorting with specific antibodies. These methods

create discrete populations of hepatocytes and other liver cells for establishing cell cultures or for immediate use. Unlike some cell types, however, hepatocytes are easily injured during cell isolation and survive for only short periods (hours) while suspended in culture medium. On the other hand, when hepatocytes are provided anchorage to tissue-culture plastic or other substrates, cell survival improves greatly and cells can survive for several days or weeks. The survival and function of cultured hepatocytes can be improved by incorporation of specific extracellular matrix (ECM) components, e.g., collagen, fibronectin, and laminin. Hepatocytes interact with the ECM via specific cell surface integrins and such interactions modulate the proliferation of the cells as well as the expression of differentiated genes. Nonetheless, it is generally difficult to induce proliferation in cultured hepatocytes. A variety of growth factors affect DNA synthesis in cultured hepatocytes. Hepatocyte growth factor (HGF) and transforming growth factor (TGF)-α are among the most potent inducers, whereas TGF-β is a most potent inhibitor of hepatocellular DNA synthesis. Incorporation of hepatic growth factors permits the survival of hepatocytes in culture over several months. It should be noted that subpopulations of hepatocytes exhibit differences in proliferation capacity under culture conditions as well as in intact animals. Hepatocytes characterized by a "small size" exhibit greater proliferation. On the other hand, hepatocytes with evidence of DNA damage show a significantly lower level of proliferation capacity. Also, the behavior of cultured hepatocytes differs depending on the condition of the donor liver. Cells isolated from a donor liver with excessive amounts of fat, fibrosis, or inflammation show poor viability and survival under culture conditions. The survival and function of cultured hepatocytes improve in the presence of additional liver cell types, especially hepatic stellate cells, which express a variety of hepatotrophic growth factors and cytokines, including HGF. Hepatocytes isolated from the adult liver do not survive in serial culture. However, hepatocytes isolated from the liver of young subjects or from the fetal liver can be cultured serially by repeated subpassaging over several months, with hepatocytes from fetal liver performing better than those from young subjects (Fig. 1). Manipulations aimed at increasing the replication potential of hepatocytes involve the introduction of oncogenes, e.g., simian virus 40T antigen, or reconstitution of telomerase activity, which could represent a more natural approach. These methods have been successful in obtaining hepatocytes that can undergo hundreds of population doublings. Such manipulations offer the potential for development of novel substrates for *in vitro* studies, development of bioartificial liver devices to support a failing liver, and use of these cells for transplantation, although whether prolonged cell culture will introduce deleterious genetic aberrations needs further analysis.

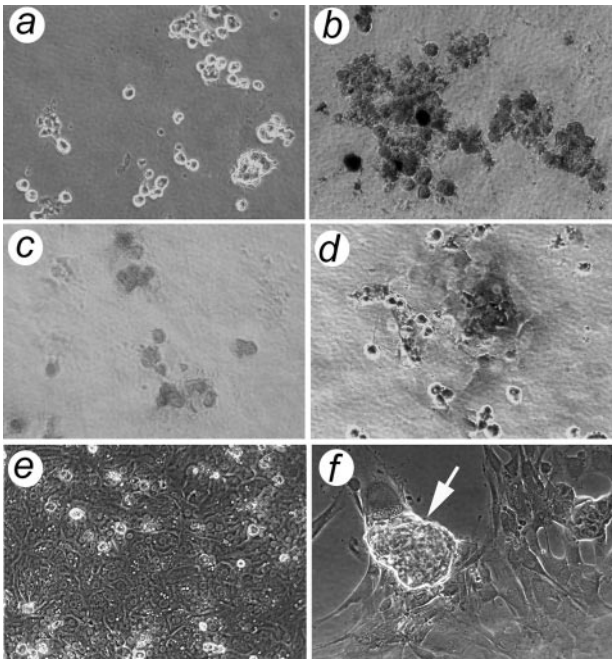

FIGURE 1 Representative examples of primary hepatocytes. (a–d) Primary hepatocytes isolated from an adult human liver. The cells were cultured in the short term on tissue-culture plastic and are shown under phase-contrast microscopy. (b, c, and d) Histochemical demonstration of glucose-6-phosphatase activity, dipeptidyl peptidase IV activity, and glycogen activity, respectively. (e) Primary hepatocytes isolated from an adult rat liver with typical confluent cell cultures on tissue-culture plastic. (f) Hepatocytes isolated from a rat pup within a few days after birth. These cells had been passaged 16 times in culture and showed significant proliferation, as shown by the area of amassed cells (arrow). Original magnification, ×200.

MANIPULATION OF CELLS FOR *IN VITRO* AND OTHER APPLICATIONS

The liver represents a complex unit of multiple cell types with a unique morphological arrangement, including dual blood supply with oxygenated blood arriving from the hepatic artery and blood enriched in nutrients and hormones arriving from the portal vein. Hepatocytes show position-dependent differences in their biological behavior. For instance, hepatocytes in the periportal areas of the liver lobule undergo earlier and greater DNA synthesis during liver regeneration, whereas hepatocytes in the perivenous areas of the liver lobule show greater expression of cytochrome

TABLE I Selected Conditions Considered Amenable to Liver-Directed Cell Therapy

Liver suffers from disease	Liver spared from disease with diseases in other target organs
Metabolic diseases	**Metabolic deficiency states**
Wilson's disease	Congenital hyperbilirubinemia, e.g., Crigler–Najjar syndrome
α-1 Antitrypsin deficiency	Familial hypercholesterolemia
Erythropoietic protoporphyria	Hyperammonemia syndromes

Tyrosinemia type 1	Oxalosis
Acquired disorders	**Hereditary coagulation disorders**
Chronic viral hepatitis	Hemophilia
Liver cirrhosis	Factor IX deficiency
Chronic liver failure	**Inherited immune disorder**
Fulminant liver failure due to viral hepatitis, drug toxicity, etc.	Hereditary angioedema

P450 genes that metabolize or detoxify injurious by-products, chemicals, and drugs. Reproducing the behavior of hepatocytes isolated from this complex microenvironment under culture conditions is obviously difficult. A variety of manipulations have been tested for augmenting specific properties of cells, e.g., culture of cells with ECM, in gels composed of various biomaterials, with feeder cells. However, maintenance of the most differentiated function of cultured primary hepatocytes is an unresolved challenge at present. Similarly, expansion of hepatocytes under culture conditions, such that a bioartificial liver device could be seeded with relatively few cells, followed by cell proliferation has not been possible. Gene transfer with retroviral vectors, which integrate in the host genome and confer permanent gene transfer, has been hampered by limited DNA synthesis in cultured hepatocytes. Another area concerns cryopreservation of hepatocytes, which would provide the ability to store cells for use at short notice. Although progress has been made in developing suitable conditions for freezing primary hepatocytes, further work is needed to develop superior methods.

MECHANISMS IN CELL THERAPY

A major use of isolated hepatocytes involves transplantation to correct or ameliorate a variety of disorders (Table I). Numerous animal studies have been conducted to establish fundamental mechanisms in cell engraftment and liver repopulation with transplanted cells. A major goal of these studies is to establish what mass of transplanted hepatocytes will be necessary for correcting specific diseases. Animal models were established initially to localize transplanted cells containing unique genetic markers for distinction between native and transplanted hepatocytes. The use of such rodents established that transplanted hepatocytes engraft, survive, and function in a most optimal manner within the liver, rather than in ectopic sites, of recipients. Transplanted hepatocytes survive in the liver of animals during the entire life span of mice and rats (approximately 2 years), when rejection of mismatched cells is avoided. Of course, transplantation of incompatible hepatocytes with mismatched major histocompatibility complex antigens leads to rejection within several days. Analysis of the biological properties and fate of human hepatocytes requires the availability of immunodeficient mice or

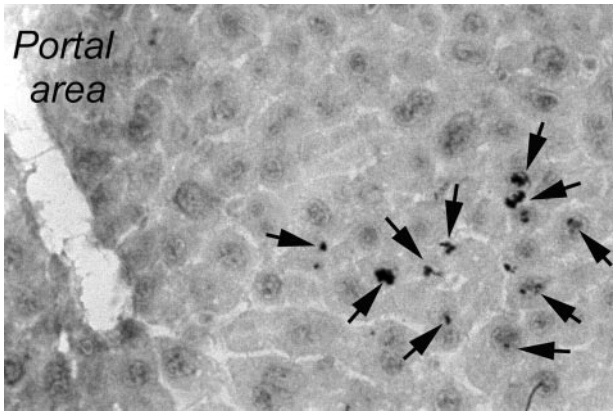

FIGURE 2 Transplanted hepatocytes in the mouse liver. An example is shown of how transplanted hepatocytes become integrated in the liver parenchyma. Primary human hepatocytes were transplanted into the liver of a NOD–SCID mouse by intrasplenic injection. Transplanted cells were identified by a human pan-centromeric DNA probe labeled with digoxigenin. This probe produced multiple dark-reaction products in transplanted cell nuclei (arrows) after detection with peroxidase-conjugated anti-digoxigenin antibody and color development with diaminobenzidine. Original magnification, ×400.

other suitable animals capable of tolerating xenografts. Fortunately, mice with severe combined immunodeficiency (SCID) represent such a host with a deficiency of T and B lymphocytes that minimizes immune responses against transplanted tissues. Mice that exhibit natural onset diabetes (NOD) in the background of SCID show additional depletion of natural killer lymphocytes and are superior animals for the analysis of transplanted human cells (Fig. 2). Other types of immunodeficient mice are being tested, e.g., NOD−SCID mice lacking in β-2-microglobulin expression. Moreover, the use of fetal sheep has been effective for analyzing the fate of human cells.

The general approach is to transplant "normal" hepatocytes into humans to correct genetically determined metabolic disorders, although the use of stem cells capable of differentiating into hepatocytes with amenability to immunological manipulations for avoiding rejection is gaining interest. Treatment of patients with liver failure could potentially utilize healthy hepatocytes from any source. Studies in authentic animal models of disease, e.g., the Gunn rat, which models Crigler−Najjar syndrome (congenital jaundice due to impaired bilirubin UDP-glucoronosyl transferase activity), the Long-Evans Cinnamon (LEC) rat, which models Wilson's disease (copper toxicosis due to ATP7B gene mutations), Nagase analbuminemic rat (NAR; hypoalbuminemia due to albumin gene mutation), Watanabe heritable hyperlipidemic rabbits (WHHL), which model familial hypercholesterolemia (low-density lipoprotein receptor mutations), and a variety of induced mutations in mice, including models for hereditary tyrosinemia, progressive familial intrahepatic cholestasis, and apolipoprotein deficiency, have been most valuable. Similarly, studies are being conducted in animals with acute liver failure or chronic liver disease and cirrhosis. In some animal models, e.g., NAR, Gunn rats, LEC rats, and WHHL rabbits, outcomes of cell therapy are monitored by demonstrating changes in serum proteins (albumin, bilirubin, ceruloplasmin, and total cholesterol, respectively). Assessment of improved outcomes by analyzing manifestations of liver disease, e.g., encephalopathy, coagulopathy, and jaundice, requires other types of physiological measurements or analysis of mortality. Insights from animal studies have begun to be translated into people. To date, initial studies of hepatocyte transplantation in approximately 50 patients worldwide indicate that cells can be transplanted safely. In selected situations, transplantation of allogeneic human hepatocytes has been effective in ameliorating metabolic diseases. These encouraging initial studies establish the framework for further development of liver cell therapies and pave the way for eventual applications of stem cells for a similar purpose.

Hepatorenal Syndrome

JOSH LEVITSKY*, TARA N. TROY*, AND THOMAS W. FAUST†
*University of Chicago Hospitals, Illinois and †University of Pennsylvania Health System, Philadelphia

acute tubular necrosis Abrupt and sustained decline in glomerular filtration rate in response to an acute ischemic or nephrotoxic insult, often characterized by brown tubular casts in the urine.

fractional excretion of sodium Percent of filtered sodium excreted in the urine, calculated based on concentrations of urinary (U) and plasma (P) sodium (Na) and creatinine (Cr): $([Na_U][Cr_P]/[Na_P][Cr_U])100$.

glomerulonephritis Inflammation of the renal glomerulus often due to infectious or immune disorders; red blood cells, and red and white blood cell casts commonly seen on urinalysis.

hepatorenal syndrome Development of renal failure in patients with acute or chronic liver failure in the absence of any other known cause of renal disease.

splanchnic Mesenteric or intestinal in origin.

transjugular intrahepatic portosystemic shunt Placement of a self-expanding metal mesh stent between the hepatic vein and a branch of the portal vein via angiographic catheters inserted through a jugular vein.

Hepatorenal syndrome is characterized by progressive renal insufficiency in patients with acute or chronic liver failure. Two types of hepatorenal syndrome exist and are differentiated by the rapidity and severity of renal dysfunction. Treatment includes the avoidance of or discontinuation of nephrotoxic medications or procedures, volume support, and therapy directed at reversing splanchnic vasodilation and improving renal perfusion.

INTRODUCTION

Renal failure is a frequent complication in patients with fulminant hepatic failure and end-stage liver disease, occurring in 40–80% of all patients. If a known cause of renal dysfunction is not determined and renal function continues to deteriorate, the patient is typically diagnosed with hepatorenal syndrome (HRS). Two types of HRS exist according to the International Ascites Club (1996). In the past, various treatments for HRS have been utilized with limited success. However, recent studies have shown improvement in HRS with the use of splanchnic vasoconstrictors or transjugular intrahepatic portosystemic shunts (TIPS). The epidemiology, pathophysiology, diagnosis, treatment, and prevention of HRS are reviewed in the following discussions.

EPIDEMIOLOGY

Because the formal diagnostic criteria for HRS were created by the International Ascites Club only recently (1996), the epidemiology of HRS has not yet been well defined. Retrospective studies have demonstrated that HRS is present in ~17% of patients hospitalized with ascites, in 30–50% of patients with spontaneous bacterial peritonitis (SBP), and in >50% of patients dying from end-stage liver disease. In a prospective study of 229 nonazotemic patients with cirrhosis and ascites, HRS developed in 18% at 1 year and in 39% at 5 years. Unfortunately, recent studies have shown that physicians often diagnose HRS when other causes of renal failure are present.

PATHOPHYSIOLOGY

Since 1956, when HRS was first recognized, various pathophysiological mechanisms have been proposed to explain the pathophysiology of the syndrome. Initially, it was believed that, despite the increased plasma volume in cirrhosis, the effective circulating plasma volume reaching vital organs, such as the kidney, is actually decreased due to pooling in the peripheral circulation. Volume expanders and surgical shunts have been used to deliver more volume to the systemic circulation and thus increase renal perfusion. Over time, it has become clear that splanchnic arterial vasodilation due to portal hypertension is more important than is reduced effective circulating volume in cirrhotic circulatory dysfunction. Endogenous splanchnic vasodilators, such as nitric oxide, are thought to be major contributors to cirrhotic circulatory dysfunction.

Three abnormalities affect renal function in patients with cirrhosis. The earliest abnormality to manifest is the lack of sodium excretion by the kidneys. At this stage, the mechanism of salt retention is unknown and ascites typically develops. Later in the course of the disease, the renin–angiotensin and sympathetic nervous systems become activated in response to splanchnic arterial vasodilation. Glomerular filtration rate (GFR) is maintained, likely due to a balance of renal vasodilation (prostaglandins) and vasoconstriction. The last

 Copyright 2004, Elsevier (USA). All rights reserved.

abnormality to manifest, in which either rapid (type 1 HRS) or slow (type 2 HRS) reductions in GFR occur, is mainly caused by systemic vasodilation and intrarenal vasoconstriction overwhelming the protective effects of intrarenal vasodilators. Most patients develop hyponatremia, extremely low urinary sodium excretion, and ascites unresponsive to diuretic therapy.

CLINICAL PRESENTATION

Hepatorenal syndrome should be suspected in any patient with advanced liver disease when there is an increase in serum creatinine level to greater than 1.5 mg/dl. Two forms of hepatorenal syndrome have been described; classification is mainly based on the severity of onset. Type 1 HRS is a rapidly progressive form associated with an 80% mortality at 2 weeks. It is often precipitated by an acute insult such as infection, nephrotoxic agents, or volume loss from gastrointestinal bleeding or overly aggressive diuresis. Deterioration of renal function is defined as a doubling of the serum creatinine level to greater than 2.5 mg/dl or a 50% reduction of the 24-hour creatinine clearance (< 20 ml/minute) within a 2-week period. Patients are usually oliguric or anuric. Type 2 HRS is the less severe, more insidious form. Deterioration of renal function occurs over months rather than weeks. Patients often have ascites resistant to diuretic therapy or are highly sensitive to the renal effects of diuretics. Although survival time is longer than type 1 HRS, the prognosis is still poor.

DIAGNOSIS

The International Ascites Club has identified specific criteria for the diagnosis of HRS (Table I). To diagnose HRS, there must be documented lack of improvement in renal function following a trial of adequate fluid repletion and the discontinuation of potential nephrotoxic agents. The major criteria must be present to diagnose HRS, whereas minor criteria serve to provide support for the diagnosis. It is important to remember that HRS is a diagnosis of exclusion; it is imperative to rule out other potential causes of acute renal failure.

DIFFERENTIAL DIAGNOSIS

Because treatment and prognosis differ greatly, it is vital to differentiate HRS from other potentially reversible causes of renal insufficiency. Patients should have a careful physical examination assessing volume status, urinalysis with microscopic examination, appropriate cultures for infection, and a renal ultrasound to evaluate for renal parenchymal disease and exclude obstruction. The three most common, reversible causes of acute renal failure in patients with advanced liver disease are prerenal azotemia, acute tubular necrosis (ATN), and glomerulonephritis.

Prerenal disease can be induced by gastrointestinal losses (e.g., vomiting and diarrhea), gastrointestinal bleeding, medications that reduce renal perfusion (e.g., diuretics and nonsteroidal antiinflammatory drugs), and cardiac dysfunction. The prognosis is excellent if the cause is identified and treated early. Volume support and achieving hemostasis are the mainstays of therapy.

ATN typically occurs after the administration of a nephrotoxic agent (nonsteroidal antiinflammatory-drugs, intravenous contrast, or aminoglycosides) or after an episode of prolonged, untreated prerenal azotemia or hypotension. ATN is usually associated with a fractional excretion of sodium (FENa) >2% and "muddy" brown casts in the urine sediment. However, in cirrhotics, the FENa may be < 1% and urinary casts may be due to hyperbilirubinemia. ATN carries a good prognosis

TABLE I International Ascites Club (1996) Major and Minor Criteria for Diagnosis of Hepatorenal Syndrome[a]

Major Criteria	Minor Criteria
Must be present for diagnosis	Provide support for the diagnosis
1. Chronic or acute liver disease with advanced hepatic failure and portal hypertension	1. Urine volume <500 ml/day
2. Low GFR, indicated by serum creatinine value >1.5 mg/dl or creatinine clearance <40 ml/minute	2. Urine Na <10 mEq/liter
3. Absence of treatment with nephrotoxic drugs, shock, infection, or significant recent fluid losses	3. Urine osmolality greater than plasma osmolality
4. No sustained improvement in renal function after diuretic withdrawal and volume expansion with 1.5 liters of isotonic saline	4. Urine red blood cells <50 per high-powered field
5. Proteinuria <500 mg/dl and no ultrasonographic evidence of obstruction or parenchymal renal disease	5. Serum Na concentration <130 mEq/liter

and usually reverses with supportive care (avoidance of nephrotoxic agents, correction of hypovolemia, treatment of sepsis, and, occasionally, hemodialysis).

Glomerulonephritis (GN) or vasculitis should be suspected in patients with a urine sediment containing red cells or red cell casts. Hepatitis B and C can be associated with cryoglobulinemia, polyarteritis nodosa, membranous GN, and membranoproliferative GN. A renal ultrasound and postvoid residual should be performed to exclude urinary obstruction as the cause of renal insufficiency.

TREATMENT

Because liver failure and portal hypertension are responsible for HRS, liver transplantation (LT) is the treatment of choice. Kidneys in patients with HRS generally function normally when transplanted into patients without liver disease. However, patients with HRS who undergo LT have more complications, have a higher in-hospital mortality, and more often require hemodialysis than do patients without HRS undergoing LT. Fortunately, the 3-year survival after LT of patients with HRS (60–65%) is only slightly lower than that of patients without HRS (70–80%); therefore, LT is an important option and carries a good prognosis.

If LT is not immediately available or recovery of liver function remains a possibility (e.g., alcoholic hepatitis or fulminant liver failure), other therapies should be attempted to improve renal function until liver function recovers. Because type 2 HRS is slowly progressive, vasoactive medications are uncommonly used. Avoidance and treatment of any process known to affect renal function (nephrotoxic drugs, excessive diuresis, gastrointestinal bleeding, infection, etc.) are the mainstays of management for type 2 HRS. Large-volume paracentesis should be performed for tense ascites, mainly to reduce intraabdominal pressure and thus improve cardiac and renal function; however, overzealous paracentesis should be avoided.

Because the greatest degree of splanchnic vasodilation and renal vasoconstriction occurs in type 1 HRS, most of the recent treatments have focused on reversing this complication. Prior studies have failed to show that surgical shunts and nonspecific vasoactive drugs (dopamine, fenoldopam, phentolamine, and metaraminol) improve renal function in HRS. Although most of the studies have been small, uncontrolled trials, recent data have demonstrated that vasoconstrictors specific to the splanchnic circulation can rapidly reverse HRS. Ornipressin, a vasopressin analogue, was found to mprove circulatory function and HRS in a small number of patients with HRS, although the studies were complicated by ischemic complications. Terlipressin with albumin given to seven patients with HRS over 5–15 days resulted in reversal of HRS and was not complicated by ischemia. A recent pilot study showed that norepinephrine combined with albumin and furosemide was safe and effective for type 1 HRS. Octreotide (a long-acting somatostatin analogue) in combination with midodrine (an oral α-adrenergic agonist) was shown to reverse type 1 HRS in five patients. Other medications, such as *N*-acetylcysteine and misoprostol, have shown limited success in some patients.

Other therapies have been attempted in the treatment of HRS. Reversal of portal hypertension after TIPS has been shown to cause a significant reduction in renin–angiotensin system activity and improvement in the GFR in both type 1 and type 2 HRS. However, this procedure is often complicated by hepatic encephalopathy and should be considered only in patients unresponsive to medical therapy. Hemodialysis and arteriovenous or venovenous hemofiltration may temporarily support patients with progressive HRS, but their efficacy is unknown and treatment may be complicated by electrolyte abnormalities and hypotension. The molecular adsorbent recirculating system (MARS), a modified dialysis method that removes albumin-bound substances from the blood, has shown promise in reversing type 1 HRS and improving short-term survival.

PREVENTION

Specific measures can significantly reduce the development or progression of HRS in patients with cirrhosis. Avoidance of nephrotoxic medications and intravenous contrast media in patients with cirrhosis and ascites is absolutely mandatory. Judicious use of diuretics is also recommended. In patients undergoing large-volume paracentesis, albumin should probably be given as fluid replacement, although studies have not shown that this treatment actually prevents HRS. However, in patients with SBP, the addition of albumin [1.5 g/kg, intravenously (iv) on admission, and 1 g/kg iv 48 hours later] to cefotaxime significantly reduces the occurrence of type 1 HRS and lowers 3-month mortality rates. Another study showed that the tumor necrosis factor inhibitor pentoxifylline (400 mg, three times daily) significantly lowers the incidence of type 1 HRS compared to placebo in patients with acute alcoholic hepatitis.

CONCLUSION

HRS represents progressive renal insufficiency in patients with liver failure characterized by splanchnic vasodilation, stimulation of the renin–angiotensin and

sympathetic systems, followed by impaired renal perfusion. Other renal diseases must be excluded before a diagnosis of HRS can be made. Type 2 HRS is characterized by a slow reduction in the GFR, usually over months, and is managed by avoiding known causes of renal dysfunction and careful use of diuretics, paracentesis, and TIPS. Type 1 HRS is a rapidly progressive disease with a high mortality if left untreated. Treatment of type 1 HRS with specific splanchnic vasoconstrictors appears to be evolving as effective therapy in liver transplant candidates and in patients with potential for hepatic recovery. TIPS and MARS are potential options for selected patients who either are not candidates for or have failed medical therapy.

sympathetic systems, followed by impaired renal perfusion. Other renal diseases must be excluded before a diagnosis of HRS can be made. Type 2 HRS is characterized by a slow reduction in the GFR, usually over months, and is managed by avoiding known causes of renal dysfunction and careful use of diuretics, paracentesis, and TIPS. Type 1 HRS is a rapidly progressive disease with a high mortality if left untreated. Treatment of type 1 HRS with specific splanchnic vasoconstrictors appears to be evolving as effective therapy in liver transplant candidates and in patients with potential for hepatic recovery. TIPS and MARS are potential options for selected patients who either are not candidates for or have failed medical therapy.

damage that represents a major mechanism leading to drug-induced hepatotoxicity.

Hepatotoxicity is the primary cause of drug-related deaths and the principal reason that pharmaceuticals are withdrawn from the market. Despite improvements in toxicological studies and in safety analyses in clinical trial protocols, the frequency of drug-induced liver injury has not decreased over the past 10 years. All liver cells can be affected by drugs. The types of lesions vary according to the mechanism of drug action, the role of the parent drug or one of its metabolites, the route of drug administration, the drug dosage, and the susceptibility of the patient. Consequently, adverse reactions to drugs affecting the liver can reproduce the entire spectrum of noniatrogenic liver diseases (Table I). More than 1100 classic drugs are known to provoke hepatotoxic reactions. Furthermore, some drug-associated excipients, herbal medicines, and recreational or illegal compounds (such as amphetamines and cocaine) are also hepatotoxic. Drug-induced morbidity and mortality of are of concern to physicians, health authorities, and pharmaceutical companies, and it is important to understand and manage the most critical aspects of potential hepatotoxicity.

EPIDEMIOLOGICAL ASPECTS

Current knowledge of drug hepatotoxicity remains limited despite many effort to obtain reliable information. Data have been collected for the past 20 years, through the establishment of drug safety agencies in many countries. A limiting factor is the difficulty in determining the causality of a drug in relation to a hepatic injury, even with the development of sophisticated diagnostic methods. A second limiting factor is the method employed to collect data. Presently, a two-step strategy—cost/benefit toxicity evaluation screens and trials and postmarketing epidemiological surveillance—is being used.

The first step, the evaluation of the safety of a new drug in order to determine the benefit/risk ratio, is necessary to obtain marketing authorization. An initial screening is performed through animal toxicological experiments and, increasingly, by using cellular models. Toxicity is then assessed prospectively in healthy volunteers and patients. This allows analysis of the prevalence and type of liver test abnormalities, and triggers investigations to determine the potential mechanisms, the susceptibility factors, if any, and the ability to predict the liver injury and its severity. The number of participants enrolled in clinical trials generally ranges from 2000 to 5000. Only frequent events (>1%) can be detected. In the majority of cases, such an event leads to a halt in the development of the new drug. However, in some exceptional situations, the importance of the compound is such that liver toxicity may be acceptable. An example is tacrine, the first drug shown to have some efficacy in Alzheimer's disease.

The risk of hepatotoxicity varies widely from one drug to another. The high risk for marketed drugs is around 1%, the major examples being isoniazid, chlorpromazine, and tacrine. In contrast, for other drugs (for instance, antihistaminic compounds, minocycline, or penicillins), the risk of hepatotoxicity is exceedingly low, affecting less than 1/100,000 or even 1/1,000,000 persons. This makes it difficult to prove hepatotoxicity, especially when liver injury exhibits no specificity, and it is practically impossible to detect such an event at an early stage. For most marketed drugs, the risk of toxicity is moderate, ranging from 1/10,000 to 1/100,000 affected persons. Such is the case with troglitazone, for which hepatotoxicity has been estimated to be around 1/50,000 persons exposed (this is probably why toxicity was not clearly detected among the 5000 patients

TABLE I Cell Types and Characteristics of Lesions Comprising Drug-Induced Hepatotoxicity

Hepatocyte	Cholangiocyte (bile duct epithelial cell)	Endothelial cell	Stellate cell
Acute cytolytic hepatitis	Acute and chronic cholangitis	Venoocclusive disease	Perisinusoidal fibrosis
Pure cholestasis	Sclerosing cholangitis	Sinusoidal dilation	
Cholestatic hepatitis		Peliosis hepatis

Phospholipidosis			
Steatohepatitis			
Granulomatous hepatitis			
Adenoma			

included in the therapeutic trials). These risk and detection factors explain why the first cases of drug-related hepatotoxicity are generally described only after a drug has been marketed for 1 to 2 years, when the drug has been administered to a statistically sufficient number of patients.

The second step in managing drug hepatotoxicity is postmarketing surveillance, which mainly relies on the spontaneous reporting of liver side effects. The process is clearly imperfect and many events are overlooked. There are very few data for estimating the proportion of underreporting and the true incidence of hepatotoxicity. The rare epidemiological studies of drug hepatotoxicity have been performed mainly on a retrospective basis and have been aimed at determining the frequencies and types of liver injuries caused by drugs, compared to other causes, over a given period. The importance of underreporting has been recently stressed by a unique prospective population-based study performed over 3 years. The analysis showed a global crude hepatotoxicity incidence of 13.9 per 100,000 persons. This emphasizes that spontaneously reported cases represent less than 10% of real events and that drug hepatotoxicity is largely underestimated as a cause of liver disease.

Although imperfect, retrospective studies provide some interesting information. A study made over 10 years in the liver unit of Hôpital Beaujon, Paris, France, revealed that among all adult patients admitted with hepatitis, 10% of the cases were related to drug toxicity. The prevalence of drug hepatotoxicity exceeded 40% for patients over 50 years. Another French national survey conducted in 1983 collected data from 980 cases of hepatitis due to drugs; 63% of the patients were women and most were over 50 years old. Similarly, the Danish Board of Adverse Reactions to Drugs recorded 572 cases of drug-induced hepatitis during 1968–1978 (6% of all drug-related side effects); again, most cases occurred in women over 50 years old. Drugs have been estimated to cause around 15–20% of all cases of fulminant and subfulminant hepatitis in Western countries, and 10% of all cases in Japan. The risk of a fulminant course in patients with drug-induced hepatitis with jaundice is around 20%, which is much higher than the risk in patients suffering from acute viral hepatitis with jaundice (1%). Further, in 70% of patients with drug-induced hepatitis with encephalopathy, the disease runs a subfulminant course.

MECHANISMS OF HEPATOTOXICITY

Despite many advances in the past 20 years, the mechanisms of hepatotoxicity of most drugs remain unknown. A single drug may have several toxic effects on the liver, or may produce either toxic or allergic hepatitis in different patients. The formation of reactive metabolites is relatively frequent. Despite several protective mechanisms, a drug may cause covalent binding of electrophilic metabolites to proteins, stimulation of lipid peroxidation by free radicals, and depletion and/or oxidation of glutathione. There follow a number of structural and functional lesions, including a sustained increase in cytosolic calcium, eventually leading to cell death. The formation of reactive metabolites may lead to two major types of hepatitis in humans: (1) toxic hepatitis, which occurs predictably after massive overdosage, e.g., with paracetamol, and (2) immunoallergic hepatitis, in which the drug triggers an adverse immune response directed against the liver. The main clinical features are the dose-independent response; the association with hypersensitivity reactions such as fever, chills, skin rash, hypereosinophilia, and immunoallergic thrombopenia; the shortened delay in response time on rechallenge; and the occasional presence of serum autoantibodies. These autoantibodies have been observed in cases of hepatitis caused by halothane, tienilic acid, dihydralazine, anticonvulsants, papaverine, and nitrofurantoin. The following mechanism has been postulated: (1) the drug is first metabolized into a reactive metabolite, which binds to the enzyme that generates it. (2) This produces a neoantigen, which, once presented to the immune system, may trigger an immune response characterized by the production of antibodies recognizing both the natural and/or the modified protein. (3) Rechallenge leads to increased neoantigen production, a situation in which the presence of antibodies may induce cell necrosis.

Several lines of evidence have recently suggested that apoptosis and mitochondrial dysfunction can also markedly contribute to acute hepatotoxicity. Other mechanisms of hepatotoxicity have been demonstrated to vary with the type of liver injury, as summarized in the Table II. For instance, microvesicular steatosis, which is induced by several drugs, including valproic acid, nonsteroidal antiinflammatory drugs, some tricyclic antidepressants, tetracycline, and acetylsalicylic acid, is caused by an inhibition at different stages of mitochondrial β-oxidation of fatty acids and/or alteration of the respiratory chain.

FACTORS MODULATING HEPATOTOXICITY

The risk of developing drug hepatotoxicity is influenced by various physiological and genetic factors, as summarized in Tables III and IV.

TABLE II Primary Mechanisms of Hepatotoxicity

Liver injuries	Mechanisms
Acute hepatitis	Metabolite-mediated toxicity
	Metabolite-mediated immunoallergy and/or autoimmunity
	Apoptosis
	Mitochondrial dysfunction
Acute cholestasis	Inhibition of biliary secretion
Macrovacuolar steatosis	Decreased secretion of lipoproteins
Microvacuolar steatosis	Inhibition of fatty acid mitochondrial β-oxidation
Nonalcoholic steatohepatitis	Mitochondrial dysfunction
	Cytokine release
Phospholipidosis	Inhibition of lysosomal phospholipases
Chronic hepatitis	Metabolite-mediated immunoallergic reaction
Vanishing bile duct syndrome	Autoimmune destruction of small bile ducts
	Abnormal multidrug resistance protein system?
Sclerosing cholangitis	Biliary ischemia caused by arterial lesions
Venoocclusive disease	Metabolite-mediated endothelial lesions
Perisinusoidal fibrosis	Activation of Ito cells

Physiological Factors

Age above 60 years is a promoting factor for hepatitis induced by isoniazid, halothane, and nitrofurantoin; children are more subject to the toxicity of valproic acid and salicylates. In particular, aspirin more frequently induces microvesicular steatosis and Reye's syndrome. Gender is also involved, women being more frequently exposed to hepatotoxic methyldopa, diclofenac, and nitrofurantoin, whereas men are more prone to azathioprine-induced injury. Pregnancy appears to be an influencing factor. For instance, most of the tetracycline-induced severe hepatitis has been observed in pregnant women receiving high doses of the drug by the intravenous route. Experimentally, pregnant mice are particularly susceptible to acetaminophen hepatotoxicity, probably because of the glutathione requirement of the fetus and placenta, which depletes hepatocyte glutathione stores.

Nutrition status can affect hepatotoxicity in different ways. For instance, obesity promotes halothane and

TABLE III Acquired Factors Contributing to Drug Hepatotoxicity

Factor	Drug
Age	
>60 years old, children	Isoniazid, nitrofurantoin, halothane, valproic acid, salicylates
Gender	
Women	Nitrofurantoin, diclofenac, isoniazid
Men	Azathioprine
Nutrition	
Obesity	Halothane, methotrexate
Fasting/malnutrition	Acetaminophen
Pregnancy	Acetaminophen, tetracycline
Chronic alcohol abuse	Acetaminophen, methotrexate
Combined drug effects	
Enzyme induction	Rifampicin–isoniazid; other anticonvulsant drugs and valproic acid
Enzyme inhibition	Troleandomycin–estrogens, phenobarbital–antidepressants
Toxicity combination	Isoniazid–pyrazinamide, isoniazid–acetaminophen
Disease	
HIV infection	Cotrimoxazole/sulfonamides, isoniazid
Hyperthyroidism	Halothane
Hepatitis B and C virus infection with liver fibrosis	Antituberculosis, antiretroviral agents, nonsteroidal antiinflammatory drugs?
Nonalcoholic steatohepatitis	Methotrexate

TABLE IV Genetic Factors Contributing to Drug Hepatotoxicity

Factor	Drug
Deficiency in CYP2D6	Perhexiline
Deficiency in CYP2C19	Atrium, troglitazone
Deficiency in NAT2[a]	Sulfonamides, dihydralazine
Deficiency in sulfoxidation	Chlorpromazine?
Deficiency in glutathione synthetase	Acetaminophen
Deficiency in GSTase type T[b]	Tacrine?
Deficiency in detoxication of reactive metabolites (unknown mechanisms)	Halothane, phenytoin, carbamazepine, amineptine, sulfonamides
HLA system	
A11	Halothane
DR6 and DR2	Nitrofurantoin
A8	Clometacin
A11	Tricyclic antidepressants
A11	Diclofenac
DR6	Chlorpromazine
DRB1 1501, DRQBI 0602	Amoxicillin–clavulanic acid

[a] NAT2, *N*-Acetyltransferase 2.
[b] GSTase, Glutathione *S*-transferase.

methotrexate hepatotoxicity whereas fasting and malnutrition facilitate acetaminophen (paracetamol) hepatitis, again, probably by depleting glutathione stores in hepatocytes. Chronic alcohol abuse facilitates acetaminophen hepatotoxicity, probably by complex mechanisms involving the induction of critical enzymes such as cytochrome P450 2E1, forming toxic metabolites (*N*-acetyl-*p*-quinone imine), and by decreasing the defense against these metabolites because of glutathione depletion. Chronic alcohol abuse also increases methotrexate toxicity.

Drug interactions can also contribute to drug hepatotoxicity. For instance, enzyme induction leading to increased formation of toxic metabolites from one drug has been demonstrated with the rifampicin–isoniazid combination; rifampicin facilitates the transformation of isoniazid into toxic metabolites. Similarly, phenobarbital increases the hepatotoxicity of antidepressants. In contrast, enzyme inhibition can also be implicated. This is demonstrated by the troleandomycin–estrogen interaction. Troleandomycin inhibits estrogen metabolism by blocking cytochrome P450 3A, thereby creating an estrogen overdose with cholestatic effects. Some drug combinations lead to a higher risk of toxicity by additional production of toxic metabolites (Table III).

A preexisting liver disease may contribute to the hepatotoxicity of some drugs, such as antiretroviral agents and methotrexate. Conversely, antiretroviral agents may exacerbate latent hepatitis C or B by restoring an efficient immune system and by modifying immunotolerance. Chronic viral hepatitis also may increase the hepatotoxicity of antituberculosis compounds and nonsteroidal antiinflammatory drugs. Some extrahepatic diseases can also contribute to drug hepatotoxicity. For instance, hyperthyroidism promotes halothane hepatitis and HIV infection is a contributing factor to the hepatotoxicity of cotrimoxazole.

Genetic Factors Contributing to Drug Hepatotoxicity

A deficiency in cytochrome P450 2D6 (CYP2D6) appears to be a major determinant of perhexilline hepatotoxicity. Indeed, more than 75% of patients with perhexilline hepatotoxicity are deficient for CYP2D6. This enzyme deficiency is present in 6–8% of Caucasian populations and is transmitted as an autosomal recessive trait in relationship with more than 10 mutations of the gene for CYP2D6.

A deficiency in cytochrome P450 2C19 (CYP2C19) may be involved in Atrium hepatotoxicity. Atrium is a complex drug combining febarbamate, difebarbamate, and phenobarbital. A recent study comprising a small number of patients with a previous history of Atrium hepatitis showed that all of them had a partial or a complete deficiency in CYP2C19. The prevalence of this deficiency in Caucasians is around 3–5% and around 20% in Asians. This small study, however, deserves to be confirmed by a study of a larger number of patients. Troglitazone hepatotoxicity also appears to be associated with CYP2C19

deficiency, with the proportion of poor metabolizers being twice as high in affected patients compared to a control group.

A deficiency in acetylation capacity related to an inactive *N*-acetyltransferase 2 (NAT2) has been shown to be involved in the hepatotoxicity of sulfonamides and hydralazine. This defect is transmitted as an autosomal recessive trait. More than 25 mutant alleles have been associated with the slow acetylation phenotype. The high frequency of the slow acetylation phenotype in most populations suggests that the defect may contribute, but is not sufficient alone, to the toxicity of sulfonamides and hydralazine.

A deficiency in sulfoxidation has been noted in one study assessing patients with chlorpromazine hepatitis. However, the lack of reproducibility of the method used for analyzing sulfoxidation has made this conclusion questionable. Further studies using reproducible tests for sulfoxidation polymorphism are required.

A deficiency in glutathione synthetase is an uncommon condition (1/10,000), responsible for a syndrome comprising oxoprolinuria and hemolytic anemia. By using an *in vitro* lymphotoxicity assay on specimens from patients with this deficiency, it has been shown that the patients may be more susceptible to acetaminophen hepatotoxicity.

Other metabolic deficiencies and liver susceptibility to drugs have been linked. By using the *in vitro* lymphotoxicity assay developed by Spielberg, several groups have shown deficiencies in detoxification capacity for reactive metabolites in patients with drug-induced hepatitis. This deficiency was also observed in some family members, suggesting a genetic defect. Such observations have been made for halothane, phenytoin, carbamazepine, amineptine, and sulfonamides. The precise defect involved in these susceptibilities has still not been identified. In another study, it has been proposed that tacrine hepatotoxicity may be promoted by a deficiency in glutathione *S*-transferase, type T. However, this has not been confirmed by any other study.

Finally, genetic variations in the immune system may be involved in drug hepatotoxicity. Indeed, an association has been observed between several human leukocyte antigen (HLA) haplotypes and some drugs (Table IV). The association between amoxicillin–clavulanate and HLA DRB1 1501 is particularly strong.

DEFINITIONS AND CLASSIFICATIONS

An international consensus meeting under the auspices of the Council for International Organizations of Medical Sciences (CIOMS) and gathering a panel of experts have come together to define a common language between the different partners involved in the assessment of drug-induced liver injury.

Definitions

The following designations for drug-induced liver disorders have been proposed, based mainly on liver test abnormalities. When a liver biopsy has been performed, the lesion should be named according to the histological findings, e.g., cirrhosis, acute hepatitis, chronic hepatitis, or hepatic necrosis. In the absence of histological data (and this corresponds to the majority of cases), the preferred term is "liver injury." Liver injury is defined by an increase of over two times the upper limit of normal range (2*N*) in serum alanine aminotransferase (ALT) or conjugated bilirubin, or a combined increase of aspartate aminotransferase (AST), alkaline phosphatase (AP), and total bilirubin, provided one of them is above 2*N*.

Clinicopathological Classifications

Albeit drug hepatotoxicity can reproduce practically the whole spectrum of liver disease, acute liver injuries (characterized by abnormalities lasting less than 3 months) predominate (about 90% of cases). Acute liver injuries can be classified in three groups using biochemical criteria based on ALT and AP, and their ratio (R). This classification has the advantage of separating types of hepatitis with different courses and prognostic features.

Acute Hepatocellular Hepatitis

Acute hepatocellular hepatitis is defined by an ALT above 2*N* or an ALT/AP ratio of ≥ 5. Acute hepatocellular hepatitis generally has no specific features and mimics acute viral hepatitis. Liver injury may remain asymptomatic, revealed only by an increase in ALT or by nonspecific symptoms such as asthenia or anorexia. Jaundice is inconstant. The main biological feature is the marked increase in transaminases. The major pathological finding is liver cell necrosis, generally associated with inflammatory infiltration. The presence of eosinophils in the infiltrate and the centrilobular predominance of the lesions argue for drug hepatotoxicity.

Hepatitis may be associated with hypersensitivity manifestations such as fever, chills, skin rash, hypereosinophilia, and immunoallergic thrombopenia, which suggest an immunoallergic mechanism. Several hundred of drugs can induce this type of hepatitis, which may also be produced by herbal medicines, illegal

TABLE V Primary Drugs Responsible for Acute Hepatocellular Hepatitis

Primary conventional drugs	
	Without hypersensitivity: acetaminophen, isoniazid, pyrazinamide, ketoconazole, valproic acid, troglitazone, tacrine, paroxetine, tolcapone, antiretroviral drugs (didanosine, zidovudine, zalcitabine, stavudine, ritonavir, indinavir, saquinavir, efevirenz, nelfinavir), anti-mycotics (itraconzole, ketoconazole, terbinafine), cytokines and growth factors (interleukin-2, interleukin-12, interleukin-2F,interleukin-3, interleukin-6, granulocyte colony-stimulating factor), leflunomide, gemcitabine
	With hypersensitivity: nonsteroidal inflammatory drugs (almost all drugs), sulfonamides, almost all antidepressants (tricyclic, iproniazid, fluoxetine), halothane and derivatives, abacavir, halothane and its derivatives
Herbal medicines	
	Pyrrolizidine alkaloids (crotaloria, senecio), *Atractylis gummifera* L., germander, chinese herbal preparations, chapparal leaf, senna, skullcap, valerian, mentha-containing pennyroyal oil, kava-kava, great celandine
Illegal compounds	
	Cocaine, "Ecstasy" (*N*-methyl-3,4-methylene dioxyamphetamine)
Excipients	
	Sodium saccharinate (dihydroergocristine; chlordemethyldiazepam; prednisolone, 20 mg), polysorbate (E-Ferol, intravenous amiodarone), propylene glycol (multivitamin intravenous solutions)

compounds, and even some excipients. The main causes are indicated in the Table V. In most instances, the discontinuation of treatment is followed by a quick improvement of symptoms and a complete recovery within 1 to 3 months. Sometimes, however, acute hepatitis may be followed by fulminant or subfulminant hepatitis. The course is then very severe, with a spontaneous mortality around 90%. The only treatment is emergency liver transplantation. The risk to develop fulminant or subfulminant hepatitis is particularly high when drug administration is continued despite the occurrence of jaundice. The course of the disease may be more insidious in the progressive development of chronic hepatitis or even cirrhosis.

Acute Cholestatic Liver Injury

Acute cholestatic liver injury is characterized by an isolated increase of serum alkaline phosphatase above 2*N*, or by an ALT/AP ratio of <2. There are two subtypes, pure (bland) cholestasis and cholestatic hepatitis.

Pure cholestasis Pure cholestasis is mainly characterized by jaundice, pruritus, and dark urine. Biologically, there is an increase in alkaline phosphatase, (-glutamyl transpeptidase, and conjugated bilirubin. Transaminases are normal or only slightly increased; liver biopsy mainly shows bilirubin deposits in hepatocytes and more or less dilated biliary canaliculi containing biliary pigments. Cholestasis predominates in centrilobular area. Pure cholestasis is observed with a few drugs, mainly hormonal derivatives (Table VI). Discontinuation of the causative drug is followed by a complete recovery.

Acute cholestatic hepatitis In addition to manifestations of pure cholestasis, acute cholestatic hepatitis liver injury may be associated with abdominal pain, fever, and chills, which can mimic acute biliary obstruction. Hypersensitivity manifestations are frequent. Liver biopsy shows cholestasis associated with inflammatory infiltration in portal tracts. The prognosis is much better than that for hepatocellular hepatitis. After drug withdrawal, symptoms rapidly disappear and recovery occurs within a few weeks. Rarely, however, chronic cholestasis simulating primary biliary cirrhosis may develop. This particular course is observed in cases with associated cholangitis. Several hundreds of drugs

TABLE VI Primary Drugs Responsible for Acute Cholestatic or Mixed Hepatitis and Cholangitis

Pure cholestasis	
	Oral contraceptives, estrogens, estrogens plus troleandomycin or erythromycin, androgens, tamoxifen, azathioprine, cytarabine
Acute cholestatic/mixed hepatitis	
	Phenothiazines, tricyclic antidepressants, nonsteroidal antiinflammatory drugs, carbamazepine, macrolide antibiotics, amoxicillin/clavulanic acid, sulfonamides, gold salts, β-lactam antibiotics, propoxyphene, antiretrovirals (didanosine, zidovudine, stavudine, ritonavir), interleukins (IL-2, IL-6, IL-2)
Acute cholangitis	
	Phenothiazines, carbamazepine, tricyclic antidepressants, macrolide antibodies, amoxicillin−clavulanic acid
Chronic cholangitis	
	Phenothiazines, arsenical derivatives, tricyclic antidepressants, macrolide antibodies, thiabendazole, tetracycline, fenofibrate

are able to cause cholestatic hepatitis; the main ones are indicated in the Table VI.

Mixed-Pattern Acute Liver Injury

Mixed-pattern acute liver injury is characterized by an ALT/AP ratio of between 2 and 5. The clinicopathological manifestations are a mixture of those observed with hepatocellular and cholestatic hepatitis, but also include granulomatous reactions. A mixed-pattern liver injury is frequently associated with immunoallergic manifestations. The prognosis is generally very good. The main causative drugs are indicated in Table VI.

Other Types of Liver Injury

Other types of liver injury were not well characterized by the international consensus meeting. It was, however, mentioned that the term "chronic" applies to liver diseases with a course longer than 3 months, without any reference to the underlying lesion. This is to distinguish from drug-induced chronic hepatitis, well characterized by histological examination. The lack of precision of this system, based on biological tests, has been recently stressed by several clinicians. The definitions of chronic and other drug-induced liver disorders rely principally on histological findings. Their frequency is globally low. Drugs are the cause of less than 1% of cases of chronic hepatitis and cirrhosis. However, for some rare lesions, drugs are an important cause. Such is the case for estrogens and hepatic adenoma, and the contribution of thiopurines and antineoplastic agents to hepatic vascular disorders such as nodular regenerative hyperplasia and peliosis hepatitis. Such drug-induced injuries and the primary drugs involved are indicated in Table VII.

TABLE VII Other Types of Drug-Induced Liver Injury and Causative Drugs

Chronic hepatitis and/or cirrhosis	
	Valproic acid, amiodarone, aspirin, benzarone, halothane, iproniazid, isoniazid, methotrexate, methyldopa, nitrofurantoin, vitamin A, papaverine, tamoxifen
Granulomatous hepatitis	
	Allopurinol, carbamazepine, quinidine, sulfonamides, gold salts, phenylbutazone, penicillamine, dapsone
Macrovacuolar steatotis	
	Corticosteroids, methotrexate, asparaginase
Microvesicular steatosis	
	Nonsteroidal antiinflammatory drugs, valproic acid, tetracycline, amineptine, tianeptine, aspirin antiretroviral drugs (dideoxynucleotides)
Steatohepatitis with phospholipidosis	
	Amiodarone, perhexilline, diethylaminoethoxyhexestrol
Steatohepatitis without phospholipidosis	
	Nifedipine, diltiazem, tamoxifen
Vascular diseases of the liver	
	Perisinusoidal fibrosis: vitamin A, azathioprine, 6-mercaptopurine, methotrexate
	Sinusoidal dilatation and peliosis hepatitis: oral contraceptives, androgens, estrogens, azathioprine
	Venoocclusive disease: pyrrolyzidine alkaloids, azathioprine, anticancerous agents
	Budd–Chiari syndrome: oral contraceptives, dacarbazine
Tumors	
	Adenoma and hepatocellular carcinoma: androgens, oral contraceptives, estrogens

DIAGNOSIS

There are generally no specific markers or tests for the diagnosis of drug-induced liver injury. Therefore, the diagnosis entirely relies on circumstantial evidence. To address the problem, various analytical methods have been developed to assess the causality of a given drug in the occurrence of liver injury. The principles of all these methods are similar. Causality assessment relies on chronological and clinical criteria to allow elimination of other causes and to demonstrate the role of the offending drug (Table VIII).

Chronological Criteria

The first criterion is the time interval between the beginning of treatment with the suspected agent and the onset of liver injury; this "latent period to onset" varies widely. It is considered suggestive when the interval is between 1 and 12 weeks. A shorter duration (1 or 2 days) may be observed in patients who have been previously exposed to the compound and have become sensitized. A delay of between 3 and 12 months remains compatible but is less common. A delay above 1 year is very uncommon; it generally makes the role of the suspected drug very unlikely in the case of acute hepatitis, but note that with unusual forms of chronic liver disease (such as hepatic adenoma and some types of vascular injury mentioned earlier), the latent period to onset is often several years.

The second criterion is the resolution of liver test abnormalities after withdrawal of the treatment. This is very suggestive when clinical features disappear within a few days, and when aminotransferases decrease by more than 50% in a week. Usually, complete recovery is obtained within a few weeks.

The third criterion is a relapse of liver test abnormalities after an accidental readministration of the offending drug. This is a very good diagnostic criterion.

TABLE VIII Diagnostic Criteria for Drug-Induced Liver Diseases

Chronological criteria
Interval between the beginning of the treatment and the onset of liver injury: 1–12 weeks
Regression of liver abnormalities after withdrawal of the treatment
Relapse of liver abnormalities after accidental readministration (rechallenge) of the offending drug; deliberate rechallenge must be avoided
Clinical criteria
Elimination of other causes
Previous hepatic or biliary disease
Alcohol abuse
Viral hepatitis (HAV, HBV, HCV, HDV, HEV, cytomegalovirus, Epstein–Barr virus, herpes
Biliary obstruction (ultrasonography, magnetic resonance imaging, etc.)
Autoimmune hepatitis/cholangitis
Ischemia and congestion of the liver
Wilson's disease
Bacterial infection (*Listeria*, *Campylobacter*, *Salmonella*, Lyme disease)
Positive clinical criteria
Age >50 years
Intake of many drugs
Intake of a known hepatotoxic drug
Specific serum autoantibodies: anti-M6, anti-LKM2, anti-CYP1A2, anti-CYP2E1
Positive blood analysis for acetaminophen, vitamin A
Liver biopsy showing drug deposits (vitamin A), microvesicular steatosis, eosinophil infiltration, centrilobular zonal necrosis, associated bile duct injury

However, such reexposure should not be done on purpose because it can be very dangerous, particularly in cases of immunoallergic hepatitis. In this situation, the readministration of a single tablet can occasionally provoke fulminant hepatic failure.

Clinical Criteria

Clinical criteria are based on the exclusion of other causes that might explain the liver injury, and on the presence of features tending to favor a drug etiology.

Eliminating or Negative Criteria

Analytical features vary according to the type of liver injury. For acute hepatitis, it is important to seek a history of hepatitis or biliary disease, alcohol abuse, or epidemiological circumstances that are compatible with viral infection (intravenous drug use, blood transfusion, recent surgery, travel in an endemic area). Appropriate serological tests should be performed to exclude viral hepatitis (hepatitis A, B, C, D, and E viruses), and in some circumstances, cytomegalovirus, Epstein–Barr virus, and herpesviruses. There does not appear to be a useful role of testing for hepatitis G virus (HGV) or transfusion-transmitted virus (TTV). However, the potential for hepatic ischemia and congestion related to cardiorespiratory failure should be excluded, particularly in the elderly and after cardiac surgery. Biliary obstruction should be eliminated by ultrasonography or other appropriate examinations (magnetic resonance imaging, endoscopic ultrasonography). Autoimmune hepatitis or cholangitis should also be ruled out, as should specific bacterial infections that can produce acute hepatitis, such as infection by *Campylobacter*, *Salmonella*, *Listeria*, and Lyme disease. Finally, Wilson's disease should be considered in children and young adults.

Positive Criteria

The presence in serum of specific autoantibodies—for instance, antimitochondrial type 6, anti-LKM2, anti-CYP1A2 and anti-CYP2E1—indicates potentially important diagnostic markers, although the diagnostic accuracy of these tests has not been studied and they are not widely available. Drug analyses of blood and liver tissue may be useful in detecting acetaminophen and vitamin A overdoses.

The presence of hypersensitivity manifestations, albeit not completely specific, is a positive argument for involvement of a drug and for an immunoallergic mechanism, as typified by the reactive metabolite syndrome for some anticonvulsants, sulfonamides, and protease inhibitors. Finally, liver biopsy may also contribute to the diagnosis by showing the presence of drug deposits (vitamin A) or lesions suggestive of drug reactions—for instance, microvesicular steatosis, eosinophilic infiltrates, centrilobular necrosis, or associated bile duct lesions.

Causality Assessment by Scoring Systems

The analytical approach is insufficient in many situations; complementary methods have been developed to provide a better diagnostic assessment, by ascribing scores to groups of items and then by calculating a global score. The main scoring system, the Roussel Uclaf Causality Assessment Method (RUCAM), was presented in the original publication of the CIOMS (Table IX). RUCAM (CIOMS) has been independently validated in a large number of patients. The global score for acute liver injury theoretically ranges from −5 to 14. On this basis, the diagnosis is classified as follows: ≤0, relationship with the drug excluded;

TABLE IX Method for Causality Assessment of Adverse Drug Reactions[a]

Criterion	Interpretation	Score
1. Time to onset of the reaction	*Highly suggestive*	+3
	Suggestive	+2
	Compatible	+1
	Inconclusive	0
If incompatible, then case "unrelated"		
If information not available, then case "insufficiently documented"		
2. Course of the reaction	Highly suggestive	+3
	Suggestive	+2
	Compatible	+1
	Against the role of the drug	−2
	Inconclusive or not available	0
3. Risk factors(s) for drug reaction[b]	Presence	+1 to 2
	Absence	0
4. Concomitant drug(s)[c]	Time to onset incompatible	0
	Time to onset compatible but unknown reaction	−1
	Time to onset compatible and unknown reaction	−2
	Role proved in this case	−3
	None or information not available	0
5. Non-drug-related causes[d]	Ruled out	+2
	Possible or not investigated [d]	+1 to 2
	Probable	−3
6. Previous information on the drug	Reaction unknown	0
	Reaction published but unlabeled	+1
	Reaction labeled in the product's characteristics	+2
7. Response to readministration	Positive	+3
	Compatible	+1
	Negative	−2
	Not available or not interpretable	0
(or plasma concentration of the drug known as toxic or validated laboratory test with high specificity, sensitivity, and predictive values)	Positive	+3
	Negative	−3
	Not interpretable or not available	0

[a] Using the Roussel Uclaf Causality Assessment Method. After Benichou *et al*. (1993).
[b] One additional point for every validated risk factor (maximal value +2).
[c] Sum of negative values of criteria 4 and 5 cannot be lower than −4.
[d] Depending on the nature of the reaction.

1−2, unlikely; 3−5, possible; 6−8, probable; >8, highly probable.

A simplified clinical diagnostic scale (CDS) for the diagnosis of drug-induced liver injury has been recently proposed by a Spanish group. The criteria are very similar to those used in the RUCAM (CIOMS). They lead to a score separating adverse reactions: score >17, definite; 14−17, probable; 10−13, possible; 6−9, unlikely; <6, drug hepatotoxicity excluded.

The agreement between the RUCAM (CIOMS) and CDS scoring systems has been tested in two recent studies. Discrepancies were observed in cases of cholestasis, metabolic idiosyncratic, fulminant hepatitis, or death. The best correlation was found in cases of liver injury with immunoallergic reactions. Presently, there are no data showing whether the CDS method has additional advantages over the RUCAM (CIOMS) method.

Performance of Causality Assessment

In rare circumstances, a link between drug and hepatotoxicity may be probable or highly probable (RUCAM score >6 and CDS score >17): examples

include clear drug overdose (acetaminophen), relapse after accidental readministration, and presence of specific features for drug hepatitis (dihydralazine, iproniazid). More often, the diagnosis is possible: liver injury exhibits no specific features, the history is chronologically suggestive, and other causes of liver injury have been reasonably excluded (RUCAM score 3–5 and CDS score 10–13). Frequently, however, the diagnosis remains doubtful or unlikely: there are no specific features to the liver injury and critical pieces of information regarding chronological or clinical data are missing (RUCAM score 1–2 and CDS score 6–9). It is noteworthy that fulminant hepatitis must always be classified in this way because it is usually impossible to assess complete recovery after drug withdrawal due to the poor outcome or treatment by liver transplantation.

The diagnosis is excluded when another cause has been demonstrated (viral infection), when chronology is not compatible (e.g., when treatment had been started at a time when symptoms were already present), or when there is a delay exceeding 15 days between the end of the treatment and the onset of liver injury (RUCAM score (0 and CDS score <6). However, again there are some exceptions. With hepatitis caused by halothane and related haloalkane anesthetics, reactions often occur 3 weeks after the first exposure (the latent period is shorter with repeat exposures). Similarly, for a clavulanic acid–amoxicillin combination, acute hepatitis frequently occurs 3–4 weeks after the discontinuation of the treatment.

TREATMENT AND PREVENTION

The main therapeutic measure to prevent the progression to a more severe liver injury consists of discontinuing the administration of the offending drug. In some circumstances, this not sufficient and liver injury continues to develop, as seen for fulminant and subfulminant hepatitis, some cases of chronic liver diseases with storage of the drug in the liver or fat tissue, or protracted immunologic reactions. The main active treatment for acetaminophen intoxication is administration of *N*-acetylcysteine as antidote. Thus, prevention of further damage represents a determining point.

Many improvements are required in managing hepatotoxicity. First, it is important to have a better evaluation of drug hepatotoxicity epidemiology. Postmarketing surveillance on the basis of spontaneous reports is clearly insufficient. Prospective studies are required, in particular to identify the most severe reactions, fulminant and subfulminant hepatitis. These represent a major consideration for the benefit/risk ratio of a drug. An unfavorable ratio will lead to withdrawal of the compound from the market. Second, improvements in the definition, classification, and diagnostic methods of drug-induced liver disease provide another challenge. The new scoring systems already represent an improvement, but they also have some limitations. They are not easy to handle in routine clinical practice and a substantial number of cases remain indeterminate or doubtful in nature because key data are missing. Therefore, it is important to find more specific markers of hepatotoxicity; some of these already exist for rare drugs. Third, it is also very important to determine which patients are most at risk. Several physiological and genetic factors can promote hepatotoxicity. The development and the wide availability of genotyping tests for drug-metabolizing enzyme polymorphisms should help to better understand the influence of genetics on drug hepatotoxicity and to prevent side effects. Finally, the importance of monitoring susceptible patients in followup settings should be reinforced.

Hepatotoxins

MARK J. CZAJA
Albert Einstein College of Medicine, New York

cytochrome P450s A superfamily of enzymes that mediate the oxidative metabolism of many endogenous and foreign compounds.

lipopolysaccharide A lipid component of the cell wall of gram-negative bacteria.

tumor necrosis factor α A cytokine released from macrophages that induces biological effects, including cytotoxicity, on other cells.

Hepatotoxins are synthetic or naturally occurring compounds that cause a variety of forms of liver injury through their direct or indirect damage to hepatocytes. Depending on the toxin, its likelihood to induce liver injury may be predictable or unpredictable (idiosyncratic). The type of liver disease that may develop depends on the toxin and can range from only asymptomatic elevations in serum liver function tests to acute or chronic liver failure. The mechanisms by which hepatotoxins injure the liver are complex and include both direct forms of biochemical cellular injury and indirect injury resulting from products of the accompanying inflammatory response.

INTRODUCTION

Many chemical compounds are able to cause hepatic injury and the vast majority of them cause injury limited only to the liver. The liver is particularly susceptible to toxic injury for two reasons. The first is that the portal blood supply from the intestine drains directly to the liver. Hepatocytes are therefore unique in their direct exposure to high levels of ingested toxins. The second is that one of the prime functions of the liver is to metabolize endogenous and foreign compounds. To perform this function, hepatocytes express high levels of a number of metabolic enzymes, such as those in the cytochrome P450 family. Although the biotransformation of these compounds is protective to the body as a whole, it may result in the generation of a metabolite that becomes toxic when large amounts accumulate in the hepatocyte. Hepatotoxins exist in a number of forms. The vast majority of clinically important toxin-induced human liver disease results from chronic alcohol ingestion. A number of medicinal drugs can also cause hepatotoxicity even when used in the usual therapeutic doses. Certain varieties of mushrooms and an increasing number of herbs usually used as alternative medicines are known hepatotoxins. Industrial or environmental chemicals are currently rare causes of hepatotoxicity.

FORMS OF HEPATOTOXIN-INDUCED LIVER INJURY

Hepatotoxins can have either predictable or idiosyncratic liver toxicities. For example, the pain reliever acetaminophen has a predictable hepatotoxicity that increases as the amount ingested exceeds the known therapeutic range. In contrast, other agents, such as inhaled anesthetics, rarely cause a sporadic, idiosyncratic hepatotoxicity even when they are used in the

prescribed therapeutic amounts. Host factors clearly play a role in determining whether hepatotoxicity occurs, even in the cases of predictable hepatotoxicity. Important host factors include gender, age, racial background, and genetic polymorphisms, particularly those related to hepatotoxin metabolism. Complex interactions may determine the toxicity of a compound, such as with the increased toxicity of acetaminophen found in chronic alcoholics due to the ability of alcohol to induce expression of enzymes that metabolize acetaminophen. Depending on the toxin, a variety of forms of liver injury can result from hepatotoxin exposure. Frequently the injury is mild and manifests itself only as asymptomatic elevations in serum liver transaminases or cholestasis. These injuries usually resolve when hepatotoxin exposure ceases. Occasionally, acute liver failure develops, with the majority of these cases being caused by the ingestion of toxic amounts of acetaminophen. Continuous hepatotoxin exposure, such as that which occurs with chronic alcohol abuse, can result in chronic liver disease and cirrhosis. Although the likelihood of developing cirrhosis from alcohol abuse clearly increases with the amount and duration of ingestion, host factors presumably explain the widely variable development of chronic liver disease among individuals.

DIRECT MECHANISMS OF HEPATOTOXIC INJURY

Hepatotoxins are taken up by hepatocytes and can injure the cell by damaging any of a number of cellular constituents. As discussed previously, typically the parent compound is harmless until it is metabolized into a toxic intermediate. For example, acetaminophen is metabolized by the cytochrome P450 enzyme isoform 2E1 to the toxin *N*-acetyl-*p*-benzoquinone amine. This potent oxidant is normally neutralized by glucuronide and sulfate conjugation. With large doses of acetaminophen, these protective factors become depleted and oxidative damage ensues. The creation of such an oxidative stress is the final common pathway of cellular injury for a number of hepatotoxins in addition to acetaminophen. Metabolized hepatotoxins may act as oxidants themselves or cause the generation of reactive oxygen intermediates, such as superoxide and hydroxyl free radicals. These highly reactive compounds oxidize and alter cellular lipids, proteins, or DNA, leading to cell injury and,\,death. The oxidative destruction of these cellular components has classically been thought to result in a form of cell death, termed necrosis. In necrotic death, the cell swells, the membranes rupture, and the cell disintegrates. However, oxygen radicals also induce hepatocyte death by apoptosis—an active process in which gene expression triggers a cell death marked by cell shrinkage and chromatin compaction. In both apoptosis and necrosis, death is regulated by cellular signaling pathways that are activated by toxin-induced changes in the redox homeostasis of the cell. Particularly important is activation of the mitogen-activated protein kinase pathway and the resultant activation of transcription factors, such as activating protein-1 and nuclear factor κB (NF-κB). These transcription factors presumably regulate the expression of genes that in turn promote or block cell death, although the identity of these genes remains unknown.

ROLE OF KUPFFER CELLS AND CYTOKINES IN TOXIN-INDUCED LIVER INJURY

One of the unique aspects of the cellular environment of the liver is that it contains 80−90% of the fixed macrophages in the body. During toxin-induced liver injury, additional macrophages are recruited from the circulation into the liver and these cells, along with the resident macrophages or Kupffer cells, undergo a morphological and physiological change, termed activation. Activated cells produce a number of products, including reactive oxygen intermediates, proteolytic enzymes, nitric oxide, eicosanoids, and cytokines (see Fig. 1). Cytokines are a large family of small secreted proteins that exert biological effects on other cells. Activated macrophages promote liver damage from hepatotoxins because toxin-induced liver injury is markedly decreased when liver macrophages are depleted or functionally inactivated. The actions of gut-derived lipopolysaccharide (LPS) are critical in this process because LPS neutralization also prevents much of the liver injury induced by toxins. LPS presumably promotes injury through its ability to activate macrophages. Although all of the previously mentioned products of activated macrophages may promote hepatocyte injury, experimental studies suggest that toxin-induced liver injury depends in large part on the effects of one cytokine, tumor necrosis factor α (TNFα). In animal models of liver injury, blocking the activity of TNFα dramatically reduces the amount of liver injury from a number of toxins, including alcohol and acetaminophen. Taken together, these findings suggest that during hepatotoxic injury LPS causes macrophage activation, leading to the production of TNFα, which then causes liver cell injury. Surprisingly, hepatotoxic liver injury in large part results therefore not from the direct effects of the toxin,

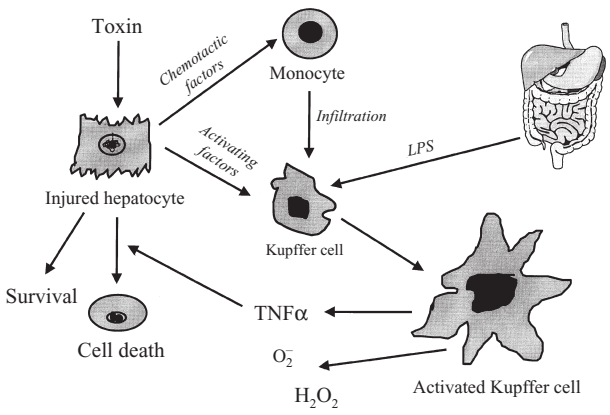

FIGURE 1 Critical events during hepatotoxic liver injury. A toxin is taken up by the hepatocyte, resulting in direct cellular injury. Injured cells release products (chemotactic factors) that attract blood monocytes to infiltrate the injured portion of the liver. These cells, along with preexistent Kupffer cells, respond to factors from injured hepatocytes and to gut-derived lipopolysaccharide (LPS) by undergoing a process termed activation. These activated macrophages release reactive oxygen intermediates, such as superoxide (O_2^-) and hydrogen peroxide (H_2O_2), and a number of cytokines, including tumor necrosis factor α (TNFα). Depending on the degree of injury, hepatotoxin-injured hepatocytes may survive or undergo cell death that is mediated in large part by their sensitization to death from macrophage-produced TNFα.

but from the actions of TNFα produced by macrophages. The mechanism by which TNFα causes hepatocyte injury remains unclear. TNFα is normally toxic to tumor cells but not to nontransformed cells, including hepatocytes. Inhibition of hepatocyte RNA or protein synthesis sensitizes hepatocytes to injury and death from TNFα. Therefore, hepatocyte resistance to the toxic effects of TNFα depends on the induction by TNFα of a protective gene(s). Since hepatotoxins almost invariably interfere with macromolecular synthesis, they presumably block expression of the protective gene, thereby sensitizing hepatocytes to death from TNFα. Although the identity of this protective gene in hepatocytes is currently unknown, it has been established that a critical factor in hepatocyte resistance to TNFα toxicity is the activation of the transcription factor NF-κB.

THERAPIES FOR HEPATOTOXIC INJURY

For many clinical episodes of hepatotoxicity, particularly those related to medicinal drugs, halting toxin exposure is sufficient treatment by itself. For more severe cases of hepatotoxicity that result in acute liver failure, treatment initially involves only supportive care and then liver transplantation if hepatic function fails to improve. Devices that are mechanical, or more recently devices that contain living hepatocytes, have been used experimentally as a temporary liver substitute until the patient's liver recovers. With increasing knowledge of the mechanisms by which hepatotoxins damage the liver, novel therapies are being developed to treat these forms of liver injury. These measures include the administration of antioxidant compounds, especially compounds targeted specifically for the liver or at particular organelles within the liver cell that are vulnerable to toxic injury, such as the mitochondria. Interventions to neutralize TNFα and its toxicity may also become effective therapies against toxin-induced liver injury. Finally, an identification of the common signaling pathways that ultimately lead to the death of the hepatocyte may eventually result in the development of even more specific therapies to prevent hepatotoxic injury.

Hereditary Fructose Intolerance

DAVID A. RUDNICK
Washington University, St. Louis, Missouri

Fanconi's syndrome A disorder of the proximal kidney tubules characterized by urinary excretion of large amounts of amino acids, glucose, and phosphate despite normal blood levels of these molecules.
gluconeogenesis The biochemical process by which glucose is synthesized from noncarbohydrate substrate.
glycolysis The sequential enzymatic conversion of glucose to lactic acid.

Hereditary fructose intolerance is associated with mutations in the aldolase B gene. Dietary exposure to fructose leads to the clinical syndrome, with disease severity related to degree of nutritional exposure. Traditionally, the diagnosis has depended on fructose tolerance testing or enzymatic assay of biopsy material; however, the recognition of specific aldolase B mutations has prompted recent development of genetic testing strategies. Treatment relies on strict adherence to a fructose-free diet, which leads to complete symptomatic resolution.

INTRODUCTION

Hereditary fructose intolerance (HFI) is a recessively inherited inborn error of metabolism in which ingestion of fructose leads to toxic effects on the liver, intestines, and kidney. Acute ingestion can cause hypoglycemia and gastrointestinal symptoms and chronic ingestion can lead to hepatic or renal injury and growth disturbance. Deficiency of fructose-1,6-bisphosphate aldolase enzyme activity (aldolase B; EC 4.1.2.13), an enzyme of fructose-1-phosphate metabolism, causes HFI. Several mutations in the human aldolase B gene have been associated with HFI. Severity of clinical disease is related to the degree of nutritional exposure and the age of the affected individual. This article examines fructose metabolism and the molecular basis, clinical presentation, pathogenesis, diagnosis, and treatment of HFI.

FRUCTOSE METABOLISM

Fructose exists as a monosaccharide in fruits and honey and is present in the disaccharide sucrose. Sucrose is hydrolyzed to glucose and fructose by the enzyme sucrase, present in the brush border membrane of intestinal epithelial cells. Fructose is transported across the plasma membranes of enterocytes and hepatocytes and metabolized in the liver, kidney, and small intestine. After cellular uptake, fructose is phosphorylated to fructose-1-phosphate, which aldolase B then metabolizes to dihydroxyacetone phosphate and D-glyceraldehyde. D-Glyceraldehyde is phosphorylated to D-glyceraldehyde-3-phosphate and further metabolized through glycolysis or gluconeogenesis (Fig. 1).

ALDOLASES

Three eukaryotic aldolases have been identified, each with distinct tissue-specific and developmental patterns of expression. Aldolase B is found in liver, kidney, and small intestine. Aldolase A exists in most tissues but predominates in muscle. Aldolase C is present in the brain. Aldolases A and C have greater activity against fructose-1,6-diphosphate than does aldolase B; thus, gluconeogenesis can proceed even in the absence of aldolase B (Fig. 1). Aldolase A is the predominant fetal isoform. During embryonic development, aldolase A is repressed and aldolase B is induced in the liver,

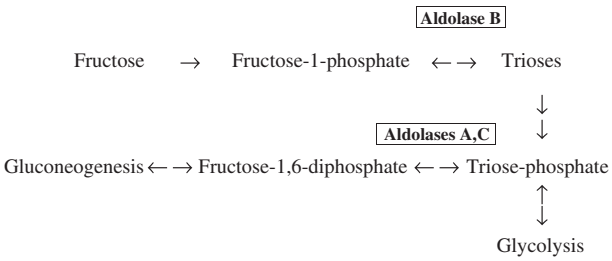

FIGURE 1 Summary of fructose metabolism. Aldolase B catalyzes the reversible cleavage of fructose-1-phosphate to the trioses, D-glyceraldehyde and dihydroxyacetone phosphate. Aldolases A and C have greater activity against fructose-1,6-diphosphate than does aldolase B.

 Copyright 2004, Elsevier (USA). All rights reserved.

kidney, and intestine. After birth, expression of aldolase B is regulated by dietary exposure to fructose, whereas aldolases A and C are constitutively expressed.

HEREDITARY FRUCTOSE INTOLERANCE

In HFI, aldolase B deficiency leads to impaired fructose metabolism. The first clinical description, in 1956, was of a 24-year-old woman with faintness, abdominal pain, and nausea after ingestion of fructose but not glucose. Investigators suspected that symptoms were secondary to fructose-induced hypoglycemia. In 1957, the same syndrome was reported in several members of a family. Aldolase deficiency was shown to be responsible based on enzymatic analyses of liver biopsies. Subsequent studies have shown that the phenotype is particularly severe in individuals unable to avoid fructose-containing sugars, particularly infants at the time of weaning from breast milk.

Molecular Basis and Epidemiology

The gene encoding aldolase B (GenBank Accession No. X01098) maps to chromosome 9q22.3, contains 9 exons, and encodes a 364-amino-acid polypeptide. HFI occurs when mutant alleles of the aldolase B gene whose protein products are deficient in enzyme activity are inherited in an autosomal recessive fashion. The disease is manifest only in homozygotes, with an estimated frequency of 1 in 20,000 individuals. In affected individuals, the enzymatic activities of aldolases A and C are normal.

Genetic Mutations of Aldolase B

The first identified mutation of the aldolase B gene associated with HFI, described in 1988, was a homozygous single base-pair change (G → C) resulting in mutation of Ala-149 to proline (A149P). A149P remains the most common mutation identified to date, accounting for more than half of mutant North American and northern European alleles. Two other mutations (A174D and A174E) have been frequently identified in HFI patients from Italy, Switzerland, and Yugoslavia but not in those from North America or northern Europe. Testing for these three mutations, using polymerase chain reaction (PCR) to amplify aldolase B DNA, can identify more than 95% of patients with HFI. A total of 22 genetic lesions in aldolase B, including several null mutations, have now been associated with HFI disease. Patients with null mutations are healthy as long as they avoid fructose. They have no morbidity associated with fasting, proving that aldolase B, though required for the metabolism of fructose and fructose-containing sugars, is not required for gluconeogenesis or glycolysis in the absence of fructose.

Structure–Function Relationships

Most of the characterized mutations in aldolase B associated with HFI abolish enzyme activity. The molecular effects of the two most common mutations, A149P and A174D, have been examined by analyses of the recombinant proteins *in vitro*. Both enzymatic activity and structural stability are profoundly disturbed in the mutant enzymes. Correlations between specific genetic mutations and the severity of clinical phenotype have not been recognized. Rather, disease severity appears to be related primarily to dietary exposure to fructose.

Clinical Presentation and Pathogenesis

Signs and Symptoms

Individuals with HFI are asymptomatic and healthy until they ingest foods containing fructose (or complex fructose-containing molecules such as sucrose and sorbitol). The signs and symptoms of acute exposure to fructose include nausea, vomiting, tremor, dizziness, and lethargy. Large doses may induce seizures or coma. Chronic exposure can be associated with failure to thrive, jaundice, cirrhosis, vomiting, diarrhea, and feeding difficulties. Symptoms are the result of fructose-1-phosphate accumulation in liver, kidney, and small intestine. Accumulation in the small intestine leads to abdominal distension, pain, colic, vomiting, and diarrhea. In the liver and kidney, buildup of fructose-1-phosphate sequesters phosphate, leading to hypophosphatemia, hypoglycemia, hyperlactic acidemia, and hyperuricemia. Hepatotoxicity may manifest as hepatosplenomegaly, edema, ascites, cholestasis, coagulopathy, and liver failure. Renal toxicity may present as a Fanconi's syndrome with generalized amino aciduria, phosphaturia, and bicarbonate wasting. With chronic exposure, the injury may be irreversible. In some children, the only manifestation of HFI may be nutritional deficiency states, such as rickets or failure to thrive, and hepatomegaly.

The severity of clinical presentation depends on age at the time of exposure and the amount of the exposure. Younger patients and those exposed to greater amounts of fructose exhibit more severe reactions. Infants with HFI are asymptomatic while breast-feeding or on sucrose-free formulas. Symptoms first appear at the time of introduction of fructose- or sucrose-containing foods in the diet, e.g., fruits, juices, vegetables, or

sucrose-containing formulas. Older children, adolescents, or adults with HFI, who are not exposed to fructose or diagnosed with HFI in infancy, learn by experience to avoid foods containing even small amounts of fructose. Such individuals may come to medical attention because of unusual feeding behaviors involving self-restriction from sweet-tasting foods. They also have low incidence of dental caries related to low sucrose intake.

Laboratory Abnormalities

Laboratory abnormalities are nonspecific and related to target end-organ dysfunction. Common findings include hypertransaminasemia, hyperbilirubinemia, prolonged prothrombin time, hypoproteinemia, hypokalemia, and hypophosphatemia. Renal Fanconi's syndrome can occur with increased urinary reducing substances (particularly fructose), protein, amino acids, and organic acids. Hypoglycemia, anemia, and thrombocytopenia also occur.

Pathogenesis and Biochemical Abnormalities

The metabolic derangements that occur after acute fructose ingestion in HFI have been examined by analyses *in vitro* and in animals, healthy controls, and affected patients. Aldolase B deficiency results in hepatic, renal, and intestinal intracellular accumulation of fructose-1-phosphate. After exposure to fructose, sequestration of intracellular phosphate as fructose-1-phosphate leads to the reduction of free intracellular phosphate pools and ATP levels. The accumulation of fructose-1-phosphate impairs gluconeogenesis and glycogenolysis, resulting in hypoglycemia. Excess fructose-1-phosphate also inhibits the activity of enzymes involved in glycoprotein synthesis and processing, leading to derangement in normal protein glycosylation patterns, i.e., a secondary carbohydrate-deficient glycoprotein syndrome. Fructose exposure also causes hyperuricemia and lactic acidosis. Excessive uric acid is generated from AMP as a result of activation of adenosine deaminase and associated purine degradation in response to hypophosphatemia and decreased ATP levels. Hypermagnesemia occurs secondary to depletion of intracellular ATP, leading to the release of magnesium ions from intracellular stores. Fructosemia and fructosuria occur as a result of fructose-1-phosphate-mediated inhibition of fructokinase, preventing further accumulation of intracellular fructose. Depletion of intracellular inorganic phosphate and ATP ultimately disrupts protein synthesis and other functions leading to cellular and organ-system toxicity. Additional biochemical disturbances occur as a result of such toxicity including hypokalemia, coagulopathy, and elevated serum amino acids.

Diagnosis

The clinical presentation of HFI is variable and nonspecific. Young infants often present with difficulty feeding, poor growth, vomiting, and hepatomegaly. Older infants and children may present with similar symptoms or for evaluation of abnormal behaviors. The differential diagnosis includes intrauterine infection, sepsis, hepatitis, hemolytic–uremic syndrome, and metabolic liver diseases including galactosemia, tyrosinemia, Wilson's disease, and others. The key to diagnosis is a careful nutritional history correlating fructose ingestion with onset of symptoms. Once HFI is suspected, all sources of fructose, sucrose, and sorbitol must be removed from the diet. Confirmation of the diagnosis is important because strict compliance with dietary exclusion of fructose prevents tissue injury and growth retardation.

Traditional Diagnostic Tests

Historically, the specific diagnosis of HFI could be made only by enzymatic analysis for aldolase B activity in hepatic and intestinal biopsies or by a controlled intravenous fructose tolerance test and simultaneous analysis for characteristic clinical and biochemical changes. Fructose-1-phosphate aldolase activity from hepatic or small intestinal biopsy material is decreased in HFI. Other tissues, such as serum, blood cells, cultured skin fibroblasts, and placenta, are not useful for diagnosis because aldolase A is the predominant isoform present and enzyme activity is not decreased. Biopsy of the liver offers advantages compared to the intestine in that histological assessment of hepatic tissue damage can also be performed. In HFI, the liver may exhibit steatosis, hepatocellular necrosis, and intralobular or periportal fibrosis or cirrhosis. Many investigators have increasingly discouraged the fructose tolerance test because of severe toxic effects observed during such studies and because of the availability of definitive genetic testing.

Genetic Testing

The development of PCR-based methodologies for the detection of mutations in the aldolase B gene offers noninvasive screening to confirm clinical diagnoses of HFI. At present, more than 95% of patients with HFI can be diagnosed by PCR-based DNA amplification performed on material obtained from blood using a limited number of allele-specific oligonucleotide pairs.

Treatment

Immediate and complete removal of *all* sources of fructose from the diet is the only effective strategy for

management of HFI and prevention of the acute and long-term consequences associated with fructose exposure. Particular care should be taken to avoid foods and medicines with fructose-containing food additives. For example, sucrose and sorbitol are often used as supplements for delivery of medications in a palatable form. Monitoring growth and nutritional status to ensure that strict adherence to the restricted diet does not lead to specific deficiencies is important.

Outcome

The natural history of HFI depends on the age at which the diagnosis is made and the degree of dietary exposure to fructose. Infants with HFI, who are unable to control their own diet, are at the greatest risk of morbidity and mortality associated with fructose exposure. Treatment of acute metabolic crises involves supportive care to correct associated metabolic derangements and complications. This may include intravenous fluids and glucose to restore normal fluid and electrolyte status and correct hypoglycemia, blood products to treat coagulopathy or bleeding, and vitamin and nutritional support to restore growth. Complete and long-term abstinence from fructose exposure often leads to resolution of hepatomegaly, reversal of organ dysfunction, normalization of intellectual function, and catch-up growth. Persistent hepatomegaly or growth failure may indicate ongoing unrecognized ingestion of fructose. Adults with HFI who adhere to an appropriate diet are usually asymptomatic and healthy. Morbidity and mortality have been reported in people with undiagnosed or unrecognized HFI who are exposed to fructose-containing parenteral nutrition. Such feeding regimens, once thought to be of benefit for patients with diabetes mellitus, have been greatly restricted because of the description of fatal and near-fatal cases resulting from their use in subjects with undiagnosed HFI.

OTHER DISORDERS OF FRUCTOSE METABOLISM

HFI is one of three known disorders of fructose metabolism. The others are essential fructosuria and fructose-1,6-diphosphate deficiency. Essential fructosuria, also known as hepatic fructokinase deficiency, is a benign condition characterized by hyperfructosemia and fructosuria in association with dietary fructose intake. It is typically diagnosed after detection of urinary reducing substances in otherwise healthy individuals. Fructose-1,6-diphosphatase deficiency is a severe inborn error of metabolism associated with deficiency of fructose-1,6-diphosphatase, an enzyme required for gluconeogenesis. It is characterized by fructose- and fasting-induced hypoglycemia, lactic acidosis, and hepatomegaly. Symptoms usually occur within the first 4 days of life and can be life-threatening. A milder variant has been described in which affected patients are resistant to the development of lactic acidosis, presumably because of retention of partial enzyme activity.

Hereditary Hemochromatosis

DAVID J. BRANDHAGEN
Mayo Clinic and Foundation

C282Y The main hemochromatosis gene mutation, present in approximately 85% of Caucasians with iron overload in the United States; tyrosine for cysteine substitution at amino acid position 282.

compound heterozygote One copy of two different mutations. In patients with iron overload, describes the presence of one copy of the C282Y mutation and one copy of the H63D mutation. The genotype is present in 1–2% of the Caucasian population; most do not develop iron overload but a few do (usually mild).

divalent metal transporter 1 Protein located in the apical villous surface of enterocytes; imports non-transferrin-bound iron from the small bowel lumen to the enterocyte cytoplasm.

duodenal cytochrome b Ferric reductase located on the apical villous surface of enterocytes; converts ferric (Fe^{3+}) iron in the small bowel lumen to ferrous (Fe^{2+}) iron, thereby facilitating its uptake into the enterocyte.

ferritin Molecule involved in cytosolic iron storage.

ferroportin 1 Protein located on the basolateral surface of villous enterocytes; functions as an exporter of iron from the enterocyte to the plasma; a mutation in ferroportin 1 is associated with an autosomal dominant form of iron overload in hereditary hemochromatosis type 4.

H63D Hemochromatosis gene (*HFE*) mutation that involves substituting an aspartate for a histidine at amino acid position 63. Approximately 25% of the general population is heterozygous for H63D and one copy of this mutation is not associated with iron overload. Homozygosity for H63D is a rare cause of iron overload (usually mild).

hepcidin Small protein produced by hepatocytes; may be the soluble iron stores regulator that controls iron absorption in intestinal crypt cells.

hephaestin Protein located on the basolateral surface of villous enterocytes; functions as a ferroxidase, converting ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron, facilitating its transfer across the basolateral membrane of the enterocyte to the plasma.

***HFE* gene** Hemochromatosis gene located on chromosome 6p. Two main mutations (C282Y and H63D) were initially described.

iron regulatory elements Stem–loop structures present on the 3′ or 5′ untranslated regions of mRNA of several molecules involved in iron regulation.

iron regulatory proteins Molecules that increase in response to iron deficiency and bind to iron regulatory elements; such binding at the 3′ untranslated region of mRNA of the transferrin receptor and the divalent metal transporter 1 will stabilize the transcript and increase expression of these molecules. Conversely, binding on the 5′ untranslated region of ferritin will block translation and decrease ferritin levels.

transferrin Circulating iron carrier; each transferrin molecule binds two atoms of diferric iron.

transferrin receptor Protein involved in endocytosis of diferric transferrin; binds the *HFE* molecule.

transferrin receptor 2 Recently discovered protein expressed predominantly on hepatocytes; also involved in endocytosis of diferric transferrin., but it is uncertain if this receptor binds *HFE*. An autosomal recessive form of hemochromatosis (hereditary hemochromatosis type 3) associated with several mutations in the transferrin receptor 2 gene on chromosome 7 has recently been described.

Hereditary hemochromatosis (HH) is an autosomal recessive disorder characterized by increased intestinal absorption of iron; excess iron is deposited in the liver, pancreas, and other organs. It is the most common genetically inherited disorder in the United States Caucasian population, with a prevalence of 0.5% and a carrier frequency of 10%. Clinical manifestations may include fatigue, diabetes, arthritis, impotence, increased skin pigmentation, cirrhosis, hepatocellular carcinoma, heart failure, and cardiac arrhythmias. Diagnosis is based on a combination of clinical, laboratory, and pathologic criteria, including an elevated transferrin saturation assay. Treatment by phlebotomy, if initiated before the development of cirrhosis or diabetes, is associated with a normal life expectancy. Approximately 85% of patients with HH are homozygous for the *C282Y HFE* gene mutation. The *HFE* gene test is useful in confirming a diagnosis of HH, screening adult blood relatives of probands, and resolving ambiguous cases of iron overload.

CLINICAL FEATURES

Iron accumulation in hereditary hemochromatosis is a slow, insidious process; only a few milligrams of excess iron may be absorbed from the duodenum each day. Clinical manifestations frequently do not occur until

 Copyright 2004, Elsevier (USA). All rights reserved.

at least the fifth decade, when 15–40 g of iron have accumulated (normal body iron stores are approximately 3–4 g). Disease expression may occur earlier in some persons and may not occur at all in others. Clinical expression is influenced by age, sex, iron content of the diet, blood loss as occurs in menstruation and pregnancy, and other unknown factors. Although the gene frequency is similar in males and females, the disease is expressed less frequently in women than in men. Factors such as alcohol and hepatitis C may also influence disease expression. Several recent studies have concluded that clinically significant disease expression may not occur in a majority of individuals who are homozygous for the C282Y mutation, even if undiagnosed and untreated.

The classic description of HH is cutaneous hyperpigmentation, diabetes mellitus, and cirrhosis of the liver (bronze diabetes). Other clinical manifestations include fatigue, abdominal pain, hepatomegaly, abnormal liver tests, hepatocellular carcinoma, cardiomyopathy, cardiac conduction disorders, hypothyroidism, hypogonadism, impotence, and arthropathy.

In the past, HH was usually diagnosed at an advanced stage; currently, most patients with newly diagnosed HH are asymptomatic. This shift toward earlier diagnosis may be due in part to increased physician awareness. Of HH patients who are symptomatic, fatigue, arthralgias, and impotence are most common. Most if not all clinical manifestations are preventable if HH is diagnosed early and treated appropriately. Some of the disease manifestations, such as skin bronzing, cardiomyopathy, cardiac conduction disorders, hepatomegaly and abnormal liver tests, frequently are reversible once excess iron stores are removed. Most of the other clinical manifestations are not reversible, however.

DIAGNOSIS

Serum Iron Studies

A diagnosis of HH is based on a combination of clinical, laboratory, and pathologic criteria, including an elevated serum transferrin saturation [100 (serum iron concentration ÷ total iron binding capacity)] result and an elevated serum ferritin concentration. There is diurnal variation in serum iron values, and measurements may be affected by the ingestion of food; therefore, an elevated transferrin saturation assay should be repeated as a fasting early morning determination. A transferrin saturation above 50% is the earliest phenotypic abnormality in HH.

Although serum transferrin saturation is the best initial screening test, the results may be normal early in the course of HH. In addition, the serum ferritin concentration and transferrin saturation may be elevated in up to 50% of patients with viral hepatitis, nonalcoholic steatohepatitis, and alcoholic liver disease, and in end-stage liver disease of various etiologies. Serum ferritin usually provides a reasonable estimate of total body iron stores, but it is also an acute-phase reactant and is elevated in a variety of infectious and inflammatory conditions in the absence of iron overload. For this reason, it should not be used as the initial screening test to detect HH.

HH should be distinguished from iron overload that is due to other causes. Secondary iron overload should be suspected in patients with chronic anemias with ineffective erythropoiesis, multiple blood transfusions, prolonged iron supplementation, and chronic liver disease. Disorders associated with iron overload are summarized in Table I.

TABLE I Disorders Associated with Iron Overload

- **Hereditary hemochromatosis**
  - HFE related
    - C282Y homozygous
    - C282Y and H63D heterozygous (compound heterozygote)
    - Other
  - Non-HFE related
    - HH type 2 (juvenile hemochromatosis)
    - HH type 3 (TfR2 mutation)
    - HH type 4 (ferroportin mutation)
- **Secondary Iron Overload**
  - **Chronic anemias**
    - Thalassemia major
    - Sideroblastic anemia
    - Congenital dyserythropoietic anemia
    - Congenital atransferrinemia
  - **Exogenous iron overload**
    - Chronic iron supplementation (in the absence of blood loss)
      - Transfusion
      - Iron dextran
      - Oral supplements (rare)
  - **Chronic liver disease**
    - Cirrhosis
    - Viral hepatitis
    - Alcoholic liver disease
    - Nonalcoholic steatohepatitis
    - Porphyria cutanea tarda
    - Portacaval shunt
  - **Miscellaneous**
    - Iron overload in sub-Saharan Africa
    - African-American iron overload
    - Neonatal iron overload
    - Aceruloplasminemia
    - Congenital atransferrinemia

Hepatic Iron

Prior to the availability of the *HFE* gene test, a liver biopsy was often necessary to confirm a diagnosis of HH. Hepatic iron may be assessed with an iron stain. In HH, iron initially accumulates in periportal hepatocytes but is eventually distributed throughout the liver. In secondary iron overload, iron is often present predominately in Kupffer cells, which may help distinguish it from HH. Histologic distinction between HH and secondary iron overload is often not possible once severe iron overload has developed. Hepatic histological features of HH and secondary iron overload are demonstrated in Fig. 1.

In HH, there is a progressive, age-related increase in hepatic iron stores. This knowledge led to the development of the hepatic iron index (HII), which is the hepatic iron concentration (in micromoles/gram dry weight liver) divided by the patient's age in years. The original intent of the HII was to distinguish HH homozygotes from heterozygotes, and those with alcoholic liver disease. In the initial study, all HH homozygotes had an HII >1.9, whereas all of the HH heterozygotes or patients with alcoholic liver disease had an HII <1.9. An HII >1.9 is not diagnostic of HH because patients with severe iron overload of any cause may have an HII >1.9. In addition, because HH is increasingly diagnosed at an earlier stage, not all

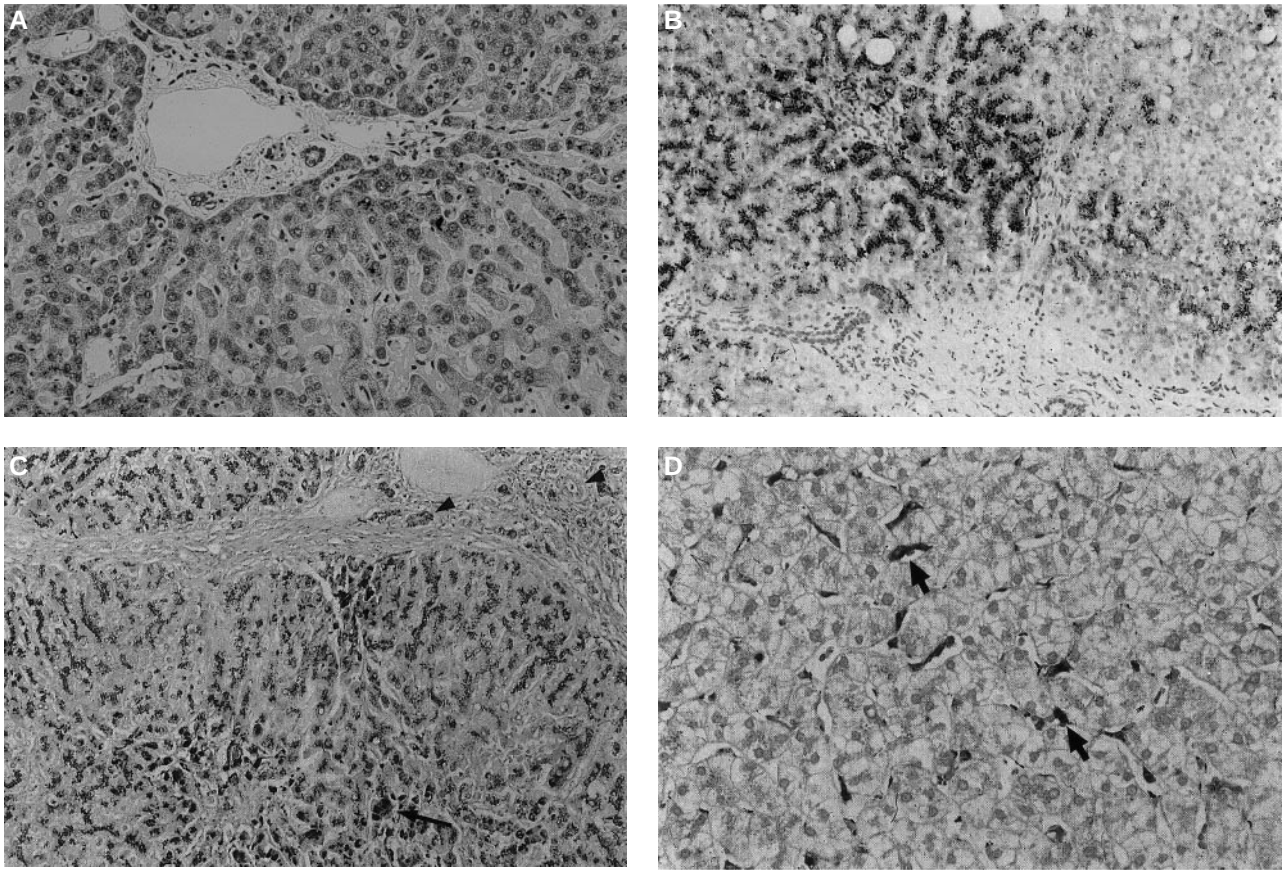

FIGURE 1 Histological hepatic iron deposition. (A) Mild (grade 1 of 4) iron deposition in hepatocytes. Reproduced with permission from *Liver Transplantation* 7(8), 663–672 (2001). (B) Moderate hemosiderin deposition in precirrhotic homozygous hemochromatosis. Zone 1 hepatocytes are predominantly involved, biliary hemosiderin is not evident, and fibrosis has not yet occurred, all indicating relatively early precirrhotic disease (hepatic iron concentration, 10,307 μg Fe/g dry weight; iron index, 3.2). (Perls' Prussian blue staining; original magnification, ×133.) (C) Marked hemosiderosis and cirrhosis in homozygous hemochromatosis. Although most iron is in the hepatocytes, some Kupffer cell (arrow) and biliary iron (arrowheads) is also present (Perls' Prussian blue staining; original magnification, ×133.) (D) Kupffer cell hemosiderosis. The presence of hemosiderin in Kupffer cells alone (arrows) is typical of mild transfusion hemosiderosis, is nonspecific, and should not prompt further consideration of hemochromatosis (Perls' Prussian blue staining; original modification, ×240). Reproduced with permission from *Hemochromatosis: Genetics, Pathophysiology, Diagnosis, and Treatment* (J. C. Barton and C. Q. Edwards, eds.), pp. 192–194 (2000).

HH homozygotes will have an HII >1.9. Since HFE gene testing has become the standard test for confirming the diagnosis of HH, the HII has assumed a less important role.

THE *HFE* GENE

The gene associated with HH, *HFE*, is located on the short arm of chromosome 6. The *HFE* gene encodes a 343-amino-acid protein that resembles a human leukocyte antigen (HLA) class I molecule. Two point mutations, designated C282Y and H63D, were initially described. Other mutations have since been discovered, including S65C, G93R, I105T, Q127H, and R330M, in addition to a couple of frameshift mutations, nonsense mutations, and one splice site mutation. Of these other mutations, S65C is most common, occurring in 2–3% of patients with iron overload. All of these mutations are rare and are not likely to be of major clinical importance. In nearly all cases, patients with these other mutations who develop iron overload are C282Y compound heterozygotes.

The greatest risk for iron overload exists in those who are homozygous for the C282Y mutation. Several studies from the United States and Europe have found that 60–93% of patients with iron overload are homozygous for C282Y. The wide range in the prevalence of C282Y homozygotes may be due in part to different diagnostic criteria for HH as well as to geographic differences in the prevalence of *HFE* mutations. Iron overload also occurs in a minority of those with other *HFE* mutations, but it is usually of lesser severity. Approximately 1–2% of Caucasians are compound heterozygotes (one copy of C282Y and one copy of H63D) or H63D homozygotes, but only a few percent will develop problems with iron overload. In addition, approximately 25% of the United States Caucasian population is heterozygous for H63D. A single copy of H63D is not associated with an increased risk for developing iron overload. Nearly all studies have demonstrated that severe iron overload can occur in the absence of *HFE* gene mutations. A negative *HFE* gene test, therefore, does not exclude iron overload. The role of *HFE* mutation analysis in the diagnosis of iron overload disorders is summarized in Fig. 2.

The gene test is most useful in screening adult blood relatives of an identified proband. Screening blood relatives is crucial, because 25% of siblings and 5% of children of a proband will have HH. *HFE* gene testing should replace more expensive HLA typing previously used to screen siblings. In addition, *HFE* gene testing often is useful in helping to resolve ambiguous cases,

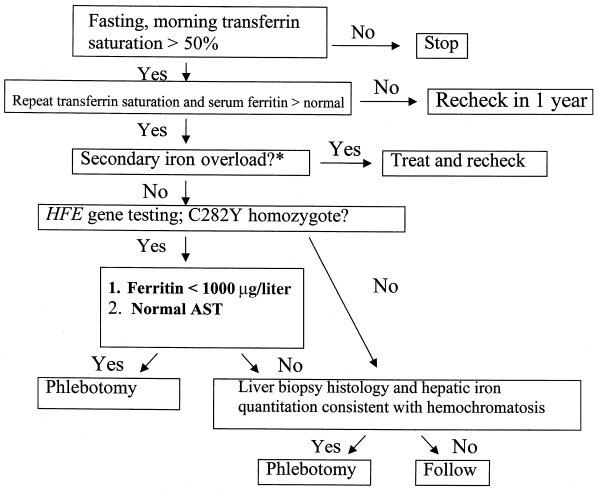

FIGURE 2 Diagnostic algorithm for hereditary hemochromatosis. AST, Aspartate transaminase. Modified with permission from Brandhagen *et al., Mayo Clinic Proceedings* 74, 917–921 (1999).

such as iron overload associated with hepatitis C, alcoholic liver disease, or other causes of end-stage liver disease. Prior to obtaining the *HFE* gene test, an individual should be counseled about the risks, benefits, and alternatives of genetic testing by a qualified professional. There is concern about the possibility of insurance, employment, or other discrimination based on *HFE* test results. For this reason, *HFE* gene testing usually is not recommended for anyone younger than 18 years old.

PATHOPHYSIOLOGY

The discovery of the *HFE* gene has furthered our understanding of the pathophysiology of iron overload. The HFE protein is expressed throughout the intestine as well as in many other tissues. It is expressed on epithelial cells throughout the gastrointestinal tract except in the small intestine, where it is localized in crypt cells. HFE protein is not expressed on hepatocytes and is, therefore, probably not directly involved in hepatic iron loading. The normal (wild-type) HFE protein binds to β2-microglobulin and is expressed on the cell surface. The HFE β2-microglobulin complex binds the transferrin receptor (TfR) and may lower its affinity for diferric transferrin. The C282Y-mutated protein does not bind β2-microglobulin and is not expressed on the cell surface. Failure of the mutated HFE protein to bind to β2-microglobulin may be important in the development of iron overload because β2-microglobulin knockout mice develop hepatic iron overload in a pattern

similar to that observed in humans with HH. The H63D protein associates with β2-microglobulin but does not lower the affinity of the TfR for diferric transferrin.

Several other iron regulatory proteins have recently been discovered. Divalent metal transporter 1 (DMT1; also known as DCT1 and Nramp2), a protein located on the apical surface of villus enterocytes, functions to import non-transferrin-bound iron from the small bowel lumen to the enterocyte cytoplasm. This is facilitated by duodenal cytochrome b (Dcytb), a ferric reductase that converts iron in the small bowel lumen from the ferric to the ferrous form, thus facilitating its uptake into the enterocyte. Once in the enterocyte, iron can be stored as ferritin or transferred to the plasma to bind to transferrin. Ferroportin 1 (FP1; also known as Ireg1), a recently discovered protein located in the basolateral surface of villus enterocytes, functions as the basolateral transporter of iron from the enterocyte to the plasma. This is facilitated by a protein closely related to ceruloplasmin, hephaestin, which functions as a ferroxidase, converting ferrous iron to ferric iron, thereby facilitating its transfer across the basolateral membrane of the enterocyte. An autosomal dominant form of HH (type 4) has recently been described in patients with a mutation in the ferroportin gene.

The duodenal crypt cell is likely involved in sensing the body's iron requirements. Dietary iron intake, iron from storage sites such as the liver, and iron needed for erythropoiesis may all influence intestinal iron absorption. Hepcidin is a recently discovered small protein produced by hepatocytes. Hepcidin mRNA levels are increased in mouse models of dietary iron loading and genetic iron overload, and hepcidin may be the soluble iron stores regulator that controls iron absorption in intestinal crypt cells.

Many of the iron regulatory proteins contain iron regulatory elements (IREs) on the 3′ or 5′ untranslated region (UTR) of their mRNA. IREs bind iron regulatory proteins (IRPs) produced in response to iron deficiency sensed at the level of the crypt enterocyte. The binding of IRPs to an IRE at the 5′ UTR of mRNA from molecules such as ferritin will block translation and decrease ferritin levels. Conversely, the binding of IRPs to an IRE at the 3′ UTR of mRNA from the TfR and DMT1 will stabilize the transcript and increase levels of TfR and DMT1. Although much has been learned about molecular aspects of iron absorption in the past few years, a great deal is still unknown, including the specifics of how the mutated HFE protein leads to the development of iron overload. Intestinal iron overload is summarized in Fig. 3.

TREATMENT

Therapeutic Phlebotomy

The treatment of patients with HH is usually reserved for those with iron overload as evidenced by

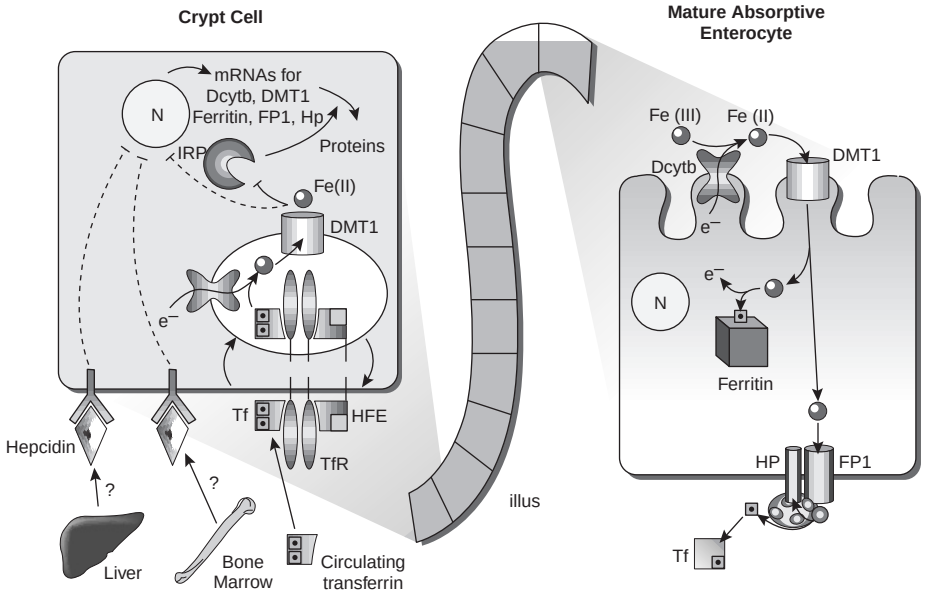

FIGURE 3 Intestinal iron absorption. Dcytb, Duodenal cytochrome b; DMT1, divalent metal transporter 1; FP1, ferroportin 1; Hp, hephaestin; IRP, iron regulatory protein; Tf, transferrin; TfR, transferrin receptor. Reproduced with permission from Philpott (2002), *Herpatology* **35**, 993–1001.

an elevated serum ferritin level. Therapeutic phlebotomy is the preferred treatment because it is simple, inexpensive, and effective. During the initial phase of therapeutic phlebotomy, 500 ml of blood is removed on a weekly basis. A hemoglobin should be checked prior to each phlebotomy. Weekly phlebotomy should continue as long as the hemoglobin is above a preselected value (usually 12–13 g/dl). If the hemoglobin is below the selected cutoff value, phlebotomy should not be performed. Once the hemoglobin remains below the cutoff for 3 consecutive weeks without phlebotomy, the serum ferritin and transferrin saturation should be rechecked. Iron depletion is confirmed if the ferritin level is less than 50 μg/liter with a transferrin saturation in the low normal range. Once iron depletion is accomplished, most patients require four to eight "maintenance" phlebotomies per year to keep the ferritin level lower than 50 μg/liter.

Iron Chelators

Iron chelators such as desferrioxamine are rarely utilized to treat iron overload in HH. Iron chelators are expensive and must be given by subcutaneous infusion. They also are much less effective at removing excess iron compared to phlebotomy. At present, an effective oral iron chelator is not routinely available in the United States.

Dietary

Patients with HH should refrain from using iron supplements, including multivitamins with iron as well as high-dose vitamin C supplements. A "low-iron diet" is not necessary, but red meat should be consumed in moderation. Patients with HH should avoid consuming raw shellfish due to an increased risk of infections with *Vibrio vulnificus*. Persons with HH should also avoid or minimize alcohol use because iron and alcohol are synergistic hepatotoxins.

Liver Transplantation

Liver transplantation may be an option for HH patients with cirrhosis and complications of end-stage liver disease. Despite being common, HH is an uncommon indication for orthotopic liver transplantation (OLT), accounting for less than 1% of all liver transplants performed in the United States. Survival in HH patients undergoing liver transplantation is poor. The 1-year patient survival rate after OLT is approximately 50–60% for patients with HH compared to over 90% for most other indications. Deaths in HH OLT recipients are usually due to cardiac or infectious complications. There are preliminary reports of improved survival in patients with HH who are depleted of excess iron stores prior to OLT.

PROGNOSIS

Patients with HH who are diagnosed and treated before the development of diabetes and cirrhosis have normal age-and sex-adjusted survival rates. Once cirrhosis or diabetes develops, the rate of survival is markedly reduced. Deaths in cirrhotic patients with HH are often due to hepatocellular carcinoma. Patients with cirrhosis due to HH usually do not develop decompensated liver disease. Up to one-third of patients with HH and cirrhosis will develop hepatocellular carcinoma. This represents a 200-fold increased risk for the development of liver cancer. HH patients without bridging fibrosis or cirrhosis do not have an increased risk for developing hepatocellular carcinoma.

ROLE OF LIVER BIOPSY

HFE gene testing may eliminate the need for a liver biopsy in many cases. Traditionally, a liver biopsy has been performed in patients with iron overload to confirm the diagnosis of HH and to exclude cirrhosis. Patients who are homozygous for the C282Y mutation with an elevated serum iron and transferrin saturation without secondary iron overload do not need a liver biopsy to confirm the diagnosis of HH. Liver biopsy still remains the "gold standard" for assessing the degree of fibrosis. Definitively excluding cirrhosis is important because of the increased risk of developing hepatocellular carcinoma. The risk for cancer persists even after patients are depleted of excess iron stores. In such patients, screening with an ultrasound scan and α-fetoprotein every 6 months may be appropriate.

There may be a subset of HH patients whose risk of cirrhosis is minimal, and a liver biopsy would be unnecessary. Several recent studies have confirmed that certain predictive noninvasive assessments are accurate in excluding cirrhosis in C282Y homozygotes. In these studies, cirrhosis was extremely uncommon in C282Y homozygotes who had serum ferritin levels lower than 1000 μg/liter and normal aspartate aminotransferase values. A serum ferritin of <1000 μg/liter seems to be the best predictor of the absence of cirrhosis in C282Y homozygotes. The positive predictive value of a serum ferritin of >1000 μg/liter is poor, however, because only about 50% of those with serum ferritin values >1000 μg/liter had cirrhosis. A recent study found that cirrhosis was present in approximately

80% of C282Y homozygotes with serum ferritin of >1000 μg/liter and a platelet count <200 k and an elevated AST. Until these findings are confirmed, a liver biopsy is advisable in C282Y homozygotes with serum ferritin values >1000 μg/liter to definitely assess for the presence of cirrhosis. There are limited data on noninvasive predictors of cirrhosis for non-C282Y homozygotes. A liver biopsy may be necessary in this group of patients to confirm the diagnosis of HH and exclude cirrhosis.

SCREENING FOR HEMOCHROMATOSIS

There is currently disagreement among experts regarding the utility of screening for HH in the general population. HH fulfills most if not all of the World Health Organization (WHO) criteria of a condition amenable to population screening. HH is common and has a long presymptomatic phase. A simple, noninvasive, inexpensive screening test exists, and effective treatment that improves survival is available. Several studies have used reasonable estimates of the number of patients who will develop life-threatening disease and concluded that population screening for hemochromatosis would be cost effective.

Despite the fact HH fulfills many of the criteria of a condition appropriate for population screening, many public health experts have not recommended screening for HH. They cite a lack of information about burden of disease and disease expression in those with *HFE* mutations as reasons why they do not endorse population screening for HH. In support of this, a recent population screening study in the United States of over 40,000 individuals did not find a difference in symptoms reported by C282Y homozygotes compared to non-C282Y homozygotes.

Unfortunately, the natural history HH in an asymptomatic patient identified by population screening may never be known because many would consider it unethical to withhold treatment once a patient develops iron overload. At present, several studies have performed both *HFE* genotyping and serum iron studies in subjects selected from the general population. Between 25 and 81% of C282Y homozygotes in these studies had a normal serum ferritin with no clinical evidence of iron overload. More data from a greater number of individuals, including those from diverse populations, are necessary before reaching definitive conclusions. Without this information, true estimates on the cost effectiveness of screening for hemochromatosis in the general population will be difficult to obtain. With the information currently available, it seems reasonable to screen for iron overload in persons with a chronic liver disease, symptoms or signs suggestive of HH, or a family history of HH.

Hernias

ZARA COOPER AND STEPHEN JOHN FERZOCO
Brigham and Women's Hospital, Boston

Ehlers–Danlos syndrome Heterogeneous group of heritable collagen disorders characterized by joint hypermobility and increased skin elasticity and tissue fragility.

Marfan syndrome Heritable disorder of the connective tissue (caused by a mutation in the fibrillin gene) that affects many organ systems.

A hernia is the abnormal protrusion of a structure through the tissues that normally contain it. A vast majority of abdominal wall hernias are located in the groin. A hernia is reducible if the protruding contents can be put back in their original location. Herniated structures that cannot be restored to their normal location are called irreducible or incarcerated, and are at risk for obstruction or strangulation. Strangulation, which implies compromise to the hernia blood supply, can eventually lead to tissue death and serious infection.

INTRODUCTION

Hernias are very common, and hernia repair is the most common reason for primary care physicians to make surgical referral. Over 700,000 groin hernias are repaired in the United States and Europe annually. Males are seven times more likely than females to develop a hernia and have a 5% lifetime risk of developing a groin hernia. Risk factors include obesity, pulmonary disease with chronic cough, steroid use, straining with exercise, urinary retention, constipation, and other conditions that chronically increase intraabdominal pressure. Connective tissue disorders such as Ehlers–Danlos and Marfan syndromes have also been associated with increased risk of hernia.

All abdominal wall hernias involve a peritoneal sac protruding through a weakness in the abdominal wall. Each side of the abdominal wall includes an inguinal canal, a canal-shaped opening to the groin. In women, this canal contains the round ligament, which supports the uterus. In men, the canal contains the spermatic cord, which includes the blood supply to the testicles and the vas deferens, through which semen flows from the testes to the penis. In the anteromedial portion of the cord, there is a potential space through which abdominal contents can herniate.

ANATOMY

The anatomy of the lower abdominal wall is complex, and even after centuries of study, there is still debate about its structure. The lower wall is composed of three musculoaponeurotic layers: the external oblique, the internal oblique, and the transversus abdominus. Inferiorly, the external oblique aponeurosis forms the superficial inguinal ring through which the round ligament or spermatic cord exits the inguinal canal. This triangular opening is just superior to the medial portion of the inguinal ligament. The internal oblique is the middle layer of the abdominal wall. In 5–10% of the population, the internal oblique aponeurosis will merge with the transversus abdominus aponeurosis to form the conjoint tendon. The conjoint tendon is in the medial aspect of the canal and can be used in reconstruction of the abdominal floor during hernia repair. When the conjoint tendon is not present, the internal oblique contributes little to the integrity of the groin. The deepest layer of the abdominal wall is the transversus abdominus, which is encased in a fascial sheath called the transversalis fascia. The deep inguinal ring, through which the round ligament or spermatic cord enters the inguinal canal, is a defect in the transversalis fascia. This is located at the midpoint of the anterior superior iliac spine and the pubic tubercle. The transversalis fascia forms the floor of the inguinal canal. The roof of the canal is composed of the external oblique aponeurosis and fibers of the internal oblique muscle. Fibers of the internal oblique and transversus abdominus form the superior wall of the canal, and the inguinal and lacunar ligaments form the inferior wall. The illiohypogastric, illioinguinal, and genitofemoral nerves all traverse the region and provide key motor and sensory functions. Nerve entrapment is a risk of herniorraphy and can cause postoperative disability.

The femoral canal is a potential space underneath the inguinal ligament, through which visceral herniation may occur. Its borders are the inguinal ligament

 Copyright 2004, Elsevier (USA). All rights reserved.

superiorly, the external iliac vein medially, Cooper's ligament posteriorly, and fibers of the illiopubic tract as they converge onto Cooper's ligament laterally. The entrance of the canal is the fossa ovalis, a defect in the fascia lata. Here, the femoral and greater saphenous veins merge.

CLASSIFICATION

Hernias are classified by their location. There are a number of types of groin hernias: indirect, direct, pantaloon, and femoral. Indirect inguinal hernias are due to congenital patency of the processus vaginalis and weakening of the transversalis fascia around the internal ring. The processus vaginalis is the peritoneal tunnel through which the testes migrate from the retroperitoneum toward the scrotum during embryological development. Here, there will be herniation of abdominal contents through the internal inguinal ring. Direct inguinal hernias are secondary to weakness in the transversalis fascia inferior to the inferior epigastric artery. The region is known as Hesselbach's triangle. When both direct and indirect hernias are present, it is called a pantaloon hernia. Femoral hernias occur when intraabdominal contents pass beneath the inguinal ligament and through the femoral canal medial to the femoral vein. This type of hernia is most likely to occur in elderly women and precipitant weakness in the abdominal floor may be related to pregnancy.

Anterior abdominal wall hernias are umbilical, incisional, and epigastric. Umbilical hernias may be congenital and appear as a protruding belly button. Umbilical and incisional hernias may also be acquired as defects through previous fascial closures. Epigastric hernias are secondary to congenital defects in the linea alba.

A lump heralds most groin hernias. Patients often describe a sudden bulge that occurred while straining while lifting or moving their bowels. Pain can be associated with an enlarging hernia and may be referred to the scrotum. With the exception of dull pain and a dragging sensation, most reducible hernias are asymptomatic. Patients must be examined while standing and supine, and while coughing and straining to fully evaluate the hernia. A finger should be inserted through the upper scrotum and into the internal ring. If a hernia is present, a sudden impulse or lump will be felt on the fingertip with cough or strain. Bowel sounds may be heard on auscultation of the hernia. It is usually difficult to discern direct from indirect hernias on physical exam, and in most cases the type of hernia is not accurately identified before surgery. However, if contents descend into the scrotum, an indirect, rather than direct, hernia is present. Most hernias in childhood and early adulthood are indirect inguinal hernias.

If a hernia is tender, discolored, or incarcerated, an experienced hand can attempt manual reduction first. Any difficulty with this maneuver signifies that strangulation of the hernia is likely, and emergent operation is indicated. Patients with strangulated hernias may be toxic, dehydrated, and febrile. In this case, reduction should not be attempted. The patients should be adequately resuscitated and taken to the operating room as soon as possible. The risks of incarceration, strangulation, and obstruction are greater compared to risks of hernia repair. Consequently, expeditious elective operative repair is standard unless there are specific contraindications or operative risk is too high. This applies to groin and ventral hernias. When all goes well, elective herniorraphy is often an outpatient procedure done with local anesthesia.

SURGERY

The surgical principles of hernia repair include division of the external oblique and transversalis fascia, isolation of the spermatic cord, high ligation of the hernia sac, and reconstruction of the inguinal canal. In general, there are three approaches to surgical repair of groin hernias: (1) open repair, (2) tension-free repair with mesh or Lichtenstein repair, and (3) laparoscopic repair. Open repair involves freeing the spermatic cord and opening the transversalis fascia to access the inguinal canal. The hernia sac is identified and ligated at its base. Hernia contents are restored to their correct position, and the floor of the inguinal canal is reconstructed with permanent sutures and minimal tension. In tension-free repair with mesh, prosthetic mesh instead of sutures is used to construct the canal. Although there is higher risk of infection with this technique, the subsequent fibrotic reaction secures the repair, resulting in a recurrence rate of less than 1%. Laparoscopic hernia repair is done via smaller incisions, which may result in less pain and disability. One advantage is that bilateral hernias can be repaired with one large piece of abdominal mesh placed posteriorly. Another advantage is that recurrent hernias can be repaired without interfering with previous surgical sites. Drawbacks to laparoscopic repair include requirement of general anesthesia and significantly more expense than open techniques. Because laparoscopic herniorraphy is a relatively new technique, long-term results are unavailable. Thus far, complication and recurrence rates are similar to those of open techniques.

Complications following hernia repair are usually minor; they include wound infections, hematoma, and

nerve entrapment. Injury to the illioinguinal nerve can cause groin and scrotal pain. Entrapment of the genitofemoral nerve is associated with ejaculatory dysfunction and hypersensitivity of the groin, scrotum, and upper thigh. Recurrence may not occur for up to 20 years and further recurrence is more likely after two or more repairs. Recurrence is more likely in the setting of related comorbidities.

Umbilical hernias are present in 10% of White infants and in greater than 40% of Black infants. A hernia in infancy is a congenital defect that usually regresses within 2 years. It is for this reason that repair is postponed until after 2 years of age. In adults, the defect does not regress. Like groin hernias, umbilical hernias tend to expand over time and are aggravated by conditions that increase intraabdominal pressure. The risk of incarceration or strangulation is greater than the risk of elective repair, and surgical treatment is preferred in the absence of contraindications. In umbilical hernias, the sac usually contains omentum. However, strangulated omentum can pose a serious risk to the patient and should not be underestimated in considering urgent repair. Epigastric hernias are often multiple, and until they become symptomatic, repair is usually postponed.

About 10% of incisional hernias occur within the first postoperative year, almost 65% occur within the first 5 years, and the remainder occur after that. In addition to risk factors for other types of hernias, age, poor nutrition, and jaundice can also predispose patients to incisional hernias. Of course, poor surgical technique and wound infection can also predispose hernia formation. Surgery is indicated for repair to prevent incarceration and strangulation. Small defects can be closed primarily, but most incisional hernias require mesh for adequate closure. Drains are often indicated to prevent fluid collections, which may contribute to infection.

In summary, abdominal wall hernias are common and usually cause minimal stress or discomfort. They should be treated with early surgical repair to prevent untoward complications, which can cause significant morbidity and mortality. There are a number of approaches to hernia repair, and the type of repair will vary by patient need and expertise of the surgeon.

Hiatal Hernia

SUBROTO PAUL*RAPHAEL BUENO†
*Brigham and Women's Hospital and †Harvard University

esophagogastroduodenoscopy Endoscopic examination of the esophagus, stomach, and duodenum.
fundoplication Procedure in which the stomach fundus is wrapped around the esophagus.

The esophageal hiatus is formed by the muscle fibers of the right crus of the diaphragm with limited contribution from the left crus. The esophageal hiatal crural fibers form a tunnel through which the esophagus travels from the thorax to the abdomen. The distal esophagus is further attached to the hiatus by the phreno-esophageal ligament, which arises from the fusion of endothoracic and endoabdominal fascia. A hiatal hernia results from the herniation of abdominal contents through the esophageal hiatus into the thoracic cavity or the mediastinum. Small hiatal hernias are common radiographic findings and may or may not be associated with clinical significance. This article focuses on the diagnosis, classification, pathophysiology, and treatment of hiatal hernias.

CLASSIFICATION AND PATHOPHYSIOLOGY

There are multiple ways to classify hiatal hernias. The two basic types are small sliding hernias that are associated with reflux and much larger hernias that progressively contain the stomach and other intra-abdominal contents. This article will use a four-type hernia classification scheme based on the extent of the defects.

Type I

The type I hiatal hernia or sliding hernia is the most common. Type I paraesophageal hernia is defined as one in which the gastroesophageal junction has migrated from the intraabdominal position through the esophageal hiatus and subsequently occupies an intrathoracic position. Type I hernia occurs chiefly as a result of a weakening or thinning of the phreno-esophageal membrane. This type of hernia is rather common and is reportedly found in 10% of Northern American adults examined by barium swallow. This defect can be temporarily induced in many normal individuals by any maneuver that increases intraabdominal pressure, such as vomiting or the Valsalva maneuver. The significance of this defect is dependent on the degree of associated symptoms of esophageal reflux as discussed below.

There are multiple potential etiological causes for type I hiatal hernias. Some individuals may have a congenitally inferior insertion of the phreno-esophageal ligament into the esophagus or a congenitally weakened ligament leading to an intra-thoracic gastro-esophageal junction and resulting in an intra-thoracic location of the gastric cardia. Some of these patients may have had symptoms of reflux or regurgitation since childhood. However, in most cases, it is difficult to know with certainty whether the defect was acquired or congenital in nature. The development of a type I hernia is also thought to result from an increase in intra-abdominal pressure that occurs in conditions such as pregnancy, obesity, protracted vomiting, or direct trauma from blunt force to the abdomen. Protracted vomiting may also cause vigorous esophageal contraction leading to the elevation of the gastro-esophageal junction into the chest.

Type I sliding hiatal hernia rarely causes symptoms. Symptoms are present in a fraction of patients with this defect and result from reflux attributed to a lower esophageal sphincter rendered dysfunctional by its intrathoracic location. Although most patients with sliding hernia do not have reflux, between 50 and 90% of patients with reflux have an associated sliding hiatal hernia. Gastro-esophageal reflux symptoms commonly present as a sensation of "heartburn" that is worsened by positional changes such as lying down. Heartburn is a nonspecific symptom complex, as it may mean many different things to different patients. In cases of hiatal hernia, heartburn is a burning sensation in the epigastrium that in severe cases can radiate to the left shoulder and be mistaken for myocardial infarction. This symptom complex is usually present after meals and may often be relieved by the ingestion of food or antacid medications.

Regurgitation of gastric contents is also an associated symptom of reflux. Patients usually describe the taste of sour liquid in their mouth. Regurgitation

 Copyright 2004, Elsevier (USA). All rights reserved.

of food is not typically reported as a symptom of reflux associated with type I hiatal hernias and the presence of such a symptom should lead to a search for another etiology such as a type II hiatal hernia or esophageal diverticulum. Dysphagia is often also associated with reflux seen with type I hiatal hernias and is thought to result from esophageal spasm, irritation, or stricture of the esophagus brought about by acid exposure in the distal esophagus. However, esophageal carcinoma can also present with dysphagia and hence these symptoms should be evaluated aggressively usually with a barium swallow and most likely with an esophagogastroduodenoscopy (EGD).

Patients with gastro-esophageal reflux may also present with respiratory symptoms resulting from aspiration of gastric acid. Typically, such patients present with a nocturnal cough that awakens the patient from sleep. Hoarseness may or may not be noted in the morning. Asthma may be a manifestation of this disease, but it is currently unclear to what extent and how frequently asthma results from aspiration. Severe aspiration episodes can ultimately lead to pneumonia, lung abscess, or bronchiectasis. There is some evidence that patients with severe uncorrected reflux after lung transplantation have a higher incidence of rejection.

Other less common symptoms associated with type I hiatal hernias include hemorrhage from diffuse erosive gastritis as well as ulcerative esophagitis with referred pain to the back and neck. Patients with the latter condition often complain of a "lump in their throat" that is unrelieved by swallowing. Frequently, these patients are misdiagnosed or dismissed as having psychological problems.

Type II

The type II hiatal hernia or para-esophageal hernia is an uncommon disorder that is anatomically distinct from the type I sliding hernia. The problem is a defect in the phreno-esophageal membrane and the underlying endothoracic and endoabdominal fasciae rather than a circumferential weakening as in type I defects (Fig. 1). The defect present in type II hernia is usually located in the left ventral aspect of the esophageal hiatus (Fig. 1), but occasionally defects can be present in other locations. Through these defects, a peritoneal sac containing a portion of the stomach protrudes along with the peritoneum into the thoracic cavity. Without the constraints of the fascia to prevent migration and the pressure gradient from the abdominal to thoracic cavity, the hiatal defect progressively enlarges and the stomach progressively migrates into the chest with total herniation of the stomach into the chest in advanced cases.

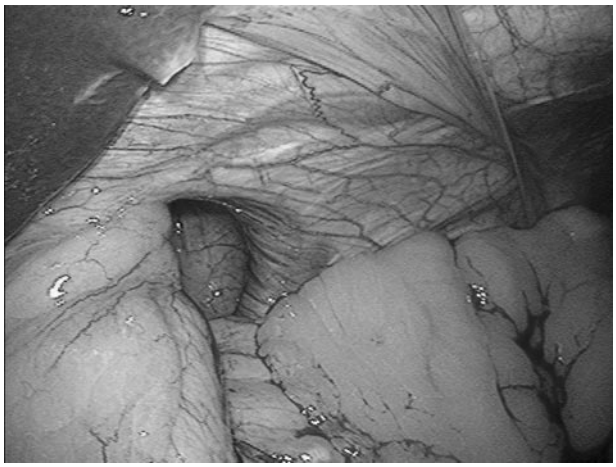

FIGURE 1 A laparoscopic view of the hernia sac of a reduced type II hiatal hernia. The stomach is reduced into the abdomen and is below and to the left of the diaphragmatic defect that is bordered on the right by the left crus.

However, since the distal esophagus and cardia of the stomach are usually still fixed by the phreno-esophageal membrane to the right crus and remain in the abdominal cavity even in advanced cases, the pylorus can come to lie next to the distal esophagus and cardia. Fixation at this single point allows for the development of gastric volvulus and its often fatal consequences. Hence, type II or para-esophageal hernias often require prompt attention.

Typically, patients with type II hernias are asymptomatic until the hernia becomes large. Most patients present in their fourth to fifth decades of life and a fair number present when very old. Symptoms of type II hernias include retching and postprandial nausea. Reflux symptoms may be present as well if a combined type I defect is also present to form a type III defect, which will be described below. In type II hernias with fixation at a single point, the intra-thoracic stomach can twist, leading to the development of gastric volvulus, gastric obstruction, gastric dilation, and gastric strangulation. With intermittent gastric distention and obstruction, patients can experience a sense of substernal pain often exacerbated after eating, as well as vomiting from obstructive pathology. Other symptoms include bleeding from gastric ulceration in the intrathoracic portion of the stomach and aspiration of gastric contents, leading to pulmonary complication as discussed for type I hernia.

The most feared complication of type II hiatal hernia is gastric volvulus and strangulation. Patients with this complication experience substernal pain and progressive dysphagia followed by protracted nausea and vomiting. As the stomach becomes progressively ischemic,

pain increases and is followed by symptoms of shortness of breath, shock, and sepsis intervening as the ischemia progresses and perforation occurs, leading to mediastinitis. Without prompt surgical management, patients rapidly deteriorate and expire. Due to the dire consequences of type II hernias, prompt surgical correction is recommended even in asymptomatic patients with significant type II paraesophageal hernias. Patients with known type II hernias who present with unremitting pain should be resuscitated and have the stomach gently decompressed with the aid of a carefully placed nasogastric tube under fluoroscopic guidance. Those who improve dramatically can be electively repaired surgically. Those who do not may require an emergent exploration usually transabdominally.

Type III

Type III, or mixed, hiatal hernia is a progression and combination of type I and II hiatal hernias. If a type I hiatal hernia is present, the phreno-esophageal membrane may weaken over time, leading to a type II defect. Conversely, the presence of a type II defect may over time weaken the phreno-esophageal ligament circumferentially, leading to a type I defect. The rate of conversion from a type I or type II hiatal hernia to a type II hernia is not known.

The symptoms of a type III hiatal hernia manifest as a combination of those seen in type I and II hiatal hernia. Typically, the symptoms of the larger defect predominate. However, once diagnosed, type III hiatal hernia must promptly be fixed as the stomach may strangulate.

Type IV

In type IV, hiatal hernia is defined as one where the stomach and other intra-abdominal organs have herniated into the chest through the esophageal hiatus. These herniate in order with the omentum followed by the transverse colon. The spleen or small bowel may be involved as well. Type IV hernias are rarely asymptomatic and symptoms are chiefly those of obstruction and strangulation. Hence, these hernias require prompt surgical treatment once diagnosed.

DIAGNOSIS AND MANAGEMENT

Most hiatal hernias are first incidentally noted on chest radiographs. The most frequent radiographic finding is a retro-cardiac air bubble. Patients are subsequently triaged according to the type of hernia and degree of symptoms. Those patients with dysphagia should undergo an aggressive workup to rule out esophageal carcinoma with EGD and biopsies if indicated. Subsequent evaluation with a barium swallow, chest and/or abdominal computed tomography scan, or EGD confirms the diagnosis in most patients.

Type II, III, and IV hiatal hernias often require prompt surgical patients even for asymptomatic treatment in order to avoid the mortality and morbidity of gastric and bowel strangulation. Operative repair can be accomplished through an abdominal or thoracic approach and by laparoscopy. There have been reports of a combined thoracoscopic or laparoscopic approach as well. Although strong proponents exist for each approach, there are no data to support the superiority of one surgical approach over another. There are several elements to the surgical repair. First, the stomach and any additional viscera must be returned to the abdominal cavity and the hernia sac excised (Fig. 2). Then, the hernia defect is repaired usually primarily and occasionally with the use of a prosthetic mesh. The esophagus is occasionally lengthened to ensure that the gastroesophageal junction remains in the abdomen. Patients who clearly have documentation of gastroesophageal reflux will also have an anti-reflux procedure (see below) performed at the same time. Whether all patients with paraesophageal hernias who are undergoing surgical repair ought to have an anti-reflux procedure is a controversial matter. The authors' group routinely performs an anti-reflux procedure as part of all advanced hernia repairs. Finally, patients with type III or IV hernias may also benefit from fixation of the stomach to the abdominal wall with a temporary gastrostomy in order

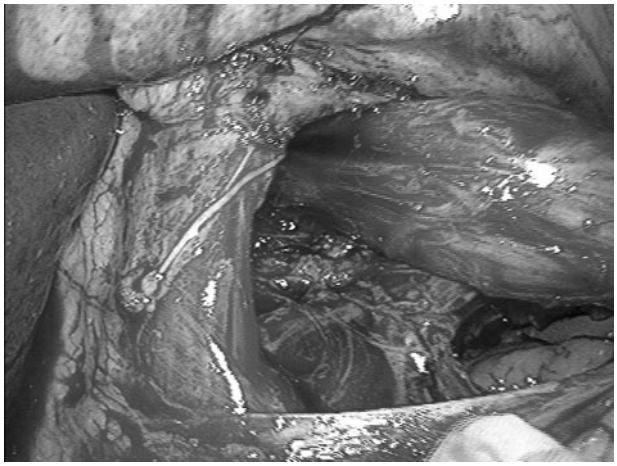

FIGURE 2 A laparoscopic view of the entire dissected hiatus in the same patient. The right crus is prominently displayed on the left side of the picture. The esophagus is coming out toward the right side of the picture and covering a portion of the left crus. Note the wide defect between the two crurae that will need to be surgically closed.

to reduce the chance of recurrent herniation and provide a simple portal to an often sluggish stomach.

Therapy for type I hiatal hernia is more controversial. The only clear recommendation is that for asymptomatic patients with small defects, expectant therapy is indicated. For symptomatic patients with gastro-esophageal reflux, therapeutic options include the following: (1) medical therapy; (2) endoscopic therapy; and (3) surgical therapy.

Medical Therapy

With the advent of proton pump inhibitors, most patients can be adequately treated for their reflux symptoms with medical therapy. However, controversy exists concerning the long-term effects of prolonged proton pump therapy. It is unclear whether acid suppression alone can prevent the metaplastic changes of Barrett's esophagus and progression to dysplasia. Also, it is unclear what constitutes maximal medical therapy and its failure. Furthermore, many patients do not wish to be on prolonged medical therapy or fail "maximal medical therapy." Finally, medical therapy cannot correct the anatomic irregularities of type I hiatal hernia. Given that most patients with type I hiatal hernias do not have reflux, it is likely that additional defects are present in those that do. In those patients, proton pump inhibitors may reduce the acid secretion but not affect adequate reduction in bile reflux, which may be harmful as well. Patients with severe reflux symptoms that are not controlled with medical therapy or complications of reflux (stricture, bleeding, and obstruction) that are not reversed with medical therapy are frequently referred for interventions to control these problems.

Endoscopic Therapy

New endoscopic techniques have recently been approved for treatment of gastroesophageal reflux by the Food and Drug Administration. At least three approaches have been described. One procedure utilizes endoscopic suturing to create a valve in the gastroesophageal junction to reduce reflux. The second is designed to thicken the same area with the administration of radiofrequency energy to the gastroesophageal junction in a manner designed to create a scar at the gastroesophageal junction. The third strategy is to inject material into the submucosa of the gastroesophageal junction in order to re-create a valve. All of these procedures are successful at least in the short term. However, the exact mechanism of action of each method is not certain. Most certainly, there is no anatomic repair of the hiatus or any hernia with these anti-reflux procedures. Although short-term results are promising and many patients are symptom- and medication-free, the long-term efficacy of these treatments is unclear. Additional long-term data are needed to better define patient selection criteria and make valid comparisons to both medical and surgical therapies.

Surgical Therapy

A variety of surgical approaches have been described to treat reflux and the reflux-associated symptoms of type I hiatal hernias. Each of these surgical approaches has been designed to approximate the normal anatomy of the gastroesophageal junction and increase the tone of the lower esophageal sphincter, in addition to repairing the hernia and hiatal defect. These techniques attempt to achieve these goals and prevent reflux by better approximating the angle of the gastroesophageal junction, by buttressing the lower esophageal sphincter or by "lengthening" the distal esophagus to create an intra-abdominal lower esophageal sphincter. A variety of operations have been described, but three main surgical approaches are currently in practice: (1) Belsey–Mark IV; (2) Nissen fundoplication; and (3) Hill repair.

A thorough evaluation of each patient with reflux symptoms is required to tailor the individual operation. Specifically, patients should undergo gastric pH probe testing, esophageal manometry, and barium swallow to demonstrate both the hiatal defect and esophageal motility prior to operative intervention.

Belsey–Mark IV

The Belsey–Mark IV operation was developed in the 1950s in England by Sir Ronald Belsey. The hallmarks of this anti-reflux procedure include restoring an intra-abdominal esophagus and creating and maintaining a narrow diameter in the distal esophagus to restore lower esophageal sphincter tone. The Belsey–Mark operation is performed through a left sixth interspace thoracotomy. In experienced hands, this procedure is effective in controlling the symptoms of 85% of patients at 5 years.

Nissen Fundoplication

Nissen fundoplication was originally developed by Rudolph Nissen in 1936 to protect the suture line after gastric resections. The Nissen procedure can be performed through a laparotomy, thoracotomy, or via laparoscopy. The procedure involves wrapping the anterior and posterior walls of the gastric fundus around the esophagus to augment the lower esophageal sphincter and thereby prevent reflux. Numerous modifications of this procedure that change the extent of gastric fundus encircling the distal esophagus (e.g., Dor, Thal) have

been added in hopes of modulating the increase in lower esophageal tone. Minimally invasive laparoscopic versions of these procedures have become quite common in modern-day surgical practice. Up to 95% of patients are still symptom free at 5 years.

Hill Repair

The Hill operation is designed to prevent reflux by re-creating the angle of the gastroesophageal junction with respect to the diaphragm (i.e., angle of His) in order to augment and thereby restore competency to the lower esophageal sphincter. This procedure can be performed through both abdominal and thoracic approaches. Laparoscopic and thoracoscopic approaches have been described as well. Long-term follow-up results of this procedure reveal that 75 to 85% of patients are asymptomatic at 5 years.

In summary, hiatal hernias can be classified into four types. Type I hernias are common and can be managed medically, endoscopically, or surgically. Type II, III, and IV hernias are more serious and once diagnosed often require prompt surgical attention in order to prevent the dire consequences of gastric strangulation.

diaphragm Muscular partition that separates the abdomen and thorax; a primary muscle used in breathing.

glottis Opening in the larynx through which exchange of air occurs between the mouth and lungs.

larynx Organ for production of voice; situated in the airway at the base of the tongue.

myoclonus Rapid involuntary alternate muscular contractions and relaxations resulting from paroxysmal outflow from the central nervous system to the involved muscles.

phrenic nerve Motor nerve arising from the third, fourth, and fifth cervical segments of the spinal cord; innervates the diaphragm.

The term "hiccup" is derived from the sound made by the rhythmic involuntary spasmodic contraction of the diaphragm and rapid closure of the glottis, followed by sharp inhalation. The medical term for hiccup, "singultus," probably originated from the Latin *singult*, which is translated as "the act of catching one's breath while sobbing." Singultus reflexes usually occur in sequence, accounting for the characteristic movements and sounds.

INTRODUCTION

The phrenic nerves are the motor nerves to the diaphragm. Inappropriate firing in the motor component of the phrenic nerves accounts for the diaphragmatic spasm associated with hiccups. The afferent arm of the hiccup reflex consists mainly of sensory nerves from receptors in the airways and upper digestive tract.

been added in hopes of modulating the increase in lower esophageal tone. Minimally invasive laparoscopic versions of these procedures have become quite common in modern-day surgical practice. Up to 95% of patients are still symptom free at 5 years.

Hill Repair

The Hill operation is designed to prevent reflux by re-creating the angle of the gastroesophageal junction with respect to the diaphragm (i.e., angle of His) in order to augment and thereby restore competency to the lower esophageal sphincter. This procedure can be performed through both abdominal and thoracic approaches. Laparoscopic and thoracoscopic approaches have been described as well. Long-term follow-up results of this procedure reveal that 75 to 85% of patients are asymptomatic at 5 years.

In summary, hiatal hernias can be classified into four types. Type I hernias are common and can be managed medically, endoscopically, or surgically. Type II, III, and IV hernias are more serious and once diagnosed often require prompt surgical attention in order to prevent the dire consequences of gastric strangulation.

The vagus nerves transmit sensory information from the digestive tract and airways to the central nervous system. Sensory afferent fibers in the phrenic nerves may also participate in the reflex. The phrenic nerves are mixed nerves containing about half as many sensory afferent fibers as motor fibers. Processing centers for the sensory information and the integrative centers for the reflex are located in the brain stem along with the centers for respiratory control. Phrenic motor innervation of the diaphragm and the motor innervation of the larynx (laryngeal nerves) make up the efferent arm of the reflex. The phrenic motor axons project from neuronal cell bodies that make up the phrenic nucleus in the cervical spinal cord. The laryngeal nerves, which are mixed motor and sensory, are derived from the vagus nerves.

ETIOLOGY

Hiccups lasting only a few minutes are commonly experienced by normal individuals. These transient bouts of hiccups are considered to be a form of myoclonus, like the isolated myoclonic "jerks" that can be observed in individuals during drowsiness or light sleep. Therapy is usually nothing more than home remedies. On the other hand, pathologic prolongation of an episode of hiccups becomes a clinical problem that compromises quality of life and requires therapeutic intervention. An episode lasting more than a few minutes is generally referred to as a "bout," and one lasting longer than 48 hours is considered to be "protracted." The term "intractable" is reserved for attacks lasting more than 1 month. The longest reported attack lasted 60 years.

Hiccups lasting for extended periods are related to a variety of etiologies. Prolonged hiccups may be related to irritation of the diaphragm, distension of the stomach, central nervous sensitization, a variety of tumors, hyponatremia, or other metabolic disorders. Hiccups in hypersensitive individuals may be initiated by sudden chilling, wet feet, cold showers, or rapid ingestion of carbonated liquids or ice-cold food or drink. Prolonged symptoms can sometimes be traced to inflammation of the phrenic nerve or a more generalized neuritis. Pressure on the upper airway, by an enlarged goiter in the neck, for instance, may cause hiccups. Tumors of the esophagus, placement of stents in the esophagus, diaphragmatic hernia, bronchitis, or asthma may involve irritation of the phrenic nerves that leads to chronic hiccups. Irritation of the diaphragm from diseases of the liver frequently sensitizes the hiccup reflex, as does irritation of central integrative centers by brain tumors, epilepsy, or meningitis. Intractable hiccups may accompany systemic toxemias, septicemia, shock, advanced arteriosclerosis, severe avitaminosis, chronic nephritis with uremia, or diabetes mellitus. Patients undergoing hemodialysis sometimes suffer from intractable hiccups.

Persistent hiccups associated with oral or intravenous corticosteroid administration have been reported, as have hiccups thought to occur secondary to glucocorticoid-like effects of the reproductive hormone progesterone. A case of anabolic steroid-induced hiccups lasting for 12 hours prior to medical attention was reported for an elite "power" weight lifter. Cases of this nature are postulated to reflect steroid-mediated stimulation of the hiccup reflex by lowering of the threshold for synaptic transmission in the integrative microcircuitry of the brain stem. A report of persistent hiccups as a consequence of thoracic epidural steroid injection as treatment in a patient with chronic back pain is reminiscent of the action postulated to occur in the brain. Hiccups and emesis are linked in patients undergoing cancer chemotherapy with cisplatin. Cisplatin therapy is usually accompanied by administration of the steroid dexamethasone, and this raises the question of whether the hiccups reflect the central actions of the steroid. Men undergoing cisplatin chemotherapy are reported to have a significantly higher incidence of hiccups compared to women undergoing the chemotherapeutic regimens.

TREATMENT

For the run-of-the-mill benign case of hiccups, home remedies include breath holding, sudden fright, mental distraction, rebreathing from a paper bag, eating dry granulated sugar, drinking cold liquids, or pressure at the back of the throat sufficient to evoke the gag reflex. The approach to the management of the patient with debilitating effects of prolonged hiccups consists of identification and treatment of the underlying cause and therapeutic interventions to achieve resolution.

Baclofen, which is an analogue of the inhibitory neurotransmitter γ-aminobutyric acid, has been used in the successful treatment of intractable hiccups in cases of brain stem lesions, infectious abscess near the diaphragm, and hiccups related to the placement of self-expandable stents in the esophagus. Drugs that block dopamine receptors are reported to be efficacious in treatment of severe hiccups. Nefopam is a centrally acting analgesic that is related structurally to antihistamines and antiparkinsonian drugs. Intravenous administration of nefopam has been reported to stop refractory postoperative hiccups and hiccups in individual patients with protracted episodes related to either lymphoblastic leukemia, esophageal infection secondary to immunodeficiency syndrome, or central vascular malformation. Additional pharmacological approaches reported to be efficacious are intravenous administration of the local

anesthetic lidocaine, the psychotropic drug chlorpromazine, and the calcium entry blocker nifedipine. Intractable hiccups have been treated effectively with short-term general anesthesia. Acupuncture also is reported to be effective.

Hirschsprung's Disease (Congenital Megacolon)

JACKIE D. WOOD

The Ohio State University College of Medicine and Public Health

megacolon A colon that has abnormally large dimensions.

recto-anal reflex A reflex relaxation of contractile tone in the internal anal sphincter, evoked by distension of the rectum.

RET A gene that encodes for a receptor Tyrosine kinase.

taenia coli Three strips of longitudinal smooth muscle spaced equidistance around the circumference of the colon.

Herald Hirschsprung (1813–1916) was a Danish pediatric surgeon, who in 1888 published the first comprehensive report on extreme dilation of the colon in infants and young children. Megacolon of congenital origin is the most obvious manifestation of the disease that is now named after Hirschsprung. The megacolon is usually filled with impacted feces proximal to a constricted rectosigmoid segment. Hypertrophy of the musculature occurs in the grossly dilated colon and is a constant finding in children with the disease and in mice that are used as models for studying the disease.

INTRODUCTION

The earliest postulates for Hirschsprung's disease focused on the dilated region of the colon. It was logical at the time to assume that the musculature of the distended colon was paralyzed and incapable of forward propulsion of feces. Now, it is known that propulsive motility in the megacolon is normal and that the defect is localized to the distal constricted segment. The megacolon develops as feces accumulate due to blockade of passage through the terminal constricted segment (see Fig. 1). This proved to be the case because the megacolon and all other symptoms of Hirschsprung's disease disappeared after surgical resection of the narrowed segment. The same resolution of symptoms occurs after surgical diversion of the fecal stream through a colostomy. Congenital absence or reduction in numbers of ganglion cells in the enteric nervous system in the constricted segment is the underlying pathology of the

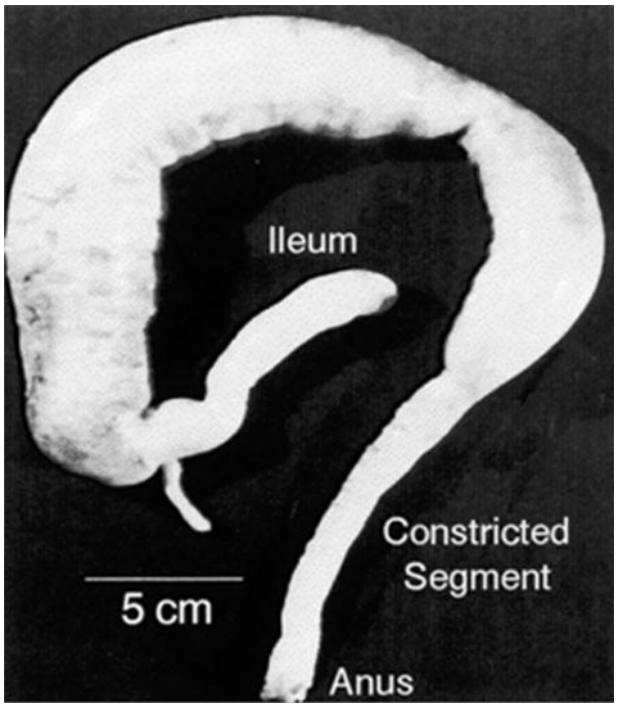

FIGURE 1 Colon from a 1-month-old infant with Hirschsprung's disease. The characteristic megacolon appears proximal to a constricted terminal segment. Histologic evaluation found a normal appearing enteric nervous system in the megacolon and absence of enteric neurons in the constricted terminal segment.

disease. Recognition of aganglionosis as the underlying factor in Hirschsprung's disease is the basis for use of the synonymous term aganglionic megacolon.

Hirschsprung's disease is usually suspected in cases of constipation during early childhood and must be ruled out by diagnostic testing. Failure of a newborn to pass the meconium within 3 to 4 days after birth also raises concern about the possibility for Hirschsprung's disease. Later in life, acquired megacolon and enteromegaly at higher levels of the gastrointestinal tract may similarly reflect pathologic loss of neurons from the enteric nervous system. Damage to the enteric nervous system can result from autoimmune attack directed against enteric neurons in patients with small cell lung carcinoma (i.e., paraneoplastic syndrome) and in patients infected with the blood-borne parasite *Trypanasoma cruzi* (i.e., Chagas' disease). The prominent histopathology in both congenital and acquired forms of the disease is distension and muscular hypertrophy proximal to an obstructive constricted segment for which enteric neurons are absent or grossly reduced in number.

In Hirschsprung's disease, both the myenteric and the submucosal plexuses are dysplastic in the distal constricted segment. The aganglionic constricted segment varies in length among different patients. The segment may involve only the distal 4 to 5 cm of rectum or it may involve the entire rectum, sigmoid colon, and descending colon. Occasionally, the entire colon is involved and in some cases the distal ileum is as well.

ANIMAL MODELS

Basic research aimed at elucidating the pathophysiology of Hirschsprung's disease has profited from animal models in which aganglionic megacolon can be induced experimentally and from mouse models in which aganglionosis reflects a congenital genetic defect. Attempts have been made to produce aganglionosis in dogs and rodents by destroying the enteric nervous system with the application of toxic substances to the intestinal surface or by restricting the oxygen supply to the intestine. Nevertheless, the confirmed and most thoroughly studied animal model of congenital megacolon occurs in mice. In 1966, researchers at The Jackson Laboratories, in Bar Harbor, Maine, reported the expression of two autosomal recessive genes in mice, both of which produced phenotypes with reduced pigmentation in the fur and decreased numbers of ganglion cells in the distal large intestine. One strain was named "piebald lethal" and the other "lethal spotting." The homozygotes ($S^{L}S^{L}$) of the piebald lethal strain have black eyes and white fur with an occasional patch of black pigment (Fig. 2). The piebald lethal mice always develop megacolon (Fig. 3) and die at the ages of a few days to several months. The heterozygous parents and siblings have black eyes and all black coat color.

The abnormal distribution of the enteric nervous system in the large intestine of the piebald mouse model is comparable with that in Hirschsprung's disease. In normal mouse large intestine, ganglia are present to within approximately 2 mm of the anus. In the abnormal mice, ganglia are absent from both the myenteric and submucosal plexuses in the distal 1 to 2.5 cm of the large intestine.

HEREDITARY FACTORS

Congenital megacolon in the mouse model is clearly a recessive trait that is not linked to sex chromosomes. Hereditary factors also seem to be involved in Hirschsprung's disease in humans. The incidence of Hirschsprung's disease in the general population of infants and children is 1 : 5000 (0.02%) and it occurs in siblings in 3.6% of cases. The incidence of Hirschsprung's disease, of the short-segment type where aganglionosis extends no higher than the sigmoid colon, is 5 to 10 times higher

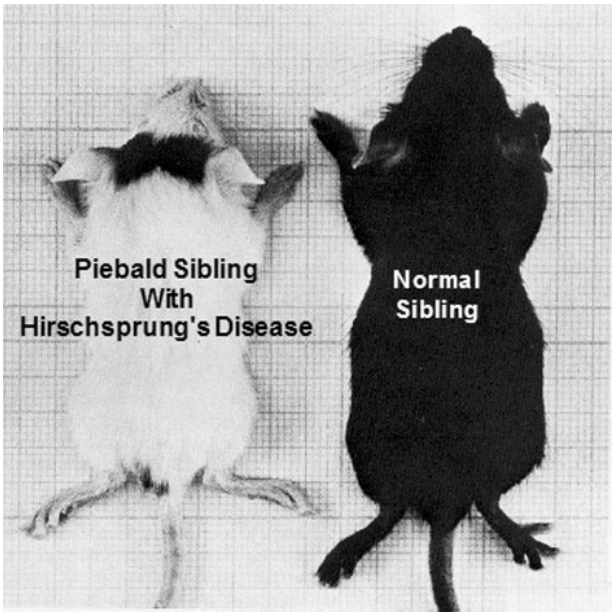

FIGURE 2 Piebald mouse model for Hirschsprung's disease. The two mice are siblings. The sibling on the right is normal and the one on the left is homozygous for the recessive gene that results in piebald pigmentation and aganglionic megacolon.

in human males than in females. Sexual differences are not apparent for the long-segment type in which the aganglionosis extends beyond the sigmoid colon.

The tools of molecular biology have enabled new insight into gene mutations that underlie the development of congenital forms of aganglionic megacolon in both humans and the mouse models. Proper functioning of two genes is now known to be necessary for the migration of enteric neuronal precursors from the embryonic neural crest to colonize the developing gut and for establishment and differentiation of the precursors into the kinds of neurons that link up synaptically to form the neural networks of the enteric nervous system. Mutations in two genes, one of which is called RET and the other of which is an endothelin gene, lead to aganglionic megacolon in mice. Nevertheless, the details of how the enteric nervous system reaches its final stages of development normally and what goes wrong when development fails in the aganglionic region of Hirschsprung's disease remain an unsolved scientific mystery.

PATHOPHYSIOLOGY

An early and often-cited hypothesis attributed failure of relaxation of the circular muscle coat in the aganglionic segment to denervation supersensitivity. Current evidence refutes this hypothesis. No increased sensitivity of the musculature of the constricted segment to the neurotransmitters acetylcholine or norepinephrine can be demonstrated either in the mouse model or in surgically resected diseased segments from children with Hirschsprung's disease.

The current hypothesis states that the behavior of the constricted terminal segment in Hirschsprung's disease directly reflects the loss of inhibitory motor neurons to the musculature. As a general rule, any condition that results in ablation of enteric inhibitory motor neurons results in contracture and achalasia of the intestinal circular muscle. Most evidence suggests that enteric inhibitory motor neurons are tonically firing and releasing their neurotransmitters at the neuromuscular junctions. Ablation of the inhibitory motor neurons releases the circular muscle from the inhibitory influence and this permits myogenic excitation and conduction to take place.

The physiology of neuromuscular relations in the large intestine predicts that spasticity and achalasia will accompany any condition in which inhibitory motor neurons are destroyed. Without inhibitory control, the self-excitable syncytium of nonsphincteric regions of the intestinal circular muscle will contract continuously and thereby behave as an obstruction to the passage of feces. This happens because each and every cycle of the myogenic pacemaker is freed to trigger

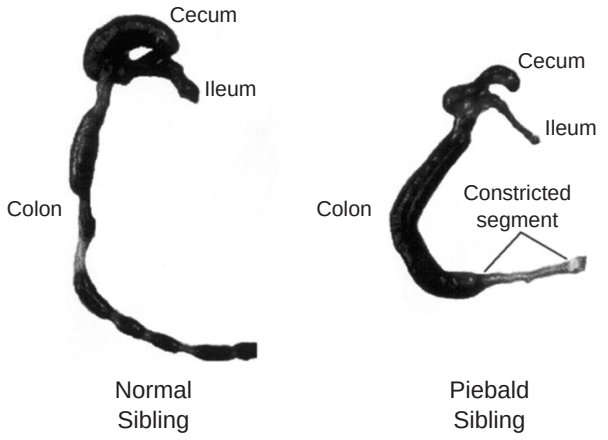

FIGURE 3 Large intestine of the piebald mouse model for Hirschsprung's disease. The two large intestines are from siblings. The one on the right is from the sibling with piebald coloration and shows the characteristics of the large intestine found in Hirschsprung's disease. The colon of the piebald sibling is grossly distended with impacted feces proximal to an empty and constricted terminal segment. The colon on the left is from the normal sibling. Histologic examination found a normally appearing enteric nervous system in the megacolon of the piebald sibling and absence of enteric neurons in the constricted terminal segment. The enteric nervous system was normal throughout the large intestine of the normal sibling.

contractions that propagate without any distance or directional control. Contractions spreading in opposite directions in the uncontrolled syncytium collide randomly, resulting in fibrillatory-like muscular activity in the affected intestinal segment.

In general, the function of enteric inhibitory motor neurons, aside from the various sphincters, is continuous suppression of activity of the inherently excitable musculature. The inhibitory neurons have the added function of mediating relaxation of contractile tone in sphincters. They are responsible for the internal anal sphincter relaxation required for defecation. The primary difference in the organization of the inhibitory outflow to the circular muscle of the intestine and the sphincters is that the inhibitory innervation of the bulk intestinal circular muscle is tonically active, whereas the inhibitory motor neurons to the sphincters are normally silent. In the intestine, myogenic contractions occur when ongoing firing of the inhibitory neurons is suppressed by the integrative microcircuits. In the sphincters, myogenic mechanisms maintain contractile tone. The sphincteric muscle is tonically contracted in the absence of inhibitory nervous input and the sphincter is relaxed when the normally silent inhibitory motor neurons are activated by the integrative microcircuits. This kind of physiology predicts that ablation of inhibitory motor neurons will lead to spasm of the intestinal circular muscle and to "achalasia" of the sphincteric musculature as found in Hirschsprung's disease and the mouse model of the disease.

Inflation of a balloon in the rectum triggers relaxation of the internal anal sphincter in humans and animals. This is called the recto-anal reflex. A normal recto-anal reflex requires that the enteric neural connections from the site of distension to the sphincter be intact and that the inhibitory motor neurons to the sphincter muscle be functional. Blockade or ablation of any of the neurons in the recto-anal reflex pathway eliminates the reflex. The inability to evoke the recto-anal reflex by balloon distension of the rectum is a diagnostic hallmark of Hirschsprung's disease.

Histamine

GEORGE SACHS
University of California, Los Angeles

enterochromaffin-like cells Neuroendocrine cells in the gastric epithelium that control the peripheral regulation of acid secretion by releasing histamine as a paracrine stimulant.
gastrin Gastrointestinal hormone released from G cells in the gastric antrum in response to food.
histamine-2 (H2) receptor antagonists Drugs that competitively block the ability of histamine to interact with H2 receptors.
pituitary adenylate cyclase-activating peptide A neuropeptide present in the vagal nerve endings innervating the gastric mucosa.

Histamine released from neuroendocrine cells in the gastric mucosa is the major stimulant of acid secretion. A histamine-2 receptor subtype is highly expressed by the acid-secreting or parietal cells of the stomach and this receptor is the target for acid inhibition by histamine-2 subtype selective antagonists.

HISTORICAL INTRODUCTION

Whereas now it is universally accepted that histamine is a major stimulant of acid secretion as a consequence of the availability of pharmacological agents antagonizing its action on the stomach, it was only in the last quarter of the 20th century that this view was fully defensible.

The problem of regulation of acid secretion became of clinical relevance when the edict "no acid, no ulcer" was promulgated at the beginning of the 20th century. There had been several approaches to control of gastric acidity dating back to earliest written history with the consumption of baking soda by the Greeks. The Renaissance heralded the administration of atropine as "tincture belladonna" as the first nonselective muscarinic antagonist. Its side effects, such as dry mouth and mydriasis, precluded acceptance by patients. The end of the 19th century saw the beginning of gastric surgery as initially practiced by Billroth in Vienna. This progressed with time to more subtle approaches to control of acid secretion, culminating in highly selective vagotomy as a means of reducing stimulatory pathways. Hence, reduction of acid stimulation became a pharmacological and therapeutic target. But what were these pathways other than vagal?

In 1905, Edkins discovered that an extract of the gastric antrum was able to stimulate acid secretion and he called the extract gastrin. The reality of this extract was questioned by the leading English endocrinologists and the effect of gastrin and its mechanism were not solved until modern cellular methods were introduced.

Dale discovered histamine as a biological amine that performed a variety of functions, such as vasodilation. However, he did not describe the effect of histamine on acid secretion. This was left to a pupil of Pavlov, Popielski, who described the action of intravenous (iv) injection of histamine on dogs with gastric fistulas.

With the synthesis of histamine antagonists by Bovet in the 1950s, it was found that these agents, such as mepyramine, were relatively ineffective at blocking acid secretion. Two interpretations were viable: (1) that histamine was not really involved in physiological stimulation of acid secretion and (2) that these antagonists did not act on the site at which histamine acted in the stomach.

Gastrin became the major focus for animal physiologists as the key substance for stimulation of acid secretion with the purification and elucidation of the structure of gastrin in the early 1960s and the popularity of histamine as a major stimulant for secretion declined. However, in the 1970s, James Black and his team managed to synthesize and characterize new chemical entities that were able to inhibit acid secretion without affecting the other actions of histamine on blood vessels or mucus secretion. These were the histamine-2 (H2) receptor antagonists (H2RAs), the first being burimamide. With the ability to analyze the pharmacology of acid secretion by these selective receptor antagonists, it became clear that the action of gastrin on acid secretion was entirely histamine dependent. The action of cholinergic stimulation was much less sensitive to H2RA inhibition.

SOURCE OF GASTRIC HISTAMINE

As histamine became the dominant stimulatory ligand, the cell that provided the source of gastric histamine

 Copyright 2004, Elsevier (USA). All rights reserved.

became of interest. Evidently, histamine must be a paracrine stimulant since the pleiotropic effect of histamine on H1 receptors would not be tolerated.

At first, the speculation was that gastric mast cells were the source, but then the enterochromaffin-like (ECL) cell was discovered and its location at the base of the fundic glands made it the most likely source of gastric histamine. With the isolation of functional ECL cells, the peripheral pathway of stimulation of acid secretion was better defined. The major two stimulants of histamine release from these cells maintained in short-term culture were gastrin and pituitary adenylate cyclase-activating peptide (PACAP). Inhibitory ligands were somatostatin and galanin. Perhaps not surprisingly, no activation of this cell was found with muscarinic agonists, explaining the lack of sensitivity of cholinergic stimulation to H2RAs. Gastrin is released from the G cell of the gastric antrum and PACAP from the postganglionic fibers of the myenteric plexus, the former agent acting as an endocrine stimulant and the latter as a neural stimulant. A model of the pathways of stimulation can be seen in Fig. 1.

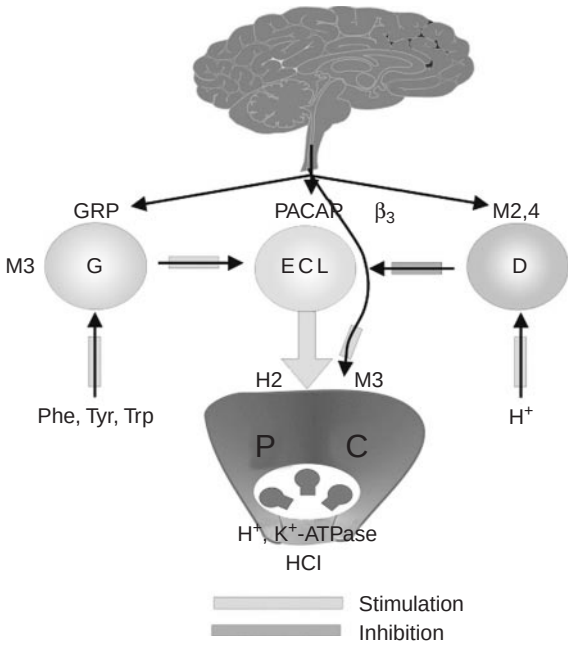

FIGURE 1 A simplified model of some of the pathways stimulating acid secretion. The central nervous system activates the myenteric plexus with release of PACAP to stimulate the ECL cell and with release of acetylcholine to stimulate the parietal cell directly. Gastrin is released from the G cell by gastrin-releasing peptide and acetylcholine as well as by aromatic amino acids in food. Somatostatin is released by the D cell in response to lumenal acidification and muscarinic M2 or M4 receptor stimulation.

THE HISTAMINE-2 RECEPTOR

The development of pharmacological agents selective for this receptor subtype long before methods were available to clone and sequence different receptors was a major breakthrough not only in therapy but in gastric biology. This receptor is expressed in the stomach, uterus, and heart but appears to have dominant function only in the stomach, allowing safe administration of H2RAs for the treatment of acid-related diseases without significant side effects.

The receptor is a seven-transmembrane segment protein inserted on the basolateral surface of the parietal

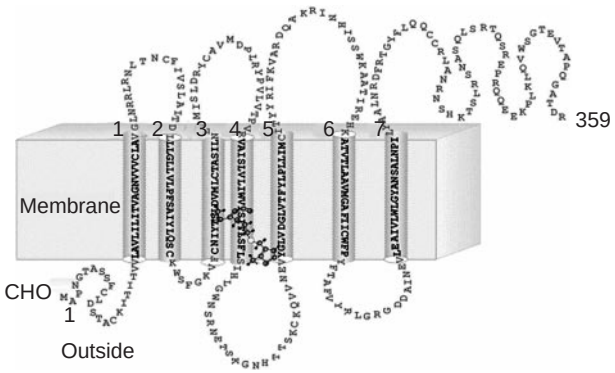

FIGURE 2 The amino acid sequence and secondary structure of the histamine-2 receptor with the antagonist docked close to the aspartyl (D) residue in TM3 and also interacting with TM5.

cell. Binding of histamine elevates cyclic AMP (cAMP) and this is the major intracellular messenger for stimulation of acid secretion by the parietal cell. However, the same receptor appears to stimulate elevation of intracellular Ca^{2+} although the role of this second messenger is not well understood. The action of cAMP is mediated by the activation of a type of protein kinase that phosphorylates several proteins in the stimulatory cascade. The action of Ca^{2+} may be mediated by a calmodulin-activated kinase.

The sequence of this receptor is known and the binding site of histamine and its antagonists is thought to involve a location between transmembrane 3 (TM3) and TM5. A model of the receptor with the region of binding of histamine receptor antagonists is shown in Fig. 2.

STRUCTURE OF HISTAMINE-2 RECEPTOR ANTAGONISTS

After the introduction of cimetidine (Tagamet), several other antagonists, such as ranitidine (Zantac) and

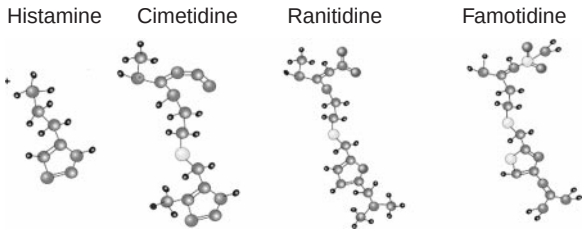

FIGURE 3 The structure of histamine compared to cimetidine, ranitidine, and famotidine. All have a protonatable amine similar to histamine, suggesting docking of a positive charge to the aspartyl in TM3. Famotidine is the most potent of these agents.

famotidine (Pepcid), were also put on the market. The structures of some of these compounds are shown in Fig. 3. They all have a similar profile of action, being able to inhibit nighttime acid secretion well but inhibiting daytime acid secretion with less efficacy. This indicates that nighttime secretion, which is low but highly acidic since there is no gastric buffering due to food, is mediated almost entirely by histamine, whereas daytime acid secretion, mediated mainly by gastrin release, is also dependent on a histamine-independent pathway. Characteristic of their action is tolerance, wherein their efficacy drops by approximately 50% after a few days of administration. The mechanism of this tolerance is not known. It is not due to receptor up-regulation since even 10-fold higher doses do not overcome the tolerance and there are no changes in gastrin levels or cAMP. Perhaps the muscarinic pathway for stimulation is enhanced.

MECHANISM OF ACTION

H2RAs are known to compete with histamine for binding to the receptor but their action is also that of inverse agonists in that they are able to inhibit the activity of the receptor's activation of adenylate cyclase in the absence of agonist. This inverse agonism probably explains their good efficacy with continuous iv administration.

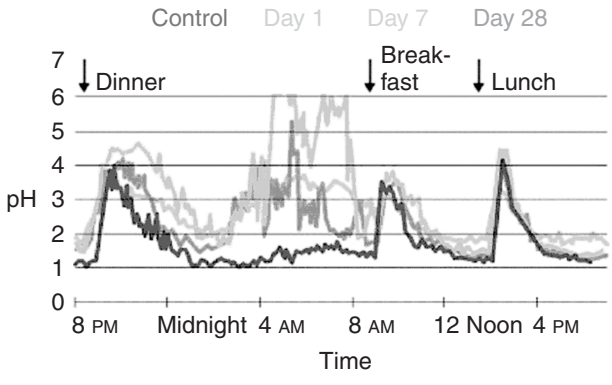

FIGURE 4 Median diurnal intragastric pH profiles following the administration of a 300 mg dose of ranitidine at 8 PM, showing excellent inhibition at night but little effect during the day. Also noteworthy is the tolerance, wherein even nighttime efficacy is much reduced by the seventh day of treatment. Reprinted from Teysson *et al.* (1995), with permission.

CLINICAL PROFILE

H2RAs and proton pump inhibitors are the mainstay of treatment of a variety of acid-related diseases, such as peptic ulcer and erosive and nonerosive esophageal reflux disease. They are considered to be almost entirely safe medications and all are available in over-the-counter formulations although at less than the therapeutic dose. A fairly typical profile of intragastric pH is shown for the standard nighttime dosage of a H2RA such as ranitidine (see Fig. 4).

H2-Receptor Antagonists

MITCHELL L. SCHUBERT
Virginia Commonwealth University's Medical College of Virginia and McGuire Veterans Affairs Medical Center, Richmond

erosion A shallow ulcer confined to the mucosal layer.
gastric H^+,K^+-ATPase An ATP-hydrolyzing enzyme responsible for catalyzing the exchange of lumenal K^+ for cytoplasmic H^+ by parietal cells, bringing about gastric lumenal acidification.
gastroesophageal reflux Backflow of acidic gastric contents into the esophagus, producing a spectrum of clinical symptoms and manifestations ranging from mild episodic heartburn and regurgitation without macroscopic esophagitis to chronic inflammation and ulceration; severe cases may involve stricture and hemorrhage.
gynecomastia Excessive development of the male mammary glands.
Helicobacter pylori A gram-negative urease-producing bacterium that causes an active chronic gastritis and is an important etiological factor in the development of gastric and duodenal ulcers.
nonsteroidal anti-inflammatory drugs Medications that reduce inflammation by inhibiting the enzymatic activity of cyclooxygenase, a key enzyme in the biosynthetic pathway leading to the formation of prostaglandins. Examples include aspirin, ibuprofen, naproxen, and diclofenac.
peptic ulcer A loss of tissue, extending through the mucosa into the submucosa, in the esophagus, stomach, or duodenum, due to acidic gastric secretions.
pharmacokinetics The disposition of drugs within the body in relation to their absorption, distribution, metabolism, and elimination.

Histamine receptors have been classified into four major subclasses: H1, H2, H3, and H4. H1 receptors are widely distributed and mediate the actions of histamine in the allergic response and as a bronchial constrictor. H2 receptors are present primarily in the stomach, where they regulate gastric acid secretion, and to a lesser extent in the heart, central nervous system, reproductive system, and on lymphocytes. Histamine-2 (H2)-receptor antagonists are drugs that competitively block the ability of histamine to interact with H2-receptors. H3-receptors were originally identified as inhibitory autoreceptors on histamine-containing nerve terminals in the central nervous system. In the stomach, H3-receptors augment acid secretion by suppressing somatostatin secretion. In the antrum, suppression of somatostatin leads to stimulation of gastrin, the main hormonal stimulant of acid secretion, whereas in the fundus, it leads to stimulation of histamine and acid secretion. Most recently, an H4-receptor has been identified in intestine, spleen, thymus, and immune cells. The H4-receptor shares 40% homology and overlapping pharmacology with the H3 receptor; its physiologic function is not known. This article focuses on the role of blocking H2 receptors in the stomach. The identification of the H2 receptor on the basolateral membrane of the parietal cell by Black in 1972 and the subsequent development of safe and effective H2-receptor antagonists have revolutionized the treatment of gastrointestinal acid-related disorders.

INTRODUCTION

Until the development of histamine-2 (H2)-receptor antagonists, the only treatments available for patients with acid-related disorders were bed rest, bland diets, milk drips, antacids, and surgery. Ulcers and ulcer pain

Hyperemesis Gravidarum

MAKAU LEE
University of Mississippi Medical Center, Jackson

hyperemesis gravidarum Severe, intractable vomiting during early pregnancy resulting in fluid and electrolyte disturbances and/or nutritional deficiencies.

Hyperemesis gravidarum (also referred to as pernicious vomiting of pregnancy) is severe, intractable vomiting during early pregnancy resulting in fluid and electrolyte disturbances and/or nutritional deficiencies. In most cases, the vomiting begins soon after the first missed menstrual period, and the symptoms generally subside during the third month of pregnancy. The incidence of hyperemesis gravidarum averages 3.5 cases for every 1000 deliveries, and it is independent of parity, race, ethnicity, or psychological issues. The incidence of hyperemesis gravidarum has been noted to decrease significantly during wartime. Epidemiological studies have shown that hyperemesis gravidarum has no adverse effect on pregnancy outcome and that patients with hyperemesis gravidarum do not have an increased incidence of toxemia of pregnancy, stillbirths, miscarriages, growth retardation, congenital abnormalities, or prematurity. Of note, several studies have shown that women with hyperemesis gravidarum give birth to a higher proportion of female newborns.

CLINICAL FEATURES AND PATHOPHYSIOLOGIC CONSIDERATIONS

Women with multiple fetuses or with molar pregnancies (i.e., hydatidiform mole) tend to have extremely high concentrations of human chorionic gonadotropin (hCG) and have a higher incidence of hyperemesis gravidarum; however, the causal relationship between elevated hCG levels and hyperemesis gravidarum has not been firmly established. Patients with hyperemesis gravidarum also have abnormal thyroid function tests, and they may exhibit signs and symptoms of hyperthyroidism. Because hCG has intrinsic thyroid-stimulating activity and hyperthyroidism is a known cause of vomiting, these observations deserve further investigations. Mild abnormalities of liver chemistry tests are often present. The role of psychological derangements in the pathogenesis of hyperemesis gravidarum is controversial.

MANAGEMENT

The metabolic consequences of hyperemesis gravidarum are generally very severe, and if untreated, the mortality rate is high. Fluid and electrolyte disturbances, dehydration, and weight loss may be marked; and rare complications of intractable vomiting (such as Mallory–Weiss tear) may occur. The physician should exclude other causes of nausea and vomiting during pregnancy, such as preeclampsia (which usually occurs in later stages of pregnancy), urinary tract infection, appendicitis, hepatitis, intrahepatic cholestasis, gallstone disease and its complications, and acute fatty liver of pregnancy, which also typically occurs later (during the third trimester). Once the diagnosis of hyperemesis gravidarum is established, treatment consists of fluid and electrolyte replacement, parenteral hyperalimentation in cases complicated by nutritional deficiencies, supportive psychotherapy, and behavior modification.

Hyperlipidemia

MANISHA CHANDALIA AND NICOLA ABATE
University of Texas Southwestern Medical Center, Dallas

Dyslipidemia Abnormalities of plasma lipoproteins that include both higher and lower levels of certain lipoproteins.
Hyperlipidemia Elevated concentration of plasma lipoproteins.
Lipoproteins Particles carrying lipids in blood. Lipoproteins consist of esterified or unesterified cholesterol, triglycerides, phospholipids, and protein.
Lipoprotein X An abnormal lipoprotein that is rich in free cholesterol and phospholipids. Accumulation of lipoprotein X is noted in cholestatic liver disease. Its potential as an atherogenic particle is as yet unclear.
Lp (a) A modified form of LDL in which a large glycoprotein [apo (a)] is covalently bound to the apoB. Serum levels of Lp(a) are genetically defined. Its association with atherosclerosis is not completely established.

Hyperlipidemia refers to elevated blood levels of lipids, including cholesterol and triglycerides, due to various underlying causes. The clinically significant consequences of hyperlipidemia are two main life-threatening conditions: atherosclerosis and pancreatitis. Cholesterol and triglycerides are insoluble in plasma and circulating lipids are bound to apolipoproteins in order to be transported in plasma to various tissues where lipids are either utilized for cell function, energy utilization, steroid hormone production, and bile acid formation or deposited as a form of energy storage.

CLASSIFICATION OF LIPOPROTEINS

A variety of lipoproteins of different chemical composition can be identified in plasma. Based on their density, lipoproteins are commonly described as very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and chylomicrons. Table I is a classification of hyperlipidemias based on these discrete forms of lipoproteins.

Chylomicrons

Chylomicrons are very large particles that carry dietary lipid. They are associated with a variety of apolipoproteins, including A-I, A-II, A-IV, B-48, C-I, C-II, C-III, and E.

Very-Low-Density Lipoprotein

Very low-density lipoprotein carries endogenous triglycerides and to a lesser degree cholesterol. The major apolipoproteins associated with VLDL are B-100, C-I, C-II, C-III, and E.

Intermediate-Density Lipoprotein

Intermediate-density lipoprotein carries cholesterol esters and triglycerides. It is associated with apolipoproteins B-100, C-III, and E.

Low-Density Lipoprotein

Low-density lipoprotein carries cholesterol esters and is associated with apolipoprotein B-100.

High-Density Lipoprotein

High-density lipoprotein also carries cholesterol esters. It is associated with apolipoproteins A-I, A-II, C-I, C-II, C-III, D, and E.

Abnormalities of plasma levels of VLDL, IDL, LDL, HDL, or chylomicrons will lead to hypercholesterolemia, hypertriglyceridemia, or mixed hyperlipidemia depending on the lipid content of the specific lipoprotein abnormality. From a clinical standpoint, it is useful to evaluate hyperlipidemias/hyperlipoproteinemia on the basis of their potential effects, i.e., atherosclerosis and pancreatitis. Abnormalities in the metabolism of VLDL, IDL, and LDL [apolipoprotein B-100 (apoB-100)-containing lipoproteins] and HDL (apolipoprotein A-containing lipoproteins) are associated with risk of atherosclerosis. Abnormalities in chylomicron (apolipoprotein B-48-containing lipoproteins) metabolism are associated with risk of pancreatitis.

METABOLISM OF LIPOPROTEINS

Metabolism of Apolipoprotein B-100-Containing Lipoproteins

The metabolism of apoB-100-containing particles is depicted in Fig. 1. The initial apoB-100-containing

TABLE I Fredrickson Classification of Lipid Disorders

Phenotype	Lipoproteins increased	Lipid abnormality
I	Chylomicrons	↑↑Triglycerides to >99th percentile
IIa	LDL	↑↑Total cholesterol to >90th percentile
IIb	LDL, VLDL	↑Total cholesterol & triglycerides
III	VLDL remnants (IDL), chylomicrons	↑Total cholesterol & triglycerides
IV	VLDL	↑Triglycerides
V	VLDL, chylomicrons	↑↑Triglycerides to >99th percentile

lipoprotein is VLDL. These particles are synthesized by the hepatocyte. They contain a core of triglycerides (60% by mass) and cholesterol esters (20% by mass). In addition to apoB-100, the surface apolipoproteins for VLDL include apoC-II, which acts as a cofactor for lipoprotein lipase (LPL), apoC-III, which inhibits this enzyme, and apoE, which serves as ligand for the apolipoprotein B/E (LDL) receptor in the liver. Some newly synthesized VLDL particles are in fact taken up again by the liver through this mechanism, soon after secretion. The triglyceride core of nascent VLDL particles is hydrolyzed by LPL in the microcirculation. During lipolysis, the core of the VLDL particle is reduced, generating VLDL remnant particles (also called IDL). Some of the phospholipid, unesterified cholesterol, and apolipoproteins A, C, and E of VLDL remnants are transferred to HDL. VLDL remnants can either be cleared from the circulation by the apoB/E (LDL) receptor or be further depleted in triglycerides by lipases and become LDL particles. LDL particles contain a core of cholesterol esters and lesser amounts of triglyceride. LDL particles should be taken up by the LDL (apoB/E) receptor in the hepatocyte. However, if the LDL particle becomes modified LDL, i.e., glycated or oxidized, the scavenger LDL receptor of macrophages will recognize these particles and increase the formation rate of foam cells in the arterial intima, leading to the formation of atherosclerotic lesions. This process is physiologically counteracted by the apoA-containing lipoproteins (HDL).

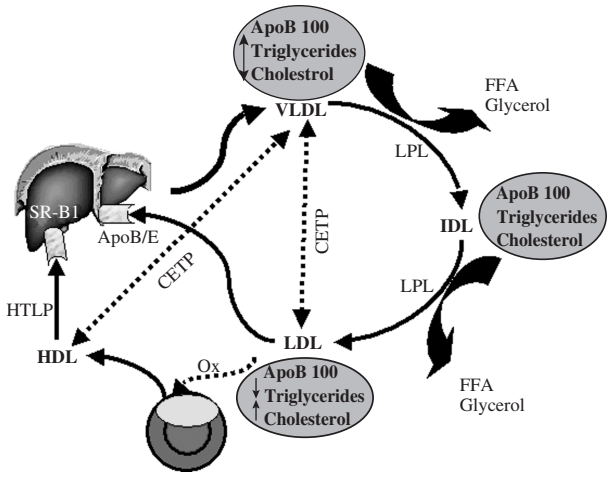

FIGURE 1 Metabolism of apolipoprotein B-100-containing lipoproteins: LPL, lipoprotein lipase; FFA, free fatty acid; Ox, oxidation; HTLP, hepatic lipase; SR-B1, scavenger receptor class B type 1; CETP, cholesterol ester transfer protein. See text for details.

Metabolism of Apolipoprotein A-Containing Lipoproteins

Figure 2 shows the metabolism of apoA-containing lipoproteins. The initial apoA-containing lipoprotein is the nascent HDL. This discoidal lipoprotein is synthesized in the gut and liver. It is rapidly hydrolyzed in the circulation unless enriched in cholesterol esters. Cholesterol ester uptake can occur from the macrophage/foam cell through a series of reactions that involve cholesterol efflux from the cytoplasm through the plasma membrane and rapid esterification of free cholesterol outside the cell. The transfer of cholesterol across the plasma membrane is mediated by the cholesterol efflux regulatory protein (CERP). Lecithin cholesterol acetyl transferase (LCAT) catalyzes the transfer of fatty acids from the phospholipid core of the nascent HDL to the free cholesterol coming out from the macrophage. Nascent HDL particles are therefore progressively enriched with cholesterol, becoming mature HDL particles. Mature HDL is recognized by scavenger receptor class B type 1 (SR-B1) receptor in the hepatocyte, adrenals, and gonads. HDL particles therefore mediate reverse cholesterol transport from the peripheral cells to the liver and to steroidogenic organs. This function seems largely to mediate the observed protective effects of HDL on atherosclerotic plaque formation. Other mechanisms have been also proposed, including antioxidant action of HDL to prevent LDL modification and recognition by the scavenger receptor of macrophages.

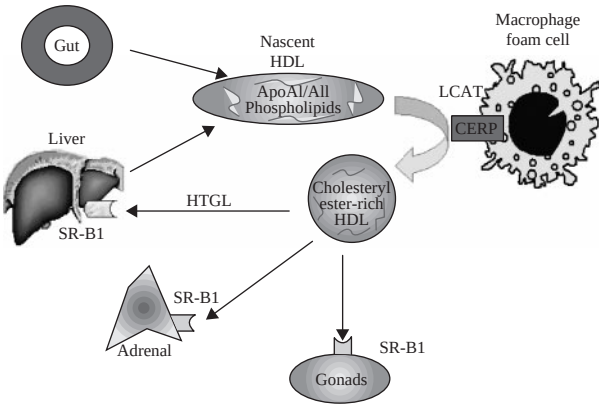

FIGURE 2 Metabolism of apoA-containing lipoproteins. LCAT, lecithin cholesterol acetyl transferase; CERP, cholesterol efflux regulatory protein; SR-B1, scavenger receptor class B type 1.

Metabolism of Apolipoprotein B-48-Containing Lipoproteins

The initial apoB-48-containing lipoproteins are chylomicrons. Figure 3 depicts schematically the metabolism of these particles. These particles are synthesized in the enterocytes and contain lipids derived from intestinal absorption. The main lipid component of chylomicrons is triglycerides. Dietary and biliary cholesterol is also incorporated into chylomicrons. These particles are exposed to LPL in the microcirculation and become progressively depleted of triglycerides. Triglycerides are utilized by the peripheral cells either as a direct source of energy or as an energy store in the adipose tissue. The result of triglyceride depletion is the formation of chylomicron remnants, which are eventually taken up by hepatocytes through the hepatic chylomicron remnant receptors. No chylomicrons should be detected under postabsorptive conditions.

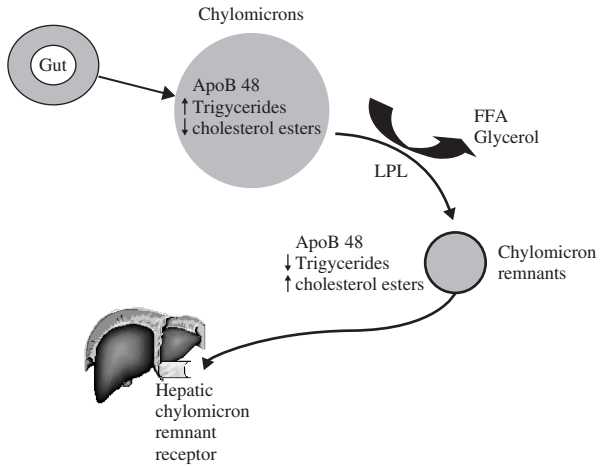

FIGURE 3 Metabolism of apoB 48-containing lipoproteins. LPL, lipoprotein lipase; FFA, free fatty acid.

PATHOPHYSIOLOGY OF HYPLIPOPROTEINEMIA

Apolipoprotein B-100-Containing Lipoproteins

Increased VLDL may occur from increased production by the hepatocyte and/or decreased clearance. Increased production of VLDL is observed in genetic conditions, such as familial combined hyperlipidemia. Secondary causes of increased production of VLDL are more common and include excessive intake of fats, calories, and alcohol, diabetes, insulin resistance, nephrotic syndrome, hypothyroidism, and obesity. Decreased clearance of VLDL is observed in genetic conditions, such as LPL deficiency and apoC-II deficiency. Secondary causes of decreased VLDL clearance include insulin resistance, type 2 diabetes, and hypothyroidism. Theseconditions decrease LPL activity either directly or through decreased production of apoC-II and increased production of apoC-III.

IDL typically increases in the presence of homozygosity for the isoform apoE-2. This isoform of apoE has the least affinity for the LDL receptor and decreases uptake of VLDL remnants/IDL. Usually, this hyperlipoproteinemia does not manifest unless a concomitant secondary cause, such as hypothyroidism, diabetes, or postmenopausal state, is present. This condition is clinically associated with palmar xanthomas and severe atherosclerosis.

LDL increases when defective clearance through the LDL receptor in the liver occurs. Defective receptor-mediated clearance of LDL is seen in familial hypercholesterolemia and polygenic hypercholesterolemias. Secondary causes of defective receptor-mediated clearance of LDL are excessive dietary intake of saturated fats and obesity. Increased LDL is the most powerful risk factor for coronary artery disease. It may also manifest with tendon xanthomas (in familial hypercholesterolemia) and xanthelasma.

Apolipoprotein A-Containing Lipoproteins

Low HDL may occur because of reduced production of HDL or increased catabolism through the SR-B1 receptor. However, low-HDL cholesterol is also seen in the condition of enhanced exchange of cholesterol between HDL and VLDL through the cholesterol ester transfer protein (CETP) when hypertriglyceridemia is present. As shown in Fig. 1, hypertriglyceridemia

through increased VLDL accelerates the transfer of cholesterol esters from HDL into VLDL in exchange for triglycerides. This explains the frequent association between hypertriglyceridemia and low-HDL cholesterol. Decreased production of HDL may occur because of a genetic mutation affecting CERP function (ABCA1 mutation in Tangier disease and familial low HDL) or a genetic mutation affecting LCAT activity.

Increased clearance of HDL particles may occur because of increased activity of hepatic lipase, an enzyme that mediates the maturation of HDL and facilitates the recognition of HDL by SR-B1 receptor. Increased activity of hepatic lipase is seen in diabetes and insulin resistance. Genetic polymorphisms responsible for decreased activity of HDL have been reported and correlate with increased levels of HDL.

Apolipoprotein B-48-Containing Lipoproteins

Increased chylomicron concentrations, leading to the presence of chylomicrons in postabsorptive conditions, may occur because of genetic conditions leading to defective triglyceride clearance, including LPL deficiency and apoC-II deficiency. Decreased clearance of chylomicrons may also occur secondary to excessive dietary triglyceride intake, hypothyroidism, obesity, diabetes, chronic renal failure, estrogens, and alcohol. Postabsorptive chylomicronemia causes eruptive xanthomas and acute pancreatitis.

HYPERCHOLESTEROLEMIA IN PRIMARY BILIARY CIRRHOSIS

Hypercholesterolemia is a common feature in primary biliary cirrhosis (PBC) and other forms of cholestatic liver disease. The lipid profile in PBC typically shows elevated total and LDL cholesterol and normal or mildly elevated triglycerides. HDL cholesterol may be elevated in the early stages of PBC and may fall markedly as the disease progresses to cirrhosis. Some of the excess LDL in PBC is composed of an abnormal lipoprotein particle called lipoprotein X, which is seen in cholestatic liver disease. Lipoprotein X is rich in free cholesterol and phospholipids. The total cholesterol concentration may be between 200 and 300 mg/dl; however, higher values have been reported in the literature. The lipid abnormalities may be identified during routine screening. However, classic presentation of patients with PBC is xanthomata and xanthelasma. Xanthomas correlate with cholesterol levels and develop on the elbow, palms, soles, buttocks, knees, back, and chest. The xanthomas are seen usually in patients with cholesterol levels >600 mg/dl. Due to their locations, xanthomas can cause significant difficulties in patients (Fig. 4). Lowering of cholesterol leads to an improvement in xanthomas. For patients with pain and disability due to xanthomas on the palm and sole, LDL aphaeresis may be required for relief. There is at present no conclusive evidence that hypercholesterolemia due to PBC is associated with increased atherogenesis and risk for coronary heart disease (CHD). A lipid profile, however, should be obtained in patients with PBC and decisions regarding treatment should be based on the risk for CHD. The efficacy of drug therapy is uncertain in PBC. However, statins and bile acid-binding resins have been tried in patients with variable results. LDL aphaeresis has been successfully used to treat symptomatic xanthomas on palms and xanthomatous neuropathy.

FIGURE 4 Xanthomata in a patient with primary biliary cirrhosis (PBC).

TREATMENT OF HYPERLIPIDEMIA

Coronary heart disease is a major cause of morbidity and mortality in the western world. Both high-LDL cholesterol and low-HDL cholesterol affect the risk of CHD. Positive risk factors for CHD include the following: (1) cigarette smoking; (2) hypertension [blood pressure $\geq 140/90$ mm Hg or on antihypertensive medications]; (3) low-HDL cholesterol (<40 mg/dl); (4) family history of premature CHD; and (5) age (men ≥ 45 years and women ≥ 55 years).

Recently, numerous clinical trials have demonstrated that lowering LDL cholesterol results in a significant reduction in CHD events and mortality. Adult Treatment Panel III (ATP III) guidelines outline identifying subjects who are at high risk of CHD and are candidates for treatment. Table II shows LDL cholesterol goals and cut-off points for intervention.

TABLE II LDL Cholesterol Goal and Cutpoint for Therapy

Risk category	LDL goal (mg/dl)	LDL level at which to initiate TLC (mg/dl)	LDL level at which to consider drug therapy (mg/dl)
CHD or CHD risk equivalents (10-year risk >20%)	<100	≥100	≥130 (100–129: drug therapy optional)
2 or more risk factors (10-year risk ≤20%)	<130	≥130	10-year risk 10–20%: ≥130 10-year risk <10%: ≥160
0–1 risk factor	<160	≥160	≥190 (160–189: drug therapy optional)

Note. Adapted from Adult Treatment Panel III at http://www.nhlbi.nih.gov, with permission. TLC, therapeutic life style changes; CHD, coronary heart disease; CHD risk equivalent: other forms of atherosclerotic diseases, diabetes, and multiple risk factors that confer a 10-year CHD risk > 20%.

Therapeutic Lifestyle Changes

Lifestyle modification in patients with hyperlipidemia forms a very important backbone of the treatment plan. Therapeutic lifestyle changes comprise diet, weight management, and increased physical activity. Table III shows the nutrient composition recommended by ATP III of the National Cholesterol Education Panel. Dietary modifications may lead to a reduction in LDL cholesterol of 8 to 15%. A low-fat diet is a very important component of treatment for hypertriglyceridemia. In addition to improving the lipid panel, therapeutic lifestyle changes can help with weight reduction, improving insulin resistance, and blood pressure. Other dietary components, such as fish oil, plant stenol incorporated in margarine, and soy protein, have been shown to improve lipid levels and their inclusion in the diet should be mentioned in the advice given regarding diet. Regular exercise, such as a brisk walk for 30 min, has been shown to improve cardiovascular fitness and should be incorporated in the treatment plan.

TABLE III Nutrient Composition of Therapeutic Lifestyle Changes Diet

Nutrient	Recommended intake
Saturated fat[a]	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Total fat	25–35% of total calories
Carbohydrate[b]	50–60% of total calories
Fiber	20–30 g/day
Protein	Approximately 15% of total calories
Cholesterol	Less than 200 mg/day
Total calories (energy)	Balance energy intake and expenditure to maintain desirable body weight/prevent weight gain

Note. Adapted from Adult Treatment Panel III at http://www.nhlbi.nih.gov, with permission.

[a] Transfatty acid intake should be kept low.

[b] Carbohydrates should be derived from foods rich in complex carbohydrates including grains, fruits, and vegetables.

Pharmacotherapy of Hyperlipidemia

Statins

This class of drugs includes lovastatin, simvastatin, pravastatin, atorvastatin, and fluvastatin. The statins are competitive inhibitors of the rate-limiting enzyme in cholesterol synthesis, HMG coenzyme A (coA) reductase. By inhibiting HMG coA reductase, they decrease the intracellular cholesterol pool and this results in the up-regulation of the LDL receptor. This up-regulation of the LDL receptor promotes clearance of the circulating particles that have apoB or apoE on the surface and lead to increased clearance of cholesterol-rich LDL and to lesser extent VLDL and IDL. As a class, these drugs are most potent in reducing LDL cholesterol. In addition, they can reduce triglycerides and raise HDL cholesterol. Statins are efficacious in patients with isolated elevations in LDL cholesterol or combined hyperlipidemia with elevated LDL cholesterol and triglycerides. The reduction in LDL cholesterol with statins ranges from 24 to 60%. Numerous clinical trials have shown that statins are effective in lowering LDL cholesterol safely and lead to a significant reduction in CHD events and mortality. The predominant route of excretion is through the bile after hepatic transformation. Major side effects are liver dysfunction and myopathy. All statins have been associated with transaminase elevation, although the incidence of an elevation greater than three times the upper limit of normal is generally <2%. Statins can also induce myopathy, especially in combination with other drugs that are cleared through the cytochrome P450 system. Although significant myopathy is uncommon, definite rhabdomyolysis occurs in ~0.1% of patients who receive statin therapy.

Bile Acid Sequestrants

The drugs available in this class are cholestyramine, colestipol, and colesevelam. The primary action of bile acid sequestrants is to interfere with intestinal reabsorption of bile acids. This activity interrupts the enterohepatic circulation of bile acids, increases the fecal excretion of cholesterol, and depletes the cholesterol pool in the hepatocyte. The hepatocellular depletion of cholesterol stimulates the up-regulation of LDL receptors, which results in increased uptake of LDL and IDL, thus lowering LDL cholesterol. A maximum reduction of 15 to 30% in LDL cholesterol may be seen with these agents. A disadvantage of these drugs is that cholesterol depletion in the liver results in increased cholesterol synthesis, which partially negates the cholesterol-lowering efficacy of these drugs. However, statin can be combined with these drugs to prevent this effect and can be used in severe hypercholesterolemias as a combination therapy. One other disadvantage of bile acid sequestrants is exacerbation of hypertriglyceridemia due to increased hepatic VLDL production. Bile acid sequestrants are contraindicated in patients who have serum triglyceride concentrations >400 mg/dl. The major side effects are usually limited to the gastrointestinal tract as bile acid sequestrants are not absorbed systemically. Common side effects are abdominal bloating, belching, flatulence, and constipation. Bile acid resins may bind to other medications, causing decreased absorption and efficacy of these medications. Therefore, other medications should be taken either 1 h before or 4 h after bile acid resins.

Fibrates

This class of drugs includes gemfibrozil, fenofibrate, clofibrate, bezafibrate, etofibrate, and ciprofibrate. The first three are currently available in the United States. However, since the use of clofibrate has been associated with an increased incidence of cholangiocarcinoma and other gastrointestinal cancers, only gemfibrozil and fenofibrate are routinely used for the treatment of dyslipidemia. Gemfibrozil and fenofibrate markedly lower plasma triglyceride concentrations (up to 50%), increase plasma HDL cholesterol concentrations (up to 25%), and have a variable effect on plasma LDL-C concentrations. Recently, it has become evident that many of the effects of fibrates on lipids are mediated by the activation of peroxisome proliferator-activated receptor-γ (PPAR-γ, a component of the subfamily of nuclear receptors known as PPARs). Fibrates bind to and activate PPAR-γ, which then forms a heterodimer with another nuclear receptor, the retinoid X receptor. The heterodimer binds to a specific peroxisome proliferator-response element and the result is a change in the transcription of target genes. Target genes include lipoprotein lipase, apoC-III, apoA-I, and apoA-II. The expression of lipoprotein lipase, apoA-I, and apoA-II has been found to increase with fibrates, whereas the expression of apoC-III has been found to decrease. As a result, fibrates induce the following: (1) an increase in lipoprotein lipase activity (resulting from PPAR-γ activation and a related increase in the production of LPL and a decrease in the production of apoC-III, an inhibitor of LPL) and (2) an increased production of HDL (resulting from PPAR-γ activation and a related increase in the production of apoA-I and apoA-II). The stimulation of LPL activity has the effect of increasing the catabolism of triglycerides in lipoproteins, such as VLDL and chylomicrons. Accelerated catabolism of VLDL and chylomicron to IDL and chylomicron remnants, respectively, induces decreased plasma triglyceride concentrations and may also lead to a higher production of LDL particles. If there is no adequate compensatory mechanism to increase the catabolism of LDL particles, the accelerated conversion of VLDL to LDL may result in the elevation of serum LDL-C concentrations. Fibrates, particularly fenofibrate, also have been shown to reduce VLDL production in the liver. This mechanism contributes to a decrease in plasma triglyceride concentrations and at the same time explains the LDL-C-lowering effect seen in some patients treated with fenofibrate. Reduction of triglyceride-containing particles also has the effect of decreasing the exchange of triglycerides for cholesterol esters between VLDL and LDL or HDL, a process physiologically mediated by CETP. This mechanism contributes to an increase in HDL-C levels and to a change in the quality of LDL from small–dense LDL to less atherogenic, large–buoyant LDL-C in patients treated with fibrates. Increased serum concentrations of HDL-C are also mediated by the increased synthesis of apoA-I and apoA-II, and hence HDL particle production. Therefore, both the quality and the number of HDL particles change with the use of fibrates. The effects of fibric acid derivatives on lipoprotein levels differ widely according to the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, and the associated environmental influences. Among all patients, hyperlipidemic subjects with apoE-2/E-2 monozygosity respond best to gemfibrozil therapy. Elevated triglyceride and cholesterol levels may be dramatically lowered and tuberoeruptive and palmar xanthomas may resolve completely. Gemfibrozil treatment in patients with mild hypertriglyceridemia [triglycerides (TG) <400 mg/dl] usually produces a decrease in triglyceride levels of 50% or more, an increase in HDL-C of 15 to 25%, and either no change or

an increase in LDL-C levels, particularly in subjects with familial combined hyperlipidemia. Fenofibrate, bezafibrate, and ciprofibrate lower VLDL levels to a degree similar to that produced by gemfibrozil, but they also decrease LDL-C levels by 15 to 20%. In patients with more marked hypertriglyceridemia (TG of 400 to 1000 mg/dl), a similar fall in triglycerides occurs. However, these patients frequently experience an increase in LDL-C of 10 to 30%. In contrast, treatment of patients with heterozygous familial hypercholesterolemia usually produces a decrease in LDL-C levels of 10% with gemfibrozil and a decrease of 20 to 30% with fenofibrate. The effect of fibrates on lipoproteins has been associated with a reduction in cardiovascular risk in both primary and secondary intervention trials.

Nicotinic Acid

Nicotinic acid is a water-soluble B-complex vitamin that has a significant hypolipidemic activity at high doses (1−3 g/day). The hypolipidemic properties of nicotinic acid are unrelated to its role as a vitamin. Nicotinic acid is used to increase serum HDL-C levels (up to 30%), reduce triglycerides (20 to 80%), and reduce LDL-C (10 to 15%). Nicotinic acid is the only hypolipidemic agent that is effective in reducing lipoprotein-a concentrations (by approximately 30%). It appears that the hypolipidemic properties of nicotinic acid are related to inhibition of peripheral lipolysis. This effect reduces free fatty acid mobilization from peripheral tissues and reduces free fatty acid delivery to the liver. As a result, triglyceride synthesis in hepatocytes is diminished. Since hepatic triglyceride synthesis is an essential step for the synthesis and transport of VLDL particles from the hepatocyte into the systemic circulation, the inhibition of lipolysis in the peripheral cells by nicotinic acid induces a reduction in the assembly and secretion of VLDL particles into the bloodstream. Reduced VLDL production explains the decreased plasma triglyceride concentrations in patients treated with nicotinic acid. Since LDL particles derive from VLDL metabolism, another effect of nicotinic acid-induced inhibition of VLDL output is a reduction of serum LDL-C concentrations. Similarly to what was described for fibrates above, the decreased VLDL synthesis induces a reduction in CETP activity, which, in turn, reduces the loss of cholesterol esters from the core of LDL particles and changes the quality of LDL particles from small−dense LDL to large−buoyant LDL and less atherogenic LDL particles. The same effects on CETP activity will contribute to increased HDL-C levels in patients treated with nicotinic acid. Another mechanism that may contribute to the significant effect of nicotinic acid on HDL-C is the reduced clearance of HDL particles and increased synthesis of apoA-II. The mechanisms underlying these effects of nicotinic acid are not completely understood. The numerous clinical trials using nicotinic acid in monotherapy or in combination therapy have confirmed the effectiveness of this drug in decreasing cardiovascular risk in patients with high triglycerides, low HDL-C levels, and elevated LDL-C. Nicotinic acid causes numerous side effects, the major one being flushing and associated pruritus that usually involve the face and upper part of the body. The interval between the intake of nicotinic acid and the onset of these side effects may be variable. With persistent use of the drug, the frequency and intensity of flushing decrease in 70 to 80% of patients within 1 to 2 weeks. Taking one aspirin per day may alleviate the symptoms in some patients, suggesting that this effect is mediated by prostaglandins. Gastrointestinal symptoms, such as dyspepsia, vomiting, and diarrhea, also occur, but these effects are reduced if nicotinic acid is taken with a meal. Nicotinic acid may precipitate peptic ulcer disease. Abnormalities of hepatic function are an important and potentially serious complication of high-dose nicotinic acid therapy. These abnormalities generally occur in patients taking more than 2 g of nicotinic acid per day. Increases in serum transaminases are the most common abnormalities in hepatic function, but jaundice may occur and hepatic failure has been observed with sustained-release preparations. With mild changes in liver function tests, reducing the dose of nicotinic acid frequently will result in normalization of tests without the need to discontinue the drug. The combined use of nicotinic acid and statins may increase the risk of myopathy and rhabdomyolysis. Finally, nicotinic acid can cause hyperglycemia and, if used in diabetics with dyslipidemia, requires careful monitoring of blood glucose levels.

Cholesterol Absorption Inhibitors

Sitostanol/sitosterol and ezetimibe interfere with cholesterol absorption at the brush border of enterocytes. Sitostanol (Benechol) and sitosterol (Take Control) used with the meals displace cholesterol from the micellar solution required for transport of cholesterol across the plasma membrane of enterocytes. Sitosterol and sitostanol are reexcreted from the enterocyte through the ABCG5/G8 cholesterol transporter protein and not absorbed in significant quantities. Ezitimibe has been recently developed as the first agent acting as cholesterol transport blocker. It recirculates through the entero-hepatic circulation and blocks a putative cholesterol transporter located at the brush border of the enterocyte plasma membrane. Absorption studies

have shown decreased cholesterol absorption and increased synthesis as a response of the hepatocytes to negative cholesterol balance. Ezetimibe promises to be a safe adjunct to other hypocholesterolemic agents to further decrease LDL-C in patients at high risk for coronary artery disease. It also seems to be a promising alternative for patients who cannot tolerate statins or other hypocholesterolemic agents.

Hyperparathyroidism

ASRA KERMANI

Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

carcinoid An endocrine tumor consisting of enterochromaffin cells or enterochromaffin-like cells.

MEN A syndrome associated with multiple endocrine neoplasms; three types are recognized (1, 2a, and 2b) and types 1 and 2a are associated with hyperparathyroidism.

primary hyperparathyroidism Inappropriately excessive parathyroid hormone production resulting in hypercalcemia.

Routine chemistry tests have made primary hyperparathyroidism the most common cause of hypercalcemia detected in the outpatient setting. Prior to the widespread availability of laboratory analysis, hyperparathyroidism was an uncommon disease that usually was discovered when a patient presented with a clinical manifestation. It has now predominantly become an asymptomatic diagnosis. Primary hyperparathyroidism is a diagnosis commonly seen in adults of all ages but is uncommon in children. The female:male ratio is 3 : 1 with the peak incidence between the third and sixth decades. The most common cause is a solitary parathyroid adenoma, accounting for approximately 80% of all causes. Multiple parathyroid adenomas constitute the next most frequent diagnosis; this entity is commonly seen in the multiple endocrine neoplasia syndromes (MEN), both type 1 and type 2A. Older literature suggested that the parathyroid glands in MEN syndromes were "hyperplastic" but many are now known to be monoclonal in origin. Very rarely seen as a cause of hyperparathyroidism is parathyroid carcinoma (<1%).

GASTROINTESTINAL SYMPTOMS AND SIGNS

Most of the symptoms of hyperparathyroidism, if any are present, pertain to the degree of hypercalcemia and the rate of increase of serum calcium levels. Gastrointestinal symptoms occur in approximately 35% of patients. These symptoms include anorexia, nausea, vomiting, heartburn, constipation, weight loss, and dyspepsia. Constipation occurs in up to 30% of patients with primary hyperparathyroidism. This is thought to occur as a result of decreased smooth muscle tone of the gut. It is believed that this is not a myopathy but actually a result of abnormal activity of the autonomic

nervous system. Constipation can also be potentiated by renal free water loss from hypercalcemia, which leads to dehydration.

Approximately 60% of patients with primary hyperparathyroidism suffer from heartburn secondary to gastroesophageal reflux. Reduced lower esophageal sphincter pressure has been documented in hyperparathyroid patients with hypercalcemia. Gastroesophageal reflux normalizes after successful parathyroidectomy and therefore might be related to hypercalcemia.

A rare but potentially life-threatening complication is acute primary hyperparathyroidism, an entity characterized by marked hypercalcemia, exceeding 15–17 mg/dl. Patients complain of severe abdominal pain, nausea, vomiting, and volume depletion and symptoms may progress to altered mentation, coma, and seizures. Peptic ulceration, occasionally with perforation, and pancreatitis occur commonly in this situation. Emergent parathyroidectomy, along with supportive care, is curative.

ASSOCIATIONS WITH GASTROINTESTINAL DISEASES

Pancreatitis

Primary hyperparathyroidism is associated with acute or chronic pancreatitis in approximately 3% of patients who underwent surgery for hyperparathyroidism. The incidence of pancreatitis was related to high serum calcium levels. Patients undergoing an operation for secondary hyperparathyroidism, who therefore were hypocalcemic or normocalcemic, did not have pancreatitis, suggesting that hypercalcemia is an important mediator of pancreatic injury in primary hyperparathyroidism.

There are several reports of primary hyperparathyroidism diagnosed in the setting of acute pancreatitis. One hypothesis for this occurrence is that hypercalcemia results in calcium deposition within the pancreatic duct, resulting in obstruction. Activation of trypsinogen by calcium also occurs in acute pancreatitis. In severe pancreatitis of any etiology, extensive formation of calcium–fatty acid soaps might render the patient hypocalcemic. Therefore, normocalcemia in the setting of acute pancreatitis may be a clue to the presence of hyperparathyroidism.

Peptic Ulceration

Whereas the association between peptic ulcer disease and hyperparathyroidism is clearly present in multiple endocrine neoplasia (MEN 1) syndrome discussed below, the case is not as clear in sporadic primary hyperparathyroidism. Peptic ulceration has been reported in approximately 15–20% of patients with primary hyperparathyroidism. This prevalence is only slightly greater than that in the general population. Although such increased reports of primary hyperparathyroidism in patients with documented peptic ulcer may be causal, these findings may reflect an increased search for it. The two conditions are highly prevalent in unselected individuals and therefore might occur coincidently in some. One hypothesis that attempts to explain peptic ulceration as a consequence of primary hyperparathyroidism relates to hypergastrinemia. Elevated circulating calcium levels stimulate gastrin secretion in humans. The best clinical evidence is the MEN 1 syndrome, discussed below.

Some reports indicated an increase in basal acid output in up to one-third of patients with primary hyperparathyroidism but there was significant overlap with normals. In another study, patients with primary hyperparathyroidism were studied after successful parathyroid adenoma removal. There was no change in the mean fasting gastrin level, gastrin response to feeding, mean basal acid output, or mean peak acid output.

Multiple Endocrine Neoplasia Syndromes

MEN 1 is an autosomal dominant disorder characterized by multiple parathyroid adenomas in 90–100% of cases, anterior pituitary adenoma in 10–60%, and entero-pancreatic endocrine tumors such as gastrinoma in 30–75%. The syndrome is difficult to define, as there may be permutations of 20 or more tumors. Therefore, an individual with two of the three above criteria may be defined as having MEN 1. The most frequent endocrine problem in MEN 1 is primary hyperparathyroidism, occurring in almost 100% of patients by age 50. The age of onset may be as early as in the twenties, which is 30 years earlier than sporadic primary hyperparathyroidism. Three or four parathyroid glands are frequently involved by tumor in MEN 1.

Gastrinomas occur in approximately 40% of patients with MEN 1 and are associated with Zollinger-Ellison syndrome (ZES). ZES results in widespread peptic ulceration due to hypergastrinemia and resulting excess acid production. Peptic ulceration in MEN 1 is potentiated by hypercalcemia from primary hyperparathyroidism, leading in turn to increased gastrin release from the gastrinoma. The converse is also true: removal of the parathyroids lowers gastrin production from gastrinoma. Most gastrinomas associated with MEN 1 have malignant potential and over half of them are metastatic at the time of diagnosis.

MEN 2A is also an autosomal dominant disorder resulting in medullary carcinoma of the thyroid in 90% of cases, unilateral or bilateral pheochromocytoma in 50%, and multiple parathyroid tumors in 20–30%. Unlike the aggressive course of patients with primary hyperparathyroidism in MEN 1, the hyperparathyroidism of MEN 2A patients is mild and often asymptomatic. Usually fewer than four parathyroid glands are affected in this condition.

Carcinoid

Foregut carcinoids may occur as part of MEN 1 syndrome. Therefore, if a diagnosis of carcinoid is made, patients should be screened for primary hyperparathyroidism.

Rode *et al.* found gastric carcinoid in three cases of primary hyperparathyroidism. Two of these had parathyroid hyperplasia and one had a parathyroid adenoma. All carcinoids were located in the nonantral part of the stomach. Interestingly, all three carcinoids showed immunoreactivity for gastrin. None of these patients had other features of MEN.

Gallstones

The prevalence of gallstones in patients with primary hyperparathyroidism ranges from 25 to 35%. It is unclear whether there is a real association.

Hyperthyroidism

ASRA KERMANI
Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

hyperthyroidism (**thyrotoxicosis**) Variety of disorders resulting in excessive thyroid hormone levels and effects throughout the body.

tachygastria Faster than the normal (three/minute) electrical slow-wave activity generated by the smooth muscle layer of the stomach.

The most common cause of thyrotoxicosis is Graves' disease, an autoimmune disorder characterized by thyroid-stimulating antibodies that bind to the thyroid-stimulating hormone receptor on the thyroid gland, resulting in overproduction of thyroid hormone. Graves' disease may occur at any age but it is most frequently seen in the third and fourth decades; there is gender prevalence, with a female:male ratio ranging from 7 : 1 to 10 : 1. Histologically, there is predominantly T lymphocytic infiltration of the thyroid gland. It is hypothesized that stimulated T lymphocytes induce B lymphocytes to produce antibodies to the thyroid-stimulating hormone (TSH) receptor. Because of a variety of human leukocyte antigen associations, several other autoimmune diseases are associated with Graves' disease. Toxic multinodular goiter is a frequent cause of hyperthyroidism in the elderly, usually appearing late in the course of a nontoxic multinodular goiter. Other causes of thyrotoxicosis are adenoma, various forms of transient thyroiditis, exogenous thyroid hormone ingestion, and iodine ingestion in populations with endemic iodine deficiency. Rare causes include pituitary tumor secretion of thyroid-stimulating hormone, pituitary resistance to thyroid hormone, and trophoblastic disease (human chorionic gonadotropin and thyroid-stimulating hormone share the same α subunit).

GASTROINTESTINAL SYMPTOMS AND SIGNS

Constitutional Symptoms and Signs

The classical gastrointestinal manifestation of hyperthyroidism is weight loss in spite of preserved or increased appetite. Although some patients with mild disease might actually gain weight if their caloric intake is in excess of their metabolism, the classic patient with severe thyrotoxicosis is unable to keep up with the increased catabolism by increased food intake. Reduced intestinal absorption of nutrients also contributes to weight loss. Apathetic hyperthyroidism is an entity characterized by atypical manifestations, particularly in the elderly, and anorexia is a common presenting feature in this population.

Motility Disturbances

Hyperdefecation is common, and is defined as greater than two bowel movements a day. Diarrhea is rare. Patients with chronic constipation who become thyrotoxic may develop normal bowel movements. Acute or vague chronic abdominal discomfort may supervene in some patients, and hyperthyroidism is a rare cause of "acute abdomen." The cause for the abdominal pain is unknown, but corrects with treatment of hyperthyroidism. Dysphagia as a result of esophageal motor dysfunction has been also been reported.

Hepatic Symptoms and Signs

Pruritus and jaundice may occur as a result of cholestatic hepatitis in Graves' disease in patients who have no evidence of autoimmune hepatitis or congestive heart failure. This entity usually resolves completely with treatment of thyrotoxicosis. Hepatomegaly and splenomegaly may also be manifestations of Graves' disease.

Malabsorption

D-Xylose absorption by the intestine is normal in patients with hyperthyroidism. Lactose malabsorption may occur in Graves' disease and may sometimes correct following successful treatment. Steatorrhea occurs in more than 25% of hyperthyroid patients and can contribute to weight loss. Reasons include rapid intestinal transit, leading to reduced contact time with the small bowel mucosal surface and poor absorption, and possibly ingestion of large amounts of fat. Minor abnormalities in pancreatic and biliary secretion may be present but they are insufficient to cause steatorrhea. Jejunal calcium absorption can also be reduced in

 Copyright 2004, Elsevier (USA). All rights reserved.

thyrotoxicosis and can contribute to weight loss and a negative calcium balance, promoting osteoporosis.

Gastric Emptying

Hyperthyroidism does not significantly affect gastric emptying of solids. Pfaffenbach *et al*. studied 23 untreated hyperthyroid patients who also had dyspepsia. Dyspepsia included retrosternal pain, epigastric pain, epigastric fullness, belching, nausea and vomiting, and/or abdominal pain unexplained by other known causes. Electrogastrography (EGG) showed tachygastria and delayed gastric emptying. EGG abnormalities did not correlate significantly with dyspeptic symptoms, but tachygastria improved with treatment of hyperthyroidism.

Orocecal Transit Time

Reports find that mouth-to-cecal stool transit in thyrotoxicosis is accelerated by 50%. Studies uniformly find that hyperthyroid patients have more rapid orocecal time, which normalizes after treatment of hyperthyroidism. This increased bowel motility may explain diarrhea in thyrotoxic patients.

Anorectal Physiology

Hyperthyroid patients exhibit lower maximum resting pressure and maximum squeeze pressure on anal manometry, with no difference in maximum tolerable rectal volumes. They also have a significantly lower threshold sensation for impending evacuation compared with controls, which could conceivably contribute to hyperdefecation.

ASSOCIATIONS WITH GASTROINTESTINAL DISEASES

Immunologic Associations

Hyperthyroidism may be associated with celiac disease, hepatitis C virus, and inflammatory bowel disease (IBD). Autoimmune thyroid diseases, including Graves' disease and Hashimoto's thyroiditis, are seen more frequently in patients with celiac disease. Female patients with hepatitis C virus infection have been reported to have an increased prevalence of thyroid microsomal antibody titers. Titers may increase with time with development of hyperthyroidism. Nonspecific IBD has been observed to be associated in various ways with Graves' disease.

Liver Dysfunction

Nonspecific Abnormalities

Severe thyrotoxicosis, including thyroid storm, is frequently associated with nonspecific liver function test abnormalities. The serum total protein level may be low, and there may be elevations in alanine aminotransferase (ALT) and alkaline phosphatase (most of the latter, however, arises from bone). Finally, in severe thyrotoxicosis, hypoxemia has been invoked as a mechanism for hepatic dysfunction, because of unaltered splanchnic oxygen delivery in the face of increased consumption, but this hypothesis is controversial.

Cholestatic Hepatitis

A particular type of cholestatic hepatitis with marked hyperbilirubinemia and mild to moderate transaminase elevation has been described. This is characterized by liver biopsy findings of intrahepatic steatosis, portal infiltration by lymphocytes, and Kupffer cell hyperplasia. There is no biliary ductal dilatation. A different histological picture but identical clinical phenotype is seen with granulomatous hepatitis. Liver biopsy shows intralobular granulomas and a mixed cholestatic and cytolytic hepatitis, in the absence of other causes, including primary biliary cirrhosis and sarcoidosis.

Autoimmune Hepatitis

Autoimmune hepatitis and Graves' disease may also coexist, with histological findings showing mononuclear cell infiltration and portal fibrosis. High globulin fraction may be seen in autoimmune and/or chronic viral hepatitis.

Heart Failure

Right-sided heart failure is a common cause of hepatomegaly in Graves' disease, resulting from chronic passive congestion of the liver.

Drug Toxicity

Drug treatment of hyperthyroidism is an important cause of hepatotoxicity. In most cases, asymptomatic elevations of transaminases are the abnormality. The two most common agents are propylthiouracil and methimazole. Methimazole can result in cholestatic hepatitis with jaundice, often in the first few months of treatment. Gradual resolution usually occurs with discontinuation of this drug. Propylthiouracil, however, may present a wider clinical spectrum of hepatic damage, including a viral hepatitis-like picture, cholestatic hepatitis, or fulminant hepatic necrosis. The mechanism

appears to be a hypersensitivity reaction, which can occur either acutely or as late as 14 months after initiation of therapy. Fulminant hepatic failure is an exceedingly rare but potentially fatal outcome related to propylthiouracil use, requiring orthotopic liver transplantation.

THYROID FUNCTION TESTING PRIOR TO TREATMENT WITH INTERFERON α FOR CHRONIC HEPATITIS C INFECTION

Treatment with interferon α (IFNα) for chronic hepatitis C infection results in thyroid dysfunction in 3–14% of patients. Consequences include thyroiditis, hyperthyroidism, or hypothyroidism; many patients develop antithyroid antibodies. Predictors for thyroid dysfunction are female gender, subclinical thyroid disease prior to interferon administration, previously manifest thyroid disease, or other autoimmune disease. All patients should have thyroid function testing prior to initiation of IFNα therapy and be periodically monitored during the course of therapy. Preexisting thyroid disease is not a contraindication to interferon therapy, however.

Hypothyroidism

ASRA KERMANI
Veterans Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

hypothyroidism A syndrome characterized by inadequate thyroid hormone production or replacement.
myxedema Synonymous with hypothyroidism, but generally used to connote a more severe (advanced) case with accumulation of mucopolysaccharide material in soft tissues, body cavities, and organs.

The most common cause of hypothyroidism in developed countries is primary thyroid failure as in Hashimoto's thyroiditis; iodine deficiency prevails as the leading cause in the developing world. Hashimoto's thyroiditis is an autoimmune disorder associated with circulating antithyroid antibodies. There are similar proportions of B-cell and T-cell lymphocytes infiltrating the thyroid gland. It occurs with a frequency of 3.5 cases per 1000 people per year in women and 0.8 cases per 1000 people per year in men. Other frequent causes of hypothyroidism include post-radioiodine or postsurgical ablation of the thyroid gland for overproduction of thyroid hormone as in Graves' disease or toxic goiter or hypothalamic/pituitary disease with inadequate thyroid-releasing or thyroid-stimulating hormone secretion. Because thyroid hormone has profound effects on metabolism and muscle contractility, the gastrointestinal tract is significantly affected by its deficiency. As Hashimoto's thyroiditis is the commonest cause of hypothyroidism in developed countries, other autoimmune diseases often coexist with it.

GASTROINTESTINAL SYMPTOMS AND SIGNS

Constitutional Symptoms

Most symptoms referable to the gastrointestinal tract are nonspecific. However, there are certain clues that, in conjunction with other systemic signs and symptoms, are characteristic. Weight gain despite reduced appetite is common. The weight gain is mild and is a result of fluid retention from mucopolysaccharide accumulation within soft tissues. A yellowish skin color occurs in hypothyroidism as a result of carotenemia, from impaired conversion of carotene to vitamin A.

Dysphagia/Compression

Although dysphagia obviously can occur in the setting of a large goiter compressing the pharynx, it is also seen in hypothyroid patients with esophageal dysmotility. Patients with myxedema can rarely develop megaesophagus. A large substernal goiter (independent of function) may cause superior vena cava syndrome, resulting in esophageal varices in up to 12% of individuals. This is a rare cause of variceal hemorrhage.

Hypomotility

Approximately 10% of patients with hypothyroidism experience nonspecific abdominal pain. Many patients complain of bloating and flatulence, which is thought to be a consequence of reduced intestinal peristalsis. Constipation is frequent and may progress to severe ileus and fecal impaction. Hypothyroidism is a rare cause of megacolon from intestinal atony. Although constipation prevails, bacterial overgrowth in the setting of intestinal hypomotility has been reported, resulting in weight loss and diarrhea. Hypothyroidism is also one of the causes of an elevated CEA (carcinoembryonic antigen) level, which, if seen in a patient with abdominal distension, can mimic colon cancer.

Gastrointestinal Motility Changes

Some studies document significant delays in orocecal transit time in hypothyroid patients, suggesting that small bowel hypomotility is an early sign of hypothyroidism. Other studies have not confirmed this finding.

Anorectal Function

The anal sphincter mechanism is unaltered in hypothyroidism. The threshold sensation for evacuation is higher than in controls, which may provide a further explanation for constipation in hypothyroid patients.

 Copyright 2004, Elsevier (USA). All rights reserved.

Myxedema Ascites

Myxedema ascites accounts for less than 1% of all causes of ascites. It usually is chronic. The ascitic fluid is protein-rich (>2.5 g/dl), has a moderate white blood cell count that is predominantly lymphocytic, and has a serum ascites albumin gradient (SAAG) of greater than 1.1 g/dl. Some authors dispute the increased SAAG as being integral to the definition of myxedema ascites and invoke congestive heart failure, which often occurs concomitantly, as the cause of the increased SAAG. Like similar pleural and pericardial effusions, there is complete resolution with thyroid hormone replacement. A solitary case of chylous ascites and chylous pleural effusions has been described.

ASSOCIATIONS WITH GASTROINTESTINAL DISEASES

Immunologic Associations

Celiac disease, an autoimmune disease characterized by gluten sensitivity and small bowel villous atrophy, is seen more frequently in association with Hashimoto's thyroiditis and Graves' disease.

Hepatitis C viral (HCV) infection is associated with an increased prevalence of thyroid microsomal antibody. Furthermore, 3% of HCV positive euthyroid patients treated with interferon-α may develop antithyroid antibodies and become hypothyroid. Other autoantibodies or autoimmune diseases were risk factors. Thyroid abnormalities were reversible after interferon-α therapy was discontinued.

Pernicious anemia may occur as part of a polyglandular autoimmune syndrome, with coexistent Hashimoto's thyroiditis. In sporadic cases of Hashimoto's disease, parietal cell antibodies occur in approximately 25% of patients. Atrophic gastritis is also more common in Hashimoto's thyroiditis and may result in achlorhydria or hypochlorhydria.

Primary biliary cirrhosis (PBC), a disease of autoimmune destruction of interlobular bile ducts, may coexist with hypothyroidism. The prevalence of thyroid failure ranges from 12 to 22%. Thyroid disease may predate the onset of PBC by years. Patients with hypothyroidism who develop cholestatic liver disease should be screened for PBC.

Autoimmune hepatitis is a rare association and has been reported in polyglandular autoimmune syndromes. Nonspecific elevations of serum transaminase and alkaline phosphatase that correct with treatment of hypothyroidism have also been reported.

Sjogren's syndrome is occasionally associated with Hashimoto's disease, which leads to diminished salivary volumes.

Nutritional Deficiencies

Although overall nutrient absorption is normal in hypothyroidism, malabsorption or deficiencies of micronutrients may occur. Iron deficiency anemia is frequently seen in premenopausal women with hypothyroidism as a result of menorrhagia, but may also occur as a result of impaired iron absorption. Folate deficiency may also rarely result from impaired intestinal absorption.

Ileal Brake

HENRY C. LIN AND NANCY LING
Cedars-Sinai Medical Center and David Geffen School of Medicine, University of California, Los Angeles

bioavailability The amount of an active agent, such as a drug, that is available at the targeted site after administration.
immunoneutralization Technique to abolish the effect of a circulating peptide by administering antibodies directed against the peptide.
peptide YY A distal gut peptide that is released in response to fat and is involved in the ileal brake and jejunal brake responses.
premeal A portion of food consumed shortly before the actual meal.

The ileal brake is one of the primary nutrient-triggered inhibitory feedback mechanisms that control transit of a meal through the gastrointestinal (GI) tract. It is activated when end products of digestion, such as fatty acids, come into contact with the distal small intestine. This braking response initiates a feedback reflex that inhibits upper GI motility to slow gastric emptying and transit through the small intestine. By controlling the speed of transit of a meal so that there is adequate time for assimilation of nutrients, the ileal brake works to optimize digestion and absorption.

COMPANION BRAKING MECHANISMS OF THE ILEAL BRAKE

The ileal brake works in concert with other transit controls, in particular, the jejunal brake, a similar transit regulatory mechanism located in the proximal end of the small intestine. However, the ileal brake is more potent than the jejunal brake. This difference allows the small intestine to vary its transit control response. For example, after a meal containing a difficult-to-assimilate food, nutrients would remain in the lumen to spread from the area of the proximal to the distal small intestine. Both the jejunal brake and the ileal brake will be activated in turn. The greater inhibitory feedback on transit that is then generated would work to ensure that there is adequate time for the assimilation of food. In addition to the jejunal brake, a duodenal brake and a colonic brake have also been described.

MEDIATORS OF THE ILEAL BRAKE

The precise neural circuitry mediating the ileal brake is an area of active research. Both gut peptides and nerves are involved in this response, as shown by the abolishment of the fat-induced ileal brake when either the distal gut peptide, peptide YY, was immunoneutralized or the inhibitory effect of an enteric opioid nerve was blocked.

CLINICAL EFFECTS OF ALTERED ILEAL BRAKE FUNCTION

The ileal brake response may be reduced or lost due to disease or intestinal resective surgery. When the control of GI transit is disrupted, the movement of a meal becomes accelerated. As a result, symptoms such as diarrhea, nausea, bloating, and abdominal pain develop. Consequences of such rapid transit may include maldigestion and malabsorption, leading to malnutrition and reduced bioavailability of oral medications. In the absence of the ileal brake, transit may become so markedly accelerated that end products of fat digestion are not adequately available. As a result, the remaining transit controls, such as the jejunal brake, are unable to compensate for the loss of the ileal brake response.

ACTIVATING THE ILEAL BRAKE AND JEJUNAL BRAKE AS TREATMENT

Intestinal transit is accelerated in many diarrheal conditions and rapid gastric emptying disorders. Since end products of fat digestion serve to trigger the ileal brake and the jejunal brake, a nutrient-based treatment using a premeal containing oleic acid has been shown to slow transit and reduce symptoms in these patients.

cystectomy Surgical removal of the urinary bladder.

familial polyposis coli General neoplastic disorder of the intestine, presenting most commonly as multiple polyps in the colon.

Anileoanal pouch is produced in a procedure whereby the colon and rectum are removed but the anus and anal muscles are retained. A reservoir, or pouch, is then created, using the ileum such that continence of fecal matter is preserved.

INTRODUCTION

The ileal pouch reservoir was first described more than 70 years ago. It was constructed from an isolated segment of ileum shaped into a doubly folded loop after rectal excision for carcinoma. The procedure has evolved from the use of a straight ileal–anal anastomosis to the use of variously shaped reservoirs (J, S, or W pouches). The rationale for the pouch came about as an idea for pooling the intestinal content in the ileal reservoir; it was experimentally described by Valiente and Bacon in 1955 for rectal replacements in dogs. The procedure for clinical use in humans, introduced by Professor Nils Kock in 1969, was initially used as a bladder replacement following cystectomy. Later, the ileal anal pouch was used as the replacement for the resected rectum, as by Parks and Nicholls. These early experiences with ileal pouch formation, along with the endoanal sleeve technique devised by Alan Parks for cancer operations, have motivated surgeons to perform these procedures such that a pouch procedure restorative has become an alternative to a permanent ileostomy after proctocolectomy for ulcerative colitis (UC) and familial adenomatous polyposis (FAP).

PREOPERATIVE PREPARATIONS

As in other major operations, the patient's medical status is optimized for the procedure to ensure low or no morbidity. Correction of anemia, fluid depletion, and

familial polyposis coli General neoplastic disorder of the intestine, presenting most commonly as multiple polyps in the colon.

Anileoanal pouch is produced in a procedure whereby the colon and rectum are removed but the anus and anal muscles are retained. A reservoir, or pouch, is then created, using the ileum such that continence of fecal matter is preserved.

INTRODUCTION

The ileal pouch reservoir was first described more than 70 years ago. It was constructed from an isolated segment of ileum shaped into a doubly folded loop after rectal excision for carcinoma. The procedure has evolved from the use of a straight ileal–anal anastomosis to the use of variously shaped reservoirs (J, S, or W pouches). The rationale for the pouch came about as an idea for pooling the intestinal content in the ileal reservoir; it was experimentally described by Valiente and Bacon in 1955 for rectal replacements in dogs. The procedure for clinical use in humans, introduced by Professor Nils Kock in 1969, was initially used as a bladder replacement following cystectomy. Later, the ileal anal pouch was used as the replacement for the resected rectum, as by Parks and Nicholls. These early experiences with ileal pouch formation, along with the endoanal sleeve technique devised by Alan Parks for cancer operations, have motivated surgeons to perform these procedures such that a pouch procedure restorative has become an alternative to a permanent ileostomy after proctocolectomy for ulcerative colitis (UC) and familial adenomatous polyposis (FAP).

PREOPERATIVE PREPARATIONS

As in other major operations, the patient's medical status is optimized for the procedure to ensure low or no morbidity. Correction of anemia, fluid depletion, and

Copyright 2004, Elsevier (USA). All rights reserved.

electrolyte and acid–base disorders and nutritional assessment are mandatory. Many patients require total parenteral nutrition (TPN) and bowel rest because eating may worsen colitis symptoms. The simplest surgical corrective procedure should be performed in such severely compromised patients. Colon preparation may not be necessary and may be poorly tolerated, because the majority of these patients have severe diarrhea. The type of bowel preparation will depend on the patient's preoperative condition (bowel obstruction, frequent diarrhea); bowel preparations that are too aggressive may further compromise the patient. A double antibiotic prophylaxis has been shown to be of benefit in immunocompromised patients and in patients on whom surgery is being performed below the peritoneal reflection. Antibiotics (neomycin and erythromycin base regimen) are given orally 1 day prior to surgery and are given intravenously at induction of anesthesia in order to decrease the incidence of infectious complications.

Often these procedures require a temporary diverting ileostomy. A staged procedure would require a marked site for the loop ileostomy preoperatively, and the patient should have been seen by a stomatherapist. Patients on high-dose steroids preoperatively will require parenteral steroids in the perioperative period until their baseline physiological dose has being reached postoperatively.

SURGICAL TECHNIQUES

Position

Most patients can have the total procedure performed in the lithotomy position However, some patients require a mucosectomy of the very last few centimeters of the rectal mucosa. To facilitate the procedure, the prone jackknife position can be used at the start of the procedure for the rectal mucosectomy performed per anus. This position allows for greater exposure than is possible with the lithotomy position. After the mucosectomy, the patient is turned to the lithotomy position for the abdominal phase of the operation.

Creation of the Ileoanal Pouch

Total abdominal proctocolectomy is carried out as for colectomy, with the colon mobilized from the ileocecal to the rectosigmoid junction. It is important to dissect as close to the rectal wall as possible to avoid injury to the pelvic autonomic nerves. To transect the distal rectum/proximal anus, a stapling device is placed in the pelvis. A finger or sigmoidoscope ascertains the position of the stapler in relation to the dentate line. The distal rectum/upper anus is stapled off, leaving no more than 3 cm of distal rectum above the dentate line (it is, in fact, preferable to leave as little mucosa as possible while preserving all of the anal sphincters).

Once the rectum is removed, the ileal pouch is created. The ileal mesentery is freed from the retroperitoneum up to the lower duodenal margin, to increase the length of the mesentery so that it can reach the pelvis. In general, the distal ileum at the apex of the pouch that is to be created needs to be able to reach to the lower border of the pubis. The ileum is then folded into the general shape of the pouch to be formed. Ileoanal pouches are usually made into two shapes. The J pouch is made out of the distal ileum folded back onto itself once, whereas the S pouch is made by folding the distal ileum twice. The J-pouch is usually made 15 cm in length and can be constructed with a bowel anastomotic stapling device. The S pouch must be hand sewn. Because of its simplicity and the speed at which it can be made using a stapler, the J pouch is made more often (see Figs. 1 and 2).

To anastomose the pouch to the distal rectum /anus, a circular stapling device is usually used. The anvil of the circular stapler is sutured into the apex of the pouch through the enterotomy made for the linear cutting stapling device, using a pursestring suture. To perform the anastomosis, the circular stapler with the trocar is placed into the anorectal stump and the trocar is advanced, piercing the stapled upper anus either near or directly through the staple line. The trocar is removed and the anvil in the pouch is brought down to the accepting socket of the circular device. The bowel ends are apposed and stapling device is fired, ensuring that the pouch is not twisted.

Mucosectomy and Cuff Formation

In some patients, the situation requires removal of the mucosa of the last 0–3 cm of distal rectum. This procedure is called a mucosectomy because only the mucosa is removed, with the anal muscles and residual muscularis propria of the rectal cuff preserved. With the patient in either the lithotomy or prone position, the dissection starts just above the dentate line. The mucosa is raised off the anal muscles using saline or a weak epinephrine solution. The mucosa is then stripped away from the internal anal sphincter and muscularis propria. All mucosa is removed. Hemostasis is ensured with cauterization.

The ileal pouch is anastomosed in a series of handsewn sutures using a long-term absorbable braided suture. Eight to 12 full-thickness sutures are placed

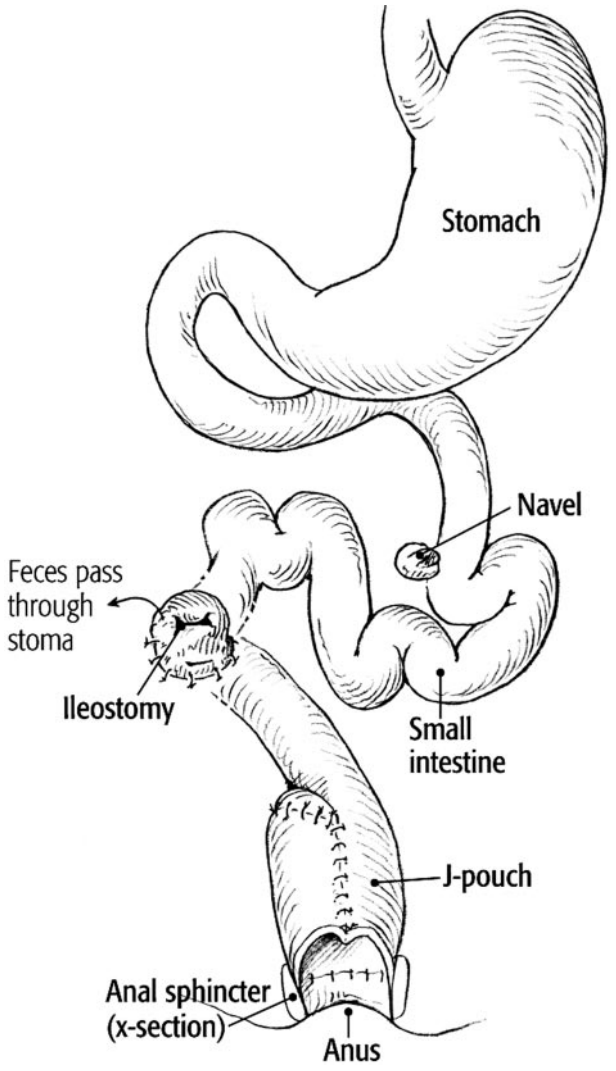

FIGURE 1 A J pouch and temporary stoma.

through the pouch wall and the internal sphincter, and out through the dentate line mucosa to complete the anastomosis. The anastomosis is then checked digitally for any gaps.

Other Pouches

Though the S pouch was the first clinically applied pelvic pouch, the J pouch is now most commonly used. The S-shaped pouch is formed by folding three ileal limbs 10 cm in length. On the distal limb, an extra 1 to 2 cm is left to project into the anal canal. This small spout is then anastomosed end to end to the anal canal. The S pouch causes greater difficulty in evacuation and takes a longer time to construct. A W pouch has been described as two J pouches placed together. The terminal end of the small intestine is folded into four loops, 12 cm long, forming the W pouch. A side-to-end anastomosis is made directly between the anal canal and reservoir. The W pouch and the J pouch have been shown to have equivalent function that, but not enough data have been collected to show that there is any value added to J pouch.

In addition to the J, W, and W types of reservoirs, several other variations have been described. The best known is the Kock, or K, pouch. This is an abdominal pouch that consists of a reservoir constructed from the small intestine, and a nipple valve that keeps the contents of the reservoir inside the body, permitting entry of an external catheter to drain the pouch when desired. Occasionally the Kock pouch can be converted to a pelvic pouch after a period of pouch dilatation, with anastomosis to the anus allowing restoration of intestinal continuity. It is an alternative for patients who have a standard (Brooke) ileostomy, or who have poor results with an ileoanal operation.

These operations can be carried out either in one, two, or three stages. The most common approach is the two-stage procedure. In the first stage, the colon and rectum are removed, the ileoanal pouch is created, and the surgeon creates a diversion ileostomy to protect the neorectal pouch and ileoanal anastomosis. This procedure is preferable to the one-stage procedure because it is associated with a lower rate of pelvic sepsis. It is especially important to limit pelvic septic complications in women of childbearing age, because the incidence of infertility after pelvic sepsis is high. The ileostomy helps ensure that any clinical problems are not worsened by a small anastomotic leak.

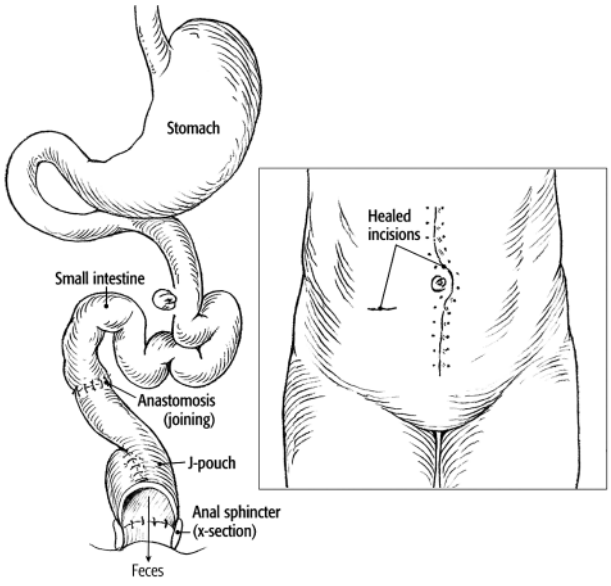

FIGURE 2 A J pouch reconnection.

Hand-Sewn vs. Stapled Anastomosis

The hand-sewn anastomosis with rectal mucosectomy was first employed for the ileoanal J pouch. However, a modification of the hand-sewn anastomosis was utilized after the introduction of the double-stapled technique for pelvic procedures. The stapled technique has resulted in a shorter operative time compared to the hand-sewn operation. It is also suggested that this technique improves continence by preserving the anal transition zone (ATZ) and by reducing the injury sustained on the anal sphincter mechanism by the prolonged dilatation required for completion of the mucosectomy. Some surgeons, however, suggest that the hand-sewn procedure is preferred, because the retained ATZ may be a source of diseased mucosa. Second, it is questionable that the early functional outcome of the stapling technique is better than the hand-sewn procedure over time. Data from retrospective series are inconclusive. The stapled anastomosis with the retained ATZ provides better nocturnal continence and better discrimination of flatus versus stool. Unless there are multiple polyps in the distal 3 cm of mucosa in a patient with FAP, or severe dysplasia in a patient with colitis, it is preferable to perform the stapled anastomosis. An attempt should be made to leave only 1–2 cm of mucosa above the dentate line in order to minimize any potential symptoms or problems associated with longer amounts of mucosa.

POSTOPERATIVE CARE

In the immediate postoperative period, observations of the vitals signs are monitored; hemoglobin and electrolytes are checked and corrected as necessary. The urinary catheter is removed after 3–5 days. Patients also should have prophylaxis against deep venous thrombosis. Watery stool usually begins within 48–72 hours after operation and can be as frequent as 10–15 times a day. Loperamide or codeine can be given to decrease the frequency of stool passage. Infection, ileus, and obstruction are the most common serious complications that need to be watched for in the first 30 days postoperatively.

After takedown of the temporary ileostomy (usually between 8 and 12 weeks after the first stage), soiled perianal skin is rinsed and kept dry to avoid skin ulcers and infections. Oral intake is allowed after 1 day, with a gradual increase in solid food. Advice is given about diet and the use of medications to slow the frequency of bowel movements if needed. Patients are followed for 1–3 months until the frequency of bowel movements settles down to six times per 24 hours. Patients are then followed on an annual basis.

COMPLICATIONS

The mortality after pouch–anal anastomosis is very low in all reported series (approximately 0.5%). General complications such as wound and chest infections, urinary retention, and deep venous thrombosis must be monitored and treated. Early complications specific to the procedure include cuff abscesses, anastomosis dehiscence, and intestinal obstruction. Metabolic disturbances due to dehydration can occur because the evacuation rate in the early days can be high. Late complications include a condition called pouchitis. Its incidence is 10–30% and it is most often treated with antibiotics or probiotics. If a patient develops severe and debilitating pouchitis or anal fistulas, Crohn's disease should be considered. Fistula formation can occur from the pouch or from the anastomosis to the urinary tract, vagina, perineum (vulva), or anterior abdominal wall.

Recurrent colitis can rarely cause disease in the residual mucosa. Polyps can sometimes occur in patients with FAP. There is a small risk for progression to malignancy both in patients who have had a mucosectomy and in those who have not, therefore all patients require annual surveillance.

QUALITY OF LIFE

The restorative proctocolectomy with ileopelvic reservoir is a safe procedure, but the incidence of postoperative morbidity can be high. Studies in the form of questionnaires with a scoring system have assessed the functional outcome and the effects on the lifestyle of patients who have undergone these procedures. For instance, quality of life (QOL) may be better in the patient group that had the procedure done for ulcerative colitis compared to patients with FAP. This may be due to the fact that, before the procedure, patients with ulcerative colitis are more symptomatic as compared to patients with FAP. In general, most patients attain a high QOL postoperatively. They show improvement in QOL compared to their preoperative condition and they also have a higher QOL than do those with a permanent ileostomy.

CONTRAINDICATIONS TO POUCH FORMATION

A contraindication to ileoanal pouch procedure, as in any operation to preserve anorectal continence, is absence preoperatively of an efficient anal sphincter complex. Therefore, the presence of fecal incontinence or lax anal tone should be screened for preoperatively. In

many major series, patients with Crohn's disease generally seem to do badly, with ileoanal pouch anastomosis complicated with fistulas and abscesses. In patients without anal or small bowel disease, there is evidence that about 80% of patients have a satisfactory outcome after creation of an ileoanal pouch.

Patients selected should be highly motivated, because complications often occur and may frequently require further operations. Therefore, patients should be fully informed of the potential risks and benefits of the procedure. Contact with other patients who have had the procedure, whatever the outcome, should be encouraged. Age does not seem to be a contraindication as long as there is no significant sphincter dysfunction and no serious comorbidity, because the operation is very lengthy.

Immunodeficiency

MATTHIEU ALLEZ* AND LLOYD MAYER†
*Hopital Saint-Louis, Paris and †Mount Sinai Medical Center, New York

agammaglobulinemia Total absence of antibody.
antibody/immunoglobulin Protein elicited in response to antigen; there are five primary forms, IgG, IgA, IgM, IgE, and IgD. There are four subclasses of IgG (IgG1–IgG4) and two subclasses of IgA (IgA1 and IgA2).
antigen/immunogen Any compound that can elicit an immune response.
B lymphocyte Precursor of an antibody-producing cell (plasma cell); has a surface antigen receptor that can recognize antigens in solution.
immunodeficiency Any state in which the host's immune system (antibodies, T cells) is not functioning at optimal capacity.
T lymphocyte Cell of the immune system that regulates immunity; recognizes only foreign protein/antigen in the context of major histocompatibility antigens.

Primary immunodeficiencies are caused by inherited defects of the immune system. Most patients manifest their immunodeficiency by developing infections involving the sinuses and the lungs. Gastrointestinal manifestations, however, are particularly frequent, and in some cases may represent the main complaint in patients with primary immunodeficiency. The most common primary immunodeficiencies are characterized by an impaired ability to produce specific antibodies. These antibody deficiencies are often diagnosed in childhood or adolescence, but are sometimes apparent only in adulthood. Primary T cell immunodeficiencies are rarer and are generally diagnosed early in life.

CLASSIFICATION OF PRIMARY IMMUNODEFICIENCIES

Primary Antibody Deficiencies

Common Variable Immunodeficiency

Common variable immunodeficiency (CVI) is the most common clinically significant antibody deficiency (Table I) of adults, with a prevalence estimated from 1 in 50,000 in Sweden. CVI is a heterogeneous group of immunodeficiency disorders, characterized by decreased serum immunoglobulin levels and heterogeneous clinical features. Patients with CVI usually develop symptoms either as adolescents or as young adults and present most commonly with recurrent sinopulmonary infections and gastrointestinal disorders. Frequently, however, the diagnosis may not be obvious until late adult life. Respiratory infections often involve encapsulated bacteria (*Haemophilus influenzae, Streptococcus pneumoniae*). CVI patients may develop bronchiectasis or restrictive or obstructive lung disease. Immunoglobulin G (IgG) levels are typically less than 300 mg/dl with concurrent low IgA and IgM levels. Circulating B cells are generally not decreased in number, but they may exhibit defects in growth and differentiation. The treatment of CVI is intravenous (iv) immunoglobulin replacement and antibiotics, which may prevent the recurrence of infections and the development of irreversible lesions in the lungs. However, iv immunoglobulin replacement does not seem to prevent the gastrointestinal disorders observed in CVI patients.

Selective IgA Deficiency

Selective IgA deficiency is the most common immunodeficiency, present in 1 in 300–700 Europeans and North Americans. Levels of serum IgA are less than 5 mg/dl, with normal or increased concentrations of other serum immunoglobulins. The number of circulating B cells is normal. In most individuals, there is a decreased level of secretory IgA at mucosal surfaces, which can be compensated for by an increased production of secretory IgM. A majority of IgA-deficient patients are asymptomatic and need no treatment. Others may have allergic manifestations, recurrent sinopulmonary infections, or autoimmune disorders. These

TABLE I Classification of Primary Immunodeficiencies

Primary antibody deficiencies	Primary T cell immunodeficiencies
X-Linked agammaglobulinemia	Severe combined immunodeficiency
Selective IgA deficiency	DiGeorge syndrome
Selective deficiency of IgG subclasses	Ataxia–telangiectasia
Common variable immunodeficiency	Wiskott–Aldrich syndrome

Copyright 2004, Elsevier (USA). All rights reserved.

symptomatic patients often have concurrent IgG2 deficiency. Only patients with severe sinopulmonary infections and those with concomitant IgG defects are candidates for iv immunoglobulin replacement therapy. A small subset of these patients have anti-IgA antibodies, which may increase the risk for anaphylactic reactions to iv immunoglobulins or other blood products.

X-Linked Agammaglobulinemia (Bruton's Disease)

X-Linked agammaglobulinemia (XLA) is a rare immunodeficiency, with an incidence of approximately 1 in 10^5 births. This deficiency is characterized by a failure of B cells to mature beyond the pre-B cell stage and the consequent inability to produce all classes of immunoglobulins. The inherited defect is mapped to the gene encoding Bruton's tyrosine kinase (Btk), located on the long arm of the X chromosome. Defects in this intracellular tyrosine kinase block the maturation of pre-B cells. XLA patients (young males) typically present with recurrent bacterial infections, especially with encapsulated bacteria such as *S. pneumoniae* and *H. influenzae*. The treatment of XLA is iv immunoglobulin replacement.

Primary T Cell Deficiencies

DiGeorge Syndrome

Patients with DiGeorge syndrome have thymic hypoplasia with or without parathyroid glands (hypocalcemia and tetany), cleft palate, and other facial anomalies (due to a defect in the migration of the third and fourth branchial pouches). The T cell deficiency is variable from patient to patient (depending on the degree of thymic aplasia) and may predispose patients to opportunistic infections, such as *Pneumocystis carinii*, candidiasis, and viral infections.

Ataxia–Telangiectasia

Ataxia–telangiectasia is inherited in an autosomal recessive pattern. The first symptoms, cerebellar ataxia and telangiectasias (of the conjunctiva, nose, ears, or shoulders), appear in young patients between 2 and 5 years of age. They have thymic hypoplasia and impaired T cell function. IgA deficiency is found in 50% of patients. These patients have a high risk of malignancy.

Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome (WAS) is a rare X-linked recessive disorder. Patients usually present with eczema, thrombocytopenia (and hemorrhage), impaired T cell function, and recurrent opportunistic infections. The genetic defect is a mutation in the WAS protein, which is involved in intracellular signaling and actin/cytoskeletal rearrangements within the lymphocyte. Bone marrow transplantation is the treatment of choice for long-term survival.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a heterogeneous set of congenital immune disorders in which there is deficiency of both T and B cell development and function. Patients usually present with severe recurrent bacterial or viral infections during the first year of life. These patients have few or no circulating lymphocytes. SCID patients are susceptible to both bacterial and opportunistic infections. The standard treatment for SCID is bone marrow transplantation.

GASTROINTESTINAL MANIFESTATIONS

Primary Antibody Deficiencies

Gastrointestinal manifestations are quite frequent in patients with CVI; 40–60% experience chronic diarrhea and many have malabsorption. These manifestations may reflect gastrointestinal infections, particularly by *Giardia lamblia*, but also diverse inflammatory disorders and malignant conditions. CVI patients may have lymphoproliferative disorders, such as diffuse nodular lymphoid hyperplasia (NLH) of the small bowel, which may represent a premalignant condition. Most patients with IgA deficiency do not have gastrointestinal manifestations, but when symptoms occur they are similar to those observed in CVI.

Infection with *G. lamblia* may cause chronic diarrhea with malabsorption in patients with antibody deficiencies, particularly with CVI. Symptoms frequently consist of an abrupt onset of watery diarrhea with abdominal cramping, bloating, and anorexia. The diagnosis is made by stool examination, demonstrating the presence of cysts or trophozoites, but frequently requires duodenal biopsies or aspirates. Duodenal biopsies may show mucosal damage with villous atrophy. The course of the infestation, which is usually short in immunocompetent patients, may last several months in CVI patients. Treatment with metronidazole reverses the symptoms and mucosal damage and is often used as a therapeutic test for *Giardia* infection. Treatment with iv immunoglobulins may reduce the risk of recurrent giardiasis, although there are limited data to support this and T cell immunity appears to be more important in the clearance of this infection. Prolonged *G. lamblia* infestation may also be observed in IgA deficiency, but is much less frequent than in CVI.

Patients with CVI have also a slightly increased prevalence of infections with *Salmonella* and *Campylobacter jejuni*. Cryptosporidiosis has also been described in CVI patients, although the incidence is low. One other real consideration is the role that *Clostridium difficile* may play in recurrent diarrhea in these patients, especially considering the amount of antibiotics used in treatment of infections.

Some patients with CVI present with atypical inflammatory gastrointestinal disease that is unrelated to *G. lamblia* and results in diarrhea, malabsorption, and weight loss. Villous atrophy on duodenal biopsies may be observed in some cases, similar to the lesions observed in celiac disease. However, antibodies against gliadin and endomysium are generally not found in the serum of these patients. More importantly, gluten-free diets seem to have no effect on the clinical course or on the villous atrophy in the majority of patients. Among the CVI patients in a series at The Mount Sinai Medical Center in New York, six had a villous atrophy that did not improve with a gluten-free diet.

After intestinal infection has been ruled out, steroid and/or immunomodulator (6-mercaptopurine/azathioprine) therapy may be considered in these patients. Such therapy should be used with caution in these patients for obvious reasons. However, the overwhelming majority of patients tolerate immunomodulators quite well while they are receiving iv immunoglobulins. The doses used to control inflammation are never so high as to further compromise immune function (1.5–2.5 mg/kg for 6-mercaptopurine and azathioprine, respectively). In contrast, severe adverse events have been reported in CVI patients receiving steroids or methotrexate (detailed later).

There is a stronger association between IgA deficiency and celiac disease. Of patients with celiac disease, 2% have IgA deficiency. Intestinal biopsy findings in these patients are similar to those seen in classical celiac disease except for an increase in IgM plasma cells in the lamina propria. In contrast to CVI, patients with IgA deficiency and celiac disease may respond normally to treatment with a gluten-free diet.

There is an increased frequency of atrophic gastritis and/or pernicious anemia in patients with CVI. Pernicious anemia may be even more frequent in IgA-deficient patients. The diagnosis is made at an earlier age (20–40 years old) than in immunocompetent patients (60 years old). In contrast to pernicious anemia in immunocompetent individuals, antibodies directed against parietal cells and intrinsic factor are not found in the serum. Histological findings are similar, except for the absence of plasma cells in the lamina propria of CVI patients. These findings suggest that pernicious anemia in this setting is not antibody mediated. CVI patients have an increased risk, compared to the general population, of developing gastric adenocarcinoma, which may be related to the increased frequency of atrophic gastritis (see later).

There is also an increased frequency of inflammatory bowel disease in CVI patients. Many cases of ulcerative colitis and Crohn's disease have been reported. In the Mount Sinai series, among 248 patients with CVI, 16 (6%) had inflammatory bowel disease (IBD), 7 had ulcerative colitis, and 9 had Crohn's disease. Hermaszewski *et al.* reported 10 cases of IBD among 240 patients with CVI, and 3 cases among 44 patients with agammaglobulinemia. Teahon *et al.* reported 12 patients with CVI or agammaglobulinemia when chronic diarrhea was explored by upper and/or lower endoscopy and biopsy; 4 of 8 patients had villous atrophy on duodenal biopsies and 8 of 10 had microscopic colitis. Two of these patients had multiple stenoses in the small bowel, suggestive of Crohn's disease. Cases of inflammatory bowel disease have been reported in IgA-deficient patients, but the frequency of IBD does not seem to be increased. IBD in patients with CVI seems to respond normally to conventional therapeutic approaches. Steroids and immunomodulatory agents (such as 6-mercaptopurine/azathioprine) can be used in these patients. Patients with CVI-associated IBD may experience long-term remissions with these therapies. However, as is the case for refractory sprue, data from the Mount Sinai series suggest that specific types of immunosuppression in CVI patients may result in complications. Indeed, four patients receiving steroids had major complications: *Pneumocystis carinii* pneumonia, a *Nocardia* brain abscess, a progressive multifocal leukoencephalopathy, and a severe anaerobic leg infection leading to amputation. Two patients receiving methotrexate for autoimmune disease (both had a prior history of Hodgkin's disease) developed either an additional malignancy or recurrent disease.

Nodular lymphoid hyperplasia, defined as multiple discrete mucosal nodules confined to the lamina propria and superficial submucosa, is found frequently in CVI patients. The nodules represent hyperplastic lymphoid tissue with prominent germinal centers. About 10–20% of CVI patients have diffuse intestinal NLH. NLH can affect the ileum and/or the colon of immunocompetent children and young adults, but the diffuse form of NLH is mainly observed in patients with primary immunodeficiencies. The exact meaning of this manifestation in these patients is unknown, but could reflect a compensatory B cell proliferative response to an increase in the precursor pool of antibody-producing cells. There have been several reports of patients with

diffuse NLH, both immunodeficient and immunocompetent, who developed small intestine lymphomas (see later), and several reports in the literature suggest that diffuse NLH could be a premalignant condition. Diffuse NLH is seen less frequently in selective IgA deficiency than in CVI patients.

Patients with CVI are reported to have an increased prevalence of, and mortality due to, malignant neoplasms. The immunodeficiency cancer registry has reported 120 cases of cancer among CVI patients. The predominant tumors were non-Hodgkin lymphomas (55 cases, 48%), followed by gastrointestinal carcinomas (30 cases, 25%), predominantly of the stomach (19/30), and Hodgkin's disease (8 cases, 7%). The relative risk of non-Hodgkin lymphoma has been reported to range from 47-to 438-fold in the general population. From 1.4 to 7% of CVI patients may develop a lymphoma, which occurs typically after 40 years of age and more often in women. These lymphomas are generally extranodal and of a B cell type, and may be associated with Epstein–Barr virus (EBV) infection. As mentioned earlier, some small intestinal lymphomas described in CVI patients are associated with diffuse NLH. Several cases of T cell lymphomas have been described in CVI patients. A majority of these lymphomas are located in the small bowel and are associated with nodular lymphoid hyperplasia. Some cases of colonic lymphomas have been reported simulating, in one case, cryptogenic colitis.

The increased risk of cancer in patients with CVI includes an increased frequency of gastric adenocarcinoma (30-fold). Three cases were reported in a series of 240 patients with CVI, and two cases in another series of 248 patients. As mentioned earlier, the increased risk of gastric adenocarcinoma in CVI patients could be linked to the increased frequency of atrophic gastritis in those patients. This risk could justify an endoscopic survey of these patients, particularly in cases of atrophic gastritis. In a recent study, there was an increased prevalence of *Helicobacter pylori* infection in CVI patients with dyspepsia, and these patients had an increased frequency of multifocal gastritis. More interestingly, this study suggested that *H. pylori* may play a role in gastric carcinogenesis in patients with CVI. Last, the incidence of colonic cancer is not increased in CVI patients but has been reported in young patients with agammaglobulinemia.

Primary T Cell Deficiencies

The clinical manifestations observed in patients with ataxia–telangiectasia are mainly related to the deficiency in IgA and IgG2. Thus, the gastrointestinal manifestations are similar to those observed in patients with antibody deficiencies. The occurrence of chronic diarrhea and/or of malabsorption suggests the possibility of an infection with *G. lamblia*. Malignant disorders are particularly increased in these patients. Indeed, patients with ataxia–telangiectasia have a risk of cancer, mainly lymphomas, 78-fold higher when compared to the general population. This may relate to the defects in DNA repair mechanisms seen in these patients. However, the frequency of cancers or lymphoma in the gastrointestinal tract has not been specified in the literature.

Gastrointestinal manifestations are rare in patients with Wiskott–Aldrich syndrome. There is also an increased risk of cancer in this population, with an incidence estimated at 2% per year. Intestinal hemorrhage may occur because of thrombocytopenia. Interestingly, the mouse model of WAS is associated with colitis and there have been some reports of colitis in patients with this disease.

The frequency of digestive manifestations does not seem increased in patients with DiGeorge syndrome, except for intestinal infections. Oral candidiasis is frequent and viral infections causing diarrhea and necrotizing enterocolitis have been reported.

Children with severe combined immunodeficiency (SCID) often present with intractable diarrhea with villous atrophy, which is resistant to medical treatment. These children may present with oral candidiasis and viral infections; rotavirus, adenovirus, or picornavirus. After bone marrow transplantation, graft-versus-host disease with wasting and diarrhea may develop.

CONCLUSION

Patients with primary immunodeficiencies, particularly with antibody deficiencies, have frequent gastrointestinal manifestations. In some cases, gastrointestinal manifestations may represent the only complaint. Thus, physicians should be aware of these manifestations and be able to recognize these immunodeficiencies, which can first present in adulthood. Furthermore, progress in the management of severe immunodeficiencies allows more patients to survive into adulthood.

Immunoglobulins

MICHAEL E. LAMM
Case Western Reserve University, Ohio

polymeric immunoglobulin receptor Transmembrane protein expressed on the basolateral surface of epithelial cells lining mucous membranes; binds polymeric IgA and also IgM and transcytoses them into the lumen.

secretory component External domain of the polymeric immunoglobulin receptor; remains attached to the secreted antibody.

The immunoglobulins of the gastrointestinal tract and their secretion reflect the special features of this branch of the mucosal immune system. Immunoglobulins of the gastrointestinal tract and antibodies in serum, which reflect systemic immunity, are markedly different.

DOMINANCE OF IgA

Although every class of immunoglobulin (Ig)—IgA, IgD, IgE, IgG, and IgM—is present in the wall of the gastrointestinal tract as a result of local synthesis and diffusion from serum, IgA is quantitatively and functionally the most important. IgA also predominates in the lumen as a result of both extensive local synthesis in the intestinal mucosa and a specific transport mechanism across the epithelium. Hence, this discussion focuses on IgA, although other immunoglobulin classes undoubtedly play significant roles under particular circumstances (e.g., IgA deficiency; allergy).

ORIGIN OF INTESTINAL IgA

Most of the IgA in the intestinal tract is produced locally by the abundant plasma cells in the lamina propria. Precursors of these cells arise in foci of organized lymphoid tissue, exemplified by the Peyer's patches, which underlie specialized epithelial cells, the M cells, that transport antigens intact from the lumen for processing and presentation. The net effect, due largely to the particular mix of local cytokines, is the start of a differentiation and maturation process on the part of B cells that results in a commitment to IgA production. The B cells then leave the Peyer's patches in the efferent lymph and reach the mesenteric lymph nodes. Next, they exit via the efferent lymph to reach the thoracic duct, from which they enter the blood and selectively traffic to the intestines, where they lodge in the lamina propria. Mechanistically, this selective homing reflects particular receptor–counterreceptor interactions between molecules on the B cell surface and the intestinal venule endothelium, as well as local chemotactic factors. In the lamina propria, the B cells complete their differentiation into plasma cells and secrete IgA, mostly in polymeric form. (In contrast, the IgA in serum is mostly monomeric.) The IgA polymers bind to the polymeric immunoglobulin receptor on the basolateral surface of the lining epithelial cells. The IgA–receptor complex is then endocytosed, transcytosed, and released as secretory IgA from the apical surface into the lumen with the IgA attached to the external domain of its receptor. The entire process results in the intestinal secretion of some 40 mg of IgA per kilogram of body weight per day. In addition to secretory IgA, the lumen contains smaller amounts of IgM, which is transported by the same active mechanism, as well as other immunoglobulins that diffuse passively from the lamina propria across the epithelium.

FUNCTIONS OF INTESTINAL IgA

IgA is thought to function in host defense mainly by providing an immune exclusion barrier in the luminal secretions. Here, IgA antibodies help prevent microbes and inert antigens from attaching to or penetrating the epithelium. In addition, during their ongoing transit through epithelial cells to the secretions, IgA antibodies are thought to be able to neutralize viruses that may be infecting the epithelium and transport antigens from the lamina propria through the epithelial cells into the luminal secretions, a kind of excretory immune system. In sum, luminal IgA antibodies should be capable of preventing infections, hence the rationale for mucosal vaccines, whereas the intraepithelial cell neutralization and excretory properties of IgA could assist in the recovery from infections.

A distinctive feature of IgA compared to other classes of antibody is its general noninflammatory tone. For example, unlike IgM and IgG, it activates

 Copyright 2004, Elsevier (USA). All rights reserved.

complement poorly, if at all, and unlike IgE, it does not promote the release of mediators of allergic inflammation. Thus, IgA antibodies can bind to ever-present antigens, such as those of food and the intestinal flora, without provoking inflammation.

Imperforate Anus

ROBERT W. CHANG, STEVEN M. ANDREOLI, AND MORITZ M. ZIEGLER
Children's Hospital Boston

appendicostomy An opening that affords access to the large intestine through the tip of the vermiform appendix. It is usually attached to the anterior abdominal wall and is used for irrigation and bowel management in some older patients with bowel dysfunction following imperforate anus repair.

cloaca A common channel for fecal, urinary, and sexual material passage, typically seen in lower vertebrates. In humans, it denotes an embryologic abnormality in which the terminal hindgut fails to divide into the rectum, bladder, and genital primordium.

fistula An abnormal communication between two or more epithelial-lined organs or between an epithelial-lined organ and the surface of the body.

Imperforate anus encompasses a wide range of congenital anorectal malformations involving atresia of the anal canal. The spectrum includes simple perineal fistulas to the complex cloacal malformations. Each anatomic anomaly requires specialized treatment and portends an individual outcome.

INTRODUCTION

Imperforate anus and associated anorectal malformations are well-known entities in pediatric surgery and pose a significant challenge to the clinician. These defects are frequently associated with lifelong debilitating sequelae such as fecal and urinary incontinence and sexual inadequacy.

The pathogenesis of imperforate anus evolves as early as the sixth week of gestation when the urorectal septum migrates caudally to divide the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. Failure of the urorectal septum to form results in an abnormal connection between the gastrointestinal and genitourinary tracts, gender differences notwithstanding. The development of the perineum can also influence the positioning of the anal opening.

Imperforate anus has long been recognized as a surgically correctable defect. In 1835, Amussat sutured the rectal wall to the skin edges, which likely constituted the first known "anoplasty." For the first half of the 20th century, perineal anoplasty without colostomy for "low" malformations and newborn colostomy plus abdominoperineal resection for "high" malformations were preferred treatments. In 1953, Stephens performed the first objective study of human specimens. He proposed an initial sacral approach followed by abdominoperineal resection when necessary. The purpose of this approach was to preserve the puborectalis sling, which was thought to be a key determinant in a successful outcome. Many of the surgical developments of the following period held to these same ideals.

appendicostomy An opening that affords access to the large intestine through the tip of the vermiform appendix. It is usually attached to the anterior abdominal wall and is used for irrigation and bowel management in some older patients with bowel dysfunction following imperforate anus repair.

cloaca A common channel for fecal, urinary, and sexual material passage, typically seen in lower vertebrates. In humans, it denotes an embryologic abnormality in which the terminal hindgut fails to divide into the rectum, bladder, and genital primordium.

fistula An abnormal communication between two or more epithelial-lined organs or between an epithelial-lined organ and the surface of the body.

Imperforate anus encompasses a wide range of congenital anorectal malformations involving atresia of the anal canal. The spectrum includes simple perineal fistulas to the complex cloacal malformations. Each anatomic anomaly requires specialized treatment and portends an individual outcome.

INTRODUCTION

Imperforate anus and associated anorectal malformations are well-known entities in pediatric surgery and pose a significant challenge to the clinician. These defects are frequently associated with lifelong debilitating sequelae such as fecal and urinary incontinence and sexual inadequacy.

The pathogenesis of imperforate anus evolves as early as the sixth week of gestation when the urorectal septum migrates caudally to divide the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. Failure of the urorectal septum to form results in an abnormal connection between the gastrointestinal and genitourinary tracts, gender differences notwithstanding. The development of the perineum can also influence the positioning of the anal opening.

Imperforate anus has long been recognized as a surgically correctable defect. In 1835, Amussat sutured the rectal wall to the skin edges, which likely constituted the first known "anoplasty." For the first half of the 20th century, perineal anoplasty without colostomy for "low" malformations and newborn colostomy plus abdominoperineal resection for "high" malformations were preferred treatments. In 1953, Stephens performed the first objective study of human specimens. He proposed an initial sacral approach followed by abdominoperineal resection when necessary. The purpose of this approach was to preserve the puborectalis sling, which was thought to be a key determinant in a successful outcome. Many of the surgical developments of the following period held to these same ideals.

Pena and colleagues performed the first posterior sagittal approach for anorectal malformations in 1980 (posterior sagittal anorectoplasty, or PSARP). Its description, published in 1982, has been time-tested and has vastly changed the treatment for this group of anatomic defects. This technique allowed direct exposure of the anatomy and enabled correlation of perineal appearance with operative findings. This has led to a terminology and classification scheme with prognostic importance.

Imperforate anus is seen in 1 in every 4000–5000 newborns. The frequency of this defect is slightly higher in males, with the most common defect being an imperforate anus with a rectourethral fistula. In females, the most common defect is a rectovestibular fistula. Congenital absence of a fistula is rare, seen in only 5% of all cases. In families with a newborn with an imperforate anus, the risk of having a second child with this affliction is approximately 1%.

TYPES OF DEFECTS

Historically, anorectal malformations were classified using three main descriptors: low, intermediate, and high. These terms loosely referred to the level of rectal fistula. These terms were not standardized and, more importantly, did not address treatment implications or outcome. With the development of the posterior sagittal approach by Pena and colleagues, a new classification scheme has been popularized. It offers anatomic descriptors based on gender, is based on therapeutic and diagnostic facts, and is of prognostic significance.

Male

Perineal Fistula

In this defect, the lowest part of the rectum is anteriorly displaced (see Fig. 1). The fistula most often opens onto the perineum anterior to the location of the "normal anus," somewhere along the midline raphe, at the scrotum, or even at the base of the penis. The diagnosis is made primarily by perineal inspection. The descriptors "anal dimple," "bucket handle," and "anal membrane" are used to refer to the external appearance of the perineal area. These patients require no further testing. One hundred percent of these patients achieve satisfactory bowel control after repair.

Rectourethral Fistula

This is the most frequent variant seen in males (see Figs. 2 and 3). The fistula is located at or near the bulbar region of the urethra or near the prostatic urethra. Immediately superior, the rectum and urethra share a common wall. Between the often distended rectum and the skin lies a band of striated voluntary muscle. Lower urethral fistulas are associated with higher quality musculature, a well-developed sacrum, and a prominent

anal dimple. Patients with this defect can frequently be observed to pass meconium or air (pneumaturia) through the urethra, an unequivocal sign.

Rectovesical Fistula

In this higher level defect, the rectum opens at the bladder neck (see Fig. 4). These patients have poor prognoses due to poor development of the levator muscle, muscle complex, and external sphincter. Ten percent of males with imperforate anus have this variant.

Anorectal Agenesis

This rare defect carries a good prognosis due to a well-developed sacrum and good muscle structures. The rectum usually ends 2 cm from the perineal skin. Approximately half of these patients suffer from Down's syndrome. This fact does not interfere with the high likelihood of achieving bowel control.

Rectal Atresia

This type is seen in approximately 1% of all anorectal malformations and has an excellent prognosis. The lumen of the rectum may be totally or partially interrupted. Patients usually possess all of the necessary elements to be continent. Usually, the anal canal is well developed and normal sensation is observed in the anorectum.

Female

Perineal Fistula

From a therapeutic and prognostic standpoint, this defect in females parallels the male situation (see Fig. 5). The rectum is located well within the sphincter mechanism and the rectum and vagina are well separated, with the anus being "anterior" to its normal location.

Vestibular Fistula

In this defect, the bowel opens immediately behind the hymen in the vestibule of the genital system (see Figs. 6–8). Immediately above the fistula, the rectum and vagina are separated by a thin, common wall. This condition is often initially misdiagnosed as a rectovaginal fistula, which is much more rare, at 1% of all defects. The correct diagnosis is usually derived by meticulous inspection of the newborn genitalia. These patients usually have well-developed muscles and a normal sacrum.

Anorectal Agenesis without Fistula

This very unusual defect carries the same implications for treatment and outcome as in males, close to 100% incidence of bowel control.

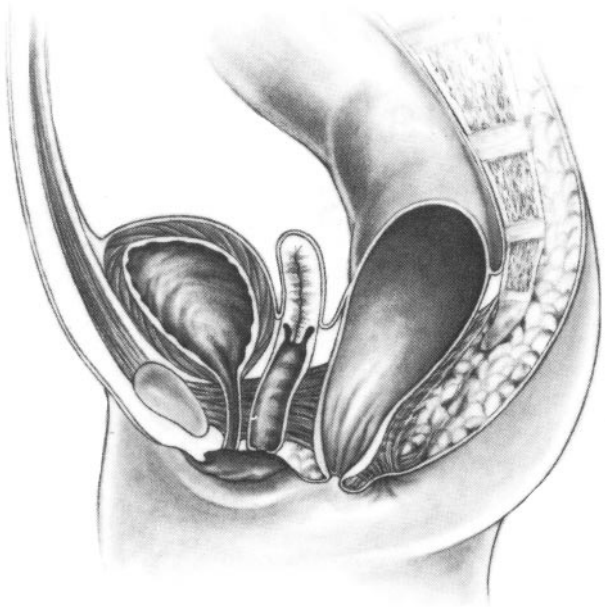

FIGURE 5 Perineal (cutaneous) fistula. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

Persistent Cloaca

This condition is usually a clinical diagnosis and should be strongly suspected in a female newborn with imperforate anus and small-looking genitalia (see Fig. 9). In this group of anomalies, the rectum, vagina, and urinary tract meet and fuse into a single common channel. Careful inspection reveals a single perineal orifice usually hidden behind the labia. The length of the common channel varies, a factor that has prognostic significance. A common channel longer than 3.5 cm usually represents a complex defect and implies difficult mobilization of the vagina. A common channel less than 3.4 cm usually signifies that repair can be accomplished without need for laparotomy (PSARP only). There are numerous other complicated variants of this defect that pose significant challenges to the pediatric surgeon.

ASSOCIATED ANOMALIES

The two main associated abnormalities usually encountered with anorectal defects involve the skeletal and genitourinary systems. Spinal or sacral deformities seem to be frequently related to anorectal malformations. These occur in approximately one-third of all patients and include absence or asymmetry of vertebrae or accessory or hemi-vertebrae. Usually, one missing vertebra does not worsen outcome. However, more than two absent sacral vertebrae is a prognostic sign for poor continence and urinary control. A radiographic

FIGURE 7 Low rectovaginal fistula. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

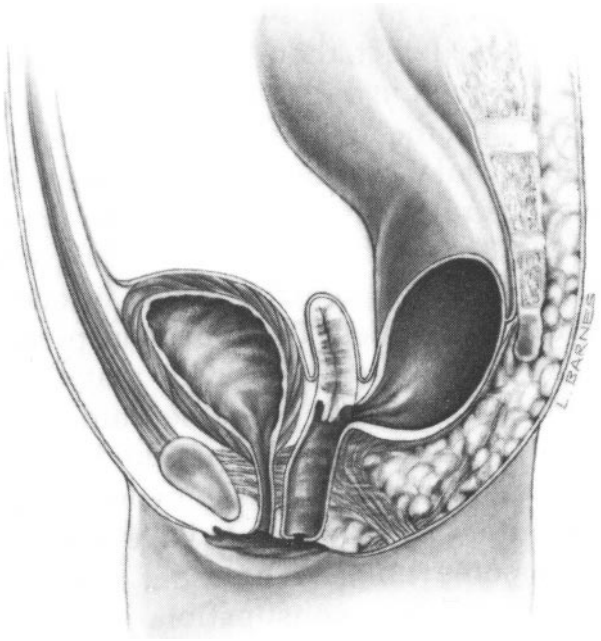

FIGURE 8 High rectovaginal fistula. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

sacral ratio has been developed for objective evaluation. It is calculated from a lateral film: a line drawn from upper and lower borders of the iliac crest is compared with a line drawn from the lowest part of the iliac crest to the lowest point on the sacrum. A ratio is made of this upper to lower portion, with the normal ratio being 0.7; poor prognosis for bowel control is predicted in patients with a ratio less than 0.3.

Concomitant genitourinary (GU) defects are seen in 20 to 54% of patients with anorectal malformations. The "higher" the malformation, the more frequent the association. Patients with rectovesical fistulas have a 90% incidence of a GU defect compared to a less than 10% incidence in perineal defects. Vesicoureteral reflux and hydronephrosis are the most common abnormalities, but other findings such as absent, dysplastic, or horseshoe kidneys must also be considered. Hydronephrosis, urosepsis, and metabolic acidosis are main sources of morbidity and mortality in affected newborns. Thus, a urologic examination, though always required, has a much higher priority in patients with higher defects. This includes a renal and abdominal ultrasound to look for hydronephrosis or other obstructive processes. A voiding cystourethrogram may be useful to localize the level of rectourethral fistula in males and it may also diagnose vesicoureteral reflux.

PRESENTATION AND DIAGNOSIS

The first step in management is to determine whether the newborn has a life-threatening anomaly. Next is the decision to perform a colostomy before definitive repair is addressed. Perineal inspection is usually sufficient to make the initial decision regarding establishment of a protective colostomy in up to 80% of boys. Initial diagnostic measures are essentially the same in females. Ninety to 95% of newborn females can be diagnosed by visual inspection alone. The presence of a single perineal orifice signifies a cloaca, which requires emergent urinary drainage/diversion and protective colostomy.

Occasionally, the diagnosis is not apparent at birth. Final evaluation is delayed 16–24 h to allow bowel distension and intralumenal pressure to increase so that air and meconium are forced through to the distal gut and potentially the urethra.

A prone cross-table lateral X ray is then obtained. The presence of a bowel pouch that is more than 1 cm from the anal skin is an indication for colostomy. On occasion, perineal ultrasound is used to define this level. The diagnostic workup must also include a high index of suspicion for esophageal atresia, which exists in 5% of patients. The completely diverting colostomy provides bowel decompression and urinary tract protection

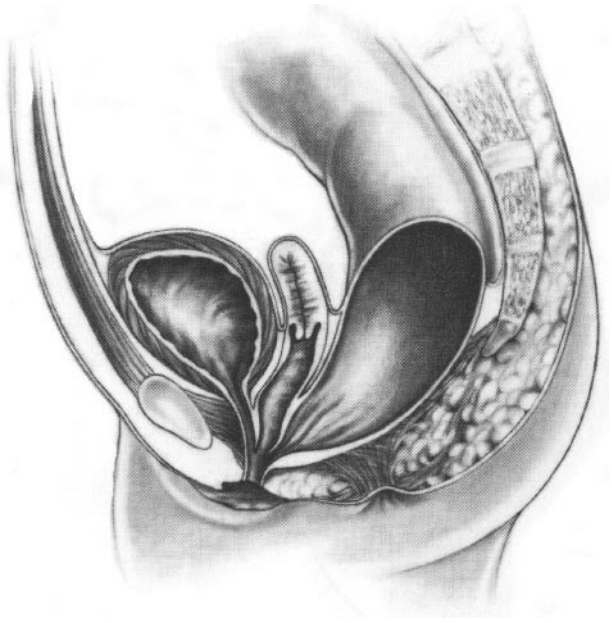

FIGURE 9 Typical cloaca. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

while waiting for the future repair. Risk of infection and dehiscence is decreased and mechanical cleansing is made easier. The procedure of choice is the divided descending colostomy. The operating surgeon must take care to provide enough length of rectosigmoid colon for adequate mobilization in the final repair. In addition, this procedure creates an additional stoma, which allows for an essential preoperative colostogram to be performed. The colostogram is the most accurate diagnostic study to determine the detailed anatomy of these defects, particularly the level of recto-vaginal or recto-urinary connection. Definitive repair is usually performed 4 to 6 weeks after colostomy placement. Though primary neonatal repair of even "high" imperforate anus anomalies has been performed, avoiding colostomy placement, its safety and efficacy are unproven.

Surgical Considerations

As mentioned above, previous corrective operations sought to preserve the puborectalis sling in order to preserve bowel control. Others have advocated endorectal dissection to avoid damaging the pelvic nerves. The standard of care today is the posterior sagittal anorectoplasty (PSARP) mentioned above (see Figs. 10–13). All anorectal malformations can be corrected by this approach with or without laparotomy. The patient is placed in the prone position with the pelvis elevated. The use of the electric muscle stimulator to elicit muscle contraction is essential; these contractions serve as a guideline for operating in the midline, leaving an equal amount of muscle on both sides. This is based on the principle that no important nerves or vessels cross the midline. In addition, a fine midline fascia divides the anatomy in two parts. As part of the PSARP, the voluntary striated muscles from both sides are separated rather than divided. This allows exposure and reduces the likelihood of damage to adjacent structures such as the vas deferens, ectopic ureters, prostatic tissue, urethra, and seminal vesicles. The PSARP proceeds by identifying, opening, and then dividing the rectourethral fistula followed by a "pull-through" of the terminal rectum into the normal, newly created anal position. The pelvic muscle complex (levator ani and parasagittal fibers of the external sphincter complex) is reconstructed around the rectum and a cutaneous anoplasty is performed where indicated by electrical stimulation to complete the pull-through.

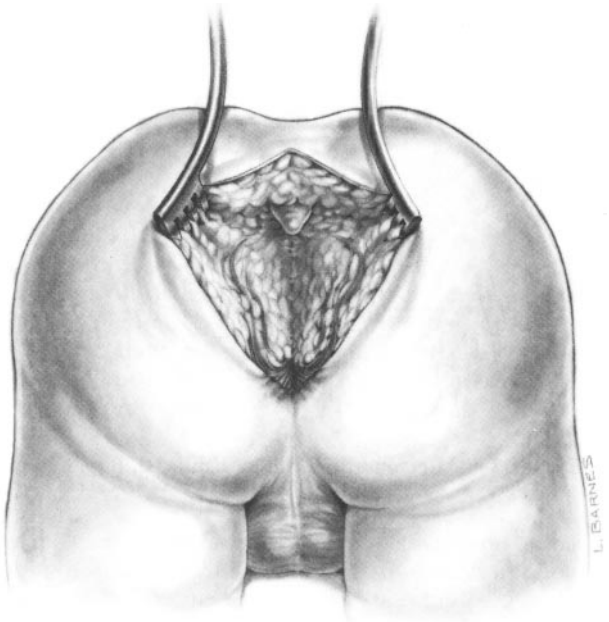

FIGURE 11 Incision continued through the center of the external sphincter showing the lowest part of the muscle complex (vertical fibers). Reprinted from Pena, A. (1992). FIGURE 12 Divided levator muscle, muscle complex, and coccyx. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

Approximately 90% of defects in boys can be repaired via the PSARP without opening the abdomen. A posterior sagittal approach should never be attempted without a technically adequate distal colostogram to determine the exact position of the rectum and the fistula. Attempting repair without this vital information poses significant risk for potential nerve damage, damage to the seminal vesicles and prostate, and bladder denervation.

Most patients experience a smooth recovery period. Patients are usually discharged from the hospital 3 to 4 days after PSARP, with longer stays for those who underwent laparotomy. Two weeks after repair, the patient is brought to the office, where anal dilations are started. This is taught to the parents and is initially performed twice a day. It is essential to have adequate follow-up during this period as severe unmanageable stricturing can result from inadequate dilation. Once the rectum is dilated to the age-appropriate size, the colostomy is closed in the third and final stage.

Urinary incontinence occurs as an overflow phenomenon in two-thirds of cloaca patients with common channel longer than 3 cm and in 20% of patients with a common channel <3 cm. Intermittent catheterization usually keeps these patients dry. In males, incontinence after imperforate anus repair usually represents inadequate primary neuromuscular development, poor surgical technique, or an element of nerve damage.

POSTOPERATIVE MANAGEMENT

Most patients who undergo operative repair for imperforate anus suffer from some departure from normal bowel function. Fecal continence depends mainly on voluntary muscle structures, sensation, and bowel motility. An intact sensory feedback mechanism as well as a muscle contraction mechanism is necessary for the complex procedure of defecation. Most imperforate anus patients do not have the highly sensitive neural feedback in the anal canal that normal patients do, as discrimination between liquid stool and soft fecal material is often severely impaired. Bowel motility is perhaps the most important factor in achieving fecal continence. The main clinical manifestation in after PSARP is constipation, afflicting those with "lower" defects. Interestingly, patients with the best prognosis have the highest incidence. Constipation may be directly related to the

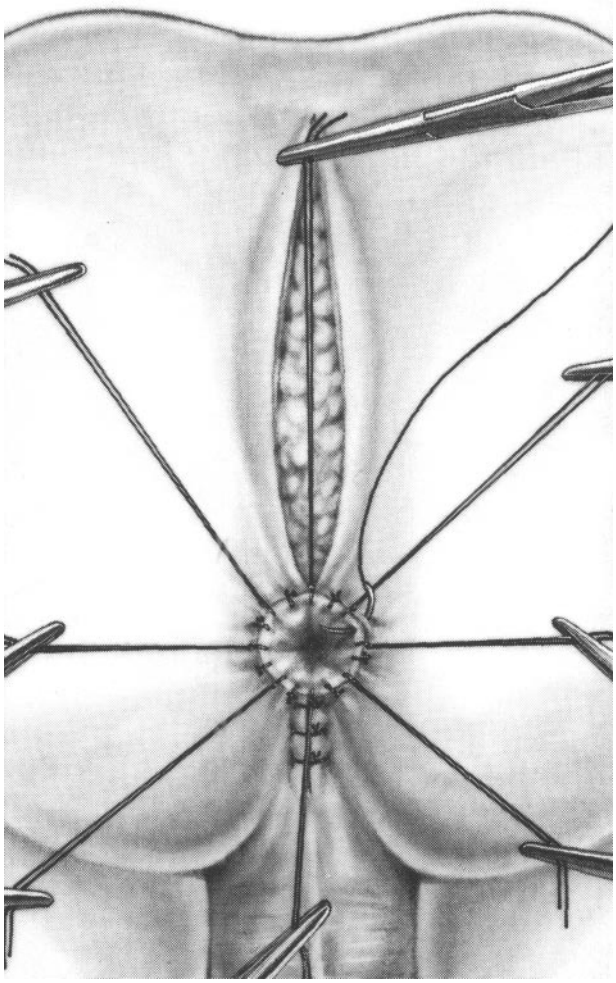

FIGURE 13 Anoplasty. Reprinted from Pena, A. (1992). "Atlas of Surgical Management of Anorectal Malformations." Springer-Verlag, New York, with permission. Copyright Springer-Verlag.

degree of rectal ectasia. Efforts to keep the rectosigmoid as decompressed as possible from the time the colostomy is established result in better ultimate bowel function. Creating and implementing a bowel management program is a trial-and-error process that must be tailored to each individual. For some, obstipation is relieved by frequent enemas. In older patients who are best managed by greater independence, appendicostomy has been performed, allowing older children to administer the treatments themselves. Still other patients may suffer from a hypermotility state and require anti-motility agents.

OUTCOMES

Pena and colleagues have published the largest series of imperforate anus cases. Of the 1192 patients, 75% had voluntary bowel movements by the age of 3. Of these, half occasionally soil. Thus, 37.5% overall are totally continent. Twenty-five percent of all patients are totally incontinent and require bowel management.

There have been two recent developments that may have benefit. Early PSARP has been performed without colostomy in the newborn period to allow infants to gain the experience of normal defecation without colostomy. Second, for the 10% of patients who require laparotomy with PSARP, a laparoscopic approach has recently been proposed to reduce posterior dissection required for accurate placement of the bowel into the muscle complex. Both modifications have uncertain efficacy and long-term data are required.

electrical slow waves Phasic electrical activity underlying generation of spontaneous mechanical activity.
gastrointestinal stromal tumors The most common mesenchymal tumors in the gastrointestinal tract.
interstitial cells of Cajal Responsible for the generation of slow-wave activity and serve as intermediaries in enteric motor neurotransmission.
Kit Type III tyrosine kinase receptor expressed on populations of interstitial cells of Cajal throughout the gastrointestinal tract.
omental mesenchymal tumors Thought to represent gastrointestinal stromal tumors of the omentum.

The interstitial cells of Cajal are specialized cells distributed in specific locations within the tunica muscularis of the gastrointestinal tract; these cells serve as electrical pacemakers, as active propagation pathways for slow waves, and as mediators of enteric neurotransmission. Mutations in these cells are also thought to be responsible for the generation of tumors within the tunica muscularis and omentum of the gastrointestinal tract.

INTRODUCTION

Until recently, evidence supporting a functional role of the interstitial cells of Cajal (ICCs) in pacemaking and neurotransmission within the gastrointestinal tract was indirect. Electron microscopy has now revealed ICCs within the tunica muscularis in sites where electrical slow waves are thought to originate. Morphological studies have also revealed close relationships between ICCs and varicose nerve fibers, and immunohistochemical techniques have shown that ICCs possess receptors for several neurotransmitters and display responses to neurotransmitters. Using a variety of specific molecular markers and mutant animal models, more direct physiological evidence now supports the hypothesis that specific populations of these cells are responsible for the generation of electrical slow waves; discrete populations of ICCs also act as intermediates between enteric nerves and smooth muscle cells in motor neurotransmission within the gastrointestinal (GI) tract.

LOSS OF ICCs, SLOW WAVES, AND NEUROTRANSMISSION IN KIT MUTANT MICE

Several classes of ICCs of the mouse and other species express a type III tyrosine kinase receptor (Kit). Activation of Kit by its ligand, stem cell factor, or "steel" factor, is important in the development of ICCs because blockade of Kit with neutralizing antibodies or mutations in c-*kit* or *steel* impair the development of ICCs. Loss of ICCs in the myenteric plexus region (ICC-MY) of the small intestine, for example, causes abnormal electrical activity that includes total loss of electrical slow-wave activity. In the white spotting mutation (W/W^V), ICCs within the circular and longitudinal muscle layers (ICC-IM) of the stomach and lower esophageal and pyloric sphincters fail to develop. Cholinergic excitatory and nitrergic inhibitory motor neurotransmissions are compromised in tissues of these animals, providing functional evidence for the idea, originally proposed by Cajal, that ICCs mediate enteric neurotransmission.

ICCs ARE DISRUPTED IN PATIENTS WITH GI MOTILITY DISORDERS

The discovery that ICCs express Kit has allowed simple morphological identification of these cells with light microscopy. Labeling of Kit receptors or c-*kit* mRNA has provided an efficient means of identifying ICCs throughout the GI tracts of several species, including humans. Kit labeling combined with confocal laser imaging techniques has improved our understanding of the structure and distribution of ICC networks (see Fig. 1) and has enhanced our perception of the anatomical relationships between ICCs and with other cell types, such as enteric neurons and smooth muscle cells. Kit labeling of ICCs has allowed pathologists to determine the viability of ICCs in a variety of GI motility disorders. ICC networks are disrupted in several motility disorders, including achalasia, hypertrophic pyloric stenosis, chronic idiopathic intestinal pseudo-obstruction, ulcerative colitis, Crohn's disease, and

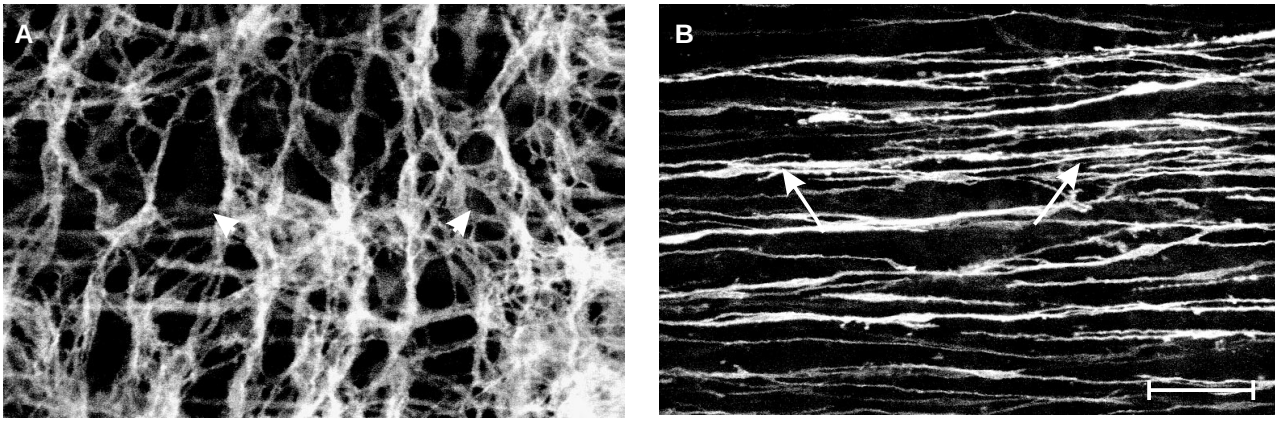

FIGURE 1 Distinct ICC populations in the murine gastric antrum revealed using whole-mount preparations and Kit immunohistochemistry. (A) ICCs are seen at the level of the myenteric plexus (arrowheads), between the circular and longitudinal muscle layers. These cells are the pacemaker cells responsible for the generation of electrical slow waves in the stomach. (B) Intramuscular ICCs are seen within the circular muscle layer (arrows) of the antrum. These cells are responsible for mediating enteric neurotransmission in the stomach (scale bar in panel B applies to both panels).

Hirschsprung's disease. Recent findings in the murine animal model and in human cases have also shown that ICCs are also disrupted in insulin-dependent diabetes.

MANIPULATION OF THE DEVELOPMENT OF ICCs

A powerful means of investigating the physiological role of ICCs is the ability to manipulate the development of these cells. Developmental studies have revealed that Kit expression within the tunica muscularis begins midway through gestation, and ICC networks are formed prior to birth throughout the GI tract. Development of specific populations of ICCs and electrical rhythmicity continues after birth. Blocking of the ICC networks in newborn animals with Kit neutralizing antibodies disrupts ICC networks, electrical rhythmicity, and enteric neurotransmission in the murine jejunum, suggesting that the Kit signaling pathway is critical for the development and maintenance of the ICC phenotype. Investigations using animal models have also revealed that ICCs do not die in some motility disorders, but rather they redifferentiate into a more smooth muscle-like phenotype. These observations provide the exciting possibility that ICCs may not be permanently lost in some motility disorders, and it may be possible to restore these cells and their function in some cases.

SLOW-WAVE PACEMAKING MECHANISM IN ICCs

Physiological studies of ICCs have demonstrated that pacemaker currents generated by ICCs result primarily from the activation of a nonspecific cation conductance in the plasma membrane. The nature of this current is not fully understood, but the current is voltage independent and may conduct Na^+ and Ca^{2+} in physiological ionic gradients. The mechanism that initiates slow-wave activity has been an ongoing subject of investigation for many decades. ICCs contain an abundance of mitochondria and it has been assumed by some that slow waves are tied to the metabolic activity of ICCs (e.g., the mechanism regulating the pacemaker current is metabolically controlled). Others have suggested that pacemaker activity depends on Ca^{2+} release from intracellular stores. A link between Ca^{2+} release, metabolic activity, and current induction in the plasma membrane has recently been made and it is now thought that there is a close physiological relationship between Ca^{2+} release from inositol 1,4,5-trisphosphate (IP_3) receptor-operated stores, Ca^{2+} uptake by mitochondria, and initiation of pacemaker currents in ICCs. Tissues of several species appear to have this mechanism in common. Thus, integrated Ca^{2+} handling by the endoplasmic reticulum (ER) and mitochondria are required for electrical pacemaking in the GI tract. See Fig. 2 for a summary of the current knowledge of ICC function in the GI tract.

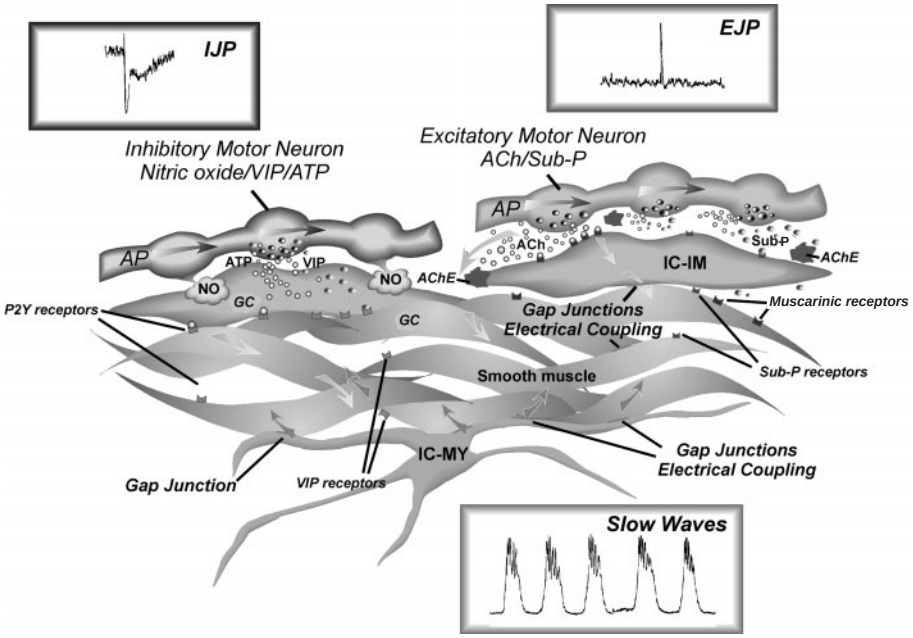

FIGURE 2 Model illustrating the role of ICCs in slow-wave generation and propagation and as mediators of enteric motor neurotransmission. Data summarize findings from several different animal species. IJP, Inhibitory junction potential; EJP, excitatory junction potential; AP, action potential; NO, nitric oxide; VIP, vasoactive intestinal peptide; GC, guanylyl cyclase; ACh, acetylcholine; AChE, acetylcholine esterase; Sub-P, substance P; ICC-IM, interstitial cells of Cajal of the circular and longitudinal muscle layers; IC-MY, interstitial cells (of Cajal) of the myenteric plexus region. Modified from Ward, S. M. (2000). Role of ICC in gastric motility and neuromuscular dysfunctions. *In* "Evolving Pathophysiological Models of Functional GI Disorders," p. 32. With permission of Health Education Alliance and International Foundation for Functional Gastrointestinal Disorders.

ICCs ARE POSSIBLE PRECURSORS TO STROMAL AND OMENTAL TUMORS

The discovery that ICCs express Kit has allowed pathologists to examine the origin of GI stromal tumors (GISTs) and omental mesenchymal tumors (OMTs). GISTs are the most common mesenchymal tumors in the GI tract and OMTs are thought to represent GISTs of the omentum. It has recently been found that both GISTs and OMTs express Kit and it has been proposed that both GISTs and OMTs originate from ICCs. Mutations of the c-*kit* gene (somatic gain-of-function gene) have been observed in solitary GISTs, and germ-line gain-of-function mutations of the c-*kit* gene have also been observed in familial and multiple GISTs. The gain-of-function mutations of the c-*kit* gene are considered to be a cause of the development of these human GI tumors.

ICCs at the level of the myenteric plexus in the stomach, small intestine, and colon and at the level of the submucosal plexus in the colon are the pacemaker cells in the gastrointestinal tract. These cells generate electrical slow waves. Pacemaker ICCs have unique ionic conductances that generate the inward currents underlying slow waves. The intracellular mechanisms responsible for the generation of the pacemaker "clock" involve Ca^{2+} release from IP_3 receptor-operated stores, Ca^{2+} uptake by mitochondria, and initiation of pacemaker currents. Smooth muscle cells do not have the slow-wave mechanism and cannot be induced to produce slow waves in the absence of ICCs. ICCs and the smooth muscle cells are electrically coupled via gap junctions. Slow waves conduct to neighboring smooth muscle cells and activate voltage-dependent Ca^{2+} channels. Influx of Ca^{2+} through these channels leads to muscle contraction.

ICCs are also necessary for the propagation of slow-wave activity around and along the phasic organs of the GI tract. Slow-wave amplitude is maintained in the ICC networks but decays in the smooth muscle syncytium when ICC networks are disrupted.

Morphological and electrophysiological data suggest that the majority of neuromuscular junctions in GI muscles are composed of excitatory and inhibitory enteric nerve terminals, intramuscular interstitial cells of Cajal, and smooth muscle cells. When action potentials invade varicosities, transmitters are released. The close apposition between nerve terminals and ICC-IMs facilitates rapid diffusion to ICC receptors. ICC-IMs are coupled to smooth muscle via gap junctions, and electrical responses elicited in ICCs are conducted to smooth muscle cells. In smooth muscle cells, excitatory depolarization responses, or excitatory junction potentials (EJPs), enhance excitability and increase Ca^{2+} influx; inhibitory hyperpolarization responses, or inhibitory junction potentials (IJPs), reduce excitability and block contraction. ICC-IMs express receptors for many neurotransmitters. Receptors for the inhibitory transmitters [nitric oxide (NO), soluble guanylyl cyclase (GC), vasoactive intestinal peptide (VIP), and ATP] and the excitatory transmitters [acetylcholine (ACh) and substance P (Sub-P)] are shown in Fig. 2.

Intestinal Atresia

MORITZ M. ZIEGLER*,† AND JENNIFER J. GARZA*
*Children's Hospital Boston and †Harvard Medical School

stenosis Incomplete obstruction, with a small opening secondary to a diaphragm or web.
web Thin sheet of tissue or large mucosal fold protruding into the lumen of a hollow organ, often causing obstruction.

An atresia is a complete obstruction caused by the filling of a natural opening; in an intestinal atresia, the obstruction is caused by pancreatic tissue or simply may be a muscular continuity of the duodenum without a lumen. There are three types of intestinal atresia: duodenal, jejunoileal, and colonic.

DUODENAL ATRESIA

Embryology

The embryologic cause of duodenal stenosis and atresia is thought to be a failure of recanalization. The formation of the hepatobiliary system and pancreas occurs in the third week of gestation, when the second portion of the duodenum gives rise to biliary and pancreatic buds at the junction of the foregut and midgut. The duodenum also undergoes a luminal reduction or obliteration during this time, and it is between the eighth and tenth weeks of gestation that the duodenal lumen is reestablished by recanalization. It is believed that an insult during this crucial time period leads to stenoses, atresias, and webs.

Classification

Atresia of the duodenum may result in formation of a short, fibrous cord that connects two atretic ends or may result in two completely disconnected atretic ends. Duodenal atresias, unlike more distal atresias, are often associated with other anomalies. In fact, 50% of duodenal atresias are associated with cardiac, anorectal, or genitourinary anomalies, and it is believed that up to 40% of affected patients have trisomy 21. With these factors in mind, there should be a low threshold for testing for suspected associated anomalies. It is generally the cardiac defects that are related to mortality.

Duodenal obstructions may be either preampullary or postampullary. However, a majority are considered periampullary. The degree of obstruction dictates the amount of resulting pathology. The obstruction causes dilatation of the proximal duodenum and stomach as well as hypertrophy and distension of the pylorus. The distal bowel, as with most obstructions, is collapsed. A common variation is the windsock anomaly, whereby the duodenum is dilated distal to the origin of the point of obstruction because of a prolapsing web or membrane. Heralding the lesions are maternal polyhydramnios and growth retardation of the fetus, the latter possibly due to the inability of the fetus to swallow amniotic fluid, which contains nutritive peptides.

Diagnosis

Prenatal diagnosis is possible by several methods. Ultrasound examination may indicate structural and associated abnormalities, such as a dilated stomach and proximal duodenum. Commonly associated anomalies may also be found by screening maternal serum and amniotic fluid for elevated levels of α-fetoprotein. Amniotic fluid and fetal blood are useful for karyotyping.

In the newborn, clear or bilious emesis is evident within hours of birth and as a result abdominal distension may or may not be present. As soon as intestinal obstruction is suspected, a nasogastric tube should be inserted. An output of more than 20 ml of gastric contents is indicative of possible obstruction. A delay in diagnosis is not uncommon with a stenosis or web, because these may present later as dehydration or failure to thrive. In an older child with unexplained recurrent episodes of emesis, a stenosis or web should be excluded.

Abdominal plain radiographs are helpful in making the diagnosis. Evidence of gas beyond the duodenum indicates a partial obstruction. The classic "double bubble" is associated with complete obstruction, but is not exclusive to atresia. If a partial obstruction is suspected, it is necessary to rule out malrotation and volvulus to determine if immediate operation is necessary. If surgery is not emergently indicated, a contrast study is necessary. Upright films using air or contrast medium may confirm the diagnosis.

 Copyright 2004, Elsevier (USA). All rights reserved.

Treatment

The patient diagnosed with duodenal atresia should be fully resuscitated before surgical correction is attempted, unless volvulus or malrotation is detected, in which case surgery becomes emergent. Ideally, correction of fluid status and electrolyte abnormalities should be handled preoperatively. Replacement fluid should be given and urine output should be monitored closely. Gastric decompression is essential to prevent aspiration, and thermoregulation should be monitored at all times. Screening for concurrent abnormalities should be done, if possible, prior to operation.

There are two basic options for surgical repair. The first and most common repair is a duodenoduodenostomy. The preferred approach for this option is through a supraumbilical transverse abdominal incision, which provides adequate exposure of the duodenum once the ascending and transverse colon segments are mobilized to the left. Malrotation occurs in 30% of patients with duodenal obstruction, and this diagnosis should be excluded by adequate surgical exposure. A catheter should then be inserted through the stomach to help isolate the lesion and rule out a windsock lesion, or bulging membrane. In addition, the whole small bowel should be explored carefully for other sites of obstruction or malformations, such as the associated annular pancreas. Care should be taken to examine the gallbladder to ensure that a preduodenal portal vein is not evident, and once the duodenum is open, it is important to locate the ampulla of Vater to avoid inadvertent injury. The proximal duodenum is usually dilated, compared to the thin-walled and flat distal duodenum and jejunum. A longitudinal incision is placed in the distal, collapsed end of the duodenum and it is brought up and anastomosed to the proximal, dilated portion of the duodenum, where a transverse incision is made at the inferior aspect of the bulbous blind end. This anastomosis maybe either a diamond-shaped or side-to-side duodenoduodenostomy. It is important to avoid kinking of the bowel or the anastomosis. A Ladd's procedure is warranted if malrotation is concomitantly present. The second approach, which is less common, involves a duodenotomy with excision of the web, the origin of which is identified by placing a catheter through the stomach. The ampulla of Vater should be identified to avoid injury. The web is then excised and the duodenum is closed transversely.

Gastric decompression is required until time for feeding or when the patient is able to tolerate the removal of the tube without nausea or emesis. An anastomotic leak, injury to the bile duct, and sepsis are early complications. Late or long-term complications include peptic ulceration secondary to alkaline reflux, blind-loop syndrome with duodenal stasis, abdominal pain, and diarrhea. Prognosis is generally good for patients with a repaired duodenal stenosis or atresia; however, the long-term outcome depends on coexisting diagnoses, such as Down syndrome and cardiac anomalies.

JEJUNOILEAL ATRESIA

Etiology

Many theories exist regarding the etiology of jejunoileal atresias. Most of these theories are based on experimental models trying to replicate the disease process. The most accepted theory regarding the etiology of jejunoileal atresia is that of an intrauterine vascular accident resulting in necrosis of the affected segment, with subsequent resorption or obliteration.

Classification

There are two broad categories of jejunoileal defects—stenoses and atresias. A stenosis has an intact mesentery and is a localized narrowing of the bowel. There is no loss of continuity of the lumen and the stenotic portion generally has an irregular muscularis and thickened submucosa. Four types of jejunoileal atresias were originally described and a subtype has been added more recently. The type classification generally guides both prognosis and therapy.

Type I

The mucosa and submucosa form a web, or intraluminal diaphragm, resulting in obstruction in type I atresias. A windsock effect may be evident secondary to an increase in intraluminal pressure in the proximal bowel, causing a portion of the web to protrude into the distal part of the bowel. A mesenteric defect is not present, the bowel length is not shortened, the bowel appears to be in continuity, and only the proximal and distal size disparity points to the location of the obstruction.

Type II

The mesentery is intact in type II atresias; however, the bowel is not joined. The dilated proximal portion has a bulbous blind end connected by a short, fibrous cord to the blind end of the distal flattened bowel. Small bowel length is usually not shortened.

Type IIIa

The defect in type IIIa is similar to the type II defect in that there are blind proximal and distal ends;

however, there is complete disconnection in this case, with a V-shaped mesenteric defect present. The proximal blind end is usually markedly dilated and not peristaltic. The compromised bowel undergoes intrauterine involution, and as a result the bowel in this category is shortened to varying lengths.

Type IIIb

In addition to a large defect of the mesentery, there is also significant shortening of the bowel. This lesion, also known as an "apple peel" or "Christmas tree deformity" (because the bowel has the appearance of a tinsel coil wrapped around a single perfusing vessel, or Christmas tree), is a proximal jejunal atresia near the ligament of Treitz. The distal ileum receives its blood supply from a single ileocolic or right colic artery because the better part of the superior mesenteric artery is absent. Prematurity, malrotation, and subsequent short bowel syndrome have been linked to this deformity, with an increased morbidity and mortality. There also appears to be a pattern of heredity or genetic transmission.

Type IV

Type IV involves multiple small bowel atresias of any combination of types I to III. This defect often takes on a "string of sausages" appearance because of the multiple lesions. The cause is unknown and theories range from multiple ischemic infarcts, to an early embryological defect of the gastrointestinal tract, to an inflammatory process occurring *in utero*. This type of defect may also have a hereditary component.

Diagnosis

Prenatal diagnosis is not as likely for the more distal atresias. Whereas 30% of neonates with duodenal atresias have associated anomalies, this percentage falls to 10% in jejunoileal atresias, making prenatal diagnosis a challenge. Postnatal diagnosis of jejunoileal atresia is more likely, and surely essential, because emergency treatment may be necessary for conditions such as a midgut volvulus. Neonates with a more proximal atresia may develop bilious emesis within hours of birth, whereas neonates with more distal lesions may take days to begin vomiting. The neonate with a normal or scaphoid abdomen and bilious emesis should be considered to have a proximal obstruction until proved otherwise. If there is a question of an atresia, a nasogastric aspirate should be obtained. A bilious gastric fluid may indicate an intestinal obstruction. Other factors include abdominal distension, usually more pronounced with distal lesions, and failure to pass meconium.

Abdominal radiographs are essential for diagnosis. With more proximal atresias, a few air–fluid levels are evident, with no apparent gas in the lower part of the abdomen. A more distal lesion demonstrates more gas-filled bowel loops with air–fluid levels, but the lower abdomen may remain without a gas pattern. A barium enema is best at defining the approximate location of obstruction and is also capable of ruling out other causes of lower obstruction, such as a Hirschsprung's disease, meconium plug syndrome, or a small left colon.

Neonates with intestinal stenosis are more difficult to diagnose and their obstruction may not manifest for weeks to years. These patients tend to present with a history of intermittent emesis and failure to thrive. The clinical presentation and radiographic evidence are dependent on the degree and severity of disease, but fortunately this more subtle form of disease is rare.

Treatment

Preoperative care should be the same as that described for repair of duodenal lesions, including preoperative resuscitation, unless a surgical emergency is apparent. A transverse supraumbilical incision affords adequate exposure of the abdominal contents. The full length of the bowel should be manually explored for malrotation, as well as for other atresias or stenoses. Malrotation should be corrected with a Ladd's procedure. The length of intestine that appears functional should be measured along the antimesenteric border, because bowel length affects the procedure and overall prognosis. Saline should be injected into the distal bowel and followed closely throughout to the cecum to ensure patency. The same should be done to the colon. This maneuver will assure that an unrecognized intraluminal obstructing membrane is not present.

Once patency of the entire length of the bowel has been established, the repair may proceed. The dilated proximal bowel generally does not have normal function and, as a result, if adequate intestinal length is present, it should be resected to normal size bowel to avoid problems with abnormal postoperative peristalsis. An end-to-end anastomosis can then be done. In the presence of short bowel length, the dilated proximal segment can instead be preserved by tapering. Postoperatively, antibiotics are given for a short course and gastric drainage should continue until there is evidence of return of bowel function. Total parenteral nutrition (TPN) should be started shortly after surgery and continued until enteral feeds are tolerated. A possible complication is an anastomotic leak. It is important to follow the baby closely after the operation,

monitoring abdominal girth, vital signs, temperature, fluid status, urine output, gastric drainage, and level of activity.

Prognosis for the jejunoileal atresia group is dependent on the amount of residual, functional bowel that exists after surgery. In general, 40 cm of functional small bowel is considered adequate, and if no other comorbidities exist, the prognosis is good. The potential major morbidity and mortality for this group is a short bowel syndrome ($<20-40$ cm) that requires a dependence on total parenteral nutrition, a therapy at times complicated by liver failure. Often the only solution for this latter circumstance is a small bowel and liver transplant, which involves a range of challenges.

COLONIC ATRESIA

Colonic atresia, like jejunoileal atresia, is believed to be the result of an *in utero* vascular accident resulting in ischemic injury. This occurs after the midgut has returned to the coelomic cavity. Colonic atresia is the least common type and encompasses 1.8–15% of all intestinal atresias and stenoses. Atresias may occur throughout the colon, but lesions to the right of the splenic flexure and distal to the vascular watershed area are the most common. Colonic atresia is often associated with other anomalies, especially when there is a complicated partial or complete absence of the hindgut. As a result, anterior wall defects, vesicointestinal fissures, and genitourinary defects are frequently associated (for example, the cloacal exstrophy complex).

Prenatal diagnosis is possible by ultrasound. Expected findings would include a colon that is larger than expected for gestational age or an expected bowel obstruction. Diagnosis after birth is usually timely, because the newborn demonstrates signs of distal obstruction and meconium is generally not passed. Abdominal distension is prominent in the first 24 hours and the hugely dilated proximal loop is often palpable. This can be confirmed by a radiograph showing the large loop of proximal colonic segment. A contrast enema may confirm the diagnosis.

Treatment

Treatment depends on the extent and location of the lesion and the clinical presentation of the patient. Care should be taken to avoid perforation secondary to severe distension. A staged procedure, beginning with resection of the affected portion and colostomy with mucous fistulas, is generally the initial treatment of choice. An initial resection with anastomosis may be appropriate in selected cases. For those undergoing a staged repair, ileocolic or colocolic anastomosis should be performed by 1 year of age and a close second look should be performed to rule out distal pathology. Outcome is dependent on the residual length of colon, the length of small bowel, and associated anomalies, including small bowel atresias. The prognosis is generally good.

Intestinal Infarction

DAVID B. LAUTZ AND CARLOS M. MERY
Brigham and Women's Hospital and Harvard University

bowel ischemia Acute or chronic syndrome resulting from inadequate blood perfusion of any portion of the small or large bowel.
embolism Partial or complete obstruction of a vessel with a plug extraneous to the site of the obstruction.
intestinal infarction Loss of viability of any portion of the bowel due to the lack of sufficient blood supply to ensure adequate perfusion over a significant period of time.
thrombosis Partial or complete obstruction of a vessel with a clot originating at the site of the obstruction.

Intestinal infarction is the necrosis of any portion of the small or large bowel due to insufficient blood flow to supply its basic metabolic demands. It represents one of the extremes of a continuous spectrum of the bowel ischemia syndrome that ranges from completely reversible alterations of the bowel to transmural necrosis of the intestinal wall. Early diagnosis and treatment of acute bowel ischemia are mandatory to avoid its progression into necrosis. Intestinal infarction may develop within hours of the first insult and has a mortality rate as high as 70 to 100%.

ETIOLOGY

The causes of intestinal infarction are diverse and in general similar to those that cause acute bowel ischemia. Chronic mesenteric ischemia resulting from inadequate perfusion of the midgut during periods of increased oxygen demand is a chronic clinical syndrome that rarely causes bowel infarction and as such will not be considered in this article.

Acute Mesenteric Artery Embolism

Embolization of the superior mesenteric artery (SMA) accounts for approximately 50% of cases of acute mesenteric ischemia. The majority of the emboli originate from the left atrium or ventricle in patients with either atrial fibrillation or cardiac hypokinesis.

Acute Mesenteric Artery Thrombosis

Thrombosis of the SMA occurs acutely in patients with preexistent stenotic lesions and accounts for 25% of cases of acute mesenteric ischemia. It usually presents in patients with previous symptoms of chronic mesenteric ischemia such as postprandial abdominal pain, early satiety, and weight loss.

Non-occlusive Mesenteric Ischemia

Non-occlusive mesenteric ischemia (NOMI) accounts for the other 25% of cases of acute mesenteric ischemia. It occurs in the absence of any anatomical obstruction and is a consequence of low mesenteric blood flow states. It is caused by mesenteric vasospasm induced by excessive sympathetic activity during cardiogenic shock or hypovolemia or after the use of vasoactive medications such as α-adrenergic agents and digitalis.

Acute Mesenteric Venous Thrombosis

Mesenteric venous thrombosis represents a rare but potentially lethal form of mesenteric ischemia, usually associated with predisposing conditions such as hypercoagulable states, inflammation, portal hypertension, trauma, bowel obstruction, or dehydration.

Strangulated Hernias

Strangulation of a hernia occurs when the intestinal veins of the bowel contained within the hernial sac are compressed by the opening of the hernia. This compression causes edema of the bowel wall with further compression and obstruction, eventually progressing to infarction of the loops of bowel. Strangulation is more common in incarcerated hernias (hernias that are not reducible), in hernias found in patients of advanced age, and in large hernias with relatively small openings.

Strangulated Bowel Obstruction

Strangulated obstruction occurs when blood flow to an obstructed segment of bowel is compromised. It is a particularly important complication of closed-loop bowel obstruction, where both inflow and outflow of a loop of bowel are occluded. Secretion of mucus and fluid into the closed loop of bowel leads to high intralumenal pressure. When this intralumenal pressure

 Copyright 2004, Elsevier (USA). All rights reserved.

exceeds the mesenteric venous and capillary perfusion pressures, bowel viability becomes compromised.

Other Causes of Intestinal Infarction

Unusual reported causes of intestinal ischemia and infarction include arterial dissection, thrombocytosis, amyloidosis, disseminated intravascular coagulation, vasculitides, and early postoperative jejunal tube feeding.

PATHOPHYSIOLOGY

With any significant reduction of the perfusion pressure of the bowel, the intestinal vascular bed reduces its vascular resistance, arterial collateral pathways open immediately, and redistribution of flow among the different layers of the bowel occurs (with increasing flow to the mucosa, the metabolically most active layer). Furthermore, oxygen extraction increases, allowing the cells to support their metabolic demands. When oxygen extraction can no longer compensate for the diminished blood flow, ischemia ensues. Within 20 min of complete ischemia, the insult affects the villi (the most superficial area of the mucosa). The ischemic insult then progresses centrifugally with time to the outer layers of the bowel. Transmural infarction is usually seen within 8–16 h of severe ischemia.

Intestinal infarction is associated with third spacing of fluid into the lumen of the bowel. These fluid shifts induce hemoconcentration and hypovolemia. Furthermore, untreated intestinal necrosis promotes bacterial translocation into the bloodstream and production of cytokines, with a resulting sepsis-like syndrome that in association with the hypovolemia can easily lead to shock.

DIAGNOSIS

Early diagnosis of bowel ischemia and infarction is a clinical challenge and requires a high index of suspicion.

Clinical Manifestations

Bowel ischemia usually presents with poorly localized abdominal pain, out of proportion to the physical examination. Presentation tends to be more acute and severe on cases of arterial embolism and more indolent and vague on cases of venous thrombosis. Pain is usually worsened with food intake and may be associated with rapid and forceful bowel movements with guaiac-positive stools.

As ischemia progresses and infarction ensues, the abdomen becomes distended and signs of peritoneal irritation, such as increasing abdominal tenderness, rebound, and guarding, appear. Other late signs that indicate compromise of bowel viability include nausea, vomiting, hematochezia, hematemesis, massive abdominal distension, back pain, and shock.

The clinical picture can be characterized according to four progressive clinical stages:

1. Hyperactive stage. Three is intermittent severe pain with passage of loose stools, sometimes with blood and vomiting. There are hyperactive bowel sounds on auscultation, reflecting hyperperistalsis.
2. Paralytic stage. Pain usually diminishes but becomes more continuous and diffuse. Abdominal distension and tenderness appear and bowel sounds disappear.
3. Disarranged fluid balance. There is leakage of fluid, proteins, and electrolytes, associated with necrosis of the bowel and generalized peritonitis.
4. Shock.

Strangulated hernias present with extreme pain, tenderness, edema, erythema, and irreducibility. Although the diagnosis of strangulation may be relatively easy on inguinal or ventral hernias, strangulated femoral or obturator hernias may be difficult to detect.

In addition to the usual symptoms and signs of bowel obstruction, strangulated obstruction of the intestine presents with peritoneal signs. Patients manifest abdominal tenderness, involuntary guarding, decreased urine output, fever, and tachycardia. Leukocytosis, metabolic acidosis, increased serum amylase, and phosphate should raise the suspicion of intestinal infarction.

Laboratory

Laboratory abnormalities appear with advanced ischemia. Leukocytosis with a left shift, metabolic acidosis, and an elevated hematocrit as a result of hemoconcentration are manifestations of intestinal infarction. Serum amylase and phosphate may also be elevated.

Imaging

Plain Films of the Abdomen

The main utility of plain radiographs of the abdomen is to rule out other causes of abdominal pain such as bowel obstruction or perforated viscus. Bowel ischemia may present with subtle findings such as adynamic ileus and distended, air-filled loops of bowel. However, in intestinal infarction, plain films can

show "thumbprinting" of the bowel with pneumatosis of the intestinal wall and gas in the portal vein. These signs, associated with an ominous prognosis, are rarely encountered.

Computed Tomography

In current practice, abdominal computed tomography (CT) is frequently obtained in patients with abdominal pain of unclear source. In addition to helping identify the source of the ischemia in certain situations (e.g., mesenteric venous thrombosis), CT may show portions of thickened bowel wall, suggestive of ischemia. On advanced intestinal infarction, intestinal wall pneumatosis and portal vein gas may also be seen.

Angiography

Although angiography is the definitive diagnostic study for bowel ischemia, it does not provide information about the viability of the involved bowel. It allows the clinician to determine the mechanism for the ischemic insult, define the anatomy of the vessels, and on certain occasions, administer therapeutic agents such as urokinase (for thrombosis) or papaverine (for NOMI).

MANAGEMENT

Initial treatment of patients with bowel ischemia/infarction includes volume resuscitation, correction of acidosis if possible, and administration of broad-spectrum antibiotics. Intravenous heparin is indicated in cases of thromboembolism to avoid propagation of the clot and to allow restoration of flow.

Any patient with major arterial occlusion from thrombosis or embolus that does not respond completely to vasodilators on angiography, and any patient with signs of peritoneal irritation regardless of the mechanism of ischemia, should undergo immediate exploratory laparotomy. The purpose of the laparotomy is twofold: to revascularize the affected bowel (if possible) and to resect all nonviable bowel. This article focuses on the management of bowel infarction; the treatment of bowel ischemia per se is beyond its scope.

Evaluation of Intestinal Viability

Revascularization should precede any evaluation of intestinal viability because bowel that may appear nonviable initially may show complete recovery after revascularization. Once revascularization has been performed, the involved loops of bowel are covered with warm saline-soaked pads for 20–30 min and are then visually inspected. Nonviable bowel is dull gray or black in color, edematous, distended, and lacking peristaltic activity. Doppler measurements of arterial flow can also be used to assess bowel viability in the operating room by showing adequate pulsations on the anti-mesenteric border of viable bowel. Another objective method used to assess intestinal viability is the injection of fluorescein followed by the inspection of the bowel in question under Wood's lamp.

Resection of Nonviable Bowel

Minimal bowel resection with liberal use of second-look laparotomy is the hallmark of treatment of bowel infarction. Clearly nonviable bowel should be excised. If the margins are unequivocally viable, intestinal continuity may be restored. Otherwise, it is recommended to restore continuity on a second operation. Similarly, areas of questionable or marginal viability are usually left in place since they may recover completely with time and a second-look laparotomy is planned 24–48 h later. This allows a clearer delineation of viable bowel and permits supportive measures to render more of the bowel viable. Once the decision to perform a second-look laparotomy is taken (during the first operation), it is upheld regardless of the clinical course of the patient.

Since in colonic ischemia it is not unusual to have a normal serosal appearance with extensive mucosal injury, the extent of the resection should be guided by preoperative evaluation rather than by the appearance of the serosa. All specimens resected for colonic ischemia should be opened at the time of the operation to ensure that margins have normal mucosa. Similarly, as in other colonic surgeries, due to the risk of contamination of the anastomosis from an unprepared bowel, ischemic emergencies of the left colon should be treated with colostomies instead of reestablishing intestinal continuity primarily.

When obvious infarction of all or most of the bowel is found on the initial laparotomy, a decision must be made between resecting the entire bowel with the subsequent need for lifetime TPN or doing nothing and allowing the patient to die by providing comfort measures only.

Second-Look Exploration

The decision to perform a second-look laparotomy is made during the initial procedure and maintained regardless of the patient's postoperative course. At the initial laparotomy, bowel segments of marginal viability are often preserved to avoid a short bowel syndrome. These segments must be reinspected to ensure viability. Laparoscopy has been proposed as an alternative method to perform the second-look

exploration but enough experience has not been accrued to evaluate its adequacy.

CONCLUSIONS

Intestinal infarction represents the end result of severe bowel ischemia. The only potential for cure lies in prompt diagnosis and management. Once the suspicion of bowel necrosis is raised, exploratory laparotomy should not be delayed. The treatment of intestinal infarction consists of the correction of the underlying cause of ischemia, assessment of viability of the bowel, and resection of clearly nonviable segments with liberal use of second-look explorations for reassessment of marginally viable bowel left in place.

INTRODUCTION

A thorough understanding of the etiologies of intestinal ischemia is key to effective treatment. Broadly, intestinal ischemia can be separated into acute and chronic

Copyright 2004, Elsevier (USA). All rights reserved.

syndromes. Etiologies of acute mesenteric ischemia include mesenteric arterial embolism, mesenteric arterial thrombosis, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia. The hallmark of chronic mesenteric ischemia is arterial insufficiency to increased blood flow demand, most often related to atherosclerotic stenoses of the mesenteric arterial orifices, trunks, and branches. Other causes of mesenteric arterial insufficiency not covered herein include vasculopathy, arterial dissection, tumor, or radiation.

ACUTE MESENTERIC ISCHEMIA

Mesenteric Arterial Embolism

The patient with embolism to the superior mesenteric artery presents with a history of a sudden onset of acute abdominal pain. This may be accompanied by nausea, vomiting, or diarrhea. The pain is constant and persistent, and, as noted above, may be accompanied by an unremarkable physical exam in the early stages of the presentation. As the bowel progresses to infarction, bloody diarrhea and peritoneal signs may present.

The patient's history may increase the suspicion that mesenteric arterial embolism is the cause of the intestinal ischemia. The origin of the embolus is most often the heart, as a consequence of intracardiac thrombus from atrial fibrillation or other arrhythmias. Other causes of intracardiac thrombus include myocardial infarction, ventricular aneurysms, and diseased or mechanical heart valves. A thromboembolus arising from a deep venous thrombosis could enter the systemic circulation if a right-to-left intracardiac shunt exists. Tumor embolus (e.g., atrial myxoma), atheroembolus (spontaneous or iatrogenic), and septic embolus have also been reported. A thorough assessment of the patient must be made to exclude the possibility of synchronous or metachronous embolism to other vascular beds.

In general, laboratory tests are nonspecific for the diagnosis of mesenteric arterial embolism and other causes of acute mesenteric ischemia. Third-space volume losses into the bowel wall and lumen may be manifested by increased blood urea nitrogen/creatinine ratios and hemoconcentration. Leukocytosis is common. Lactic acid levels are sensitive for detecting bowel ischemia and infarct, but can be elevated in other etiologies of the acute abdomen. Serum phosphate is elevated after a significant bowel infarction has occurred.

The gold standard for diagnosis is selective mesenteric angiography. The embolus will typically lodge at a branch point several centimeters from the origin of the superior mesenteric artery, thus sparing the first few jejunal branches. However, because of the overlap of symptomatology with many other intraabdominal etiologies of pain, patients with a mesenteric arterial embolus may have already undergone several other diagnostic tests to rule out other disease processes. A plain film of the abdomen may be essentially normal in the early stages of mesenteric arterial embolism. As the ischemia worsens, small bowel dilation, air–fluid levels, and evidence of bowel wall thickening and eventual pneumatosis intestinalis may be apparent. Abdominal computed tomography (CT) scan may be more effective at diagnosing alternative causes for the patient's abdominal pain, such as diverticulitis or ureterolithiasis. Although an abdominal CT scan is able to demonstrate bowel thickening, ileus, pneumatosis, and, in some cases, occlusion of the superior mesenteric artery, it should not be considered the equivalent of mesenteric angiography.

The treatment for arterial mesenteric embolus should commence simultaneously with the completion of the workup. The patient should be aggressively volume resuscitated and broad-spectrum antibiotics should be given. Once the diagnosis of mesenteric arterial embolus has been confirmed with angiography, the patient should be brought to the operating room for surgical embolectomy. The superior mesenteric artery is approached at the root of the transverse mesocolon and a transverse arteriotomy is made. An embolectomy catheter is passed anterograde and retrograde to remove the embolus. Once vigorous flow is achieved, the arteriotomy is closed primarily or with a patch if stenosis is a concern. Assessment of distal flow should be made with direct palpation or Doppler insonation of the vessels.

Only after the blood flow is restored should any grossly nonviable intestine be resected. Questionably viable intestine should be reassessed with a "second-look" operation in 24–48 hours. This strategy is employed to minimize resection of any potentially viable bowel at the first operation, while at the same time ensuring that marginal bowel that does not recover its viability is then removed before further complications ensue. In addition to visual inspection of bowel color, peristalsis, and edema, viability may be assessed by adjunctive measures such as Doppler insonation of antimesenteric blood flow or fluorescein injection and inspection under a Wood's lamp.

Mesenteric Arterial Thrombosis

The patient with mesenteric arterial thrombosis also presents with abdominal pain out of proportion

to physical exam, although possibly of a more gradual onset. Because this acute ischemic syndrome most often represents the end stage of progressive atherosclerotic disease of the visceral arteries, it may be possible to elicit a history of chronic mesenteric ischemic symptoms, i.e., intestinal angina (abdominal pain after meals), food aversion, weight loss, and diarrhea. Similar to mesenteric arterial embolism, physical findings and laboratory studies with mesenteric arterial thrombosis may be unremarkable and nonspecific until progression of the ischemia leads to irreversible infarction of the bowel.

The plain film and abdominal CT findings are similar to those for mesenteric arterial embolism. There may be additional evidence of chronic visceral atherosclerosis on CT, such as prominent calcifications of the aorta and its branches. Angiography is the mainstay of diagnosis. Unlike embolism, thrombosis of the superior mesenteric artery usually leads to occlusion of the vessel most proximally, up to its origin of the vessel from the aorta.

Volume resuscitation, heparin anticoagulation, and broad-spectrum antibiotics should be instituted concomitantly with the diagnostic workup. The operative strategy is to revascularize first, then assess nonviable bowel for resection. The revascularization may involve transaortic endarterectomy of the orificial lesion, or retrograde or anterograde bypass grafting. Autogenous vein or prosthetic graft may be used as conduit, though it has been suggested that vein graft may be preferred in the setting of bowel infarct, with its attendant bacterial translocation or peritonitis. Multiple grafts may be necessary to adequately revascularize a diffusely diseased mesenteric arterial bed, but this more extensive procedure may be less optimal in a sick patient with infarcted bowel with marginal nutritional status. A second-look operation again may be employed to most appropriately resect nonviable bowel.

Nonocclusive Mesenteric Ischemia

Nonocclusive mesenteric ischemia results from persistent vasospasm of the visceral vessels, usually in response to diminished mesenteric blood flow. Inciting events include low-cardiac-output states, sepsis, hypotension, hypovolemia, or numerous vasoactive medications such as α-adrenergic agents, vasopressin, or digitalis. Vasospasm may also cause persistent ischemia after surgical revascularization of mesenteric embolism or thrombosis. The diagnosis of nonocclusive mesenteric ischemia should be considered if a patient has abdominal pain with these risk factors. The patient's exam may be out of proportion with complaints of pain, but with this etiology of acute mesenteric ischemia in particular, it must be recognized that the patient's comorbid condition may mask early subjective awareness of symptoms. Laboratory findings of leukocytosis, lactic acidosis, or hemoconcentration may be noted. Late findings of infarction are also similar to those in thrombotic or embolic cases.

Treatment of nonocclusive mesenteric ischemia begins with attempts to correct the underlying condition and maximize the patient's hemodynamic status. Vasoconstrictive medications should be stopped if possible. Expeditious mesenteric angiography is essential, provided the patient can tolerate it clinically, because both diagnosis and treatment may be provided with this procedure. Superior mesenteric arterial branches will show evidence of severe vasospasm, with an absence of occlusion. Vasodilators (e.g., papaverine) are then selectively administered using a catheter directed into the superior mesenteric artery.

Mesenteric vasodilator therapy should be instituted first when possible, even if the patient's initial evaluation reveals likely infarcted bowel, which would require a subsequent operative resection. Often, however, these patients cannot tolerate vasodilator therapy, in which case exploration is warranted. Conversely, during infusion of vasodilators in patients who initially appear to have threatened but not necessarily nonviable bowel, any sign of progression of bowel ischemia (e.g., worsening leukocytosis, abdominal pain, or acidosis) should trigger a trip to the operating room for abdominal exploration. Persistence of symptoms and signs of bowel ischemia after 12–24 hours of vasodilator therapy should alert the clinician that an operation will be required to resect nonviable bowel. During therapy, the patient should also undergo close hemodynamic monitoring.

Mesenteric Venous Thrombosis

The patient with mesenteric venous thrombosis may also present as an acute ischemic syndrome, but the presentation may be more protracted compared with nonocclusive mesenteric ischemia or mesenteric arterial embolism or thrombosis. Though abdominal pain is still a hallmark of the disease, several days may elapse between the onset of pain and progression of symptoms to the point where the patient seeks medical attention. Once evaluated, however, the patient with acute mesenteric venous thrombosis may display the classic finding in intestinal ischemia, i.e., pain out of proportion to physical exam. Symptoms of diarrhea, anorexia, nausea/vomiting, and bloating are common. Laboratory findings of leukocytosis or lactic acidosis may be less profound and less prevalent than what is seen with

other etiologies of acute mesenteric ischemia. Mesenteric venous thrombosis is associated with hypercoagulable states, previous deep venous or mesenteric thrombosis, as well as intraabdominal inflammation or infection and previous abdominal surgery.

Abdominal CT scan is the most useful test in diagnosing mesenteric venous thrombosis, with a sensitivity that exceeds that of mesenteric angiography. Findings on CT scan include presence of thrombus within the superior mesenteric vein or portal vein, or less specific findings of ascites, bowel wall thickening, mesenteric congestion, or stranding, or pneumatosis intestinalis. Angiography may be useful if the possibility of an arterial etiology needs to be ruled out. Mesenteric venous thrombosis is diagnosed by angiographic venous phase findings of thrombus or nonfilling of the superior mesenteric vein, or prolonged emptying of the arterial phase.

Treatment of mesenteric venous thrombosis begins with the institution of heparin anticoagulation, which will be continued as chronic oral anticoagulation after the acute episode is resolved. The decision of whether the patient should go to the operating room depends primarily on the abdominal exam. Evidence of localized or generalized peritonitis requires that the patient be explored and nonviable bowel resected.

CHRONIC MESENTERIC ISCHEMIA

As previously mentioned in regard to acute mesenteric arterial thrombosis, chronic mesenteric symptoms result most commonly from atherosclerotic lesions in the visceral arteries. This compromised blood flow manifests as intestinal angina (abdominal pain after meals) and may result in food aversion and weight loss. Diarrhea and other nonspecific abdominal complaints may be present. Though chronic mesenteric ischemia is not immediately life-threatening or bowel-threatening, its progression to an acute thrombotic state is unpredictable.

The diagnosis of chronic mesenteric ischemia is made with angiography. Multiple stenoses and occlusions may be present. Treatment is intestinal revascularization. Trap-door endarterectomy or bypass grafting are the operative means to achieve this. Depending on the anatomy of the mesenteric arteries, single or multiple grafts may be used. Recent results with percutaneous angioplasty and stenting have also demonstrated effective treatment of this condition.

It should also be noted that mesenteric venous thrombosis can have a chronic presentation as well. In these patients, venous collateral flow allows bowel viability, though symptoms of vague abdominal pain may be present. Incidental findings of partially or completely occlusive mesenteric venous thrombus may be noted during abdominal CT scanning to rule out other pathology. Long-term anticoagulation may be of benefit.

SUMMARY

Modern series of acute mesenteric ischemia still demonstrate the lethality of this set of disease entities. Early recognition of the possibility of acute mesenteric ischemia and prompt diagnostic imaging (angiography in mesenteric arterial embolism, mesenteric arterial thrombosis, and nonocclusive mesenteric ischemia; abdominal CT scan for mesenteric venous thrombosis) ensure that adequate perfusion is restored to the ischemic intestine as rapidly as possible. Even with expeditious diagnosis, however, there are futile cases in which the overwhelming extent of bowel infarct precludes any further surgical intervention.

Intestinal Pseudoobstruction

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

myopathic Pertaining to diseases of the musculature.
neuropathic Pertaining to disordered function caused by disease or malfunction of the nervous system.

Pseudoobstruction is a neuromuscular disorder of motor propulsion that occurs most commonly in the small or large intestine. It is a chronic disorder for which both myopathic and neuropathic forms are recognized. Chronic intestinal pseudoobstruction is characterized by symptoms of intestinal obstruction in the absence of any form of mechanical obstruction, such as strictures or tumors. It is a condition in which the mechanisms for control of organized propulsive motility fail while the intestinal lumen is patent. The general symptoms of colicky abdominal pain, nausea, and vomiting and abdominal distension in pseudoobstruction simulate the symptoms arising from a mechanical obstruction.

MYOPATHIC FORM

Degenerative changes in the musculature underlie the myopathic form of pseudoobstruction. Familial visceral myopathies are genetic diseases characterized by degeneration and fibrosis of gastrointestinal smooth muscle. Progressive weakening of the contractile forces the musculature is able to generate compromises propulsive motility and underlies the clinical symptoms that include pseudoobstruction in the affected patients. Hypomotility characterizes this form of chronic intestinal pseudoobstruction when studied manometrically.

There are two well-recognized types of familial visceral myopathy based on the pattern of inheritance. The histopathologic appearance of degenerating muscle fibers and fibrosis is essentially the same for both types. One type is transmitted by an autosomal dominant gene and the second type by an autosomal recessive gene. Prognosis is poor for both types of myopathy because there is no effective treatment and the patients require long-term parenteral feeding to avoid severe malnutrition.

NEUROPATHIC FORM

Neuropathic forms of intestinal pseudoobstruction reflect degenerative changes in the enteric nervous system. Failure of propulsive motility in the affected length of bowel reflects loss of the neural networks that program and control the repertoire of motility patterns required for the necessary functions of the affected region of intestine. Pseudoobstruction occurs in part because contractile behavior of the circular muscle is hyperactive but disorganized in the denervated regions. Hyperactivity of the musculature is a diagnostic sign of the neuropathic form of chronic intestinal pseudoobstruction in humans. The hyperactive and disorganized contractile behavior reflects the absence of inhibitory nervous control of the muscles that are self-excitable (i.e., autogenic) when released from the braking action imposed by inhibitory motor neurons. Chronic pseudoobstruction is therefore symptomatic of the advanced stages of a progressive enteric neuropathy.

Degenerative noninflammatory and inflammatory enteric neuropathies both culminate in pseudoobstruction. Noninflammatory neuropathies can be either familial or sporadic. The mode of inheritance may be autosomal recessive or dominant. In the former, the neuropathologic findings include a marked reduction in the number of neurons in both myenteric and submucosal plexuses. Members of two families have been described with intestinal pseudoobstruction associated with the autosomal dominant form of enteric neuropathy. The numbers of enteric neurons were decreased in these patients, with no alterations being found in the central nervous system or parts of the autonomic nervous system outside the gut.

Degenerative inflammatory enteric neuropathies are characterized by a dense inflammatory infiltrate confined to the enteric nervous system. Paraneoplastic syndrome, Chagas' disease, and idiopathic enteric neuronal degenerative disease are recognizable forms of pseudoobstruction related to inflammatory neuropathies.

cobalamin Refers to the entire vitamin B_{12} molecule except for the cyanide moiety, which may be substituted for by other organic ligands (methyl, adenosyl) and still retain full activity.

cubilin Multifunctional protein in the apical (luminal) membrane of intestinal and renal cells; composed of multiple closely related repeating units, two of which are responsible for binding the IF–Cbl complex.

haptocorrin Cobalamin-binding glycoprotein of unknown function produced by the salivary glands, stomach, and other foregut tissues of mammals.

intrinsic factor Glycoprotein produced by the stomach or other foregut tissues of mammals; specifically binds vitamin B_{12} (cobalamin).

transcobalamin Cobalamin-binding nonglycosylated protein that is produced by all epithelial cells, circulates in the blood, and delivers cobalamin to the tissues of mammals.

vitamin B_{12} Cobalt-containing compound produced by microorganisms; consists of a planar four-pyrrole ring (corrin), with a central cobalt molecule coordinately bound to a dimethylbenzimidazole-ribose moiety below and to a cyanide above. This vitamin is essential for cell growth.

Intrinsic factor is a 399-amino-acid glycoprotein produced by mammalian stomach or other foregut tissues, primarily gastric parietal cells in humans. Intrinsic factor specifically binds cobalamin, a large water-soluble molecule that cannot be absorbed by diffusion across the intestinal wall but is essential for growth of mammalian cells.

INTRODUCTION

The intestinal epithelial cell layer does not permit absorption of peptides larger than five or six amino acids in size. The enterocytes responsible for this barrier express apical carriers and transporters that are highly efficient for the uptake of the products of digestion, such as vitamins, minerals, and amino acids. Cobalamin (Cbl), which is essential for growth of mammalian cells, is large (molecular weight, 1356) and cannot be absorbed by diffusion across the intestinal wall. Gastric intrinsic factor (IF) and salivary haptocorrin (Hc) are the main Cbl binders in the gastrointestinal lumen, and the corresponding receptor for each one is found on the enterocyte apical membrane. Transcobalamin (TC) also binds Cbl and is necessary for the transport of Cbl to peripheral tissues; its receptor is present in basolateral membranes of all somatic cells (Table I).

OCCURRENCE AND DISTRIBUTION

Intrinsic factor is produced by mammalian tissues derived from the foregut, especially in the mucosa of the gastric body (corpus), but not in cardiac or antral

TABLE I Properties of Cbl-Binding Proteins[a]

Property	Intrinsic factor	Haptocorrin	Transcobalamin
Expression	Gastric body Medium-sized ducts (salivary, pancreatic)	Granulocytes, yolk sac, mammary glands, salivary acini, and ducts	Most tissues
Carbohydrate	15%	33–40%	0
Molecular mass	45–59 kDa	58–60 kDa	44 kDa
Number of subunits	1	1	1
Number of Cbl binding sites	1	1	1
K_a for Cbl[b]	1–4 n*M*	0.1 n*M*	0.02 n*M*

[a] Data are from Schneider and Stroinski (1987); adapted from Allen *et al*. (1978).
[b] The large range of values for K_a may represent differences in methods used, and may not reflect the true degree of relative affinity.

mucosa in most species. Both parietal cells and chief cells in the gastric body produce IF. In humans, most IF is expressed in parietal cells, but IF in rat and mouse is produced primarily in chief cells. IF is expressed in the minority of enteroendocrine cells in the gastric body of dogs and humans. The cells of medium-sized pancreatic ducts are the principal source of IF in the dog, and these cells respond to hormonal stimuli that stimulate pancreatic function (e.g., cholecystokinin).

SYNTHESIS AND SECRETION

Any increase in acid secretion from the parietal cell (by histamine, gastrin, or cholinergic stimulation) also increases IF production in those species (including humans) in which the parietal cell is the principal source of IF. The regulated step in IF expression is secretion from the cell, as the rate of IF mRNA content and rate of synthesis is constant, independent of the addition of stimulators of secretion. Drugs that directly diminish acid secretion in man can inhibit IF secretion, including histamine-2 receptor antagonists and proton pump inhibitors. In the rat and mouse, stimulators of chief cell secretion (cholinergic stimulators and dibutyryl camp), but not histamine or gastrin, increase IF secretion.

STRUCTURE AND FUNCTION

IF is a 399-amino-acid glycoprotein essential for nearly all uptake of cobalamin from the intestine of most vertebrates. IF purified by affinity chromatography using a Sepharose-coupled monocarboxylic acid derivative of Cbl has a molecular mass of 45–47 kDa. Larger apparent sizes have been reported, presumably due to the carbohydrate content of 15%. The sequence of human IF deduced from its cDNA clone is 80% identical with that of rat IF, and the gene is found on chromosome 11. The carbohydrate chains on IF are not important for binding function, but glycosylation of IF creates a protein more resistant to degradation by gastric and pancreatic proteases.

The entire Cbl molecule is important for IF binding. Binding of Cbl to IF is dependent on interactions with both the 5,6-dimethylbenzimidazole and the corrin ring, initiating a change in folding as IF closes around the Cbl molecule. This change in structure presumably accounts for the higher affinity for the intestinal IF receptor of the [Cbl : IF] complex versus the IF molecule alone. The ribazole fragment in the Cbl side chain and the Co–N coordination bonds of the lower cobalt nucleotide ligands are needed to promote conformational changes in IF to allow Cbl binding.

Although there are six regions of high sequence homology between IF, Hc, and TC, the predicted secondary structure within these proteins is not well conserved, perhaps accounting for the different binding affinities of these proteins for cobalamin (Table I) or for their individual receptors. There are two domains on IF identified by monoclonal antibody binding, one for binding Cbl and the other for IF–Cbl receptor binding. Binding of the IF–Cbl complex to its receptor, cubilin, is dependent on the N terminus of IF.

CELLULAR UPTAKE AND METABOLISM OF IF–CBL

Dietary Cbl is released from Cbl-binding enzymes by gastric proteases, and binds first to Hc in the stomach. The Hc–Cbl complex is then hydrolyzed by pancreatic proteases and the Cbl is transferred to IF in the proximal duodenum. The IF–Cbl complex survives proteolysis within the intestinal lumen due to its relative protease resistance, and is bound by the IF–Cbl receptor located on villous cells of the ileal epithelium. This receptor is now known to be the multiligand 460-kDa protein, cubilin. Transcobalamin may be involved in

TABLE II Physiological Causes of Cobalamin Malabsorption Related to Intrinsic Factor

Organ	Disorder/condition	Pathophysiology
Stomach	Pernicious anemia	Insufficient IF
	Total gastrectomy	Absence of IF
	Subtotal gastrectomy, atrophic gastritis	Decreased acid/pepsin secretion with impaired food cobalamin release
	Abnormal IF expression or structure	Genetic variation in IF
Gut lumen	Vegetarian diet, anorexia	Lack of cobalamin in foods of nonanimal origin
	Zollinger–Ellison syndrome	Low pH with impaired transfer of cobalamin from haptocorrin to IF
	Pancreatic insufficiency	Protease deficiency with impaired transfer of cobalamin from haptocorrin to IF
	Bacterial overgrowth	Competition for uptake of cobalamin by bacteria
Small bowel mucosa	Ileal resection or disease	Decreased number/function of receptors for IF–Cbl complex
	Imerslund–Grasbeck syndrome	Abnormal receptor-mediated endocytosis of IF–Cbl complex
	AIDS enteropathy	Combination of mucosal disease and decreased surface exposure time

transcytosis of Cbl across the enterocyte, because a low concentration of TC receptors has been demonstrated on the apical membrane of enterocytes.

Rapid internalization of IF–Cbl into enterocytes occurs by receptor-mediated endocytosis, and agents that inhibit lysosomal enzymes also inhibit transcytosis of Cbl. Radioautographic studies using ^{125}I-labeled IF have demonstrated localization in endosomes and early lysosomes of the apical cytoplasm. A half-life of 4 h for degradation of internalized IF has been estimated from studies in cultured epithelial cells, and this time frame is consistent with the 2–4 h needed to transfer Cbl from the luminal IF–Cbl complex to the serum TC–Cbl complex. The initial mechanism for intracellular IF degradation proceeds via cathepsin L activity. Following intracellular release of Cbl, Cbl exits the cell bound to TC, which is probably produced in the enterocyte.

Cbl deficiency occurs most commonly in pernicious anemia (loss of IF from chronic autoimmune gastritis), following resection of the gastric body (containing parietal cells the source of IF), with atrophic gastritis (a sequela of *Helicobacter pylori* infection), after resection or disease (usually Crohn's disease) of the terminal ileum (the site of IF–Cbl absorption via receptor-mediated endocytosis), or following malabsorption from any cause (especially AIDS enteropathy) (Table II). Less common causes of deficiency include congenital absence of IF or TC, Imerslund–Grasbeck syndrome (abnormal IF–Cbl receptor, or cubilin), small bowel bacterial or parasitic overgrowth (utilization of Cbl), and pancreatic insufficiency (lack of transfer of Cbl from Hc to IF).

Intussusception

JOEL SMITH AND ROY MCCAULEY
Tufts–New England Medical Center

intussuscepiens The intestinal loop, or sheath, into which the intussusepting bowel (the intussusceptum) invaginates.
intussusception Telescoping or invagination of one portion of the bowel into the adjacent, distal intestinal lumen.
intussusceptum Invaginating and returning bowel of the intussusception, including the adjacent mesentery.
lead point An anatomic or congenital abnormality, neoplasm, or postsurgical change in the intussusceptum that causes secondary invagination into the intussuscepiens.

Intussusception is the telescoping of one region of the small or large bowel into the adjacent intestinal lumen, secondary to focally abnormal peristalsis. The large majority of intussusceptions present as acute abdominal emergencies in children, although they may occur at any age, including *in utero*. When seen in children, the cause is almost always idiopathic, occurring near the ileocecal valve. Reduction is frequently by liquid or air enema under fluoroscopic or ultrasonic guidance, although some cases require surgery. In adults, intussusception is usually secondary to a definable cause and thus requires surgical reduction and removal of the lead point.

INTRODUCTION

Intussusception has been recognized as a cause of obstruction for nearly 300 years and has been successfully reduced by surgical, hydrostatic, and pneumatic methods for more than 100 years. The frequency is approximately 2 to 4 in 1000, but varies according to the series. It is more common in boys than in girls. Two of three cases are seen within the first year of life, with the vast majority of cases occurring between 3 months and 6 years of age. Most intussusceptions originate near the ileocecal valve (ileocolic intussusception), but may occur elsewhere in the small or large bowel. The tendency is to occur at junctions between "free" and intraperitoneal bowel. Treatment of intussusception first requires resuscitation with fluids and antibiotics. In cases of obstruction, decompression of the stomach with a nasogastric tube may be necessary.

ETIOLOGY

Idiopathic intussusception is likely secondary to kinking of the bowel secondary to inequilibrium between contraction of circular and longitudinal muscles in the bowel wall. This may be secondary to lymphoid hyperplasia of the distal ileum. This abnormal peristalsis may also occur at a lead point, such as a Meckel's diverticulum, neoplasm (lymphoma), polyp (Peutz-Jeghers syndrome, juvenile polyposis), duplication cyst, ectopic pancreas, inspissated stool (cystic fibrosis), hemangioma, or bowel wall hematoma (trauma; Henoch-Schonlein purpura). Recurrent intussusceptions are more common if a lead point is present.

PRESENTATION

Signs and Symptoms

Classically, children with intussusception are previously healthy and well nourished, with sudden onset of severe colic. Approximately 50% will have the triad of abdominal pain, "red currant jelly" stool, and a palpable abdominal mass. These symptoms are caused by compression of the intramural and mesenteric lymphatics and veins, with ultimate arterial compromise, resulting in bowel wall edema, hemorrhage, ischemia, and infarction. Symptoms may progress as continued normal peristalsis results in lengthening of the intussusception. Episodes of pallor and "doubling over" may occur at intervals of approximately 20 min, with pulling up of the knees to the chest, cringing in pain, and occasional vomiting. Between such attacks, the child may be apathetic, normal, or even playful. As the bowel mucosa becomes compromised, the stool will contain the bloody mucus (red currant jelly stool).

Physical Exam

A "sausage-shaped" mass may be palpated, most frequently in the right upper quadrant. Of course, not all cases are typical, and children may have no pain, red currant jelly stool, or mass. In such cases, Henoch-Schonlien purpura, and other forms of obstruction,

 Copyright 2004, Elsevier (USA). All rights reserved.

including malrotation with volvulus, should be considered. Older children may have pain as their only symptom. If this is the case, the differential diagnosis includes simple gastroenteritis. When bowel compromise has occurred, signs of peritonitis may be present.

DIAGNOSIS

Radiographic Evaluation

The role of abdominal radiographs in suspected intussusception is controversial, as false negatives may occur, and correct diagnosis based on radiographic findings alone occurs in less than 50% of cases (see Table I). Radiographic findings may include a lack of gas and stool and/or the presence of a soft tissue mass in the right lower quadrant. The mass may obscure the liver edge. Classic radiographic findings include the "meniscus sign" and the "target sign." A meniscus is formed if the gas-filled distal colon outlines the leading edge of the intussusceptum (Fig. 1). A target shape may be seen if the central, lucent, mesenteric fat of the intussusceptum is identifiable in the soft-tissue mass. With obstruction, distended small bowel loops may be identified. Free air, very rarely identified in children with intussusception, signifies perforation and the need for immediate surgery.

Enema Diagnosis

Until recently, barium enema was the "gold standard" diagnostic modality. Air contrast enema and ultrasound have largely replaced this technique. The diagnosis is confirmed on enema with outlining of the intussusceptum by barium or air (meniscus sign) (Fig. 1). With barium, a "coiled spring" appearance of the bowel may be present if barium coats the outer surface of the intussusceptum and the inner surface of the intussuscipiens.

Ultrasound Diagnosis

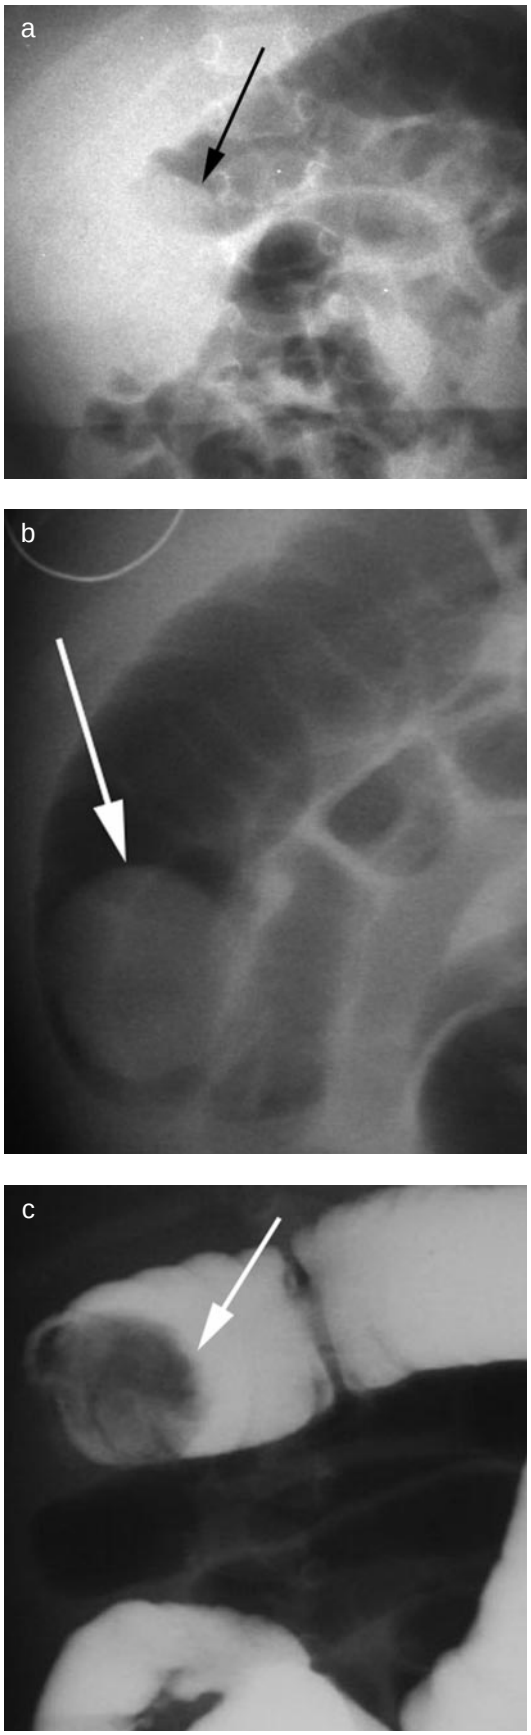
Ultrasound is very sensitive for the diagnosis, especially by an experienced radiologist. The mass is usually large (~5 cm) and displaces adjacent loops. Ultrasound diagnosis and reduction is advantageous as it precludes the need for radiation and is more comfortable for the patient. False positives are rare, but may occur with misidentification of abnormal bowel wall thickening, stool, or psoas muscles. Ultrasound is likely the best method for depicting a lead point in children. Transverse views along the axis of the bowel show central echogenic mesenteric fat and vessels and a hypoechoic outer bowel wall, sometimes referred to as the "doughnut" or target sign (Fig. 2). Longitudinal views may demonstrate a "pseudo-kidney" or "sandwich" sign when imaging through the middle of the intussusception and the "hayfork sign" at images near the apex of the intussusception. These signs are descriptive variations on the appearance of alternating hypoechoic muscle (intussusceptum), hyperechoic mesentery (intussusceptum), and hypoechoic muscle (intussuscipiens). Incidental peritoneal fluid may be identified, but does not necessarily indicate the presence of perforation or peritonitis. Lack of Doppler flow in the intussusceptum may suggest ischemia or necrosis and often indicates a lower rate of reduction.

Computed Tomography Scan Diagnosis

Computed tomography (CT) scan is sometimes used for diagnosis, most often in a symptomatic

TABLE I Comparison of Methods for Diagnosing and Treating Intussusception

	Diagnosis	Reduction rate	Advantages	Disadvantages
Radiograph	Not sensitive or specific	—	Noninvasive	Diagnostic in less than 50%; not therapeutic
Barium enema	Sensitive and specific	70–80%	High success rate; low perforation; evaluation of lead point	Barium irritates peritoneum if perforation occurs
Air enema	Sensitive and specific	Higher than barium	High success rate; low perforation; quicker than barium; less irritating	May not fully evaluate colon and lead point
Ultrasound	Sensitive and specific	Comparable to enema	High success rate; low perforation; no radiation; evaluation of lead point	Occasional false-positives
CT scan	Used for adults	Not therapeutic	Evaluates small bowel and lead points	Not therapeutic
Surgery	—	Very high	Can remove lead point	Invasive



adult. Axial images may show a complex target mass, containing eccentric mesenteric fat (Fig. 3). Mesenteric vessels are frequently identified in the intussusceptum. An appearance analogous to the "coiled spring" on barium enema may be present if the oral contrast outlines intussusceptum. A lead point is occasionally identified.

REDUCTION

Image-Guided Reduction

Introduction

Image-guided reduction is less invasive, has a lower morbidity and cost, and leads to a shorter length of hospitalization, when compared to surgery. Such reduction may be accomplished under fluoroscopic guidance with air, barium, or other contrast material or with ultrasound using saline or, occasionally, air. Ultimately, the choice of technique is often dependent on the experience of the radiologist. With any image-guided technique, reduction is approximately 90% successful. Success rates are lower in younger infants, those with longer duration of symptoms, and those with more severe obstruction.

Barium Enema Reduction

Traditionally, barium reduction follows the "rule of threes." These include raising the barium bag not more than 3–3.5 feet above the table, making not more than three attempts at reduction, and sustaining pressure for not more than 3 min during each attempt. This rule is arbitrary and often physicians attempt reduction more vigorously. Barium has demonstrated high reduction rates, 70–80%, infrequent perforation, and better evaluation of lead points and colonic pathology than air.

Air Enema Reduction

Air reduction has a higher successful reduction rate, but may result in higher perforation rates compared with barium. Reduction is often accomplished more rapidly, with a secondary decrease in radiation exposure. If perforation does occur, air in the peritoneal cavity is less irritating than barium, although tension pneumoperitoneum may rarely occur. Air insufflation

FIGURE 1 (a) Abdominal radiograph demonstrates a "meniscus sign" as the intussusceptum (arrow) is outlined by air in the proximal transverse colon. (b) Spot radiograph from air enema reduction demonstrates displacement of the filling defect to the proximal ascending colon (arrow). Complete reduction was confirmed by reflux of air into the terminal ileum. (c) Following recurrent intussusception in the same patient, reduction was accomplished by barium enema. The intussusceptum is outlined by barium (arrow).

FIGURE 2 Ultrasound image of intussusception. Image obtained axially through the abnormal bowel. The hypoechoic muscle of the intussuscipiens (arrow) surrounds the hyperechoic mesenteric fat and hypoechoic wall of the intussusceptum (arrowhead).

of the colon is usually performed with a pressure release system and manometer, to avoid pressures above which perforations usually occur. The initial suspicion that air had a higher perforation rate than barium was likely related to the initial learning curve and the true rate is probably less than 1% with either method. With either technique, complete reduction is confirmed with free reflux of barium or air reflux into the distal ileum. When possible, the patient may be requested to perform the Valsalva maneuver during treatment as it may help reduction and decrease the risk of perforation.

Ultrasound Reduction

Hydrostatic (saline) reduction under ultrasound evidence is gaining in popularity. It has the advantage of having no radiation exposure. Reduction rates are high and perforation rate is comparable to that of other techniques. Another advantage is a more detailed visualization of the intussusceptum and lead point, if present. Recently, air reduction with ultrasound guidance has been advocated and also has a high success rate in initial studies. Ultrasound may have a role after enema reduction for confirming reduction and evaluating for a lead point.

Surgical Reduction

Contraindications to attempted enema reduction include the presence of peritonitis ("surgical abdomen"). When symptoms have been present for more than 48 h, careful evaluation of the abdomen is needed. Surgical reduction is also necessary if there is perforation during nonoperative reduction. Therefore, the surgical team should be informed when an enema reduction is to be attempted. At surgery, manual reduction is usually curative, but resection and primary anastomosis may be necessary, if manual reduction cannot be accomplished or if a lead point is identified.

PROGNOSIS

Delayed diagnosis or inadequate fluid and antibiotic resuscitation may lead to fatal complications. When treated promptly, however, recovery almost always occurs. There is an approximately 10% rate of recurrence. If complete reduction is accomplished by image-guided methods, each recurrence is considered a new event and alone is not an indication for surgery. To monitor for recurrence, patients are usually observed for 12–24 h after reduction. The major cause of morbidity is perforation, which tends to occur in younger patients and those with longer duration of symptoms. Perforation may occur in the intussusceptum or intussuscipiens. Ultrasound is useful in evaluating patients with recurrence of or persistent abdominal pain after air reduction, at times revealing recurrent intussusception or findings suggestive of an inflammatory process.

POSTOPERATIVE INTUSSUSCEPTION

Postoperative intussusception is an unusual entity, making up less than 1% of cases. It most often occurs after abdominal surgery, but may be seen after thoracotomy as well. Unlike idiopathic intussusception in a child, the jejunum is the most frequent site of origin. Only rarely is a lead point identified, such as a drain, tube, suture line, adhesion, or focus of bowel wall edema. When no lead point is present, the cause is likely related to bowel manipulation or an electrolyte abnormality, with secondary paralytic ileus. Diagnosis is often delayed, so this entity should be considered in cases of postoperative obstruction, especially within 2 weeks of surgery. Operative reduction is usually curative.

ADULT INTUSSUSCEPTION

Intussusception is rare in adults and, when present, rarely results in obstruction. Preoperative diagnosis is

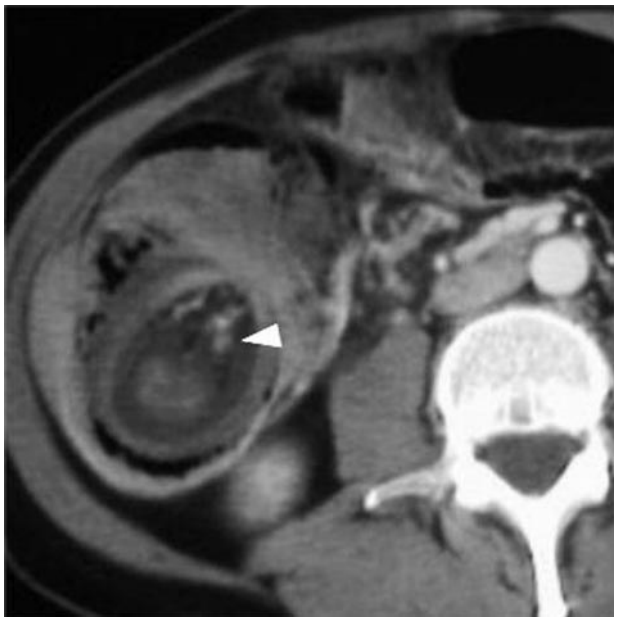


FIGURE 3 Axial CT scan with IV contrast enhancement. The intussusceptum with mesenteric vessels (arrowhead) is seen within the colonic intussuscipiens.

established in only approximately one-third of patients. Common symptoms are intermittent pain, nausea, and vomiting. These symptoms may present acutely, but are frequently chronic over weeks or months. Mild, focal tenderness may be elicited on physical exam. Unlike findings in children, bloody stool and abdominal masses are uncommon. A lead point is almost always present, necessitating surgery. The intussusception occurs most frequently within the small bowel and is almost always secondary to a benign lead point, such as adhesions. The rarer colonic intussusception is more likely to be related to a malignant lead point, predominantly metastatic disease (Fig. 3). CT may be the most accurate means of diagnosis, as the small bowel is not usually visualized by enema. Endoscopy is sometimes employed for diagnosis, and, at times, reduction via air insufflation. Intussusception of the appendix is a separate, rare entity, also seen in adults.

Iron Absorption

DAVID F. NUTTING
University of Tennessee Health Science Center

divalent metal ion transporter-1 (DMT1) Also called divalent cation transporter-1 (DCT1) and Nramp2. DMT1 moves ferrous iron from the lumen into enterocytes.

duodenal cytochrome b (Dcytb) A ferric reductase found in the brush border membrane of proximal intestinal enterocytes. Dcytb converts the poorly absorbed ferric form of iron (Fe^{3+}) to the ferrous form (Fe^{2+}) that is transported into the cells by divalent metal ion transporter-1.

ferritin A mainly cytosolic molecule that binds excess iron, in both enterocytes and the liver. Ferritin complexes have the capacity to bind approximately 4500 iron molecules.

hereditary hemochromatosis A disorder of iron metabolism in which affected individuals absorb an excessive amount of iron that accumulates in internal organs and may eventually interfere with cellular function.

iron-responsive gene element (IRE) and iron-regulatory protein (IRP) These participate in the regulation of expression of some genes involved in iron absorption. IRPs bind to IREs and increase or decrease the expression of specific genes.

transferrin (Tf) An iron-binding molecule found in several compartments in the body. Circulating transferrin carries iron to and from body tissues and may apprise intestinal cells about body iron status. The cytosol of villus enterocytes contains a similar, but not identical, form of transferrin. Some of the cytosolic transferrin (as apotransferrin, which has no iron bound to it) is secreted into the intestinal lumen, where it promotes iron absorption by chelating two molecules of Fe^{3+} and then binding to a transferrin receptor in the brush border membrane.

Dietary iron is poorly absorbed in most circumstances, but absorption is regulated and increases when needed, such as in pregnancy and iron deficiency. In contrast, the body has few mechanisms for removing excess iron, which must therefore be stored to prevent it from catalyzing reactions that may produce undesired products, such as free radicals. Other than blood loss, as occurs during menstruation, the only mechanism to remove iron is by trapping some of the iron in enterocytes, which are then sloughed off. A typical meat-containing diet provides 10–30 mg iron each day. Of this, only approximately 1 mg is absorbed (3–10% of dietary iron). During pregnancy, iron absorption may increase to provide 5–6 mg/day. However, if a pregnant woman takes iron supplements, efficiency is down-regulated to the normal low percentage of ingested iron. Thus, the amount of iron absorbed increases linearly with the quantity ingested from all sources, but the proportion absorbed decreases. Multiple mechanisms are involved in iron absorption. Some of them are regulated; others appear not to be. Furthermore, the relative contributions of the various pathways to overall iron absorption have not yet been fully quantitated. Most iron absorption takes place in the proximal intestine, mainly the duodenum and proximal jejunum. However, a small amount of iron is absorbed by the stomach, distal small intestine, and colon.

LUMENAL IRON METABOLISM

In the stomach, acid helps to release iron from dietary nutrients and to release heme from ingested hemoglobin and myoglobin in meat. The low pH in the stomach promotes dissolution of iron in the aqueous medium; at very low pH (<3), both Fe^{2+} and Fe^{3+} are soluble. People with deficient acid production absorb iron even more poorly than do normal individuals. Most dietary iron is not in heme and most of this nonheme iron is trivalent (ferric) iron. When the pH is >3, iron (especially the less soluble Fe^{3+}) must be kept soluble; this occurs through the binding of iron to other nutrients. A variety of substances chelate iron, including organic acids (lactic acid, citric acid, ascorbic acid), bile acids, fatty acids, some amino acids, mucin, and apotransferrin secreted by enterocytes. In addition to helping solubilize iron, ascorbate reduces Fe^{3+} to Fe^{2+}. Not all dietary organic acids aid iron absorption, though, and significant amounts of some inhibitors may occur in vegetarian diets. Examples are phytate and oxalate, which are well known to interfere with calcium absorption, but they prevent iron absorption as well. In addition, iron binds to two intestinal proteins, mucin and apotransferrin. Mucin is a large glycoprotein with

 Copyright 2004, Elsevier (USA). All rights reserved.

multiple ion-binding groups. By binding many iron molecules, it reduces the formation of large, insoluble (and thus unabsorbable) iron–hydroxide complexes. Once the mucin-bound iron diffuses to the surface of the enterocyte, the iron can be released for absorption.

ENTEROCYTE IRON UPTAKE, PROCESSING, AND RELEASE

A carrier-mediated process takes up heme iron (see Fig. 1). Fe^{2+} is extracted from heme by the enzyme heme oxygenase. This iron is then taken up by cytosolic

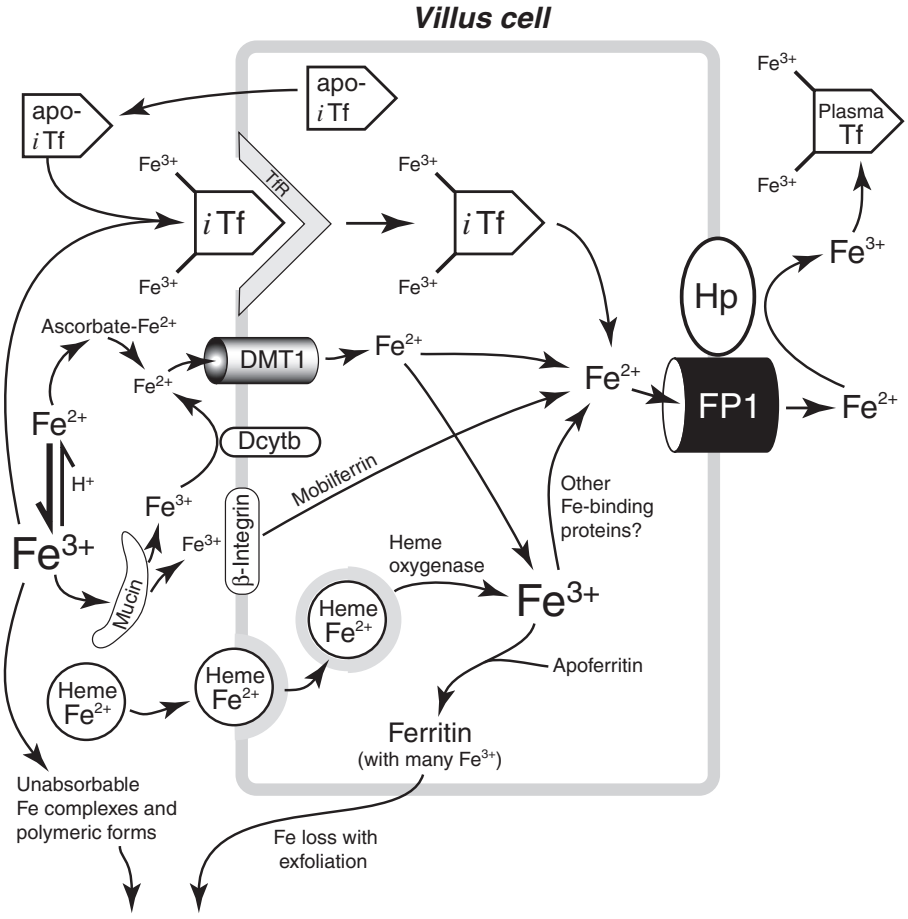

FIGURE 1 Processes involved in iron absorption in the proximal intestine. Iron is released from food by acid and enzymes. Heme is removed from hemoglobin and myoglobin. The heme is absorbed intact, probably by pinocytosis. Inside, heme iron is released and oxidized to Fe^{3+} by heme oxygenase. In the duodenal lumen, the less acidic environment promotes the oxidation of ferrous iron (Fe^{2+}) to the trivalent form. Fe^{3+} is poorly absorbed unless bound. Fe^{3+} may bind to mucin or other molecules, such as ascorbate, or to intestinal apotransferrin (apo-*i*Tf) that has been secreted by enterocytes. Tf-bound iron is carried in via a Tf receptor (TfR). Lumenal iron binding stabilizes the iron and reduces the formation of insoluble iron polymers. Ascorbate also reduces ferric iron back to Fe^{2+}. In addition, Fe^{3+} that reaches the microvilli is either transferred to β_2-integrin, which carries it into the cell, or reduced by duodenal cytochrome b (Dcytb). A well-regulated uptake pathway exists for Fe^{2+}, which is transported into the cell by DMT1 (divalent metal transporter-1). In the cytosol, iron is bound to iron-binding proteins, such as mobilferrin and apotransferrin, and carried to the basolateral side. Excess iron is captured by ferritin. A small amount of iron from ferritin may be released for export, but most stays with the cell and is lost to the lumen when the enterocyte is sloughed at the villus tip. At the basolateral membrane, iron is secreted by a transport protein, ferroportin (FP1). In order to be carried to the body via circulating Tf, it must be oxidized again. This is carried out by a protein, hephaestin (Hp), that is closely associated with FP1.

iron-binding proteins, such as mobilferrin, apotransferrin, and ferritin. The former two transport iron to the basolateral side for export. Ferritin binds Fe^{3+} in times of iron excess.

Some nonheme iron that reaches the apical surface may be absorbed after binding to β-integrin. Once inside the cell, it binds to ferritin or is carried across the enterocyte by cytosolic Fe-binding proteins. The details of the regulation of this pathway are not yet known. Another mechanism involves apotransferrin (apo-Tf). Apo-Tf secreted into the lumen binds two molecules of Fe^{3+}. The iron–transferrin complex then binds to a Tf receptor (TfR) located in the brush border membrane. This complex is absorbed, perhaps by pinocytosis. Once inside, the Fe^{3+} may be reduced, transferred to another molecule of apotransferrin or other cytosolic binding proteins for export, or bound to ferritin for storage or excretion. The physiological regulation of this pathway also has not been established.

A substantial amount of iron is taken up by carrier-mediated transport in the brush border of the villus and this is a regulated process. The transporter is divalent metal transporter-1 (DMT1), which has a marked preference for ferrous iron. Since much of the nonheme iron in the lumen is ferric iron, this carrier-mediated transport requires prior reduction. Brush border membranes have ferric reductase activity provided by the enzyme duodenal cytochrome b (Dcytb). An individual's iron status regulates both Dcytb and DMT1 expression in parallel.

Iron that is not trapped by enterocyte ferritin is carried to the basolateral side, where it is transported outward by a specific protein called ferroportin-1 (FP1). This transporter is also known as iron-regulated gene transcript and metal transport protein-1 and it carries ferrous iron. The divalent iron released at the basolateral side must be reoxidized to trivalent iron before it binds to circulating apotransferrin for transport to the rest of the body. A protein, hephaestin (Hp), is associated with FP1 and may serve this function.

REGULATION

Various stimuli increase iron absorption, for example, increased erythropoiesis following hemorrhage or ascent to high altitude, pregnancy, and iron deficiency. In most cases, the nature of the signal remains to be determined. Tissues such as bone marrow and liver may release as yet unidentified signaling molecules that regulate duodenal enterocytes. In addition, evidence supports the hypothesis that circulating levels of transferrin may play a role in some of these situations.

Intestinal iron absorption appears to operate around a "setpoint" that changes only under specific conditions, such as those listed above (see Fig. 2). When more iron is needed, absorption of both heme and nonheme iron increases, as do the rates of apical iron uptake and basolateral iron release. Expression of three apically targeted proteins, Dcytb, DMT1, and TfR, increases. Conversely, expression of apoferritin decreases, reducing

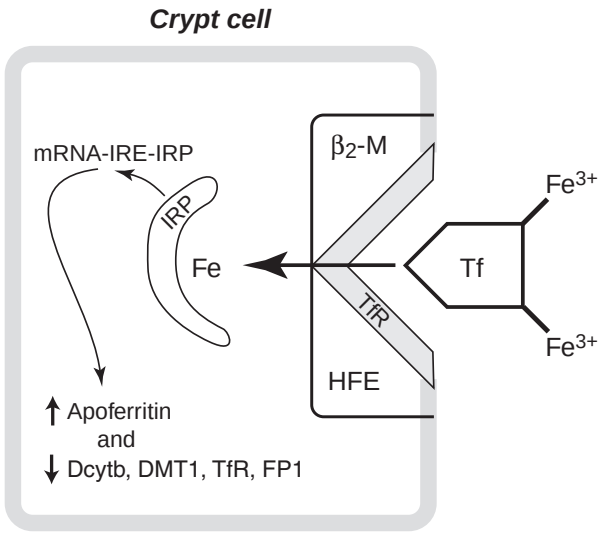

FIGURE 2 Regulation of iron absorption. One mechanism is depicted here. There may be other signals, perhaps originating from the hematopoietic system or the liver. In the mechanism shown, the setpoint for iron absorption is determined in the intestinal crypts. A high level of plasma iron feedsback negatively on the newly formed enterocytes to reduce iron absorption once these cells mature. A fraction of plasma iron-bound transferrin (Tf) escapes from the capillary lumen. This Tf binds to a Tf receptor (TfR) located on the basolateral side of cryptal enterocytes, bringing the Tf-bound iron into the cell. TfR is associated with at least two basolateral membrane proteins, β_2-macroglobulin (β_2-M) and a gene product termed HFE. Defects in HFE lead to unregulated iron absorption, because the iron overload is not sensed by the developing crypt cells. The iron is released and binds to iron-regulatory proteins (IRPs). Under conditions of iron-deficiency, the IRPs that lack iron interact with iron-responsive gene elements (IREs) of certain messenger RNAs. This interaction stabilizes some of the mRNAs, thereby increasing translation (as occurs for the proteins Dcytb, DMT1, TfR, and FP1), or it inhibits translation of other mRNAs (as occurs for apoferritin). These effects become manifest once the cells migrate to the absorptive region along the villi. Thus, iron absorption is increased and loss of absorbed iron is reduced (because less iron is bound to ferritin). The opposite occurs when plasma iron levels are normal or high: when they contain iron, the IRPs do not bind to the IREs, so the expression of proteins that promote iron absorption is diminished, whereas apoferritin expression is high. The apoferritin binds more of the iron that does cross the apical membrane and then takes it back to the intestinal lumen during exfoliation at the villus tip.

iron sequestration in the cytosol. Expression of the basolateral iron exporter FP1 increases, but expression of Hp does not. Perhaps the amount of Hp normally present is sufficient to oxidize any iron transported outward by FP1.

One system of regulation involves iron-regulatory proteins (IRPs) and iron-responsive elements (IREs), but likely there are other regulatory mechanisms. In iron deficiency, more IRPs bind to the iron-regulatory elements in the genome. Iron repletion reverses this. Binding of IRPs increases the transcription of several proteins whose IREs are at the 3′-end of the gene (by stabilizing their mRNAs), but inhibits the transcription of those proteins encoded near the 5′-end, such as apoferritin. Thus, iron absorption is facilitated, whereas iron trapping (and subsequent loss by exfoliation of villus tip cells) is reduced. The converse processes occur during iron repletion and excess, presumably as a consequence of more iron being available to bind to IRPs and thereby inhibiting IRP association with IREs.

Surprisingly, much of the regulation apparently takes place in the newly developing cells in the intestinal crypts, rather than in mature enterocytes in the villi. The strongest evidence for this comes from studies of hereditary hemochromatosis (HH), in which iron absorption increases and remains inappropriately high, due to the lack of normal down-regulating controls. Genetic defects have been identified in a gene product termed HFE. In the basolateral membranes of intestinal crypt cells, HFE associates with at least two other molecules, β_2-macroglobulin and a transferrin receptor. A working hypothesis is that by binding a fraction of transferrin that escapes into the extracellular space, this TfR monitors the circulating Tf level. When iron stores and circulating Tf are adequate, some of this Tf is taken up by crypt cells and this reprograms them so that by the time they reach the villus tip, they have low levels of key proteins such as Dcytb, DMT1, and FP1 and high levels of ferritin. This reduces iron absorption and enhances the loss of absorbed iron after sloughing of the villus tip cells. When HFE is absent or defective, as in some types of HH, the crypt cells are incapable of sensing the high levels of circulating Tf iron and thus produce enterocytes with enhanced iron absorption. Ultimately, this results in excessive deposition of iron in various tissues and disruption of cellular and organ function.

Irritable Bowel Syndrome

INES SCHWETZ AND LIN CHANG
University of California, Los Angeles

brain–gut axis Bidirectional communication between the central nervous system and the gut via nervous and endocrine pathways to ensure that digestive function is optimal for the overall state of the organism.
dysmenorrhea A condition marked by painful menstruation.
dyspareunia Difficult or painful sexual intercourse.
high-amplitude propagating contractions Colonic contractions that produce mass movements when present in the transverse and ascending colon and defecation when present in the descending or sigmoid colon.
maladaptive coping styles Beliefs and strategies on how to master a crisis or a problem that are not helpful or even counterproductive, e.g., catastrophizing, internalization.
pelvic floor dyssynergia Inappropriate contraction of failure to relax the pelvic floor and/or anal sphincter muscles during attempts to defecate, resulting in the impedance of stool passage.
Sitzmarker colon transit test Simple, validated method using radiopaque markers to calculate segmental and colon transit by counting markers on abdominal radiographs.
stress A perceived threat to homeostasis; an event or stimulus that causes an often abrupt but always a large physiologic change from what is expected.
sustained stress Chronically ongoing stressful situations in a person's life, e.g., marital problems, death of a family member, change in role in life, change in job, significant financial loss.

Irritable bowel syndrome (IBS) is a functional disorder characterized by symptoms of abdominal pain or discomfort associated with a change in bowel habit. It accounts for up to 12% of total visits to primary care providers and is one of the most common conditions diagnosed by gastroenterologists. The economic burden in terms of medical expenses, loss of productivity, and work absenteeism is considerable. The diagnosis of IBS is based on identifying characteristic symptoms and excluding organic disease. Novel treatments have broadened therapeutic options that currently include dietary recommendations, lifestyle modifications, pharmacotherapy, and behavioral and psychological therapy.

EPIDEMIOLOGY

Irritable bowel syndrome (IBS) is a very common disorder worldwide, with prevalence rates of 9–23% in the general population. In a recent report on gastrointestinal (GI) illnesses in the United States, IBS was second only to esophageal reflux disease in its prevalence (15.4 million people). Several population-based studies have found women to be at least twice as frequently affected as men, with prevalence ratios ranging from 2 : 1 to 3 : 1.

The first presentation of patients to a physician usually takes place between the ages of 30 and 50 years, with a decrease in reporting frequency among older subjects. However, not all individuals with IBS seek medical care for their symptoms. Based on epidemiological studies conducted in different countries, 20–75% of persons that meet diagnostic criteria for IBS will seek medical attention at some point in their lives. Cultural factors as well as differences in healthcare systems and access to medical care may influence the wide range of these rates. Although most persons with IBS do not consult a physician, there are still between 2.4 and 3.5 million physician visits annually for IBS in the United States. The burden of illness of the disease was recently estimated to be $1.6 to $10 billion in direct costs and $19.2 billion in indirect costs.

PATHOPHYSIOLOGY

In the past, IBS has been considered to be primarily a disorder of altered gut motility or a purely psychological disorder. Currently, a dysregulated brain–gut axis resulting in altered gut motility and visceral hypersensitivity is felt to be the principal pathophysiologic mechanism underlying IBS. Many factors (both central and peripheral) may contribute to this dysregulation in IBS and include genetic predisposition, chronic stress, inflammation/infection, and environmental factors.

Central dysregulation can result in alterations of autonomic outflow, pain modulation pathways, and

 Copyright 2004, Elsevier (USA). All rights reserved.

neuroendocrine systems. Downstream, these alterations subsequently may lead to disturbances in intestinal motility, visceral sensitivity, and mucosal immune response and permeability. Peripheral mechanisms that can contribute to a dysregulated brain–gut axis include enteric infections or inflammation leading to peripheral and spinal sensitization and/or the release of inflammatory mediators (e.g., cytokines) that can further perpetuate alterations in the brain–gut axis.

Altered Intestinal Motility

In the ileum, colon, and rectum, IBS patients show an enhanced response to a variety of stimuli including meals, distension, and stress. Altered motility patterns have been reported in IBS patients but are not consistently found. Patients with diarrhea and abdominal pain experience significantly more high-amplitude propagating contractions (HAPCs), which are of higher amplitude than those found in healthy controls. These HAPCs are more likely to be associated with a sensation of pain. Motility abnormalities can interact with altered perception of visceral events to produce typical symptoms in IBS. Delayed transit of gas with enhanced perception of gas causes patients to feel bloated. It should be noted, however, that altered motility is present in a subset of patients and cannot be used as a diagnostic marker.

Altered Visceral Perception

The initial clinical observations that led to the hypothesis that IBS patients have visceral hypersensitivity include recurrent abdominal pain, tenderness during palpitation of the sigmoid colon during physical examination, and excessive pain during endoscopic evaluation of the sigmoid colon. Experimental evidence suggests that a variety of perceptual alterations exist in IBS patients: visceral hypersensitivity involving the upper and lower GI tract, as well as with a heightened perception of physiologic intestinal contractions. Multiple studies using various balloon distension paradigms have reported lowered colorectal perceptual thresholds and increased sensory ratings and viscerosomatic referral areas in IBS patients than in healthy individuals. In contrast, most studies have demonstrated that IBS patients do not exhibit generalized hypersensitivity to noxious somatic stimulation. At least two underlying distinct mechanisms contribute to the visceral hypersensitivity in IBS: a hypervigilance toward expected aversive events arising from the viscera and a hyperalgesia, which is inducible by sustained noxious visceral stimulation.

Alteration of Gut Immune Function

A subset of patients associate the development of IBS symptoms with the onset of gastroenteritis. In recent studies, IBS-like symptoms were found in 7–30% of patients who had recovered from a proven bacterial gastroenteritis. Risk factors associated with the development of postinfective IBS include female gender, duration of acute diarrheal illness, and the presence of significance life stressors occurring around the time of the infection. Furthermore, increased cellularity of colonic mucosa and lamina propria has been described in IBS patients. These findings suggest that in a subgroup of patients there is an up-regulation of gut immune function. Further studies are needed to explore these findings and their possible association with clinical factors (e.g., symptom severity, bowel habit, and gender) in unselected IBS patients.

Central Nervous System Modulation

In general, brain–gut interactions play a key role in the modulation of gastrointestinal functioning in health and disease. Signals from the brain to the gut ensure that digestive function is optimal for the overall state of the organism. Signals from the gut to the brain play an important role in reflex regulation of the GI tract and in modulation of mood states.

A unifying hypothesis to explain functional GI disorders is that they result from a dysregulation of the brain–gut neuroenteric system. These proposed alterations in the brain–gut axis are best supported by recent findings in functional neuroimaging studies. Using distal colonic stimulation, several studies have demonstrated alterations in regional brain activation in IBS patients compared to healthy control subjects. These brain regions include the anterior and midcingulate cortices, insula, and dorsal pons (in the region of the periaqueductal gray), which are some of the most consistently activated brain areas in response to visceral as well as to somatic nociceptive stimuli. One area that is consistently activated to a greater degree in IBS patients than control subjects is the anterior midcingulate cortex, a brain region concerned with cognitive processing of sensory input including attentional processes and response selection. Furthermore, midcingulate activation correlates with the subjective unpleasantness of visceral and somatic pain. These observations suggest that IBS patients may fail to use CNS down-regulating mechanisms in response to incoming or anticipated visceral pain. They show altered activation or deactivation of brain areas involved in the emotional or cognitive processing of visceral stimuli, ultimately resulting in the amplification of pain perception.

Role of Stress and Psychosocial Factors

Stress is widely believed to play a major role in the pathophysiology and clinical presentation of IBS. It has been postulated that in the predisposed individual, sustained stress can result in permanent increased stress responsiveness of central stress circuits and vulnerability to develop functional and affective disorders. Stress may be central (e.g., psychological distress) or peripheral (e.g., infection, surgery). Numerous studies indicate that IBS patients report more lifetime and daily stressful events, including abuse, than medical comparison groups or healthy controls. In addition, in IBS patients stress is strongly associated with symptom onset, exacerbation, and severity. Even though the effects of stress on gut function are universal, patients with IBS appear to have greater reactivity to stress than healthy individuals.

A large proportion of patients with IBS or other functional bowel disorders have concurrent psychological disturbances, particularly those with severe symptoms or those seen in tertiary care referral centers. In tertiary care centers, the prevalence of psychiatric disorders in IBS patients ranges from 40 to 90%. Psychosocial factors have been recognized to modify the illness experience and influence healthcare utilization and treatment outcome. Factors that adversely affect health status and clinical outcome include a history of emotional, sexual or physical abuse, stressful life events, chronic social stress, anxiety disorders, or maladaptive coping styles.

A current conceptual model of the role of psychosocial factors in IBS suggests that early adverse life experiences influence later physiologic functioning, stress responsiveness, and susceptibility to developing a functional disorder. A stressor may produce symptoms through changes in gastrointestinal function, through central amplification of normal gut signals, or through a combination of both. The combined effect of altered physiology and psychosocial status via the brain–gut axis will modulate symptom experience, illness behaviors, and ultimately clinical outcome. Thus, although psychosocial factors are not etiologic to IBS, they are important for the understanding and treatment of the disorder.

Gender Differences in IBS

It is well established that a greater number of women seek healthcare services for symptoms of IBS than men. Reports of nausea, bloating, constipation, and extraintestinal symptoms seem more prevalent in women with IBS than in men. Furthermore, recent clinical trials suggest that gender differences in response to pharmacological treatments also occur. Numerous factors need to be considered in the exploration of these differences. These factors include biological, hormonal, behavioral, psychological, and sociocultural differences between men and women. Several studies indicate that the menstrual cycle influences GI symptoms, which are reportedly increased immediately before and during menses. In addition, brain imaging studies have reported gender differences in the central processing of aversive information originating from pelvic viscera in IBS. Further studies are needed to provide additional insight into gender differences in the epidemiology, pathophysiology, symptom expression, and response to treatment in IBS.

In summary, IBS is best viewed as a biopsychosocial disorder in which dysregulation of neuroenteric systems is heavily influenced by central and/or peripheral stress. Modulation of brain–gut pathways, including autonomic and pain modulation systems, by psychologic and biologic processes results in physiologic alterations affecting gut motility and visceral perception.

CLINICAL FEATURES

Gastrointestinal Symptoms

Abdominal Pain/Discomfort

The hallmark symptoms of IBS are chronic abdominal pain and/or discomfort. The pain is usually described as crampy or as a generalized ache with superimposed periods of abdominal cramps. The intensity and location of abdominal pain is highly variable even within a single patient. Several factors can exacerbate or reduce pain in IBS. Patients often report worsening of symptoms in periods of stress or emotional distress such as problems at work or in a relationship. Ingestion of certain foods may exacerbate symptoms, usually up to 60 to 90 min after the meal.

Altered Bowel Habits

Based on bowel habits, patients are usually subclassified into those having diarrhea-predominant IBS (IBS-D) or constipation-predominant IBS (IBS-C). In many patients, the predominant bowel habit is not stable over time but may alternate between diarrhea and constipation. If this occurs in a short time period, the pattern is referred to as alternating bowel habit (IBS-A). As many as 30–50% of patients alternate between diarrhea and constipation.

IBS-D accounts for approximately one-third of cases. Stools in these patients are typically loose and watery but of normal daily volume. Usually, diarrhea occurs only during the waking hours. Many patients

experience fecal urgency and loose stools associated with stressful events and an urgent desire to defecate is often noted postprandially.

In IBS-C (30% of IBS cases), stools are usually hard and pellet-like and long periods of straining on the toilet are often reported. A sensation of incomplete evacuation may prompt patients to make multiple attempts at stool passage over a short time period.

Other Gastrointestinal Symptoms

Symptoms of upper GI tract dysfunction are common in IBS patients. These symptoms include early satiety, heartburn, nausea, abdominal fullness, bloating, and vomiting. It is possible that upper GI symptoms are exclusively related to IBS. However, there is evidence for an overlap in patient populations between IBS and another functional gastrointestinal disorder called functional dyspepsia (FD). FD is defined as the presence of persistent or recurrent pain or discomfort centered in the upper abdomen, without identifiable cause by conventional diagnostic means. Epidemiological data suggest that the overlap of FD and IBS may range from 13 to 87% of patients. The wide range of reported overlap can be explained by the different diagnostic criteria applied across studies, in particular in regards to FD.

Extraintestinal Symptoms

IBS patients commonly report extraintestinal complaints. Prevalent symptoms include fatigue, musculoskeletal pain, urinary complaints, sleep, and sexual disturbances. IBS patients have a high incidence of genitourinary dysfunction (e.g., dysmenorrhea, dyspareunia, impotence, nocturia). Sleep-related disturbances such as difficulty falling asleep or repeated awakening also occur frequently in IBS patients. Furthermore, a high prevalence of psychiatric diagnoses, most commonly anxiety disorders and depression, has been reported. Epidemiologic studies have confirmed the clinical impression that IBS and other functional disorders often overlap in the same patients. In particular, there seems to be a significant overlap with fibromyalgia, a chronic somatic pain disorder, and interstitial cystitis, a chronic pelvic pain syndrome with symptoms referable to the bladder.

DIAGNOSIS

Symptom-Based Criteria

The clinical diagnosis of IBS is based on identifying symptom criteria with a "positive diagnosis" and excluding, in a cost-effective manner, other conditions with similar clinical presentation, which may include organic (e.g., inflammatory bowel disease, GI infections, and malabsorption syndromes) or other functional disorders (e.g., functional diarrhea or bloating, pelvic floor disorders, or slow-transit constipation). Because IBS is a functional disorder and biologic markers do not exist, it is diagnosed using the recently revised symptom-based ROME II criteria (Table I). Additional symptoms, which support the diagnosis of IBS, include bloating, urgency, sensation of incomplete evacuation, and mucus in the stool. When "alarm signs" such as weight loss, fever, anemia, GI bleeding, family history of colon cancer, or onset of disease late in life are excluded, the ROME II criteria reach a sensitivity of 65%, a specificity of 100%, and a positive predictive value of 100%. In a recent study, 93% of patients diagnosed based on ROME II criteria and the absence of red flags were found to be true positive cases after 2 years. Hence, if diagnosis is made properly, the risk of missing organic disease is low.

Evaluation

Initial Evaluation

During the first visit, a detailed history should be followed by a physical examination. This is useful to identify findings not consistent with IBS (e.g., enlarged liver, abdominal mass, signs of bowel obstruction) and to meet the patient's expectations of a thorough examination. In general, physical examination in IBS patients is unremarkable with the exception of mild–moderate abdominal tenderness consistent with visceral hypersensitivity in these patients. Care should be taken to avoid unnecessary investigations that are costly and

TABLE I Diagnostic Criteria for Irritable Bowel Syndrome as Developed by International Consensus

At least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two out of three features:
1. Relieved with defecation; and/or
2. Onset associated with a change in frequency of stool; and/or
3. Onset associated with a change in form (appearance) of stool.

Symptoms that cumulatively support the diagnosis of IBS:
- Abnormal stool frequency (>3 bowel movements per day or <3 bowel movements per week)
- Abnormal stool form (lumpy/hard or loose/watery stool)
- Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation)
- Passage of mucus
- Bloating or feeling of abdominal distension

Adapted from ROME II (2000), with permission.

harmful. A recent systematic review of studies investigating the utility of diagnostic tests in IBS concluded that there is insufficient evidence to recommend the routine performance of a standardized battery of tests in patients who meet symptom-based criteria.

Minimal diagnostic procedures to exclude organic disease include complete blood count, erythrocyte sedimentation rate, blood chemistries, thyroid panel, and examination of stool for occult blood and ova, and parasites (latter in diarrhea-predominant patients). A colon examination consisting of a colonoscopy or barium enema and flexible sigmoidoscopy should also be performed in patients 50 years or older. Once the initial therapeutic strategy is found to be unrevealing, the physician should initiate symptomatic treatment for IBS and reassess in 3 to 6 weeks. When red flag signs are present and for those patients that present with short symptom duration or worsening severity, onset late in life, or a family history of colon cancer, a more detailed diagnostic evaluation should be considered (Fig. 1).

Further Diagnostic Approach Based on Predominant Symptoms

Depending on the quality and severity of a patient's symptoms and his or her response to treatment, further diagnostic studies may be performed and are based on whether diarrhea, constipation, or abdominal pain is the predominant symptom.

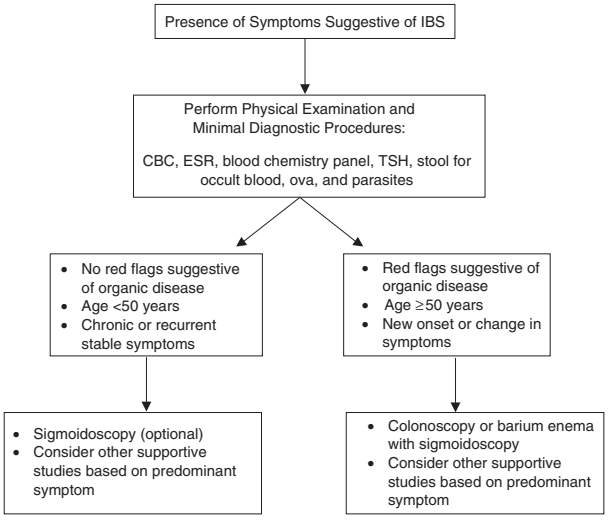

FIGURE 1 The diagnosis of IBS should be based on the history and physical examination as well as the presence or absence of red flag signs suggestive of organic disease. Stool should be examined for ova and parasites in patients who are diarrhea predominant and not in those who are constipation predominant. CBC, complete blood count; ESR, erythrocyte sedimentation rate; TSH, thyroid-stimulating hormone.

In patients with constipation-predominant IBS with infrequent bowel movements, a colon transit study by Sitzmark technique or scintigraphy is recommended. When symptoms, such as dyschezia or incomplete evacuation, suggest obstruction to defecation, further anorectal testing should be considered. This includes anorectal motility testing with balloon expulsion, defecography, and possibly dynamic pelvic magnetic resonance imaging. These studies may be useful in the diagnosis of pelvic floor dyssynergia, rectal prolapse, rectocele, and anismus.

If diarrhea is persistent, colonoscopy or sigmoidoscopy with mucosal biopsies should be performed to rule out collagenous or lymphocytic colitis even in the absence of macroscopic mucosal findings. In patients with refractory diarrhea, especially in those with associated weight loss, further testing should include 24 h stool volume and 72 h fecal fat. If an increase in stool volume is determined (> 400 cc/day), screening for electrolytes and laxatives is useful. Upper endoscopy with biopsy specimen from distal duodenum or proximal jejunum is helpful in excluding celiac sprue, Whipple's disease, intestinal lymphoma, and infections. A jejunal aspirate can be obtained to rule out *Giardia lamblia* or bacterial overgrowth. Finally, when postprandial symptoms of bloating and gaseousness accompany diarrhea and suggest bacterial overgrowth, a breath hydrogen test can be considered.

In patients with pain predominance, an abdominal and pelvic CT scan may help exclude intra-abdominal masses.

TREATMENT OPTIONS

The treatment of IBS can be challenging to both the clinician and the patient. It is therefore important for the physician to strive to gain the patient's confidence with a concise, appropriate work-up and by offering reassurance that IBS is a common, functional disorder that can impact quality of life but without long-term health risks. The therapeutic management of IBS patients requires a multidisciplinary approach including education, reassurance, dietary recommendations, lifestyle modifications, pharmacotherapy, and psychosocial intervention in more severe cases.

Severity of Symptoms

Patients can be categorized into groups based on symptom severity. Many IBS patients have mild intermittent symptoms that correlate closely with

gut-related physiologic events (e.g., pain/diarrhea worse after meal, stress, or menses). Primary care physicians, rather than specialists, usually treat these patients. Treatment is directed toward education, reassurance, and dietary/lifestyle changes. Some patients suffer from moderate symptoms that are intermittent but can at times be disabling. Symptoms can be associated with considerable symptom-related distress. These patients are often evaluated by specialists and seem to benefit from a combination of pharmacotherapy and psychological intervention. Finally, a relatively smaller subgroup of IBS patients present with severe symptoms characterized as refractory and severely disabling. They predominate among patients seen in tertiary referral centers and frequently have psychiatric co-morbidity and psychosocial difficulties (history of adverse life events or maladaptive coping styles) associated with high healthcare utilization. In addition to pharmacological treatment, often with antidepressant medication, and a referral to mental health professionals, an ongoing and effective relationship with a healthcare provider through brief and regularly scheduled visits is beneficial.

Establishing an Effective Physician–Patient Relationship

An effective physician–patient relationship is the cornerstone of successful management of an IBS patient. The physician is encouraged to listen actively to identify the patient's concerns and his or her understanding of the disorder. It is important to set realistic and shared goals and to involve the patient in treatment decisions rather than issuing directives.

After the physician assesses the patient's level of knowledge about the disorder, information should be provided verbally and/or in print to enhance the patient's understanding. Patients commonly want to understand the basis of their symptoms and sometimes seek validation that their symptoms are "real." The clinician can explain that the intestine is overly sensitive to a variety of stimuli such as food, hormonal changes, or stress. These stimuli can produce enhanced visceral motility or visceral perception or both. These alterations in physiologic function are experienced as pain or discomfort, diarrhea or constipation, bloating, or any combination anywhere in the abdomen.

Reassurance that IBS is a benign disorder even though it can drastically affect quality of life should be given after the physician has appreciated the patient's concerns and worries and after an adequate diagnostic workup. If reassurance is given prior to evaluation or in a perfunctory manner, the patient is likely to reject it.

This kind of treatment approach is associated with improved patient satisfaction and reduced physician visits. Patients who feel adequately informed tend to have less healthcare visits.

Dietary Recommendations and Lifestyle Modifications

Symptom Monitoring

Monitoring symptoms by asking the patient to use a diary for 2–3 weeks can assist the physician in identifying the presence of possible aggravating factors. The diary may help to reveal dietary indiscretions or specific stressors that were not previously considered and can give the patient a sense of participation in the planning of care. Physician and patient together can review diet, lifestyle, or behavioral modifications.

Dietary Measures

Patients often attribute their symptoms to specific food substances. There may be some patients that have intolerance to certain foods and may benefit from elimination of foods that trigger their symptoms. It is more likely, however, that most patients experience symptoms as a generalized effect of eating without a specific food trigger. Foods known to be associated with increased flatulence include beans, onions, celery, carrots, raisins, bananas, apricots, prunes, brussels sprouts, wheat germ, pretzels, and bagels. Patients suffering from excess gas may benefit from avoiding these foods.

Lactose intolerance can mimic symptoms of IBS and may co-exist with IBS. A dietary history for carbohydrate intolerance should be assessed, particularly in patients with excess gas with and without diarrhea. Intolerance to other carbohydrates (fructose and sorbitol) may also contribute to GI symptoms. Therefore, a history of carbohydrates should be obtained and managed accordingly if found. However, care should be taken to avoid an unnecessarily restrictive diet.

Role of Fiber in IBS

The most widely recommended agents for treatment of IBS are dietary fiber supplements. These agents serve to enhance water-holding properties of the stool, form gels to provide stool lubrication, provide bulk for the stool, and bind agents such as bile acids that may be responsible for some symptoms in IBS. Soluble fiber, such as pectin, psyllium, or oat bran, is thought to act by enhancing water-retentive properties of stool, whereas insoluble fiber, such as cellulose or lignin, is likely to be a more effective bulking agent. Increased dietary fiber or psyllium products are frequently

recommended for IBS-C patients, even though, as a group, these patients do not consume less dietary fiber than controls. In IBS-C patients, fiber accelerates oro-anal transit time and significant improvement of constipation was demonstrated when 20 to 30 g of fiber was consumed. In summary, whereas fiber has an established role in relieving constipation symptoms, its value in IBS for the relief of diarrhea is controversial and it is not helpful for pain.

Pharmacological Treatment

At present, no pharmacological agent has been found to improve all symptoms of IBS. Therefore, the pharmacotherapeutic approach should be tailored to remedy the patient's most bothersome symptom. However, novel agents have been shown to improve the multiple symptoms of IBS.

The Constipation-Predominant Patient

The principles of management of IBS-C patients are to improve stool frequency and consistency and reduce the effort needed for defecation. Bulking agents such as psyllium, bran, and methylcellulose, in concert with a high-fiber diet, are recommended. Patients should be informed that fiber supplementation may take several weeks to produce a satisfactory result and that fiber should be introduced slowly to prevent excess distension and gas. Patients with an inadequate response should be given osmotic agents such as milk of magnesia or polyethylene glycol. If the patient is unresponsive or intolerant of osmotic laxatives, stimulant laxatives can be prescribed on an intermittent basis, e.g., three times per week. Tegaserod is a recently approved 5-HT_4 (serotonin type 4) agonist that is recommended for treating the multiple symptoms of IBS with constipation in women (see below).

The Diarrhea-Predominant Patient

IBS-D is associated with acceleration of small bowel and proximal colonic transit. The management of these patients focuses on the reduction of defecation frequency and urgency and improvement in stool consistency. The agents most commonly employed are the synthetic opiate derivatives loperamide (Imodium) and diphenoxylate (Lomotil). Loperamide decreases intestinal transit, enhances intestinal water and ion absorption, and increases anal sphincter tone at rest. These physiologic actions are thought to explain the improvement in diarrhea, urgency, and fecal soiling observed in patients with IBS. The effect on resting anal sphincter tone possibly helps to reduce fecal soiling at nighttime when the internal sphincter is the predominant mechanism of continence. Systematic review of randomized clinical trials has demonstrated placebo superiority of loperamide in controlling IBS-associated diarrhea but not in relieving abdominal pain. Loperamide is prescribed at a dose of 2 mg orally after each loose stool with a maximum of 16 mg/kg but can also be used to reduce postprandial urgency. It can also be used prophylactically as a means of improving control at times of anticipated stress or other adverse stimuli (e.g., before exercise, social gatherings, or eating in a restaurant). Common side effects include drowsiness, dizziness, dry mouth, constipation, nausea, and abdominal pain/distension. Loperamide is generally favored over diphenoxylate because the latter contains atropine and may cause adverse anticholinergic side effects that can be worrisome in the elderly (e.g., urinary retention, glaucoma, tachycardia, and glaucoma).

Cholestyramine may be considered for a subgroup of patients with cholecystectomy or who may have bile acid malabsorption. However, evidence for its efficacy in IBS is limited. The starting dose is 4 g orally before meals and can be increased up to 4 g three times daily.

The Pain-Predominant IBS Patient

Severe abdominal pain represents one of the most difficult symptoms to treat in IBS. Antispasmodic drugs, especially anticholinergics, are most commonly prescribed and some patients, especially those with postprandial symptom exacerbation, may benefit from such therapy. The rationale behind the use of antispasmodic agents is that they relax intestinal smooth muscle and thereby decrease cramps and painful sensations. In one meta-analysis of smooth muscle relaxants in IBS, five drugs showed efficacy over placebo in improving abdominal pain: cimetropium bromide, pinaverium bromide, octylonium bromide, mebeverine, and trimebutine. However, none of these drugs underwent extensive trials in North America and they have not been approved by the Food and Drug Administration (FDA) for use in the United States. Although the available agents have not been shown to be superior over placebo, they are often used on an as-needed basis up to four times a day for acute attacks of pain, distension, or bloating. Agents such as dicyclomine or mebeverine seem to retain efficacy when used on a *pro re nata* basis, but become less effective with chronic use.

Tricyclic antidepressants (TCAs; e.g., amitriptyline, imipramine, doxepin) are now frequently used in the treatment of IBS, particularly in patients with more severe or refractory symptoms, impaired daily function, and associated depression and panic attacks. A recent systematic review uncovered only one high-quality trial

of amitriptyline, which showed a trend for global symptom improvement. The efficacy of TCAs as a visceral analgesic agent at lower doses than those used to treat depression suggests neuromodulatory analgesic properties. Treatment with these agents should start with low doses (e.g., 10–25 mg nightly) and titrated up as needed to the lowest most effective therapeutic dose, e.g., amitriptyline (Elavil) or doxepin (Sinequam) at a dose of 10–50 mg at bedtime. These agents may have strong sedative effects and can be used to promote sleep with a single nightly dose.

Selective serotonin reuptake inhibitors are often used to treat IBS patients although they have not yet been shown to reduce IBS symptoms in well-designed published studies. They have been shown to be effective in treating fibromyalgia alone or in combination with a TCA. They may be most useful in treating the co-morbid psychological distress symptoms in IBS patients.

Emerging Therapies

Serotonin type 3 and 4 receptors are involved in mediating reflexes that control gastrointestinal motility and secretion, bowel function, and perception of pain. They have recently been studied extensively as novel targets for pharmacological therapy of IBS.

Tegaserod (Zelnorm), a partial 5-HT_4 agonist, appears to be a promising agent for treatment of constipation-predominant IBS. Tegaserod was associated with an acceleration of orocecal transit time and superiority to placebo in global relief of IBS symptoms in female IBS patients. The effective dose is a total of 12 mg per day in two divided doses prior to meals. The drug appears to be safe with no serious adverse events reported in clinical trial programs. Only small but significant increases in the prevalence of headache and diarrhea, often transient, were associated with tegaserod compared to placebo. The FDA approved this medication in July 2002 for the short-term treatment of the multiple symptoms of IBS with constipation in females.

Prucalopride, a full 5-HT_4 agonist, has recently been demonstrated to accelerate colonic transit time in functional constipation. The effect of the agent on abdominal pain has not been adequately investigated. Clinical trials have been discontinued because of carcinogenicity in animals.

5-HT_3 antagonists reduce visceral pain, rate of colonic transit, and small intestinal secretion. Alosetron (Lotronex), a selective 5-HT_3 antagonist, is effective in relieving pain, normalizing bowel frequency, and reducing urgency in diarrhea-predominant, female patients with IBS. The most common side effect is constipation. Acute ischemic colitis was observed in 0.1–1% of patients receiving the medication, which led to the voluntary withdrawal from the market in November 2000. In June 2002, the FDA approved the restricted use of alosetron to treat women with severe diarrhea-predominant IBS. This medication became available in November 2002. Other drugs in this class (i.e., cilansetron) are currently undergoing multicenter phase III clinical trials.

Other novel drugs that are being investigated as therapeutic agents for IBS include neurokinin (NK)-1 and NK-3 antagonists, cholecystokinin-1 (CCK_1) antagonist, and κ-opioid agonist. It is hoped that continued research in the pathophysiologic mechanisms of IBS will result in the identification of potential targets of action from which more effective therapies for IBS can be developed.

Psychological Treatment

Psychological treatment can be considered when IBS symptoms are moderate to severe, when symptoms have failed to respond to medical treatments, or when there is evidence that stress or psychological factors are contributing to GI symptom exacerbation. The symptoms associated with a favorable response are diarrhea, abdominal pain, and psychological distress. The patient's understanding of the rationale for such a treatment and his or her motivation to engage in it are critical to a successful outcome. A recent review demonstrated the superiority of psychological treatment over conventional medical therapy in 8 of 13 studies. To date, no psychological intervention technique is known to be superior to another. Therefore, the choice of the specific treatment option depends on patient requirements and resource availability.

Cognitive-behavioral therapy consists of a wide range of strategies and procedures designed to bring about alterations in the patient's perception of his or her situation and ability to control GI symptoms. Relaxation training includes a variety of different methods to teach patients to counteract the psychological effects of stress and anxiety. Among the most widely used techniques are progressive muscle relaxation training, biofeedback, and autogenic training.

The efficacy of gut-directed hypnotherapy in IBS has been demonstrated in several studies. The hypnotic state is a state of heightened suggestibility. Following induction, the therapist couples progressive muscle relaxation with "gut-directed" therapeutic suggestions. Recent results suggest that hypnotic relaxation increases the distension volume required to induce discomfort, whereas anger induced in the hypnotic state reduces this threshold.

SUMMARY

IBS is one of the most common functional bowel disorders and is characterized by the presence of chronic or recurrent abdominal pain and/or discomfort associated with altered bowel habits. It is prevalent in 9–23% of the general population and accounts for 12% of primary care visits and 28–37% of visits to gastroenterologists. It appears to be more common in women, particularly those with constipation-predominant symptoms. The healthcare and economic burden of IBS is considerable and has been estimated to be up to $30 billion per year. A unifying hypothesis to explain functional GI disorders is that they result from a dysregulation of the brain–gut neuroenteric system, which may result in altered GI motility, visceral perception, autonomic responses, and central nervous system modulation of visceral sensory information. The diagnostic approach in IBS is based on making a positive symptom-based diagnosis of IBS and excluding organic disease. The management of IBS includes nonpharmacologic (e.g., education, reassurance, and psychological treatment) and pharmacologic approaches and should be based on predominant symptoms, symptom severity, and the presence of co-morbid psychological features.

Kaposi's Sarcoma

SONALI S. MASTER AND JOHN M. CARETHERS
University of California, San Diego

hemorrhage Loss of blood from blood vessels.
intussusception Telescoping or invagination of one portion of the bowel into the adjacent, distal intestinal lumen.

Kaposi's sarcoma, a multicentric malignant vascular neoplasm, was first described in 1872. In its classic form, it was originally seen in elderly men of Eastern European or Mediterranean background. With the advent of acquired immunodeficiency syndrome (AIDS), epidemic Kaposi's sarcoma became more widely recognized in its cutaneous form and is one of the most common AIDS-associated cancers in the United States.

EPIDEMIOLOGY

Extracutaneous Kaposi's sarcoma (KS), including visceral KS, has been well described in the setting of cutaneous disease. Reported sites of visceral involvement include the esophagus, stomach, small and large bowels, liver, spleen, pancreas, mesentery, and biliary tree. Although KS can develop anywhere in the gastrointestinal (GI) tract, the stomach and proximal small bowel are most often involved. Less commonly, KS may involve the gastrointestinal tract in the absence of cutaneous disease.

At one time, gastrointestinal KS was estimated to occur in up to 40% of patients with AIDS, but more recently its incidence has declined. In addition to occurring in patients with AIDS, visceral KS has also been confirmed in organ transplant recipients as well as in patients receiving immunosuppressants for other diseases. In these patients, KS occurs several months to a few years after initiation of immunosuppression. Although skin lesions may regress with a reduction in immunosuppression, patients with visceral involvement may succumb to their disease.

DIAGNOSIS

Early gastrointestinal KS consists of asymptomatic macular, plaquelike lesions with a red–blue appearance. Endoscopically, these lesions are described as being multiple, flat, violaceous lesions ranging in size from a few millimeters to 1–2 cm (see Fig. 1). The lesions may become progressively bulky and nodular, with central umbilication or ulceration. Tumors may also be sessile or polypoid. Clinically, nausea, abdominal pain, intussusception, obstruction, or perforation may occur. Gastrointestinal hemorrhage from KS lesions has also been described.

Endoscopic biopsies, using standard biopsy forceps, are low yield in the diagnosis of gastrointestinal KS due to the submucosal location of these tumors. In one study, biopsy specimens were positive for KS in only 7 of the 17 patients with macroscopic gastrointestinal lesions. Diagnosis of gastrointestinal KS is, therefore, largely based on gross endoscopic findings in the appropriate clinical setting.

Early gastrointestinal KS is not detectable on air-contrast barium radiography due to its macular nature. As a lesion progresses and develops central umbilication, it may be seen as a target, or bull's eye lesion. Small intestinal KS may be seen as focal nodular

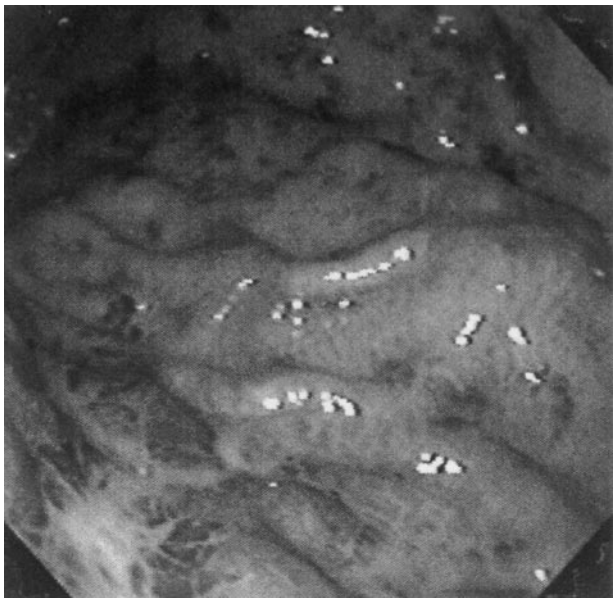

FIGURE 1 Gastric body. Endoscopic appearance of gastric Kaposi's sarcoma in an AIDS patient.

 Copyright 2004, Elsevier (USA). All rights reserved.

thickening. However, because the findings are nonspecific, barium studies may be of limited use in diagnosing gastrointestinal KS.

PATHOLOGY/PATHOGENESIS

Microscopic examination of KS lesions reveals a proliferation of spindle-shaped cells in the lamina propria and submucosa. The spindle cells form slits and vascular clefts in which there are extravasated erythrocytes. Hemorrhage and central necrosis are also often seen within the tumor. KS is thought to arise from a malignant proliferation of lymphatic endothelial cells, which may explain its multicentric nature. Evidence suggests that KS results from an infectious agent. In 1994, a specific type of human herpesvirus was found to be present in KS lesions. The genomic sequences of this herpesvirus, also called KS-associated herpesvirus (KSHV), are found in virtually all KS lesions. KSHV is also referred to as human herpesvirus-8 (HHV-8) and is part of the same gammaherpesvirus subfamily that includes Epstein–Barr virus.

PROGNOSIS

Diagnosis of gastrointestinal KS is important, because prognosis worsens with visceral involvement. The 2-year survival of AIDS patients with endoscopic evidence of KS was found to be 11% compared to an 88% 2-year survival in those without intestinal KS. This survival difference reinforces the observation that KS is yet another manifestation of the compromised immune state seen in AIDS.

Visceral KS lesions require treatment only if they are symptomatic. Treatment with immunomodulation, radiation, or chemotherapy can reduce tumor bulk and improve symptoms but does not change overall survival in AIDS patients.

SUMMARY

Gastrointestinal Kaposi's sarcoma is an uncommon neoplasm that should be considered in patients with AIDS-related or iatrogenic compromise of their immune system.

Kawasaki Syndrome

H. CODY MEISSNER
Tufts University School of Medicine

atypical or incomplete Kawasaki syndrome Variation of classical Kawasaki syndrome in which fewer than five criteria are present but coronary artery aneurysms still develop.

giant aneurysm Most severe complication of Kawasaki syndrome in which a coronary artery aneurysm develops and measures more than 8 mm in diameter.

Kawasaki syndrome Vasculitis; has replaced rheumatic fever as the most common cause of acquired heart disease in children and is diagnosed on the basis of fever plus five criteria.

superantigen Protein antigen that differs from a conventional antigen in several aspects, but one of the most important is its ability to elicit a massive cytokine response, typical of what occurs in Kawasaki syndrome.

Kawasaki syndrome is an acute, multisystem vasculitis that primarily affects infants and young children under 5 years of age. The illness was first described by Tomisaku Kawasaki in 1967 in Japanese in the *Journal of Allergology*. Although Kawasaki syndrome was originally described as a benign illness of early childhood, it is now recognized that this disease is a leading cause of acquired heart disease in children in the United States and Western Europe. Children with Kawasaki syndrome who do not receive treatment with intravenous immunoglobulin and aspirin within the first 10 days of onset of fever have a 20–25% risk of developing coronary artery abnormalities. Early recognition and prompt treatment reduce the prevalence of coronary artery abnormalities to less than 5%, placing emphasis on the need for early diagnosis and treatment.

INTRODUCTION

A diagnosis of Kawasaki syndrome (KS) is based on the presence of fever plus at least four of five criteria, just as a diagnosis of rheumatic fever is based on the Jones criteria. Although the etiology of Kawasaki syndrome is not fully defined, features of this syndrome are similar to those found in certain illnesses that are known to be caused by toxin- or superantigen-producing bacteria, including toxic shock syndrome and scarlet fever.

Kawasaki syndrome has been reported from countries throughout the world, although the highest rates of disease are found in Japan and children of Japanese ancestry living outside of Japan. In the United States the prevalence of Kawasaki syndrome is highest in Asians, intermediate in blacks, and lowest in Caucasians. The hospitalization rate for Kawasaki syndrome among American Indians and Alaskan natives appears to be lower than that among Caucasians. Disease occurs in males about 1.5 times more often than in females. The peak age at which disease occurs is 12–24 months. More than 80% of cases occur in patients before 5 years of age and most cases occur before 2 years. The onset of disease after 8 years is rare, representing less than 10% of cases reported to the Centers for Disease Control and Prevention (CDC). Recurrent disease develops in fewer than 2% of patients. It is not clear whether older patients are predisposed to more severe disease or whether older patients are more likely to have a delay in diagnosis and initiation of treatment later in the course of their illness, with correspondingly greater morbidity. Infants less than 12 months of age and particularly those less than 6 months appear to be at increased risk of developing coronary artery abnormalities.

CLINICAL DISEASE

The possibility of Kawasaki syndrome should be considered in any patient with a fever lasting 5 or more days without an alternative explanation and the presence of at least four of the five clinical criteria listed in Table I. Kawasaki syndrome typically begins with an acute onset, with daily fevers to 40°C or greater in a toxic-appearing child. Fever may last 2 weeks or longer without treatment. The mucocutaneous manifestations of Kawasaki syndrome are varied and not all patients will exhibit each feature. In the first days of acute febrile illness, approximately 90% of children with Kawasaki syndrome develop a polymorphous exanthem, which may demonstrate a variety of forms. The eruption

TABLE I Diagnostic Criteria for Kawasaki Syndrome[a]

Fever for ≥ 5 days without other explanation, and at least four of the following five criteria:
Nonexudative bulbar conjunctival injection
Oropharyngeal changes, including injected or fissured lips, injected pharynx, or strawberry tongue
Extremity changes, including erythema of the palms or soles, edema of the hands or feet, or periungal desquamation
Polymorphous rash
Acute nonsuppurative cervical lymphadenopathy

[a] A diagnosis of atypical Kawasaki syndrome can be made when more than four criteria are present when coronary artery aneurysms are present.

tends to be most prominent on the trunk and extremities. One early sign may be accentuation of a perineal rash.

In most patients a nonexudative, bilateral conjunctival injection begins shortly after the onset of fever and generally involves the bulbar conjunctiva to a greater extent than the palpebral conjunctiva. Conjunctival vessels become engorged and dilated. Purulent discharge is generally not present. Conjunctival injection is associated with anterior uveitis in about 80% of patients.

Oral mucosal findings occur in almost all typical cases. The lips become red, dry, and often cracked, producing small hemorrhagic fissures. There are no punctate ulcerations such as those seen in herpes gingivostomatitis and no erosions suggestive of Stevens–Johnson syndrome. The tongue is often "strawberry" in appearance with hypertrophied papillae and hyperemia, similar to that seen with streptococcal infections. A generalized erythema of the oropharynx is common although ulceration of the mucosal surface is not characteristic.

Changes in the extremities may be the most distinctive finding among the five criteria. Erythema and edema of the hands and feet with fusiform swelling of the fingers and toes are often observed. Swelling usually begins within a few days of the onset of illness. The hyperemic areas desquamate during the second or third week. The desquamation characteristically begins at the tips of the fingers and toes (the periungal region) and may extend to involve the palms and soles in a manner similar to that seen in scarlet fever. Lymphadenopathy is the least frequent finding, seen in 50–75% of patients. It is most often unilateral and the nodes are firm and nontender.

Other associated clinical features of Kawasaki syndrome are listed in Table II. Polyarticular arthralgia and arthritis may occur soon after onset of fever and involve the small joints. Pauciarticular arthritis involving the large weight-bearing joints (hips, knees, and ankles) may occur in the second or third week of illness. Urethritis associated with sterile pyuria is common. A mononuclear cell pleocytosis of the cerebrospinal fluid, with normal glucose and protein levels, occurs in approximately 1/3 of patients who undergo lumbar puncture. It should be remembered that a small number of patients will develop aseptic meningitis (fever, headache, vomiting, and nuchal rigidity) within 48 hours following intravenous immunoglobulin infusion.

Cardiac abnormalities are the major complication of Kawasaki syndrome and constitute the most serious complication of this disease. Myocarditis may develop during the first few days following onset of fever and is manifest by tachycardia out of proportion to fever elevation, conduction irregularities, a gallop rhythm, or electrocardiogram changes. Pericardial effusion may develop as a manifestation of carditis. Congestive heart failure may develop as a complication of myocardial dysfunction secondary to ischemia or infarct. Coronary artery abnormalities occur in 20–25% of untreated patients. Dilatation of the coronary arteries can be detected by echocardiography soon after the onset of fever. Aneurysms of the coronary arteries may be demonstrable by echocardiography as soon as a few days after onset of illness, but more typically occur between 1 and 4 weeks of illness. Rarely, patients experience aortic regurgitation or mitral regurgitation due to valvulitis, transient papillary muscle dysfunction, or myocardial infarction. Occasionally, patients develop aneurysm of the brachial, renal, or iliac arteries. This usually occurs in association with coronary artery abnormalities.

The likelihood of resolution of the aneurysm is determined by the initial size of the aneurysm, with smaller aneurysms having a greater likelihood of regression. Patients with giant aneurysms (diameter >8 mm) have the worst prognosis. Nakano *et al.* have reported that 71% of patients with giant aneurysms progress to stenosis or obstruction over an 11-month followup

TABLE II Associated Features of Kawasaki Syndrome

Cardiovascular abnormalities, including myocarditis, arterial aneurysms, pericarditis, aortic or mitral regurgitation, and ventricular arrhythmias
Arthralgia and arthritis

Hydrops of the gallbladder
Diarrhea, vomiting, or abdominal pain
Peripheral gangrene
Uveitis
Sensorineural hearing loss

period. At a mean followup of 32 months, 30% of giant aneurysms develop obstruction. Nearly all late deaths from Kawasaki syndrome occur in patients with this complication.

Kawasaki syndrome is based on diagnostic criteria using clinical signs and symptoms that overlap with other illnesses. This can result in diagnostic dilemmas, particularly in atypical cases that do not completely fulfill the diagnostic criteria but are associated with the development of coronary artery abnormalities. Reports of atypical or incomplete Kawasaki syndrome have increased in recent years. In certain cases, the decision to treat with intravenous immunoglobulin (IG) and acetylsalicylic acid (ASA) can be a difficult diagnostic dilemma. The risk of coronary artery abnormalities increases in direct proportion to the interval of time between the onset of fever and intravenous administration of IG. Instances of atypical Kawasaki syndrome are most common in infants, the age group that is at greatest risk of coronary artery abnormalities. The decision to initiate therapy in children who do not satisfy the American Heart Association criteria can be supported by laboratory results showing acute-phase reactants (elevated white blood cell count, elevated sedimentation rate), an ultrasound showing a pericardial effusion, or a slit lamp exam showing anterior uveitis.

GASTROINTESTINAL ABNORMALITIES

Kawasaki syndrome is a multisystem inflammatory disorder and a number of organ systems may be involved, as shown in Table II. Early in the acute stage, gastrointestinal complaints include nausea, abdominal pain, and diarrhea. Mild hepatic dysfunction in association with modest elevation of serum transaminases and elevated bilirubin values may occur during the acute febrile phase of disease. Hypoalbuminemia is associated with more severe disease. Hydrops of the gallbladder is well described in patients with Kawasaki syndrome and typically presents with a right upper quadrant mass in the first 10–14 days of illness and may occur with or without obstructive jaundice. Gallbladder hydrops can be detected and monitored by ultrasonography. Cholecystectomy is not indicated. Involvement of the liver and gallbladder resolves soon after administration of intravenous IG and aspirin and is not associated with any long-term abnormality. Pancreatitis has also been reported in association with Kawasaki syndrome.

The laboratory features of Kawasaki syndrome include leukocytosis with an increased band count and an elevated platelet count by the second week of illness. During the acute early febrile stage, "acute-phase reactants" are generally elevated, including the erythrocyte sedimentation rate, C-reactive protein, α2-globulin, and α1-antitrypsin. An increase in fibrinogen and a prolongation of prothrombin time (PT) and partial thromboplastin time (PTT) values have been reported.

DIFFERENTIAL DIAGNOSIS

The clinical manifestations of Kawasaki syndrome are not specific and they occur in a number of other infectious and rheumatologic diseases. Other diseases that may resemble Kawasaki syndrome are shown in Table III. A firm diagnosis of KS is often difficult because the symptoms are not unique and because not all symptoms are seen in all patients. Because therapy within the first 10 days of onset of fever is clearly desirable in terms of reducing the risk for cardiac complications, rapid diagnosis and treatment are important. In many patients, differentiation of KS from other illnesses that resemble this syndrome may be difficult. Viral illnesses that may enter the differential diagnosis include measles, Epstein-Barr virus, adenovirus, and influenza virus infections. Nasal secretions should be cultured in a patient whose symptoms include evidence of an upper respiratory tract infection, especially to rule out adenovirus infection. Group A β-hemolytic streptococcus and *Staphylococcus aureus* infections may also mimic KS. Noninfectious diseases that frequently appear in the differential diagnosis include drug reactions and juvenile rheumatoid arthritis. Findings at physical examination that are not typical of KS include discrete intraoral ulcerations, exudative conjunctivitis, and generalized lymphadenopathy.

THERAPY

Management of patients with Kawasaki syndrome is directed at reducing inflammation in the myocardium and coronary artery wall during the acute phase. Once

TABLE III Differential Diagnosis of Kawasaki Syndrome

Measles

TABLE IV Treatment of Kawasaki Syndrome

Acute phase
Intravenous immunoglobulin 2 g/kg over 10–12 hours
Aspirin, 80–100 mg/kg/day in four divided doses until afebrile
Convalescent phase in patients with uncomplicated Kawasaki syndrome
Aspirin, 3–5 mg/kg/day once daily for 6–8 weeks
For patients with coronary artery disease
Aspirin, 3–5 mg/kg/day once daily
Dipyridamole, 1 mg/kg/day in selected patients
Anticoagulant therapy as needed in patients with arterial thrombosis

the acute stage has passed, therapy is directed at prevention of coronary artery thrombosis. ASA in combination with high-dose intravenous IG forms the basis of current therapy (Table IV). ASA is used for both antiinflammatory and antithrombotic actions, although convincing data that ASA reduces coronary artery abnormalities are not available. Aspirin is administered at a dose of 80–100 mg/kg/day in four divided doses to achieve a serum salicylate level of 20–25 mg/dl during the acute phase of the illness. This is the only dose of ASA that has been carefully studied in the United States. Although gastrointestinal hemorrhage is a known complication of aspirin therapy, this adverse event is a rare complication of high-dose salicylate therapy in patients with Kawasaki syndrome. Efficacy from intravenous IG therapy has only been demonstrated when administered within the first 10 days of illness. Patients who present beyond the tenth day of fever should still be treated with intravenous IG and ASA, although supporting data are not available. It is not clear whether different preparations of intravenous IG have similar efficacy in the prevention of coronary artery abnormalities. In afebrile children, the ASA dose is reduced to 3–5 mg/kg/day to continue antithrombosis activity. ASA is discontinued if no coronary abnormalities have been detected by 6–8 weeks after onset of the illness. ASA therapy is continued indefinitely if coronary artery aneurysms develop.

At present, the treatment of choice for acute Kawasaki syndrome is a single intravenous dose of IG at 2 g/kg administered over 10–12 hours in combination with ASA. Using this regimen, the prevalence of coronary artery abnormalities falls to less than 5%. Peak adjusted serum globulin levels are lower among patients who subsequently develop coronary artery abnormalities and are inversely related to fever duration and laboratory indices of acute inflammation.

All children diagnosed with Kawasaki syndrome should have two-dimensional echocardiography at the time of diagnosis. Repeat studies are recommended at 4–6 weeks and again at 6–12 months. The major long-term morbidity in Kawasaki syndrome is related to cardiovascular complications. Approximately 50% of children with arterial aneurysms will show angiographic regression within 6 months to 2 years after onset of their disease.

MECHANISM OF ACTION OF INTRAVENOUS IMMUNOGLOBULIN

The mechanism by which high-dose intravenous IG works to reduce the vasculitis associated with Kawasaki syndrome is unknown. The observation that intravenous IG works rapidly in reducing the laboratory parameters of the acute-phase response associated with KS suggests a generalized antiinflammatory effect. In this regard, it has been reported that prior to intravenous IG therapy, peripheral blood mononuclear cells from patients with acute Kawasaki syndrome secrete high levels of interleukin-1 (IL-1), an endogenous pyrogen, and tissue vascular endothelial cells express IL-1-inducible endothelial activation antigens. IL-1 secretion remains elevated in intravenous IG-treated patients in whom coronary artery abnormalities develop. However, IL-1 secretion levels fall to normal in-patients who respond to intravenous IG therapy. These data support the notion that intravenous IG may work in Kawasaki syndrome by reducing cytokine-inducible endothelial activation.

Intravenous IG has been shown to contain high concentrations of neutralizing antibodies that inhibit the T cell response to staphylococcal superantigens. Using affinity absorption techniques, it has been shown that this T cell inhibitory effect is mediated by antitoxin-specific antibodies in intravenous IG. Thus the beneficial effect of intravenous IG may be due in part to antibodies that inhibit bacterial toxin-induced stimulation of the immune response.

The following hypothesis has been proposed to explain the pathogenesis of this illness (although this has not been uniformly accepted as the universal pathogenetic mechanism): an organism colonizes the mucous membranes of the gastrointestinal tract of a genetically susceptible host and produces a toxin that behaves as a superantigen. Toxin is absorbed through the inflamed mucosal surface and stimulates local or circulating mononuclear cells to produce proinflammatory cytokines, which in turn cause fever and the clinical picture of Kawasaki syndrome. In response to cytokine-induced stimulation, antigens are expressed on the surface of vascular endothelial cells, rendering them susceptible to attack by cytotoxic antibodies and activated T cells.

Neoantigens on endothelial cells render the vessels more thrombogenic.

Understanding the etiology of Kawasaki syndrome remains a major unresolved issue of pediatrics. It is important that the etiology of this illness be resolved so that a definitive test can be developed to identify children with typical Kawasaki syndrome as well as those who present with atypical disease and who do not satisfy the diagnostic criteria, but are still at risk for coronary artery disease. In addition, it is unlikely that a more specific form of therapy than intravenous immune globulin will be found without understanding the etiology.

Kernicterus

RENE DAVILA AND CLAUDIO R. TOMBAZZI
University of Tennessee Health Science Center

bilirubin A bile pigment formed during the catabolism of heme-containing compounds, primarily hemoglobin.

Crigler-Najjar Syndrome of severe unconjugated hyperbilirubinemia that presents as congenital familial nonhemolytic jaundice and is related to a lack of ability to conjugate bilirubin, as well as a blockage in bilirubin excretion from the hepatocyte.

Kernicterus (German: *kern*, nucleus; *icterus*, yellow) is the condition associated with severe unconjugated hyperbilirubinemia that causes yellow staining of certain regions of the brain and presents with neurological manifestations. Bilirubin-related brain damage occurs most commonly in the neonatal period, but it has also been reported in adults with Crigler-Najjar syndrome.

ETIOLOGY

All conditions related to increases in serum unconjugated bilirubin levels are potentially capable of inducing kernicterus. Some of the most common causes are fetal–maternal blood group incompatibilities, accumulation of extravascular blood in body tissues due to hemorrhage, polycythemia, and red blood cell abnormalities.

PATHOPHYSIOLOGY

Kernicterus develops when the rate of bilirubin deposition becomes overwhelming as a result of high serum bilirubin concentration, low albumin-binding capacity, or low serum pH. Low serum albumin levels or the use of drugs that displace bilirubin from albumin can increase the risk for kernicterus. Kernicterus is likely to occur when serum levels of unconjugated bilirubin are greater than 30 mg/dl and is unlikely to occur when levels are lower than 20 mg/dl. The areas of the brain damaged by bilirubin toxicity are the basal ganglia, hippocampus, cerebellum, and nuclei of the floor of the fourth ventricle. Early evidence of bilirubin toxicity in the brainstem has been detected by auditory evoked potentials.

CLINICAL FINDINGS

Acute clinical manifestations include sluggish Moro's reflex, opisthotonos, hypotonia, vomiting, high-pitched cry, hyperpyrexia, seizures, paresis of gaze, oculogyric crisis, and death. Long-term clinical manifestations include hearing loss, spasticity, and choreoathetosis. Mild forms can present as cognitive dysfunction and learning disabilities.

MANAGEMENT

Preventive measures such as avoidance of administration of pharmacologic agents that bind to albumin and displace bilirubin are reasonable. Therapeutic options include phototherapy, exchange transfusion, pharmacologic interruption of the enterohepatic circulation, enzyme induction, and alteration of breast-feeding.

Phototherapy consists of irradiation of the jaundiced child with light. Photon energy changes the structure of bilirubin, allowing its excretion without hepatic glucuronidation. Special blue light appears to be better than white or green light. In general, phototherapy is used to prevent the serum bilirubin concentration from rising to a level that necessitates exchange transfusion. Intensive phototherapy should induce a decline in total serum bilirubin of 1 to 2 mg/dl within 4 to 6 h. The bilirubin level should continue to decline until it remains below the level that necessitates exchange transfusion (see below). Failure of phototherapy is evident when the newborn continues to experience dangerously high levels of bilirubin.

Exchange transfusion is the best method to acutely lower the serum bilirubin concentration. Mortality associated with this procedure is 0.6%. The indications for exchange transfusion in otherwise healthy term newborns are shown in Table I.

Interruption of the enterohepatic circulation is achieved by the use of agents that prevent the reabsorption of bilirubin from the intestines, such as cholestyramine, activated charcoal, and calcium phosphate.

Conjugation of bilirubin takes place because of the action of the enzyme bilirubin uridine diphosphate

 Copyright 2004, Elsevier (USA). All rights reserved.

TABLE I Indication for Exchange Transfusion to Prevent Kernicterus

Bilirubin levels >20 mg/dl in newborns between the ages of 25 and 48 h who fail to respond to phototherapy
Bilirubin levels >25 mg/dl in newborns between the ages of 25 and 48 h
Bilirubin levels >25 mg/dl in newborns age 49 h or older that fail to respond to phototherapy
Bilirubin levels >30 mg/dl in newborns age 49 h or older
Bilirubin levels >15 mg/dl for more than 48 h
Ratio of total serum bilirubin level to total serum protein level >3.7

glucuronosyltransferase (BUGT). The activity of this enzymatic system is reduced in neonates. The use of phenobarbital in the neonate has proven to increase the activity of BUGT, thus inducing an improvement in the level of unconjugated bilirubin.

Increases in the frequency of breast-feeding to an average interval between feeds of 2 h and no feeding supplements may increase intestinal peristalsis with a subsequent decrease in the absorption of bilirubin.

pneumoperitoneum Insufflation of carbon dioxide gas into the abdominal cavity performed in all laparoscopic procedures to increase the work space available inside the abdomen.

Laparoscopy refers to the minimally invasive technique of assessing the abdominal cavity through small incisions for the purpose of diagnosis and treatment of various intra-abdominal conditions. Although simple laparoscopy has been in use since the turn of the 20th century as a tool for intra-abdominal diagnosis, its popularity has only recently grown as a result of the introduction of many therapeutic laparoscopic procedures. The success of laparoscopic cholecystectomy, confirmed in multiple randomized trials over the past 10 years, has reawakened surgeons' interest in laparoscopy and fueled the development of this new field of modern general surgery. Although the laparoscopic approach to cholecystectomy and fundoplication has proven superior to the open method, whether these same advantages exist for other procedures, such as hernia repair, colectomy, and appendectomy, awaits confirmation of randomized trials. This article will summarize the current status of diagnostic and therapeutic laparoscopy and provide an overview of "minimally invasive" gastrointestinal procedures for the gastroenterologist.

HISTORY

Modern laparoscopy traces its origins to the Italian physician Bozzini, who in the 19th century viewed the peritoneal cavity using reflected candlelight. In 1901, Kelling performed the first reported "minimally invasive" examination of the abdomen after creating pneumoperitoneum and inserting a cystoscope through a trocar in a dog. Soon thereafter, Jacobeus used laparoscopy to diagnose syphilis, tuberculosis, cancer, and cirrhosis. The technique of diagnostic laparoscopy was advanced with the subsequent introduction of the Veress spring-loaded needle in 1938 as well as CO_2 pneumoperitoneum, which improved visualization and increased the intra-abdominal working environment. Unfortunately, the early years of laparoscopy required the operator to peer into the small lens of the scope, thus limiting visualization and concomitant bimanual instrumentation. The advent of computerized video monitors in the 1980s revolutionized the field and liberated the surgeon from the role of "scope holder." The surgeon could now operate with both hands, using two separate instruments, while another operator held the camera. Until a general surgeon named Semm performed the first laparoscopic appendectomy in 1983, laparoscopy was used almost exclusively by gynecologists. Shortly thereafter, the French surgeon Mouret performed the first recorded laparoscopic cholecystectomy in 1987 followed by Reddick and Olsen and also McKernan and Saye in the United States a year later. The ensuing decade saw an explosion of interest in laparoscopic techniques, partly fueled by the overwhelming zeal of the lay public for more minimally invasive surgical procedures as well as the growing interest among general surgeons in these new, intriguing techniques.

TECHNIQUE OF LAPAROSCOPY

Laparoscopic surgery is defined by its equipment that can be grouped into three categories: (1) image production, (2) intra-abdominal access, and (3) instruments. The basic set-up for either diagnostic or therapeutic laparoscopy includes a camera attached to a video monitor for viewing, trocars that traverse the abdominal wall and provide airtight access to the peritoneal cavity, and instruments used to manipulate abdominal contents.

Every laparoscopic procedure begins with safe access to the peritoneal cavity. The open technique of intra-peritoneal access, popularized by Hasson, involves making a small, cutaneous incision, usually periumbilical, which is then extended under direct visualization through the midline abdominal fascia into the peritoneal cavity in a technique similar to diagnostic peritoneal lavage (DPL). After the absence of abdominal adhesions in the area of access is confirmed, the Hasson trocar with a blunt-tipped obturator is advanced directly into the peritoneal cavity and secured in place. The closed technique for access is

slightly different and calls for the blunt-tipped Verres needle. Here, the surgeon advances the Verres needle through a small cutaneous periumbilical incision into the pelvis at a 45° angle while maintaining upward traction on the abdominal wall with clips. Two or three "clicks" of the obturator sheath may be heard as the needle passes through the fascia and peritoneum into the peritoneal cavity. Absence of blood, urine, or stool on aspiration and rapid flow of saline through the needle by gravity corroborate correct needle location. Although the open technique is claimed to be safer, both methods can cause serious complications. The open technique is advantageous in patients with a "hostile" abdomen, including those who have undergone previous laparotomies, as well as in pregnancy, where the exact position of the tip of the Verres needle is in doubt.

After safe access to the peritoneal cavity is achieved, a working space is created either by insufflating gas into the peritoneum or by setting up devices that lift the abdominal wall. Most centers use CO_2 as the agent of choice to create a pneumoperitoneum (PNP) since it is noncombustible (allowing the use of electrocautery) and highly soluble in blood (preventing air embolism). However, the absorbed CO_2 is converted into H_2CO_3 and can lower the plasma pH as well as irritate the peritoneal surface. Thus, other gases with varying properties have been used to create PNP. Nitrous oxide (NO) causes less peritoneal irritation than CO_2, but is combustible, obviating its use in any case requiring electrocautery. Helium (He) is inert and noncombustible, yet poorly soluble in plasma, thus increasing the risk of air embolism. Mechanical lifters have been compared to CO_2 and He PNP in animal studies and have been found to create less hemodynamic embarrassment than either technique of PNP; however, other animal studies have confirmed that the effects of open or laparoscopic surgery with gasless lifters, He, or CO_2 PNP on hemodynamic parameters are minimal and no method is superior to another. Typically, the abdominal cavity is insufflated to an intra-abdominal pressure (IAP) of 12–15 mm Hg. The video laparoscope, connected to an external monitor, is introduced through the previously placed trocar and the abdominal cavity is inspected. The standard 0° Hopkins rod-lens laparoscope ranges in size between 5 and 10 mm in diameter with options for oblique viewing scopes (30° and 45°).

Various specially designed laparoscopic instruments are available for diagnostic as well as therapeutic maneuvers. Basic equipment includes graspers, dissectors, scissors, and a needle holder, along with a clip applier, stapling device, and suction/irrigator. More advanced procedures require the use of specialized equipment. Tissue coagulation can be accomplished with simple electrocoagulation as well as with more advanced tools such as the harmonic scalpel, a tool that tamponades a blood vessel between the jaws of the instrument and seals the vessel with denatured protein, achieving precise cutting with minimal lateral thermal tissue damage. Traditional laparoscopic instruments are 5 to 12 mm in diameter, but a new generation of fine-caliber instruments with outer diameters ranging from 1.7 to 2.5 mm have been developed. These second-generation instruments produce minimal, if any, postoperative pain, obviate the need for trocar-site closure, prevent trocar-site hernia, and achieve excellent cosmetic results, yet are much more fragile to work with. Reports have confirmed the feasibility of several operations (including cholecystectomy, appendectomy, and fundoplication) with fine-caliber instrumentation using traditional sized laparoscopes. Objective clinical data must demonstrate a clinical benefit before widespread use of fine-caliber instrumentation can be adopted.

PHYSIOLOGY OF LAPAROSCOPY

A wide variety of physiologic changes occur with the administration of PNP during laparoscopic surgery. As with any surgical procedure, there is a certain upregulation of the acute-phase and postoperative inflammatory response. This response occurs in proportion to the generalized physiologic insult. Laparoscopic approaches to traditional procedures involve limited abdominal access and less systemic stress and subsequently produce a blunted acute-phase response compared to their open counterparts. At the same time, however, the additional insult of PNP creates a whole other set of altered physiologic parameters of which the surgeon and anesthesiologist must be cognizant for each individual patient.

During laparoscopy with CO_2 PNP, there is a measurable increase in central venous pressure and pulmonary capillary wedge pressure, yet a paradoxical decrease in cardiac preload and a resultant slight decrease in stroke volume. Furthermore, there is an overall increase in mean arterial pressure and systemic vascular resistance, contributing to an increase in afterload, likely a result of both increased IAP and a systemic catecholamine surge. Most studies have shown no appreciable decline in cardiac output (CO), in healthy individuals with IAP between 10 and 15 mm Hg, the typical insufflation pressures used in most diagnostic and therapeutic laparoscopies. In canine studies, though, there is a noticeable decrease in CO at an IAP of 25 mm Hg or greater. While most would

agree that these subtle changes in CO during PNP are unlikely to adversely affect cardiac function in healthy subjects, patients with cardiopulmonary disease may face risks. These concerns were evaluated in multiple prospective trials that concluded that the effects of PNP on CO are clinically insignificant in patients with compromised cardiopulmonary function and that laparoscopy is safe in this population if appropriately managed intraoperatively. In addition, this specific population benefits the most from the diminished postoperative pulmonary embarrassment and faster return to function with laparoscopic approaches. In addition to a decline in CO with PNP, there is a measurable decrease in mesenteric blood flow, which is clinically most evident in a decline in renal perfusion. Again, in healthy subjects, this is well tolerated; yet there are no data documenting the response of patients with preoperatively impaired renal function to this transient, albeit real decrease in renal perfusion.

Intraoperative pulmonary function is affected by laparoscopy with CO_2 PNP. The increase in IAP forces the diaphragm cephalad, compromising ventilation and increasing the work of breathing, resulting in alveoli collapse. In plasma, the increased CO_2 absorbed intraperitoneally causes a metabolic acidosis that typically leads to an increased respiratory rate. Ventilated patients under anesthesia require higher minute ventilations to maintain the same pH. Postoperatively, many studies have clearly documented that there is less pulmonary dysfunction and quicker return of spirometry values in patients undergoing laparoscopic procedures than in those undergoing open procedures.

A decrease in systemic immune response following surgery or other major stresses is well documented. The acute-phase response generated is proportional to the inciting stress and creates a state of postoperative immunosuppression. Systemic cell-mediated immunity is better preserved following laparoscopic procedures, owing to a blunted acute-phase response, yet intraperitoneal cell-mediated immunity appears to be impaired by PNP. Macrophages incubated in CO_2 produce significantly less tumor necrosis factor and interleukin-1 in response to stimulus than those incubated in He or air, thus implicating CO_2 as a mechanism behind the impaired intraperitoneal immunity. Though this may explain initial reports of increased trocar site recurrences following laparoscopic colon resections, more recent studies have found no recurrences at a 5-year follow-up. Compared to open procedures, laparoscopy produces less of an inflammatory response and thus fewer intra-abdominal adhesions.

Intestinal function is affected by surgical procedures, and the rapidity of return of bowel function as evidenced by flatus and bowel movement is directly correlated with the degree of abdominal stress. Bowel function returns faster after laparoscopic cholecystectomy and colon resection than after similar open procedures. Unfortunately, studies of myoelectric activity do not completely corroborate these clinical findings.

As with all surgical procedures, laparoscopy produces a transient state of hypercoaguability. Increased IAP with PNP and certain positions required during laparoscopic procedures produce a decrease in antegrade femoral venous flow, further increasing the risk of deep venous thrombosis (DVT) and pulmonary embolism (PE). Since these factors were recognized early and aggressive DVT prophylaxis has been the rule at most all centers, there have been relatively few reported cases of PEs.

ADVANTAGES OF LAPAROSCOPY

There are multiple advantages of laparoscopy over traditional open procedures. The lessened physiologic stress encountered with laparoscopic approaches translates into easily identifiable clinical parameters that the lay press has promulgated. The most frequently reported benefits include decreased postoperative pain, improved cosmetic result, and a shorter hospital stay. Detailed prospective randomized studies are currently under way to discover the advantages of laparoscopy compared to traditional open surgery with respect to individual procedures. Currently, only laparoscopic cholecystectomy and fundoplication have become the "gold standards" of their respective procedures.

COMPLICATIONS OF LAPAROSCOPY

Serious complications following laparoscopy are rare, occurring in less than 1% of all cases. However, there are specific complications of laparoscopic access that must be considered in addition to those that occur during traditional open surgery. The initial intra-abdominal access and trocar placement, the creation of PNP, and laparoscopic instrumentation are all unique to laparoscopy and can result in complications. The technique of initial intra-abdominal access, by either Hasson or Veress needle technique, has been associated with injury to internal organs, of which the small bowel is the most commonly injured (52%), followed by colon, duodenum, and stomach. Though damage to the small bowel is easily and safely repaired by externalization and direct visual repair, injury to other internal structures can result in more devastating consequences. During initial intra-abdominal access, major vascular

structures can be violated, resulting in sudden hemoperitoneum or more delayed retroperitoneal hematoma formation, both of which must be recognized and addressed with immediate conversion to open laparotomy. The overall morbidity rate for trocar complications is between 0.2 and 0.5%, with mortality rates of 0.0033 to 0.1%. In addition to immediate complications following trocar placement, delayed complications identical to any abdominal incision can occur, namely, bleeding, wound infection, or hernia formation. Bleeding from a trocar site is easily managed with electrocautery or direct suture ligation. Wound infection can also occur and is more common at the umbilical port, especially after laparoscopic cholecystectomy and removal of the infected gallbladder through that port. Finally, the creation of PNP can cause complications, the most devastating of which is an insufflation gas embolization, which can cause sudden cardiovascular collapse by obstructing the pulmonary outflow tract. Overall, though, these complications are exceedingly rare, and with appropriately trained surgeons, laparoscopy is very safe.

DIAGNOSTIC LAPAROSCOPY

Laparoscopy has recently become a very useful modality in the evaluation of an acute or chronic abdominal process, obviating the need for a laparotomy and providing addition data to traditional imaging. Laparoscopy is being increasingly applied in the diagnosis and workup of acute and chronic abdominal pain and masses, triage of trauma, and staging of malignancy. Compared to traditional noninvasive imaging techniques, diagnostic laparoscopy can more accurately characterize an intra-abdominal process and detect lesions less than 1 mm, which is below the resolution of magnetic resonance imaging or computed tomography (CT) scans. Furthermore, compared to exploratory laparotomy, diagnostic laparoscopy results in a smaller incision, less postoperative pain, and faster return of bowel function. Clearly, diagnostic laparoscopy has a place in the management of both acute and chronic abdominal processes.

The evaluation of the acute abdomen includes an extensive list of differential diagnoses that must be quickly and accurately considered. For example, the premenopausal female who presents with lower abdominal pain may have appendicitis, pelvis inflammatory disease (PID), or a ruptured ectopic or ovarian cyst. Laparoscopy has been shown to provide both a diagnosis and therapeutic options in such situations. There are several settings where diagnostic laparoscopy is favored over traditional exploratory laparotomy:

1. in patients who have a suspected intra-abdominal process that could be easily managed laparoscopically; such patients may be those in whom appendicitis or adnexal pathology is suspected;
2. in patients in whom the suspected diagnosis would not typically be managed operatively, especially those with suspected PID, pancreatitis, or low-flow mesenteric ischemia; in these situations, a definitive diagnosis is imperative and usually cannot be accurately provided by conventional imaging modalities;
3. in trauma patients in whom the inclusion or exclusion of major intra-abdominal pathology is critical to the management of other life-threatening injuries;
4. in critically ill ICU patients in whom bedside laparoscopy may avoid the need for hazardous transport to the operating room.

Similarly, there are situations where diagnostic laparoscopy should not be performed:

1. in trauma patients who are suspected of having a myocardial injury, significant hypovolemia, or closed head injury; and
2. in ICU patients who are suspected of having a highly correctable lesion that would necessitate an operative procedure (whether open or laparoscopic).

Suspected Acute Appendicitis or Gynecologic Abdominal Disease

Diagnostic laparoscopy has become an accepted technique for the assessment and management of lower abdominal pain. Today, appendicitis is often detected through a combination of CT scan, history, and physical examination. However, there are many cases where the radiographic findings are inconclusive, thus necessitating abdominal exploration. Traditionally, appendicitis was solely a clinical diagnosis and a negative appendectomy rate of 20% was accepted since the morbidity and mortality associated with a perforated appendix was so much higher. Several studies have documented a decline in the negative appendectomy rate with the use of diagnostic laparoscopy for cases of acute lower abdominal pain. Adnexal disease in young women can mimic acute appendicitis and it is in this population that diagnostic laparoscopy is especially useful, decreasing "unnecessary" laparotomies by one-third. Ruptured ovarian cysts, ovarian torsion, PID, and tubal pregnancy can all present similarly to appendicitis and can be conclusively diagnosed at laparoscopy. Though the treatment of PID and ruptured ovarian cysts is usually supportive, management of ovarian torsion and tubal

pregnancy can easily be accomplished laparoscopically. In fact, laparoscopic treatment of tubal pregnancy is as safe as open laparotomy and results in a decreased length of stay, lower cost, and earlier return to full activity. Clearly, laparoscopic abdominal exploration is an excellent method of conclusively determining the etiology of lower abdominal pain and in most instances can be used to treat the offending condition with no added morbidity or mortality.

Suspected Mesenteric Ischemia and Abdominal Sepsis

Abdominal sepsis of unknown cause has been successfully diagnosed by a systematic method of laparoscopic abdominal inspection. In a recent series, laparoscopic exploration has discovered multiple causes of abdominal sepsis, including perforated viscus (colon, appendix), gangrenous cholecystitis, ischemic bowel disease, and closed-loop small bowel obstruction, most of which can be successfully treated laparoscopically. If evaluation reveals no abdominal source, the patient is spared the physiological insult of a traditional exploratory laparotomy. Mesenteric ischemia can often be a difficult diagnosis to confirm, especially in the elderly patient with abdominal pain, multiple medical problems, and nonspecific laboratory findings. Laparoscopy can provide a means of examining the adventitial side of the bowel, whereas concurrent colonoscopy can evaluate the mucosa for evidence of intestinal ischemia. Diagnosis can be aided with the laparoscopic use of adjunctive tools for assessing blood flow, including Doppler ultrasound, laser Doppler, pulse oximetry, and spectrophotometry. When mesenteric ischemia is confirmed and a bowel resection is performed, laparoscopy can be used to provide a "second look" 24–28 h later, sparing a reoperative laparotomy.

Trauma

The use of laparoscopy in the evaluation of trauma remains controversial and review of the literature reveals multiple varying opinions as to appropriate candidates for diagnostic laparoscopy. Most importantly, trauma patients must be hemodynamically stable and not have significant hypovolemia, closed head injury, or a definitive diagnosis that demands immediate laparotomy. Previously, all penetrating wounds of the abdomen underwent exploration to exclude fascial and/or peritoneal penetration, whereas significant blunt abdominal injury was evaluated with CT scan or DPL. Diagnostic laparoscopy has been used in the acute evaluation of both blunt and penetrating abdominal trauma; however, certain limitations exist. Laparoscopy frequently misses injuries to the flank and epigastric regions as well as the retroperitoneum; for injuries to hollow viscera, it carries 100% specificity but only 18% sensitivity. Many authors would suggest that the patients most likely to benefit from laparoscopy are those with stab wounds to the flank or back or tangential gunshot wounds to the abdomen. These patients are typically stable and need abdominal or wound exploration to confirm that the peritoneum has not been violated. Laparoscopy could easily accomplish this task in this limited trauma subgroup. Thus, while the role of laparoscopy in trauma patients awaits the results of multiple randomized trials, diagnostic laparoscopy offers an effective means to timely diagnosis with little co-morbidity in certain carefully selected patients.

Small Bowel Obstruction

The use of laparoscopy in the management of small bowel obstruction (SBO) is novel, but has recently been championed by Metzger and colleagues. In a series of 40 patients with symptoms of complete or partial SBO, laparoscopy was successful in identifying and treating the cause (usually adhesions) in a majority of patients. Furthermore, this method led to a decreased length of stay by avoiding exploratory laparotomy. Unfortunately, many patients with SBO already have significant abdominal distension, which precludes a thorough diagnostic or therapeutic laparoscopy.

Chronic Abdominal Pain

Laparoscopy is being used with increasing frequency in the evaluation of patients with chronic abdominal complaints. Compared with exploratory laparotomy, laparoscopy allows a thorough abdominal evaluation and results in fewer postoperative adhesions. Recent studies have suggested that laparoscopy used in patients with chronic abdominal complaints usually uncovers adhesions, hernias, or endometriosis, all of which can be easily treated laparoscopically. Interestingly, it has also been noted that even in the absence of definitive findings, many patients report an improvement in their symptoms after diagnostic laparoscopy.

Staging of Malignancy

Diagnostic laparoscopy has found its place in conjunction with conventional imaging techniques in determining the nature of intra-abdominal malignancies. Minimally invasive methods of viewing intra-abdominal contents and obtaining visually guided biopsies can help differentiate benign from malignant processes as well as assess for metastatic spread within the abdomen and pelvis. With the aid of laparoscopic ultrasound,

diagnostic laparoscopy can determine the resectibility of a lesion before proceeding to formal laparotomy and has been used in the management of benign and malignant hepatic tumors, pancreatic cancer, gastric cancer, and distal esophageal cancer. Laparoscopy can also be used to formally stage Hodgkin's lymphoma. Furthermore, if a lesion is found to be unresectable, laparoscopy can be used to perform palliative procedures such as loop colostomies, gastrojejunostomies, cholecystojejunostomies, and feeding tube placement.

THERAPEUTIC LAPAROSCOPY

The scope of laparoscopic surgery is constantly expanding and with it the need for formal studies comparing minimally invasive methods with traditional open techniques. After the introduction of a new procedure, refinements in technique occur with an eye toward increasing safety and efficacy. Eventually, investigators focus on more wide-ranging measures of patient outcome in an attempt to objectify the overall benefits and disadvantages of a particular laparoscopic procedure in comparison to the current standard of care. This section will review the current status of laparoscopy surgery.

Cholecystectomy

Laparoscopic cholecystectomy has replaced the conventional open method as the gold standard for the treatment of symptomatic cholelithiasis, biliary dyskinesia, acalculous cholecystitis, and select patients with asymptomatic gallstones after several well-designed multicenter trials clearly demonstrated that laparoscopic cholecystectomy results in shorter length of hospital stay, less postoperative pain, less postoperative pulmonary embarrassment, quicker return of bowel function, and overall improved patient satisfaction. Following Soper's retrospective and Barkum's randomized prospective studies in 1992 demonstrating the safety and efficacy of laparoscopic over open cholecystectomy, the National Institutes of Health Consensus Conference in 1993 recommended that laparoscopic cholecystectomy replace open cholecystectomy as the preferred method of management of patients with symptomatic cholelithiasis. MacFayden *et al*. showed in a multicenter retrospective study of 114,005 patients that mortality from laparoscopic cholecystectomy was 0.06% with a conversion to open procedure rate of 2.1% and a common duct injury rate of 0.50%. Though the original operation was designed for young, thin patients without previous abdominal procedures, now even elderly and obese patients, as well as those having had past abdominal surgery, have been shown to benefit from laparoscopic cholecystectomy.

Appendectomy

Although multiple studies have demonstrated the feasibility and safety of laparoscopic appendectomy, most surgeons find it difficult to improve on the success of open appendectomy, a procedure that enjoys a short length of stay, minimal pain, and a small incision, especially in young, thin male patients. The laparoscopic approach allows for a comparable, or shorter, length of stay and similar complication rates when compared to open appendectomy. In a meta-analysis of 17 randomized, controlled trials, Chung *et al*. found that laparoscopic appendectomy resulted in less postoperative pain, faster recovery, and lower infection rate than open appendectomy. However, most surgeons reserve the laparoscopic approach for a select subgroup of patients. Obese patients or those who have a retrocecally located appendix typically require a larger incision for adequate mobilization of the appendix. These patients may very well benefit from a laparoscopic approach as the larger incision with the open approach increases postoperative pain and the risk of wound infection. Finally, patients with lower abdominal pain and an unclear diagnosis of appendicitis are appropriate candidates for laparoscopy, as a thorough evaluation of the abdomen and pelvis to exclude other diagnoses is possible with the laparoscope but not through a limited lower abdominal incision. Future outcomes research will need to determine the clear benefits of laparoscopic appendectomy and define its position in the routine treatment of uncomplicated appendicitis.

Splenectomy

Laparoscopic splenectomy has become a recognized modality for the treatment of idiopathic thrombocytopenic purpura (ITP) in patients who are surgical candidates. Studies have shown that laparoscopic splenectomy is safe and feasible, resulting in shorter hospital stays with costs and complication rates comparable to its open counterpart. Patients typically leave the hospital 2–4 days earlier and recover much quicker if they have a laparoscopic splenectomy. Laparoscopy does not allow as thorough a search for accessory spleens as does open splenectomy, but the long-term complications of missing accessory spleens have not been realized. Clearly, in the hands of skilled laparoscopists, laparoscopic splenectomy has become the gold standard for treatment of ITP.

Inguinal Hernia Repair

Traditional inguinal hernia repair has evolved significantly over the past two decades. The original

time-honored primary repairs (e.g., Bassini, McVay) have recently been supplanted by tension-free repairs (e.g., Lichtenstein) that involve the placement of a prosthetic mesh to either reinforce existing tissue or plug a defect. The open Lichtenstein repair can be accomplished under local anesthesia, with a relatively minimal groin incision, short length of stay, and minimal level of postoperative pain, and it has enjoyed excellent short-term results in various randomized trials. Currently, there are two approaches to laparoscopic inguinal hernia repair, the transabdominal preperitoneal approach (TAPP) and the totally extraperitoneal approach (TEPP). In each of these repairs, a mesh is placed over the myopectineal defect and held in place by the pressure created from the intra-abdominal contents. TAPP requires intraperitoneal access and PNP, and thus general anesthesia, whereas TEPP can be performed with regional anesthesia since it entails access to the properitoneal space and maintenance of a working environment with CO_2 insufflation, avoiding any intraperitoneal instrumentation. In randomized controlled trials comparing open Lichtenstein with laparoscopic hernia repairs, there was no significant difference in lengths of hospital stay and morbidity, but patients undergoing laparoscopic repair recovered quicker and had less postoperative pain and narcotic requirement. Laparoscopic repairs, however, take longer and have higher in-hospital costs, thus raising questions as to the actual benefits of laparoscopic hernia repair. Most would agree that laparoscopic repair is clearly superior in cases of bilateral inguinal hernias (obviating bilateral groin incisions) and recurrent repairs (thus avoiding the scar tissue and distorted tissue planes in the previously used anterior open approach). The largest and most complete randomized controlled trial thus far was undertaken by Liem *et al.* in 1997. They treated 487 patients with the TEPP technique and 507 patients with a traditional open technique (suture or mesh repair) and found that those patients who had the laparoscopic repair had fewer hernia recurrences than those who had the open repair (3% versus 6%). As with laparoscopic appendectomy, randomized controlled trials quantifying outcomes measures will be needed to conclusively demonstrate benefits of laparoscopic inguinal hernia repair in the typical patient population.

Fundoplication

Gastroesophageal reflux disease (GERD) is a very common disorder in the United States, with one survey reporting approximately 20% of the population with reflux symptoms occurring on a monthly basis, 14% weekly, and 7% daily. With its introduction in 1991 by Dallemagne of Belgium, laparoscopic Nissen fundoplication has replaced open fundoplication as the gold standard for control of severe GERD. The Nissen repair entails mobilization of the gastric fundus and gastroesophageal junction, then wrapping of the distal esophagus full-circle with the gastric fundus. The Nissen method of GERD surgical correction has become the accepted method for the majority of patients, with long-term results showing excellent control of symptoms and minimal complications at a mean follow-up of 10 years in patients who had undergone the traditional open Nissen fundoplication. The laparoscopic Nissen repair is the same fundamental operation, just performed in a less invasive manner. For this reason, many authors believe that the long-term results of the laparoscopic repair will parallel those of the traditional open procedure. Multiple large clinical series have demonstrated that laparoscopic Nissen fundoplication affords patients excellent control of reflux symptoms with a significantly shorter length of hospital stay, less postoperative pain, and faster return to normal function. Patients are typically discharged within 3 days and more than 90% report complete relief of reflux symptoms at a mean follow-up of 5 years.

Small Intestinal Surgery

Laparoscopic small bowel resection for benign and malignant disease is both safe and feasible and the recent advances in endoscopic anastomotic devices have rekindled interest in laparoscopic bowel surgery. Studies have shown that laparoscopy can be used to reliably explore the small bowel, resect various segments, and complete an anastomosis in a variety of conditions, including leiomyomas, carcinoids, diverticula, ischemic segments of bowel, and localized complications of IBD. An excellent application of laparoscopy is in patients with isolated small bowel Crohn's disease who require limited resection or strictureplasty. This can usually be easily accomplished through externalization of the involved segment of bowel through a limited incision and does not necessarily require totally laparoscopic repair. Also, patients requiring a loop ileostomy to provide temporary fecal diversion for anorectal Crohn's disease are excellent candidates for laparoscopy. Laparoscopy can also be used to create a feeding jejunostomy in patients who require enteral access for feeding but have significant gastric reflux or gastric outlet obstruction, which would prevent the use of a percutaneously placed gastrostomy tube.

Colon Resection

Laparoscopic colon resection has been successfully performed for both benign and malignant colon disease and initial studies showed that it is safe and effective, resulting in less postoperative pain, a shorter hospital stay, and faster return to normal function. Initial enthusiasm, however, was quelled by reports of an alarmingly high rate of port site recurrences compared to open procedures (21% versus 3.3%). In a recent randomized, prospective clinical study, though, Milsom and colleagues documented no trocar site recurrences after 5 years of follow-up. When performed by adequately trained surgeons, laparoscopic colon resection achieves equivalent margins of resection, lymph node dissection, and survival compared to open procedures. Tumor localization, however, must be accomplished without the aid of direct palpation and sensory feedback and therefore relies on preoperative barium enema, colonoscopy (with the use of India ink or colored marker), or other radiographic study. Enthusiasm for laparoscopic or laparoscopic-assisted colon resection for cancer continues to rise, but long-term follow-up data will be required to confirm the excellent results thus far. Laparoscopic colectomy has also been successfully applied to a variety of nonmalignant lesions, including complications from inflammatory bowel disease (IBD), benign polyps, and diverticular disease. Multiple authors have reported favorable results for laparoscopic colon resections for Crohn's disease. Laparoscopy is especially successful in managing isolated ileal or ileocolic Crohn's disease, for which a limited resection or strictureplasty is required. Patients typically have faster return of bowel function, less postoperative narcotic requirement, shorter length of hospital stay, and no more complications than comparable open procedures. When severe inflammation, abscess, or fistula is present, the laparoscopic approach becomes more difficult and conversion rates are higher; however, the overall benefit to the patient is significantly higher if successfully completed laparoscopically. With colonic Crohn's disease, in which a total abdominal colectomy or total proctocolectomy is required, laparoscopy has not yet proven superior to open procedures.

Laparoscopy has also become a more commonly accepted method for the treatment of all forms of diverticular disease, including acute and chronic forms. Sher *et al*. compared laparoscopic and open colectomies for diverticular disease of varying severity. The 5-year series found that laparoscopic resection of diverticulitis can be successfully completed with no additional morbidity or mortality in patients with pericolic, distant, or complex abscesses with or without a fistula. Patients in whom there was generalized purulent or fecal peritonitis, however, should not undergo laparoscopic resection.

Laparoscopic Surgery in Pregnancy

Laparoscopy during pregnancy does not pose any threat to the developing fetus. Diseases requiring surgical correction that are normally encountered during pregnancy, including appendicitis, cholecystitis, and bowel obstruction, can be managed laparoscopically, thus saving the expectant female from significant postoperative pain and fetal narcotic exposure. The same advantages of laparoscopy exist for the pregnant patients, namely, decreased postoperative pain, quicker return of bowel function, and faster recovery. The second trimester is the safest time to intervene surgically in pregnancy and thus surgical procedures should be appropriately scheduled as best as possible.

Other Procedures

Many common gastrointestinal surgical procedures have been performed laparoscopically. There has been recent growth in laparoscopic bariatric surgery for morbid obesity. The traditional vertical banded gastroplasty and Roux-en-Y gastric bypass have both been performed laparoscopically with slight modifications from their open counterparts. Initial reports from multiple centers document excellent results. Living donor nephrectomy for kidney transplantation has also become a popular means of procuring a kidney for living-related renal transplants. Limited hepatic resections, adrenalectomies, gastrectomies, and biliary bypasses have been performed laparoscopically. Randomized prospective trials will need to be performed to determine the benefits of these procedures.

SUMMARY

Great advances have been made in laparoscopic surgery over the past decade. Outcomes data have led to new consensus statements that shifted the gold standard for cholecystectomy and fundoplication away from convention open techniques to laparoscopic techniques. Sophisticated databases have been created to record and analyze details of patient follow-up in an effort to define the benefits of laparoscopic approaches to various procedures. Advances in instrumentation have led to the miniaturization of laparoscopic equipment and prospective trials evaluating the efficacy of these instruments will soon become available.

Large Intestine, Development

ROBERT K. MONTGOMERY
Children's Hospital Boston

Hirschsprung's disease A disease that is characterized by the absence of parasympathetic intrinsic ganglion cells in the hindgut, caused by the failure of neural crest cells to migrate into the distal end of the intestine.

neural crest cells Cells originating from the dorsal region of the neural tube, a subpopulation of which migrate into the wall of the developing intestine and give rise to enteric neurons.

The primitive gut tube consists of three regions, the foregut, midgut, and hindgut, demarcated by the origins of their blood supply. The large intestine is derived from part of the midgut and from the hindgut. As development proceeds, length increases and the intestines protrude into the umbilical cord and then are retracted, and the ascending colon, transverse colon, and descending colon become identifiable. Less is known of the mechanisms regulating the development of the large intestine than of other portions of the gastrointestinal tract. The most intensively studied aspect of large intestine development is that of neural crest cell migration and development into the enteric nervous system, because of its role in Hirschsprung's disease. Because of their application as *in vitro* model systems, a number of cell lines derived from tumors of the large intestine have been widely studied.

MORPHOGENESIS

As the gut tube lengthens and the vascular system develops, the foregut, midgut, and hindgut regions may be distinguished as regions supplied by the celiac, superior mesenteric, and inferior mesenteric arteries, respectively. The cecum, appendix, ascending colon, and right and middle thirds of the transverse colon arise from the distal portion of the midgut. The hindgut will give rise to the left third of the transverse colon, the descending colon, the rectum, and the upper third of the anal canal. The gut tube rapidly increases in length as development proceeds, protruding into the umbilical cord and subsequently being retracted into

TABLE I Development of the Human Large Intestine

4 weeks	Intestine present as simple tube
5 weeks	Cecum identifiable
7 weeks	Intestine protrudes into umbilical cord
8 weeks	Circular muscle layer identifiable; Meissner's plexuses present; peristaltic waves and motility
10 weeks	Intestine reenters abdominal cavity; enteroendocrine cells identifiable; longitudinal muscle layer
12 weeks	Auberbach's plexuses present; goblet cells identifiable
14 weeks	Villi; sucrase–isomaltase and other enzymes detectable
20 weeks	Mature anatomic position
23 weeks	Disappearance of colonic villi
30 weeks	Circular folds of colon complete

the abdominal cavity (see Table I). During this process, the growing intestines rotate around the superior mesenteric artery, leaving the large intestine ventral to the duodenum. As the intestines rotate and return to the abdominal cavity, the cecum and appendix, initially in the upper right, come to lie in the right lower quadrant. The dorsal peritoneum of the ascending and descending colon fuses with the posterior abdominal wall, making these segments retroperitoneal. Failures in the rotational process or fixation can lead to a number of malformations. Initially, the developing gut tube is contiguous with the urogenital sinus. The anal canal normally separates from the urogenital tract, but developmental anomalies sometimes result in fistulas or an imperforate anus. The upper and lower portions of the anorectal canal have distinct embryonic origins that are reflected in their respective blood supplies and enervation. The pectinate line marks the boundary between the region derived from the distal hindgut and that derived from the anal pit, which is ectodermal in origin.

A striking characteristic of the developing fetal colon is its initial similarity to the small intestine. The development of the colon is marked by three important cytodifferentiative stages: the appearance of a primitive stratified epithelium, similar to that found in the early development of the small intestine, the conversion of this epithelium to a villus architecture with developing crypts, and the remodeling of the epithelium when villi disappear and the adult-type crypt epithelium is established. Stem cells are located at the base of the colonic crypts and proliferation occurs in the lower third of the crypt. As they migrate toward the surface, the epithelial cells differentiate into colonocytes, goblet cells, and enteroendocrine cells. The three cell lineages become evident around the time of villus formation. Emerging evidence indicates that regulation of colonic goblet cell differentiation is distinct from that of small intestinal goblet cells. The mRNAs for mucins are detectable in the early intervillus epithelium, with strong expression in the crypts later in development.

The apical surface of columnar colonocytes displays enterocyte-like microvilli and glycogen stores are abundant. The quantity of intracellular glycogen, as well as the number of glycogen-positive cells, decreases from the end of the first trimester. By the end of gestation, very few glycogen-positive cells are found in the fetal colon. During malignant transformation, glycogen expression reappears and is a prominent feature of cell lines derived from human colonic adenocarcinomas.

Concurrent with the presence of villus morphology, the colonic epithelial cells express differentiation markers similar to those in small intestinal enterocytes. Sucrase–isomaltase becomes detectable early, increases as the villus architecture emerges, and then decreases rapidly to barely detectable levels at term. Alkaline phosphatase and aminopeptidase follow a pattern generally similar to that of sucrase–isomaltase. Analysis of isolated fetal colonic epithelial cells demonstrated low levels of the disaccharidases typical of the small intestine, including lactase. In addition, the fetal human colon during the second trimester can synthesize and process lipids, phospholipids, and apolipoproteins. The villi disappear by the end of the second trimester. Data on the functional development of the human colon remain sparse. Examination of premature infants suggests that sodium transport develops in the last trimester, whereas anion-exchange mechanisms remain immature until the end of the first year.

Analysis of *hox* gene expression patterns in experimental animals suggests that these genes are responsible for patterning of the large intestine and may delineate the boundaries between different parts. Mice with null alleles of several distally expressed *hox* genes display defects in formation of the anal region. Null alleles for members of the sonic hedgehog signaling pathway also result in anal region defects. These data suggest that, these gene families regulate, at least in part, overall patterning. In addition, some of the genes regulating specification of the different colonic cell lineages, for example, goblet cells, are now being identified, but much of the regulatory network remains to be elucidated.

HIRSCHSPRUNG'S DISEASE

The most extensively studied aspect of the development of the large intestine is the mechanism of Hirschsprung's disease, which is characterized by the absence of

parasympathetic intrinsic ganglion cells in both the submucosal (Meissner's) and the myenteric (Auerbach's) plexuses of the hindgut. The disorder is caused by failure of vagal neural crest cells to migrate into the distal end of the intestine and represents the most common form of congenital bowel obstruction.

Analysis of mutant mouse models has elucidated the causes of the disease. In the lethal spotted mutant mouse, the terminal segment of the gut is congenitally aganglionic. The aganglionic colon results from the failure of migrating neural crest cells to penetrate an abnormally thickened basal lamina and colonize the bowel normally. Laminin in this basal lamina interacts with a receptor on the neural crest cells and causes them to stop migration prematurely. In a different mouse model, the congenital megacolon of transgenic mice overexpressing *hoxa-4* appears to arise from a similar defective interaction between enteric neuron precursors and smooth muscle.

The genetic and molecular mechanisms underlying the disease are the subject of intense investigation and have generated an extensive and growing literature. Mutations in five genes affecting neural crest cell development that may give rise to Hirschsprung's disease have been identified thus far. The most extensively studied are mutations in the *ret* receptor tyrosine kinase gene and in the endothelin B receptor gene. The *ret* proto-oncogene encodes a transmembrane receptor tyrosine kinase. Its ligand has been identified as glial cell-line-derived neurotrophic factor (GDNF), which is expressed in the developing gut. Current evidence indicates that GDNF binds to another receptor, GDNFRα, and together they form a signaling complex with Ret. Mice homozygous for a truncated Ret protein lacking the kinase domain failed to form enteric ganglia. Numerous mutations in the *ret* gene have been identified in patients with Hirschsprung's disease. Similarly, a targeted disruption of the endothelin-B receptor gene produces mice with aganglionic megacolon, consistent with a critical role for this receptor as well in migration or differentiation of the neural crest cells that give rise to the enteric ganglia. In addition to Ret and endothelin B receptor defects, deficits in the ligands GDNF and endothelin 3, as well as in endothelin-converting enzyme, all result in Hirschsprung's-like phenotypes in mouse models. Unrelated to either of these receptor–ligand systems, a mutation in *sox-10*, a transcription factor expressed early in neural crest cell development, has also been identified in Hirschsprung's patients.

ONCOFETAL RELATIONSHIPS IN CULTURED CELLS

The expression of differentiation markers, for example, sucrase–isomaltase, and of small intestinal enterocyte-like morphology similar to that transiently seen in fetal colon, by several cell lines derived from human colonic adenocarcinomas has provided model systems for *in vitro* studies of enterocyte development. Of the available cell lines, the Caco-2, HT-29, and T-84 cell lines are the most widely used, as under suitable conditions they display some characteristics of differentiated small intestinal epithelial cells. Caco-2 cells have been shown to express a mixture of colonic and enterocytic markers, which varied over time in culture. Although useful models for many purposes, differentiation patterns in these cell lines may be quite heterogeneous and experimental data must be interpreted with caution.

Laxatives

LAWRENCE R. SCHILLER
Baylor University Medical Center and University of Texas Southwestern Medical Center, Dallas

constipation A symptom complex that includes infrequency of defecation, straining to have a bowel movement, or increased hardness of stool consistency.
dyschezia Difficulty in evacuation of stool, including straining, painful defecation, and incomplete evacuation.
laxatives Agents that induce defecation and thereby increase stool frequency, soften stools, and ease the passage of stools.

Laxatives are drugs that induce defecation. Types of laxatives include purgatives and cathartics, which produce voluminous stools, stool softeners and emollients, which have only a mild effect, and lavage solutions, which are ingested in large volumes and flush out the gastrointestinal tract in preparation for diagnostic procedures such as colonoscopy. Laxatives can be usefully categorized as bulking or hydrophilic agents, which add additional hydrophilic solids to the stools, osmotic laxatives, which reduce fluid absorption by retaining water intralumenally, secretagogues, and agents with direct effects on epithelium, nerves, or smooth muscles, and the lubricating agent, mineral oil.

PHARMACOLOGY OF LAXATIVES

Bulking or Hydrophilic Agents

Organic polymers, such as dietary and medicinal fiber preparations, complex with substantial amounts of water when they are in aqueous solution. This physiochemical property allows such molecules to hold extra amounts of water intraluminally, thereby increasing intraluminal volume, speeding transit through the colon and increasing fecal weight. Stool consistency may be softened and defecation eased.

The effectiveness of these agents depends on the amount ingested, the water-holding capacity of the agent, the amount of the agent surviving bacterial fermentation in the colon, and the net effect of fermentation products on water absorption by the colon. Water-holding capacity varies by an order of magnitude among the various agents. For example, *in vitro* bran complexes with 4.2 g of water per gram of bran, whereas pectin holds 56.2 g of water per gram. Fermentation of fiber by colonic bacteria destroys the polymer and results in the production of short-chain fatty acids and gas (mainly carbon dioxide and hydrogen), accounting for the bloating and flatulence that complicate the use of these agents. To the extent that short-chain fatty acids are absorbed by the colonic mucosa, the laxative effectiveness of fiber is reduced. To the extent that they remain within the colonic lumen, they obligate water retention osmotically and increase the laxative effect. The interactions of these factors are largely unpredictable. Thus, bran is more effective at increasing stool weight than is pectin despite the large difference in water-holding capacity. Supplementing a general diet with increasing amounts of cereal rich in bran increases stool weight linearly by 2.7 g for every gram of increased fiber intake. Constipated patients should take 20–40 g of fiber daily.

Instead of dietary fiber, "medicinal" bulking agents, such as psyllium, polycarbophil, or altered cellulose, can be used. Psyllium is a natural product that consists of hydrophilic polysaccharides that form a gel when mixed with water. Ingestion of 10 g of psyllium daily increases stool weight by an average of 45 g/24 h, largely due to excretion of an additional 40 g of water daily. Polycarbophil is a derivative of polyacrylic acid and forms a gel that is not subject to fermentation when it interacts with divalent cations and water. Methylcellulose and carboxymethylcellulose are relatively resistant to fermentation by gut bacteria and tend to cause less bloating than dietary fiber. Medicinal fiber should always be taken with extra water to avoid intestinal obstruction.

Osmotic Laxatives

Osmotic agents are osmotically active ions or molecules that are poorly absorbed by the intestine and thereby obligate water retention intralumenally to maintain isotonicity with plasma. Magnesium salts, phosphate and sulfate salts, poorly absorbed disaccharides, such as lactulose, sugar alcohols, such as mannitol and sorbitol, and polyethylene glycol are classified as osmotic agents. These agents work because gut contents are in osmotic equilibrium with plasma after equilibration in the upper intestine and so any water-soluble

 Copyright 2004, Elsevier (USA). All rights reserved.

material remaining intraluminally must retain sufficient fluid to maintain intralumenal osmolality at 290 mosm/kg. For example, stool weight increases linearly by 7.3 g for each additional millimole of soluble magnesium in stool water. Quite large stool outputs can be achieved; for example, a standard 10 oz. bottle of citrate of magnesia contains 116 mmol of magnesium and therefore could increase stool weight by as much as 850 ml.

The side effects of saline laxatives relate to excess absorption of the poorly absorbed ion in the face of large intakes. Thus, hypermagnesemia, hyperphosphatemia, and hypernatremia have been reported with ingestion of magnesium and phosphate laxatives, especially when given in high doses or to patients with renal insufficiency. Complications, such as seizures or congestive heart failure, have also been observed with these agents. Mannitol, sorbitol, and lactulose can be fermented by colonic bacteria; this can produce excess flatus and bloating.

Polyethylene glycol is a large polymer (molecular weight ~3350) that should not exert much osmotic activity. However, polymers that interact strongly with water, such as polyethylene glycol, exert an anomalous osmotic activity that is proportional to the number of monomer units in the polymer. Thus, ingestion of 17 g of polyethylene glycol obligates intraluminal retention of approximately 80 ml of water. Larger doses of polyethylene glycol and supplemental electrolytes are used in gastrointestinal lavage solutions that are designed to be consumed in large volumes and to produce no net water or electrolyte absorption or secretion. Because polyethylene glycol is not absorbed appreciably and is not fermented by bacteria, it typically does not produce electrolyte disturbances or result in excess flatus.

Secretagogues and Agents with Direct Effects on Epithelium, Nerves, or Smooth Muscle

Many different categories of drugs produce laxation by various effects on the intestine and its regulatory elements (Table I). These agents have been called "stimulant" laxatives because of presumed stimulation of motility, but they also may have independent effects on mucosal transport.

The least active of these agents are the surface-active agents, including docusates and bile acids. These substances are detergents that inhibit fluid and electrolyte absorption or stimulate secretion. Although these chemicals may have measurable (if small) effects in increasing stool water and thus "softening" stools, clinical studies suggest that docusates are of little help in the prophylaxis of constipation in the bed-bound elderly.

TABLE I Classification of Laxatives

I. Bulking or hydrophilic agents
  A. Dietary fiber
  B. Psyllium (*Plantago*)
  C. Polycarbophil
  D. Methylcellulose, carboxymethylcellulose
II. Osmotic agents
  A. Poorly absorbed ions
    1. Magnesium sulfate (epsom salt)
    2. Magnesium hydroxide (milk of magnesia)
    3. Magnesium citrate
    4. Sodium phosphate
    5. Sodium sulfate (Glauber's salt)
    6. Potassium sodium tartrate (Rochelle salt)
  B. Poorly absorbed disaccharides, sugar alcohols
    1. Lactulose
    2. Sorbitol, mannitol
  C. Polyethylene glycol
III. Secretagogues and agents with direct effects on epithelium, nerves, or smooth muscle
  A. Surface-active agents
    1. Docusates (dioctyl sulfosuccinate)
    2. Bile acids
  B. Diphenylmethane derivatives
    1. Bisacodyl
    2. Sodium picosulfate
    3. (Phenolphthalein)[a]
  C. Ricinoleic acid (castor oil)
  D. Anthraquinones
    1. Senna
    2. Cascara
    3. Aloe
IV. Lubricating agent
  A. Mineral oil

[a] No longer available in the United States.

Diphenylmethane derivatives are frequently used stimulant laxatives. Bisacodyl is a common component of over-the-counter laxatives, especially since the withdrawal of phenolphthalein because of animal studies suggesting carcinogenicity. Bisacodyl is hydrolyzed in the small intestine and colon by endogenous esterases to its free, active form, which inhibits water absorption by effects on prostaglandins, kinins, and perhaps mucosal Na^+,K^+-ATPase. Bisocodyl can be given as 10 mg tablets, which produce an effect in 6–8 h, or as 5 and 10 mg suppositories, which work within 15–30 min.

Ricinoleic acid is the active component of castor oil (ricinoleic acid triglyceride). Castor oil is hydrolyzed by lipase, releasing free ricinoleic acid, which seems to stimulate both intestinal secretion and motility. Doses of 30–60 ml of castor oil produce catharsis within a few hours. Cramping frequently complicates its use and limits long-term use. Castor oil is most frequently used for bowel preparation.

Anthraquinones are a group of chemicals that contain the tricyclic anthracene nucleus. Substitutions in the ring structure define various monoanthrones, including aloe-emodin, rhein, and frangula. The monoanthrones are usually coupled together to form dianthrones, which are conjugated with sugars to produce glycosides. Plants that produce these agents include senna, aloe, cascara, and rhubarb. Available preparations are derived from plant material and are mixtures of various chemicals. The conjugated anthraquinones pass into the colon, where bacterial metabolism converts them to active forms. The drugs seem to work by both stimulating secretion and speeding transit through the colon. Defecation usually occurs 6–8 h after ingestion. Side effects include allergic reactions, electrolyte depletion, and melanosis coli, a benign discoloration of the mucosa due to apoptosis of the colonic epithelial cells. Anthraquinones have been blamed for the development of "cathartic colon," a neurogenic atony, but this does not seem to occur frequently with currently available anthraquinone laxatives.

Lubricating Agent

Mineral oil (petrolatum) is a lubricating agent that is not chemically active within the body, but instead alters the physical characteristics of stool, thereby easing defecation. It can be taken by mouth or as an enema. Aspiration is a hazard with oral intake and may produce lipoid pneumonia. Depletion of fat-soluble vitamins with chronic use and seepage through the anus are additional side effects.

THERAPEUTIC USE

Laxatives are used to treat the symptom of constipation, to prepare the colon for procedures, such as colonoscopy or surgery, and to empty the gastrointestinal tract after ingestion of poisons.

Use in Constipation

The symptom of constipation may mean infrequency of defecation, straining to have bowel movements (dyschezia), or excessively hard stools. Constipation may be due to systemic diseases, such as diabetes mellitus or hypothyroidism, or to disorders of the colon, such as diverticulitis or colon cancer, or may be idiopathic. Idiopathic constipation is attributed to the slow transit of material through the colon or functional outlet obstruction due to dysfunction of the anal sphincters or pelvic floor muscles or to transient anatomical obstruction.

For mild symptoms, increased dietary fiber or the use of medicinal fiber may be all that is needed. Docusates are frequently utilized by patients with chronic constipation, but are usually insufficient for use in patients consulting their physicians with constipation. For severe, acute constipation, more potent laxatives are needed; stimulant laxatives or large doses of osmotic laxatives work well in this setting. For more chronic symptoms, osmotic agents are preferred. When straining (dyschezia) is the main problem, modification of stool consistency with osmotic agents or mineral oil can be useful. Fiber supplementation should be avoided in patients with straining, since ingestion of more fiber results in the need to pass bulkier stools.

Use for Colon Preparation before Procedures

Adequate preparation of the colon for colonoscopy, radiography, or surgical procedures is essential for ideal viewing conditions and patient safety. Gastrointestinal lavage solutions are the standard against which other preparation regimens are compared. These solutions are designed to be ingested rapidly in large volumes to "wash out" colon contents. Unfortunately, even with flavorings they taste badly and it sometimes becomes difficult for patients to ingest the full dose. They remain the safest option for thorough colon cleansing, however.

Ionic osmotic laxatives, such as sodium phosphate or magnesium citrate, are popular alternatives. Laxatives that contain lactulose, mannitol, or sorbitol should not be used for colon preparation because of their potential to produce potentially explosive hydrogen gas. The ionic osmotic agents can be absorbed and may produce hyperphosphatemia or hypermagnesemia. They should not be used in patients with renal insufficiency. Sufficient water should be ingested with the ionic laxatives to avoid dehydration.

Traditional cathartics, such as castor oil and bisacodyl, can be used in various combinations or with enemas to prepare the colon. Their use may be complicated by cramping and dehydration.

Use in Toxic Ingestions

The role of laxatives in reducing absorption of orally ingested poisons is limited. Most cathartics work too slowly to have much effect and studies with gastrointestinal lavage solution suggest little effect on the kinetics of absorption of potential toxins.

Lipoproteins

NICHOLAS O. DAVIDSON

Washington University School of Medicine, St. Louis, Missouri

ABC-type transporter Members of a large multigene family of transport proteins expressed in the membranes of epithelial cells. ABC-type transporters contain an ATP-binding cassette, signifying that transport of the particular substrate is energy-dependent. Members of this family play an important role in lipoprotein metabolism by regulating lipid transport (particularly cholesterol and other sterols) both into and out of cells.

apolipoprotein Members of a large multigene family of proteins with the ability to bind lipids (cholesterol and triglyceride) in order to facilitate their transport in plasma.

brush border membrane Apical membrane of the enterocyte, facing the intestinal lumen. This is the site from which uptake of dietary lipid occurs.

chylomicron The largest lipoprotein particle. This is the particle secreted by the intestine following lipid absorption and allows the transport of triglyceride and cholesterol out of the enterocyte, into the lymphatic circulation, and ultimately into plasma. The major protein components are apolipoprotein B48, apolipoprotein A-I, and apolipoprotein A-IV.

chylomicron remnant Chylomicron particles enter the plasma and undergo metabolism of the triglyceride cargo through the actions of an enzyme called lipoprotein lipase. This results in liberation of fatty acids to adipose tissue and muscle. Removal of the core triglyceride leads to shrinkage of the surface and production of a smaller particle (chylomicron remnant) that is targeted to the liver for receptor-dependent uptake, a process facilitated by apolipoprotein E.

complex lipid The major lipid products of intestinal and hepatic lipid assembly. The major classes of neutral lipid include triglyceride and cholesterol ester, whereas complex polar lipids are represented by phospholipids.

endoplasmic reticulum Compartment of the cell responsible for the synthesis of complex lipids and apolipoproteins; it is the site where initiation of lipoprotein synthesis occurs.

fatty acid-binding protein Two classes of fatty acid-binding proteins are discussed. The first class comprises members of a large multigene family of cytoplasmic transporter proteins participating in shuttling fatty acids in the liver and small intestine. The second consists of a family of membrane-associated fatty acid transport proteins presumed to be involved in the uptake of fatty acids from plasma.

Golgi complex Compartment of the cell responsible for maturation of lipoprotein particles prior to their secretion into the plasma.

high-density lipoprotein The smallest and densest lipoprotein particle. Sites of formation include the small intestine, liver, and the plasma compartment following catabolism of large triglyceride-rich lipoproteins.

lipoprotein receptor Several classes of receptor demonstrate affinities for different lipoproteins. Some, such as the low-density lipoprotein receptor, cluster in coated pits and participate in the regulation of cholesterol homeostasis. Others, such as scavenger receptor type B1 and the ABC-type transporters ABC-A1, ABC-G5, and ABC-G8, play a role in cholesterol secretion and/or uptake that is yet to be fully understood.

low-density lipoprotein (LDL) The major carrier of cholesterol in plasma of humans. LDL is formed predominantly from very-low-density lipoprotein as a result of catabolism of the core triglyceride, analagous to the formation of chylomicron remnants. The major protein component is apolipoprotein B100.

Lipoproteins

NICHOLAS O. DAVIDSON

Washington University School of Medicine, St. Louis, Missouri

ABC-type transporter Members of a large multigene family of transport proteins expressed in the membranes of epithelial cells. ABC-type transporters contain an ATP-binding cassette, signifying that transport of the particular substrate is energy-dependent. Members of this family play an important role in lipoprotein metabolism by regulating lipid transport (particularly cholesterol and other sterols) both into and out of cells.

apolipoprotein Members of a large multigene family of proteins with the ability to bind lipids (cholesterol and triglyceride) in order to facilitate their transport in plasma.

brush border membrane Apical membrane of the enterocyte, facing the intestinal lumen. This is the site from which uptake of dietary lipid occurs.

chylomicron The largest lipoprotein particle. This is the particle secreted by the intestine following lipid absorption and allows the transport of triglyceride and cholesterol out of the enterocyte, into the lymphatic circulation, and ultimately into plasma. The major protein components are apolipoprotein B48, apolipoprotein A-I, and apolipoprotein A-IV.

chylomicron remnant Chylomicron particles enter the plasma and undergo metabolism of the triglyceride cargo through the actions of an enzyme called lipoprotein lipase. This results in liberation of fatty acids to adipose tissue and muscle. Removal of the core triglyceride leads to shrinkage of the surface and production of a smaller particle (chylomicron remnant) that is targeted to the liver for receptor-dependent uptake, a process facilitated by apolipoprotein E.

complex lipid The major lipid products of intestinal and hepatic lipid assembly. The major classes of neutral lipid include triglyceride and cholesterol ester, whereas complex polar lipids are represented by phospholipids.

endoplasmic reticulum Compartment of the cell responsible for the synthesis of complex lipids and apolipoproteins; it is the site where initiation of lipoprotein synthesis occurs.

fatty acid-binding protein Two classes of fatty acid-binding proteins are discussed. The first class comprises members of a large multigene family of cytoplasmic transporter proteins participating in shuttling fatty acids in the liver and small intestine. The second consists of a family of membrane-associated fatty acid transport proteins presumed to be involved in the uptake of fatty acids from plasma.

Golgi complex Compartment of the cell responsible for maturation of lipoprotein particles prior to their secretion into the plasma.

high-density lipoprotein The smallest and densest lipoprotein particle. Sites of formation include the small intestine, liver, and the plasma compartment following catabolism of large triglyceride-rich lipoproteins.

lipoprotein receptor Several classes of receptor demonstrate affinities for different lipoproteins. Some, such as the low-density lipoprotein receptor, cluster in coated pits and participate in the regulation of cholesterol homeostasis. Others, such as scavenger receptor type B1 and the ABC-type transporters ABC-A1, ABC-G5, and ABC-G8, play a role in cholesterol secretion and/or uptake that is yet to be fully understood.

low-density lipoprotein (LDL) The major carrier of cholesterol in plasma of humans. LDL is formed predominantly from very-low-density lipoprotein as a result of catabolism of the core triglyceride, analagous to the formation of chylomicron remnants. The major protein component is apolipoprotein B100.

required for the transfer of complex lipid (above) to the growing polypeptide chain of apolipoprotein B. Defects in the gene encoding MTTP result in the autosomal recessive disorder abetalipoproteinemia, a condition that is associated with lipid accumulation in enterocytes and hepatocytes.

reverse cholesterol transport The process through which high-density lipoprotein acquires cholesterol from peripheral cells and transports and delivers it to the liver for secretion into bile or for use in the synthesis of bile salts.

RNA editing A form of posttranscriptional modification in which the nucleotide sequence of the transcript is modified from that encoded in the genome.

transcript messenger RNA The required intermediate between the genetically encoded sequence and protein product.

very-low-density lipoprotein (VLDL) A large lipoprotein particle synthesized in the liver and small intestine containing complex lipid for export. VLDLs are the major lipoproteins secreted by the liver and contain apolipoprotein B100 as the predominant protein.

Lipoproteins are huge multicomponent complexes containing lipids and proteins. These complexes are essential for the transport of cholesterol and triglyceride throughout the body. Lipoproteins allow the transport of dietary lipids, mostly in the chemical form of cholesterol and triglyceride, following their absorption by the small intestine. In addition, the liver synthesizes cholesterol and triglyceride to supply tissues that may lack the ability to make sufficient quantities of these forms of fat. The ability of the small intestine to absorb dietary lipid and of the liver to package newly synthesized lipid is absolutely dependent on the process of lipoprotein assembly and secretion. The small intestine and liver produce a range of different lipoproteins. These different lipoproteins have distinct importance in lipid delivery as a result of the protein components that accompany each particular lipoprotein class. The different protein components play a central role in targeting each lipoprotein to a specific receptor on the cell surface. This process in turn facilitates the regulation of cellular lipid metabolism and provides a mechanism for the cell to regulate its content of cholesterol. Genetic defects in the expression of certain transport proteins or of receptors for certain lipoprotein classes are associated with abnormalities in plasma lipid levels and in some circumstances accumulation of lipid within intestinal and hepatic cells.

INTRODUCTION

The challenge of transforming water-insoluble lipids such as cholesterol and triglyceride into a form that can be transported through the aqueous medium of plasma is achieved by the formation of large macromolecular particles containing both complex lipid and apolipoproteins into structures called lipoproteins. Different classes of lipoproteins are produced by the liver and small intestine, each with distinct functions in lipid transport and delivery. In view of the importance of dietary fat as an energy source (~30–40% of the daily energy requirement of the average U.S. diet), these transport vehicles assume considerable importance in maintaining nutritional balance. In addition, lipoproteins are required for cholesterol delivery to all cells in connection with their growth, renewal, and proliferation. The need for cells to acquire cholesterol from circulating lipoproteins is particularly noteworthy since all cells have the innate capacity to synthesize their own cholesterol from two-carbon precursors. This latter observation indicates that the demands for cholesterol may exceed the capacity of cellular production in certain circumstances, particularly during growth or for specialized metabolic purposes. Certain specialized cells, for example, hepatocytes and adrenal cortical cells, require cholesterol for the synthesis of bile acids and steroid hormones, respectively, and cholesterol destined for these purposes is derived largely from circulating lipoproteins. In addition, the developing brain and central nervous system require prodigious amounts of cholesterol and certain fat-soluble vitamins, notably vitamins A and E, for appropriate development. Taken together, lipoproteins represent a vital adaptation for organ-specific delivery and control of nutrient metabolism in addition to playing a role in the regulation of cholesterol homeostasis. These features are summarized in Fig. 1, elements of which are discussed in the following paragraphs.

INTESTINAL LIPOPROTEIN ASSEMBLY

Complex Lipid Synthesis

Complex lipid synthesis and the formation of lipoproteins within the intestinal enterocyte require several coordinated steps. Dietary lipid is presented to the brush border in the form of a mixed micelle containing fatty acid, monoglyceride, and bile salts, from which fatty acid and monoglyceride are transported into the enterocyte. It is likely that one of several fatty acid transporter proteins (FATPs) participates in this process, the most reasonable candidate being FATP4. Cholesterol and other sterols are transported across the intestinal brush border membrane, but the mechanisms and transporters involved are not fully defined. Potential candidates include ABC-type transporters and scavenger receptor type B1 (SR-B1) (Fig. 1). Once across the enterocyte brush border membrane, fatty acids are

activated to their coenzyme A derivative and transferred to the endoplasmic reticulum (ER) for assembly into complex lipid. The role of fatty acid-binding proteins in this transfer process has been proposed but has not yet been formally proven. Two fatty acid-binding proteins, known as intestinal fatty acid-binding protein and liver fatty acid-binding protein, are expressed at high levels in the enterocyte. Once delivered to the ER, fatty acids and monoglycerides are used for the assembly of complex lipids, including phospholipids, triglycerides, and cholesterol esters. Enzymes that participate in this process include monoacylglycerol acyltransferase (MGAT), diacylglycerol acyltransferase I and II, and acylcholesterol acyltransyltransferase I and II (ACAT I and II). Some of these enzymes have a more or less important role in the intestine (MGAT and ACAT II) than in the liver and other tissues. Once complex lipid assembly has been initiated in the ER, the process of intestinal lipoprotein assembly begins almost simultaneously (Fig. 1).

Role of Microsomal Triglyceride Transfer Protein and Apolipoprotein B

The efficient assembly of lipoproteins in the intestine requires the coordinated interaction of many genes, among which two gene products in particular are indispensable. These include microsomal triglyceride transfer protein (MTTP) and apolipoprotein B (apoB). Neutral lipid, including cholesterol ester and triglyceride, is synthesized in the ER and accumulates as small droplets. These lipid droplets are transferred to and appear to fuse with the nascent peptide chains of apoB within the lumen of the ER (Fig. 1). This neutral lipid transfer step allows the appropriate folding and conformation of the apoB protein such that it is transferred through the secretory pathway. In the absence of lipid transfer, for example, in the setting of genetic MTTP deficiency accompanying abetalipoproteinemia, apoB is degraded and neutral lipid accumulates within the ER. Similarly, in the absence of apoB or in the setting of truncating mutations that eliminate the lipid-binding domains of apoB, neutral lipid accumulates within the ER. The prototype for genetic deficiency of apoB is homozygous hypobetalipoproteinemia.

ApoB RNA Editing

ApoB is required as an integral structural component of lipoproteins. The protein is synthesized in the liver and in the small intestine, but each organ produces a distinct isoform. The liver produces a large protein referred to on a centile scale as apoB100. The intestine produces a protein approximately half the size of the liver form, referred to as apoB48. A specialized form of apoB mRNA processing, which results in the formation of these two protein products from a single structural *APOB* gene, occurs in the small intestine. In this process, referred to as RNA editing, a cytidine to uridine deamination of the nuclear apoB mRNA results in the introduction of a UAA stop codon and leads to translation of a truncated apoB protein (apoB48). In humans, the liver expresses apoB mRNA but synthesizes only the full-length protein (apoB100) since apoB mRNA is not edited in the liver. ApoB100 is the major protein component of low-density lipoproteins (LDL), the principal transport vehicle for cholesterol in humans (Fig. 1). ApoB48 is the major protein component of chylomicrons (Fig. 1). These two isoforms of apoB have distinct metabolic fates, as detailed below. ApoB mRNA editing is postulated to represent a metabolic advantage by way of targeting dietary lipid from the small intestine to the liver for rapid delivery as an energy substrate and also for the delivery of fat-soluble vitamins that are targeted to liver stores.

INTESTINAL LIPOPROTEIN SECRETION

Enterocytes secrete two major classes of lipoprotein. Bulk triglyceride transport is achieved through the assembly and secretion of chylomicrons, as detailed above. These are large (75−1200 nm) particles that are well adapted for the transport of triglyceride into the circulation and ultimately to the liver. By virtue of their size, a limited amount of apoB is capable of transporting a large amount of lipid (Fig. 1). ApoB is proposed to wrap itself around the lipid droplet, belt-like, and, together with the addition of other apolipoproteins, notably apoA-I, apoA-IV is secreted into the lymphatic circulation, where it acquires apoE (Fig. 1). Chylomicrons undergo hydrolysis of their core triglyceride in the peripheral circulation through the action of an enzyme, lipoprotein lipase, which is tethered within the capillary endothelium of muscle and adipose tissue beds. Following hydrolysis of the core triglyceride, the surface of the chylomicron shrinks and the particle becomes smaller, allowing more apoE to bind. This step is required for the receptor-dependent uptake of chylomicron remnants by the liver, through the chylomicron remnant receptor (Fig. 1). Enterocytes also secrete high-density lipoprotein (HDL). These are small (8−12 nm) particles composed mostly of phospholipid, apoA-I, and apoA-IV, together with a small amount of neutral lipid (Fig. 1). The importance of HDL secretion from the intestine is unknown although estimates suggest that ∼50% of the daily HDL input arises from this source. HDL plays a central role in "reverse

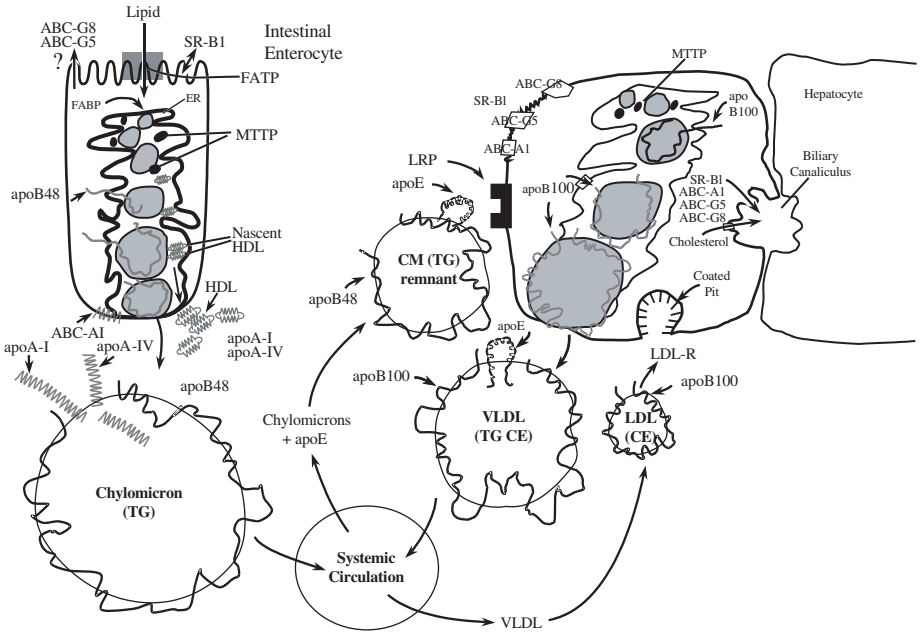

FIGURE 1 Intestinal and hepatic lipoprotein assembly and secretion and an integrated view of lipoprotein metabolism. Dietary lipid is absorbed into the intestinal enterocyte with the participation of members of the fatty acid transport protein (FATP) family. Fatty acids are bound by fatty acid-binding proteins (FABP) and are transferred to the endoplasmic reticulum (ER) for complex lipid assembly. Neutral complex lipids (cholesterol ester and triglyceride) are transferred by the microsomal triglyceride transfer protein (MTTP) to the growing chain of apolipoprotein B (apoB48) and this process initiates lipoprotein formation. The lipoprotein particles enlarge through the addition of progressively more lipid to the core and are secreted into the lymph as a chylomicron. The core lipid in chylomicrons is largely triglyceride (TG). Additional proteins are added to the chylomicron in the later stages of lipoprotein assembly, including apoA-I and apoA-IV. Intestinal enterocytes also secrete small high-density lipoprotein (HDL) particles containing apoA-I and apoA-IV. HDL metabolism in the intestine is also influenced by the expression of various HDL receptors, including ABC-type transporters (ABC-A1, ABC-G5, and ABC-G8) as well as the scavenger receptor, SR-B1. These HDL receptors and transporters likely also play a role in regulating cholesterol absorption from the diet. The assembly and secretion of lipoproteins from the liver follow many of the same patterns as in the intestinal cell. Fatty acids and cholesterol are assembled into complex lipid within the ER and are transferred to the growing chain of apoB100 through the actions of MTTP. Hepatocytes assemble very-low-density lipoproteins (VLDLs), which are smaller than chylomicrons and contain apoB100 rather than apoB48. The core lipid in VLDL is both TG and cholesterol ester (CE). Both VLDL and chylomicrons enter the systemic circulation where the core lipids undergo hydrolysis, releasing fatty acids to muscle and adipose tissue. Chylomicrons are converted into chylomicron remnants and are directed to the chylomicron remnant receptor (also known as low-density lipoprotein receptor-related protein, or LRP). This targeting is dependent on the transfer of apoE to the remnant particle. VLDLs are converted into low-density lipoproteins (LDLs), which are the major transport carrier of cholesterol in humans. LDLs are directed to the LDL receptor, which localizes in coated pits on the surface of all cells. This interaction is dependent on a domain in the carboxyl-terminus of apoB100 that is absent from apoB48. HDL transporters and HDL receptors are also expressed on hepatocytes and may participate in the regulation of cholesterol secretion into bile.

cholesterol transport," the process by which cholesterol is removed from the membranes of peripheral cells and delivered to the liver for excretion. This pathway represents an important mechanism of the body to rid itself of excess cholesterol and perhaps is the reason that HDL (the so-called good cholesterol) is protective against atherosclerosis. Intestinal cells express the transporter proteins ABC-A1, ABC-G5, and ABC-G8, recently identified as cholesterol and sterol transport proteins (Fig. 1). In addition, enterocytes express the macrophage scavenger receptor protein SR-B1, presumed to function as an HDL receptor. The precise role of these

receptors and transporters in reverse cholesterol transport and their importance in the recognition and transport of cholesterol—both into and out of the enterocyte—are important questions for future investigation. Increased HDL levels in plasma are protective against the development of atherosclerosis in humans and factors that regulate intestinal secretion of HDL are under investigation. A further aspect of the ability of intestinal epithelial cells to secrete lipoproteins is that expression of the ABC-type transporters may allow these cells to discriminate between cholesterol and other, more toxic sterols. Rare genetic diseases are associated with the indiscriminate absorption of plant sterols, which are normally not absorbed by humans. Some of these defects have been linked to mutations in ABC-type transporters.

HEPATIC LIPOPROTEIN ASSEMBLY

Assembly of lipoproteins within the liver follows much of the same basic principles outlined above for the enterocyte. Fatty acids are transported into hepatocytes through fatty acid transport proteins and are transported to the ER by the hepatic fatty acid-binding protein. Once inside the ER, complex lipid assembly occurs and transfer of the neutral lipid to a nascent apoB100 protein again requires binding by MTTP (Fig. 1). Neutral lipid is fused to the growing apoB protein and protects the peptide from degradation within the ER. During the later stages of lipoprotein assembly, apoE is added to the particle, which is then secreted into the circulation. Lipoprotein assembly in the hepatocyte and enterocyte differs in several respects (Fig. 1). First, hepatic lipoprotein assembly and secretion involve the delivery of complex lipid into the space of Disse in the form of very-low-density lipoprotein (VLDL) rather than chylomicrons (Fig. 1). VLDLs differ from chylomicrons in two important respects, namely, their smaller size (30−80 nm) and the presence of apoB100 and apoE in place of apoB48. In addition, there are two distinct routes for lipid secretion from hepatocytes since these cells secrete cholesterol directly into bile in addition to secreting lipoproteins into plasma (Fig. 1). The metabolic regulation of this partitioning process (i.e., VLDL versus biliary cholesterol) is poorly understood. A further major distinction between hepatic and intestinal lipoprotein assembly is that VLDL production is driven by both substrate (e.g., fatty acid delivery) and metabolic demands (e.g., insulin and other hormones) and is subject to feedback and feed-forward regulation by numerous genes involved in the bile acid biosynthetic pathway. Hepatic VLDLs are the major source of circulating LDL and thus factors that regulate hepatic secretion rates of VLDL in turn regulate the levels of LDL.

HEPATIC LIPOPROTEIN SECRETION

The liver plays a central role in the secretion of lipoproteins into the circulation as a mechanism for delivering newly synthesized complex lipid and cholesterol to peripheral tissues and organs. In addition to its role in lipoprotein secretion, however, the liver plays an essential role in regulating circulating lipid levels through lipoprotein uptake and catabolism. In the process of receptor-dependent LDL uptake, the liver is quantitatively the most important organ. This property of hepatocytes is relevant to an understanding of how cholesterol levels in plasma are maintained in humans and the accompanying increase in atherosclerotic heart disease and stroke that accompanies elevated LDL cholesterol levels. Most of the plasma cholesterol in humans is transported in LDL, and since elevated levels are strongly predictive of susceptibility to atherosclerosis, LDL is often referred to as the "bad cholesterol." Two major mechanisms contribute to the regulation of LDL levels. These include VLDL synthesis and LDL clearance from the circulation. Most of the circulating LDL is cleared from the circulation through its interaction with a receptor, the LDL receptor (Fig. 1).

LDL receptors are clustered in coated pits throughout the basal-lateral membranes of hepatocytes and permit binding and internalization of LDL, which in turn reduces LDL levels in plasma. The clearance of LDL through its interaction with the LDL receptor is quantitatively the dominant mechanism for regulating plasma cholesterol levels in humans. Genetic defects in the LDL receptor result in familial hypercholesterolemia, which is associated with extremely high levels of LDL in plasma and an increased risk of atherosclerotic heart disease.

The physical interaction of LDL with the LDL receptor is mediated through two regions that are present in the carboxyl-terminus of apoB100. The regions or domains in apoB100 responsible for the high-affinity binding of LDL to the LDL receptor are absent from apoB48, which cannot bind to the LDL receptor as efficiently as apoB100. As a result, intestinal apoB48-containing lipoproteins (chylomicrons and remnant particles) are directed to a different receptor (chylomicron remnant receptor or LDL receptor-related protein) that recognizes apoE (Fig. 1). ApoB RNA editing thus permits rapid delivery of intestinal lipoproteins to the liver (the half-life of chylomicrons and remnants is <60 min) versus the fine regulation of plasma

cholesterol levels achieved through their association with LDL and LDL receptor-dependent transport (a half-life of approximately 2 days).

Hepatocytes express the transporter proteins ABC-A1, ABC-G5, and ABC-G8, as well as the HDL receptor SR-B1. The ABC-type transporters have an important role in allowing cholesterol to be exported from cell membranes. This process is separate from the lipoprotein secretion pathways outlined above. Cell membranes accumulate cholesterol and other sterols within the bilayer and this may be transferred to an HDL acceptor particle from the plasma in the presence of an ABC-type transporter. The classical example of such a transporter that functions in this manner is ABC-A1. This transporter is widely expressed and is proposed to act as a cholesterol pump, transferring cholesterol to an acceptor HDL particle. Genetic defects in ABC-A1 have been linked to Tangier disease, in which circulating HDL levels are extremely low. The role of these ABC-type transporters in cholesterol secretion into bile and their participation in regulating levels of HDL in plasma are under investigation.

Liver Abscess

NATALIE J. TÖRÖK AND GREGORY J. GORES
Mayo Clinic and Foundation

hematogenous spread Dissemination via the circulation.
hydatid cyst Vesicular structure formed as a consequence of *Echinococcus* infection.
pyogenic Pus forming.
scoleces Anterior parts of the *Echinococcus*; they are formed within the hydatid cyst.
trophozoite Vegetative form of a parasite.

Liver abscesses do not represent a specific liver disease, but rather a final common pathway of many pathologic processes. In the preantibiotic era, liver abscesses were typically sequelae of intraabdominal infectious processes (e.g., appendicitis) or of tuberculosis. Currently, most liver abscesses are secondary to biliary tract diseases or amebiasis. Many advances, including the development of antibiotics, recognition of the role of the anaerobic bacteria, the advent of noninvasive imaging, and the use of nonsurgical drainage for pyogenic abscesses, have improved outcome.

EPIDEMIOLOGY

The incidence of liver abscess shows a wide range of variation, depending on the etiology. The incidence of pyogenic liver abscess ranges from 8 to 20 cases per million people. With the availability of effective antimicrobials, pyogenic liver abscess has become a disease of middle-aged persons, probably because of the prevalence of biliary disease as a major cause is higher in this population. No significant sex, ethnic, or geographic differences seem to exist in disease prevalence, in contrast to the epidemiology of amebic liver abscess. Amebic liver abscess is marked by a significant male preponderance and is a disease seen most commonly in patients who reside in or have emigrated from an endemic area, or who have travel history to an endemic area. Countries with the highest *Entamoeba histolytica* endemic activity include Mexico, India, East and South Africa, and Central and South America. As estimated by the World Health Organization (WHO) in 1995, approximately 40 million to 50 million people worldwide are symptomatic with amebic colitis or liver abscess, resulting in 40,000–100,000 deaths each year. In the United States, immunosuppression seems to be an important risk factor. Patients with HIV infection, malnourishment, and alcoholism are at risk of developing amebiasis.Echinococcosis may result in hydatid liver cyst formation; the most common pathogen is *Echinococcus granulosus*. The resulting cystic hydatid disease has worldwide distribution. In tuberculosis, the liver is commonly involved, with a granulomatous reaction, but the formation of tuberculous liver abscess is rare worldwide and usually is not considered in the differential diagnosis of liver abscesses. Worldwide, only 43 cases have been reported.

PATHOGENESIS

Pyogenic liver abscesses are classified by the presumed route of hepatic invasion: (1) biliary tree, (2) portal vein, (3) hepatic artery, (4) direct extension from contiguous focus of infection, and (5) penetrating trauma. Cholangitis is now the major cause of pyogenic liver abscess. Patients with Caroli's disease and primary sclerosing cholangitis (PSC) have a particularly high rate of pyogenic abscess formation. In Third World countries, infection of the biliary tree by *Cryptococcus neoformans* or direct invasion by *Ascaris lumbricoides* may occur. Mechanical manipulation of the biliary tree, such as after endoscopic retrograde cholecystopancreatography (ERCP), or percutaneous biliary tube placement can be complicated by abscess formation. The portal venous system drains almost all of the abdominal viscera. Pylephlebitis from diverticulitis, inflammatory bowel disease, pancreatitis, and prostatitis can result in pyogenic abscess formation (Table I). Historically, untreated appendicitis was a major cause of liver abscess in the past, but its occurrence has greatly diminished with the use of antibiotics. Systemic bacteremia may also result in microabscess formation in the liver because bacteria are disseminated via the hepatic artery. Direct extension from a contiguous source of infection can occur with cholecystitis and subphrenic abscesses.

In terms of pathogens, *Escherichia coli* and *Klebsiella* species are by the far the most common isolates.

TABLE I Occult Causes of Pyogenic Liver Abscesses

Diverticulitis
Inflammatory bowel disease
Prostatitis
Pelvic inflammatory disease
Pancreatitis
Appendicitis

Klebsiella abscesses are frequently associated with gas formation. Enterococci and the *viridans* streptococci are also common, especially in polymicrobial abscesses, whereas *Staphylococcus aureus* is more commonly associated with monomicrobial abscesses. In hemochromatosis, abscesses are often caused by *Yersinia enterocolitica*.

Amebiasis is caused by ingestion of infective *E. histolytica* cysts through a fecal–oral route of exposure. The cysts are resistant to degradation in the stomach and pass to the small intestine, where excystation and liberation of the trophozoite form of the parasite occur. The trophozoites then pass to the colon, where they cause mucosal invasion and subsequent spread to the liver. The pathology in amebic abscess involves three consecutive stages: acute inflammation, granuloma formation, and progressively advancing necrosis with abscess formation and periportal fibrosis. The abscess contains necrotic tissue surrounded by a rim of amebic trophozoites.

Echinococcosis causes human disease when humans become hosts for a cystic intermediate stage of canine tapeworms. *Echinococcus granulosus* most often infects humans in contact with sheep-herding dogs. The hydatid liver cysts are fluid-filled structures lined by a parasite-derived membrane. The cysts caused by *Echinococcus multilocularis* are less defined; they tend to invade the liver parenchyma and also seed the adjacent organs.

CLINICAL PRESENTATION

Only 10% of patients with pyogenic liver abscess present with the classic triad of fever, jaundice, and right upper quadrant pain. Fever and constitutional symptoms including malaise, fatigue, and anorexia are common. In the presence of cholangitis, pruritus and jaundice may also be additional features. There seems to be an association between the cause of the abscess and the duration of the symptoms: hematogenous liver abscesses present most acutely (3 days), whereas those secondary to pylephlebitis (42 days) have the longest duration of symptoms.

In the case of amebic liver abscesses, 80% of patients present with symptoms that develop over 2–4 weeks. The symptoms are similar to those in patients with pyogenic abscesses; gastrointestinal symptoms also occur in 10–35% of patients and may include nausea, vomiting, diarrhea, abdominal cramping, diarrhea, or constipation.

Echinococcal liver cysts are often asymptomatic and present as a hepatic mass with a typical appearance on computer tomography (CT) or magnetic resonance imaging (MRI).

DIAGNOSIS

Laboratory tests in cases of pyogenic liver abscesses reveal leukocytosis in many cases. Liver biochemistries are also abnormal in most of the patients; however, normal results do not exclude the diagnosis. Serum alkaline phosphatase level is elevated in two-thirds of patients and tends to be more markedly elevated than transaminase levels. Blood cultures are positive in about half of the patients. Multiple samples should be obtained, because this may be the only clue to the pathogenic agent prior to starting antimicrobial therapy.

Leukocytosis is moderate in cases of amebic liver abscesses, and eosinophilia is rare. Anemia is a typical finding. Overall, the incidence of liver test abnormalities is the same in patients with amebic liver abscess or with pyogenic liver abscess. Most patients ($>70\%$) with amebic abscess do not have detectable parasites in the stool, therefore serologic testing for antibodies to *E. histolytica* is the most useful diagnostic test. The most commonly used serologic test currently is the enzyme immunoassay (EIA), because it is rapid, stable, and more specific and sensitive than other diagnostic tests.

In hydatid liver disease, the *Echinococcus* cysts are rarely found in the stool. Eosinophilia is usually present. Enzyme-linked immunosorbent assay (ELISA) is the test of choice and is positive in about 90% of cases with the disease.

Radiographic imaging studies are essential in making the diagnosis. Ultrasonography (US) and CT have proved particularly useful for abscess visualization and subsequent drainage (see Fig. 1). US is the study of choice in patients with suspected biliary disease. Intravenous contrast-enhanced CT offers improved sensitivity and is superior for guiding complex draining procedures. MRI studies are now also recognized to be useful alternatives to CT imaging, especially if the abscesses arise as a result of cholangitis, allowing better definition of disease extent. Magnetic resonance cholangiography may further add to the sensitivity, especially if there is a suspicion of a cholangiocarcinoma. Chest radiographs are abnormal about half of the time,

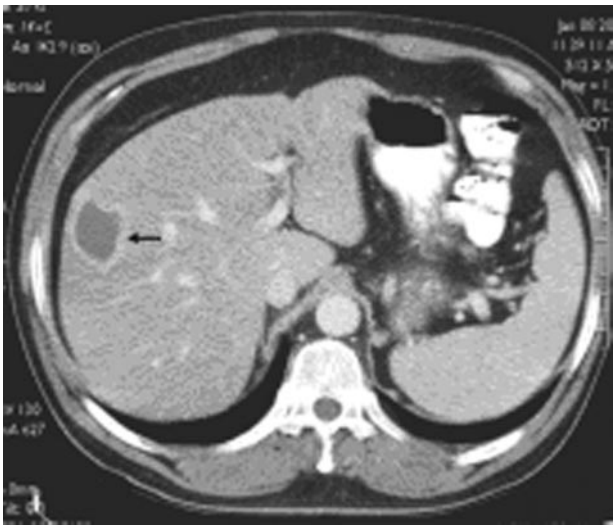

FIGURE 1 CT image of a pyogenic liver abscess (arrow); note the peripheral enhancement.

but are of no real value in making the diagnosis. A ^{99m}Tc nuclear hepatic scan is useful in differentiating an amebic abscess from a pyogenic abscess. Because amebic liver abscesses do not contain leukocytes, they appear as "cold" lesions on a nuclear scan, with a typical "hot" halo of radioactivity surrounding the abscess due to increased focal activity of leukocytes.

TREATMENT

The treatment of pyogenic abscesses consists of antibiotic administration and drainage of the abscesses. Radiographically guided percutaneous drainage is now pursued in most patients. Over the past 20 years, several studies have shown that percutaneous catheter drainage with antibiotic therapy has a success rate between 70 and 90%. Observations by Giorgio and co-workers suggest that repeated needle aspiration in selected patients with low viscous material within the abscess cavity may be a reasonable alternative.

Antibiotics should be started as soon as the diagnosis is suspected, after blood cultures are obtained. Pyogenic abscesses that arise in patients with biliary disease often include enterococci and enteric gram-negative bacilli. Biliary drainage is also essential if the abscess is secondary to an obstructed bile duct. If the source of the infection is the colon or pelvic organs, antibiotic coverage for coliforms and anaerobes is needed. The usual course of treatment is 2–3 weeks of parenteral antibiotic therapy with adequate abscess cavity drainage. The clinical response is followed by serial interval studies.

Treatment options for uncomplicated amebic liver abscess include amebicidal drugs and, if indicated, percutaneous or open aspiration of the abscesses. Therapeutic aspiration of the amebic liver abscess should be considered in patients with (1) high risk of abscess rupture as defined by a cavity size of 5 cm or greater, (2) left lobe abscess (because of the associated higher mortality rate), and (3) failure to respond to drug therapy. Metronidazole remains the drug of choice for treating amebic liver disease. Metronidazole, 750 mg orally three times a day for 10 days, has been reported to be curative in more than 90% of patients with amebic liver abscess. If a patient fails to respond to metronidazole in 5 days, then chloroquine (base) may be substituted or added to the therapy.

Albendazole has become the current standard for medical therapy of hydatid disease. It is generally administered two to three times daily at doses ranging between 10 and 50 mg/kg/day, for 12 weeks. Frequent monitoring for leukopenia and elevation of aminotransferase levels is required. The standard and final therapy is surgery, with the careful aspiration the of cyst fluid to avoid spillage of viable scoleces or anaphylaxis. Laparoscopic drainage and ultrasound-guided drainage have also been reported.

Liver Biopsy

CHEN LIU AND JAMES M. CRAWFORD
University of Florida

alcoholic liver disease Liver abnormality caused by excessive ingestion of alcohol.
hematoxylin and eosin stain A tissue stain that is routinely used for histology evaluation.
immunostain A laboratory histochemical procedure that detects a specific antigen using a specific antibody.
Masson trichrome A histochemical stain that highlights the connective tissues.
needle biopsy A surgical procedure to obtain liver tissue using a needle.
periodic acid-Schiff stain A histochemical stain that highlights glycogen and glycoproteins.
reticulin stain A histochemical stain that highlights the delicate collagen fibers.
viral hepatitis Liver inflammation caused by viral infection.
wedge biopsy A surgical procedure to obtain liver tissue by excision.

Liver biopsy is a medical procedure to remove a small piece of liver tissue to diagnose liver disease and assist in disease management. Liver biopsy may be percutaneous, i.e., through the abdominal skin, or open, as during laparoscopy or laparotomy. It is the required technique for visualizing disease processes in the liver at the microscopic level. Liver biopsy may be carried out by "cutting," whereby intact pieces of tissue are obtained either by cutting needle or by scalpel for histological processing. Liver biopsy may also be carried out by "aspiration," in which a thin needle is inserted into the liver substance and cellular material is withdrawn under suction; this variant yields dispersed specimens for cytologic analysis and/or clumps of tissue for histological examination. The first cutting-needle biopsy device was introduced by Vim and Silverman in 1938 and was used in procedures requiring several minutes for percutaneous placement of the needle and withdrawal of tissue specimens. A key refinement was the introduction of Menghini cutting needle in 1958 and the use of this needle in percutaneous needle biopsy procedures requiring only a second or two of penetration and withdrawal. The resultant substantial decrease in bleeding complications enabled percutaneous liver biopsy to become a routine procedure in the evaluation and management of patients with suspected liver disease. More recently introduced cutting-needle biopsy devices, such as the Tru-cut biopsy and biopsy guns, provide for semiautomation of the percutaneous procedure.

TYPES OF LIVER BIOPSY

Liver biopsy is an invasive procedure. It requires a skilled clinician and special monitoring of the patient for postbiopsy complications, of which intra-abdominal bleeding is the chief concern. The mortality rate from percutaneous liver biopsy is on the order of 0.1% for cutting needle biopsies and much less for aspiration biopsies that utilize a finer needle. Percutaneous liver biopsy is by far the most commonly performed procedure. Blind needle biopsy uses abdominal percussion only as the guide for needle placement. Guided biopsy uses computed tomography (CT) or ultrasound to visualize liver anatomy and guide the placement and direction of the percutaneous needle biopsy thrust. In patients with clotting abnormalities, a transvenous route through jugular vein permits specimens to be obtained adjacent to the root of the hepatic vein, without risk of extravascular bleeding. Cutting or aspiration biopsies may be obtained at the time of laparoscopy or laparotomy. With a scalpel, a triangular segment of liver approximately 0.5 cm in maximal dimension is cut out from the anterior convexity of the liver surface or from the lower edge of a liver lobe; the defect can be sutured closed and hemostasis verified before exiting the abdomen.

The typical cutting-needle biopsy specimen is a 2 to 3 cm cylindrical core of tissue, between 0.4 and 0.8 mm in diameter, depending on the diameter of the cutting needle (Fig. 1). This sample represents approximately 1/50,000 of the organ. Liver biopsy thus has an inherent problem of sampling error in a variety of hepatic disorders. Liver biopsy is well suited to assessment of diffuse disorders, since the entire liver corpus is affected by many injurious events, particularly inflammatory and toxic process. Liver biopsy to diagnose disorders that exhibit irregular distribution of focal lesions within the liver is more problematic. The latter disorders

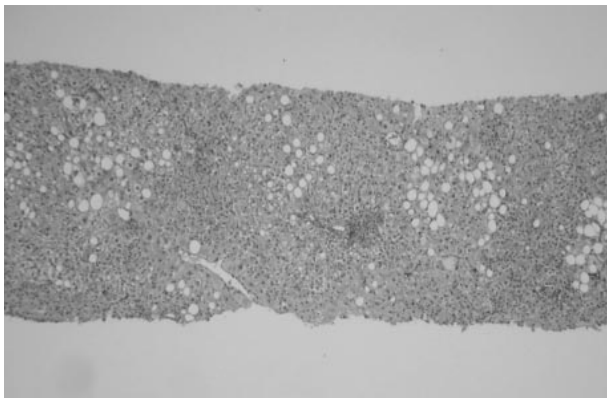

FIGURE 1 Middle portion of a liver needle core biopsy tissue from a patient with hepatitis C viral infection. Original magnification, ×40.

include primary biliary cirrhosis, primary sclerosing cholangitis, graft-versus-host disease, and nonhepatotropic viral infections such as cytomegalovirus. The needle may harvest tissue exhibiting definitive diagnostic histology or it may miss such tissue.

Liver wedge biopsy is excellent for the evaluation of focal lesions that are immediately below the capsule of the liver. It is not as well suited to general diagnosis of liver disease, since the liver tissue obtained from the subcapsular region is not representative of the whole liver. In particular, the normal penetration of fibrous septa from Glisson's capsule into the superficial 0.5 cm of the liver substance makes assessment of liver fibrosis in the immediate subcapsular region unreliable. If a wedge biopsy is to be obtained for assessment of diffuse liver disease, a cutting-needle biopsy penetrating deep into the liver should also be obtained. Despite the smaller size of the sample obtained from the cutting-needle biopsy, it frequently is the more reliable source of histologic information.

Fine-needle aspiration biopsy is particularly useful for evaluating hepatic mass lesions. It is usually performed with ultrasound or CT imaging. Considering that neoplasms such as liver cell adenomas and hepatocellular carcinomas have a rich arterial circulation, the lower risk of postbiopsy bleeding often makes fine-needle aspiration biopsy greatly preferable to cutting-needle biopsy. If the fine needle is properly placed, the samples obtained often (but not always) provide the needed information for diagnosis of the mass lesion. Liver aspiration is not suitable for evaluation of medical hepatic diseases because the samples do not preserve much if any of the architecture of the tissue. It should also be noted that no form of needle biopsy is recommended for diagnosis of hemangiomas. Noninvasive imaging techniques are usually sufficient to identify hemangiomas without incurring the strong likelihood of bleeding following biopsy of such lesions.

INDICATIONS FOR LIVER BIOPSY

Serum biochemical tests that remain of consistent value for screening for liver disease include aminotransferases as measures of hepatocellular injury; alkaline phosphatase and γ-glutamyl transpeptidase as measures of cholestatic injury to either hepatocytes or bile ducts; serum bilirubin (direct and total), albumin, and clotting times as measures of hepatocellular function; and serological markers for infections and autoimmune events. With the continued evolution of laboratory testing for liver disease, a clinical differential diagnosis is usually well established at the time of liver biopsy. The indications for liver biopsy—percutaneous or open—include the following: *de novo* histologic diagnosis of liver disease; assessment of liver disease severity; guidance in dealing with a difficult differential diagnosis; monitoring of multiple causes of liver disease simultaneously affecting the liver; and assessment of focal lesions. Liver biopsy is now frequently used to provide prognostic as well as diagnostic information. For these reasons, liver biopsy plays a critical role in clinical hepatology practice.

In the community care setting, the most common indication for an initial liver biopsy is an abnormal liver laboratory test. Many insidious chronic liver diseases cause mild liver abnormalities and liver biopsy plays an indispensable role in determining the underlying etiology. Sustained fever of unknown origin or unexplained hepatic or splenomegaly also may prompt a liver biopsy. Identification of a liver mass lesion, either incidentally or as part of evaluating right upper quadrant symptomatology, also frequently leads to liver biopsy. When diagnoses have been established, especially for viral hepatitis, liver biopsy is used to monitor the progression of disease and/or efficacy of treatment. Liver biopsy is a critical part of managing liver transplant patients, as early histological identification of graft injury, allograft rejection, recurrent disease, or new causes of liver damage greatly assists effective management of this patient population.

LIVER BIOPSY SPECIMEN PREPARATION IN THE LABORATORY

In order to accurately interpret a liver biopsy, it is essential to handle and prepare the tissue specimen

correctly. Depending on the nature of the suspected diseases, a variety of laboratory techniques can be used to enhance the diagnostic sensitivity and specificity. Therefore, there must be effective communication between the clinician and the pathologist about the patient's status before the biopsy is taken, so that the correct processing is chosen. In most instances, all liver biopsy tissue is routinely fixed in buffered formalin and processed for microscopy, but this is not always the best choice. In the setting of possible hematological disorders affecting the liver, it is essential to have some fresh (not fixed) tissue submitted for flow cytometric analysis. When inherited metabolic disorders are suspected, it is necessary to preserve a portion of the liver tissue by immediate immersion in liquid nitrogen for biochemical, enzymatic, and/or molecular analysis; a small portion also should be placed in electron microscopy fixative for potential ultrastructural analysis. If an infectious etiology other than hepatotropic viral infection is suspected, a portion of fresh tissue may be submitted for microorganism cultures.

Liver tissue fixed in buffered formalin can be stained with a variety of techniques. The most common tissue stain is hematoxylin and eosin. The commonly used stains and their utility are listed in Table I.

PRINCIPLES FOR LIVER BIOPSY INTERPRETATION

A systematic approach is best for evaluating liver biopsy. Individual histopathologic features should be integrated into a clinically relevant differential diagnosis. It is true that definitive diagnosis based on a liver biopsy cannot be rendered all the time. However, a thorough and systematic description of the histologic findings forms an important basis for ongoing clinical management of patients. Conversely, morphological findings must be considered in the context of clinical information.

Microscopic examination must first determine the hepatic architecture. This is usually performed under light microscopy with low magnification, e.g., $\times 40$. This examination includes noting the presence of adequate portal tracts, the presence of focal lesions, the presence of distortion of hepatic architecture, the distribution of portal tracts and terminal hepatic veins, sinusoidal and liver plate architecture, the presence of inflammatory cell infiltrates in the portal tracts or in the lobules, and the presence of zonal injury (i.e., periportal, midzonal, or centrilobular).

Next, attention should be directed to specific anatomic compartments. Portal tracts should be examined for the status of hepatic arteries and portal veins, the presence or absence of bile ducts, evidence of bile duct epithelial damage, bile ductular proliferation, the composition of inflammatory cells if present, the integrity of the hepatocyte-limiting plate at the margin of the portal tract, the presence of granulomas, and the presence of significant portal tract or periportal fibrosis. Examination of the lobular parenchyma should be focused on the presence or absence of an inflammatory cell infiltrate; the extent of hepatocellular apoptosis, necrosis, atrophy, ballooning degeneration (swollen hepatocytes), and steatosis (microvesicular or macrovesicular); and the presence or absence of retained bile pigment (cholestasis) and Mallory bodies (clumps of intermediate filaments in hepatocytes). In addition, sinusoids should be examined for dilation and congestion, increased Kupffer cell numbers, and sinusoidal fibrosis (the result of stellate cell activation and collagen deposition in the space of Disse). Terminal

TABLE I Selected Histological Stains in Liver Biopsy Interpretation

Stain	Comment
Hematoxylin and eosin	All-purpose stain for histological assessment
Masson trichrome	Connective tissue in portal tracts, parenchyma, and around terminal hepatic veins
Reticulin	Delicate collagen fibers of the subendothelial space, parenchymal architecture
Iron	Hepatocellular pigmented granules, Kupffer cell granules
Periodic acid-Schiff	Hepatocellular glycogen, basement membrane around bile ducts
Periodic acid-Schiff with diastase	Hepatocellular glycoproteins (especially α-1-antitrypsin), cellular debris in macrophages
Shikata	Elastin fiber deposition in long-standing fibrosis
Orcein	Copper-binding protein in Wilson disease, elastin fibers, hepatitis B surface antigen
Rubeanic acid	Copper granules in Wilson disease
Hall	Bilirubin stains green, connective tissue stains red
Oil red O	Lipid droplets stain red
Congo red	Amyloid

hepatic veins are examined for vascular injury and occlusion.

Certain patterns of hepatocellular damage are particularly significant for diagnosis. Apoptosis of individual hepatocytes is common in many liver diseases. It is pronounced in the setting of viral hepatitis, especially when it is associated with the inflammatory disruption of limiting plates (interface hepatitis) and a portal tract and parenchymal infiltrate that is predominantly lymphocytic. The term confluent necrosis is used when there are contiguous areas of hepatocyte death. It occurs in the setting of viral or drug-induced hepatitis. The term "bridging necrosis" refers to confluent hepatocyte death that links portal tracts one to another or to terminal hepatic veins. It is commonly associated with acute hepatitis or fulminant hepatic failure. Ischemic necrosis of hepatocytes, as results from cardiovascular shock, leads to ghosts of poorly staining hepatocytes in the pericentral area. Microvesicular steatosis of hepatocytes may result from the metabolic overload of acute alcohol exposure or may signify mitochondrial injury from drugs, acute fatty liver of pregnancy, or Reye's syndrome. Macrovesicular steatosis is featured in alcoholic liver disease and nonalcoholic fatty liver disease.

Evaluation of cholestasis is an essential part of the liver biopsy examination. Cholestasis is defined as retention of bile substances in hepatocytes, biliary channels, or both. Cholestasis may be nonobstructive, the result of hepatocellular dysfunction from many forms of injury. Hepatocytes become discolored by the brown bilirubin pigments and bile canaliculi may be expanded by retained bile. Sepsis may lead to dilation of bile ductules with massive retention of bile. Obstruction of bile flow in major bile ducts leads to edema and neutrophilic inflammation of portal tracts, inspissation of bile in bile ducts, and bile ductular proliferation, as well as hepatocellular and canalicular cholestasis.

In addition to the above important findings from the routine hematoxylin and eosin stain, special tissue stains are an important adjunct in the assessment of a liver biopsy. A Masson trichrome stain is helpful for determination of the degree of the fibrosis, up to and including identification of the liver disruption of cirrhosis. A reticulin stain defines the architecture of the parenchyma, in particular the width of hepatocellular plates and whether they are expanded, atrophied, or collapsed from hepatocyte destruction. Periodic acid-Schiff stains—without and with diastase digestion of glycogen—are useful for evaluating parenchymal injury at the portal tract interface, accumulation of debris-containing macrophages, bile duct architecture, and whether metabolic storage diseases are present (especially α-1-antitrypsin storage disorder and type IV glycogen storage disease). An iron stain helps to characterize the nature of hepatocellular and Kupffer cell pigment granules.

Additional information can be gained from immunohistochemical staining, which allows the pathologist to identify particular molecular markers in the liver tissue (Table II). These include immunostains for the antigens of hepatitis B virus, cytomegalovirus, adenovirus, or herpesvirus. Immunostain for hepatitis C virus remains of questionable clinical utility, particularly given the excellent serological and virological markers that are available. Immunostaining has also been widely used to characterize the nature of a neoplasm based on the differential molecular expression of tumor cells. It should be noted that immunohistochemistry permits evaluation of metastatic disease to the liver

TABLE II Selected Immunohistochemical Stains in Liver Biopsy Interpretation

Stain	Comment
Hepatitis B surface antigen	Active hepatitis B infection or the carrier state with retained HBsAg in hepatocytes
Hepatitis B core antigen	Active hepatitis B infection
Hepatitis D antigen	Active hepatitis D infection (with hepatitis B)
Pancytokeratin	All hepatocytes and bile duct epithelial cells
Cytokeratin 7	Bile duct epithelial cells, hepatocytes to variable degrees in cholestatic injury
Cytokeratin 19	Bile duct epithelial cells
Cytokeratin 20	Metastatic adenocarcinoma (as from colon), but not bile duct malignancy
HepPar 1	Hepatocytes, variable staining of hepatocellular carcinoma
α-Fetoprotein	Variable staining of hepatocellular carcinoma
Polyclonal carcinoembryonic antigen	Bile canaliculi of hepatocytes (including hepatocellular carcinoma), apical membrane of bile duct epithelial cells
Monoclonoal carcinoembryonic antigen	Metastatic adenocarcinoma, cytoplasmic staining
CD34	Endothelium, including sinusoidal endothelium

and determination of whether a tumor is hepatocellular carcinoma, cholangiocarcinoma, or a mixture of both. However, immunohistochemistry is not the basis for determining whether a hepatocellular nodule is malignant. Rigorous assessment of tissue architecture and cytology on hematoxylin and eosin stain, with the assistance of connective tissue stains such as the reticulin stain, remain the gold standard for diagnosis of hepatocellular carcinoma. Finally, on occasion *in situ* RNA hybridization is of value, particularly for identifying Epstein-Barr virus early mRNA in the diagnosis of posttransplantation lymphoproliferative disorder.

All the above-mentioned histologic findings must be considered in the context of the clinical presentation, laboratory tests, and other physical findings in order to render an accurate and helpful clinical diagnosis.

LIVER DISEASES WITH CHARACTERISTIC LIVER BIOPSY FINDINGS

Comments are made about some of the more common liver diseases.

Viral Hepatitis

Biopsies from patients who are infected with hepatitis B or hepatitis C virus usually exhibit a portal tract lymphocytic infiltrate, interface hepatitis, lymphocytosis in the lobules with associated hepatocyte apoptosis, and a variable degree of portal fibrosis. Hepatitis B liver can exhibit hepatocytes with a smudgy "ground glass" cytoplasm, the result of accumulated hepatitis B surface antigen (HBsAg). Hepatitis C liver tends to have more lymphoid aggregates in the portal tracts and focal hepatocyte macrovesicular steatosis.

Alcoholic Liver Disease

The characteristic features of alcohol-related liver histopathology are hepatocellular steatosis (microvesicular and macrovesicular—fatty liver) and, with severe alcohol exposure, a parenchymal neutrophilic infiltrate, hepatocyte ballooning degeneration and apoptosis, Mallory bodies (clumps of intermediate filaments in the hepatocyte cytoplasm), and sinusoidal and perivenular fibrosis (alcoholic hepatitis).

Nonalcoholic Fatty Liver Disease

Bland macrovesicular steatosis may occur in patients who do not consume alcohol but have mild elevations in serum aminotransferase levels. This may signify nonalcoholic fatty liver disease. When the macrovesicular steatosis is accompanied by a parenchymal neutrophilic infiltrate, ballooning degeneration, and apoptosis, nonalcoholic steatohepatitis merits consideration.

Drug-Induced Hepatitis

Drug-induced liver injury can produce almost any form of histologic outcome, ranging from a frank hepatocyte necrosis with direct hepatotoxins, an inflammatory hepatitis with hepatocyte destruction, or variable hepatocyte injury with drugs that induce immunological injury, ranging from moderate to severe cholestasis to outright cirrhosis. The possibility of drug-induced liver injury should be in the differential diagnosis of any histological assessment of liver pathology.

Hemochromatosis

The most significant finding for a diagnosis of hemochromatosis is the marked increase in iron storage, especially in the hepatocytes. The more reliable criterion is the quantification of iron by chemical analysis of liver tissue.

α-1-Antitrypsin Storage Disorder

The failure of the liver to secrete α-1-antitrypsin leads to α-1-antitrypsin deficiency, with its attendant lung injury. Some, but not all, patients with α-1-antitrypsin deficiency accumulate mutated protein within hepatocytes and develop severe liver injury, constituting α-1-antitrypsin storage disorder. The critical finding for this disease is the presence of periodic acid-Schiff-diastase-resistant globules in the cytoplasm of hepatocytes. Most of the affected hepatocytes surround the portal tracts.

Primary Biliary Cirrhosis

The key histology of primary biliary cirrhosis is a dense infiltrate of lymphocytes and plasma cells in portal tracts, with lymphocytic infiltration of bile ducts and bile duct destruction. Portal tract granulomas centered upon degenerating bile ducts is even more pathognomonic. Secondary changes include hepatocellular cholestasis, bile ductular proliferation, and progressive portal and periportal fibrosis.

Primary Sclerosing Cholangitis

Progressive fibrosis around portal tract bile ducts leads to their obliteration in this disease; secondary

changes of hepatocellular cholestasis and progressive periportal fibrosis develop.

Cirrhosis

Cirrhosis is defined as diffuse subdivision of the liver by interconnecting fibrous tissue, isolating individual islands of hepatocytes. The islands may undergo regenerative proliferation, generating spherical nodules embedded in constricting fibrous tissue. The nodules may be consistently less than 3 mm in diameter (micronodular cirrhosis) or variable in size and greater than 3 mm in diameter (macronodular cirrhosis). Liver biopsy of the cirrhotic liver frequently yields a fragmented specimen consisting of spherical tissue fragments composed of hepatocyte nodules surrounded by a rim of fibrous tissue. If the needle successfully cuts through the cirrhotic liver tissue, the biopsy shows tracts of fibrous septa subdividing a disorganized hepatocellular parenchyma.

Hepatocellular Carcinoma

Hepatocellular carcinoma is diagnosed on the basis of both architecture and cytology. Markedly thickened liver cell plates consistently greater than three cells thick is the single most important architectural feature. Unlike essentially any other form of solid malignancy, hepatocellular carcinoma tissue consists of thick tongues of hepatocytes (trabeculae) coated by a thin external endothelial layer. Unlike normal liver cell plates, there is diminished to absent reticular staining of collagen fibers in the subendothelial space of malignant trabeculae in hepatocellular carcinoma. Other architectural configurations of hepatocellular carcinoma include circular "pseudoacinar" configurations of hepatocytes and thick cords of hepatocytes invading fibrous tissue of an otherwise cirrhotic liver. The cytologic features of hepatocellular carcinoma are a modest increase in hepatocellular diameter, with an increased nuclear: cytoplasmic ratio and variable degrees of nuclear atypia. Well-differentiated hepatocellular carcinomas may have little cytologic atypia, hence the importance of assessing architecture.

Metastatic Malignancy

By far the most common malignancy in the liver is metastatic disease. Metastases in the liver frequently originate from colon carcinoma, pancreatobiliary carcinoma, breast carcinoma, lung carcinoma, hematologic malignancy, and malignant melanoma.

CONCLUSION

The key to liver biopsy evaluation is systematic examination of the parenchyma, portal tracts, and component cellular populations. Rigorous identification of patterns of injury and their distribution among cellular elements permits alignment of histologic findings with the clinical differential diagnosis and possible definitive diagnosis of the cause of liver injury. Even without definitive understanding of the cause of liver disease, the liver biopsy findings provide important information for patient management and prognostication.

Liver Cysts

STANLEY MARTIN COHEN AND PHILLIP Y. CHUNG
University of Chicago

autosomal dominant polycystic kidney disease A disease characterized by the presence of multiple kidney, and often liver, cysts. The condition is inherited in an autosomal dominant pattern.
Caroli's disease Congenital cystic dilatation of the intrahepatic bile ducts.
cavernous hemangioma A benign vascular malformation presenting as a vascular mass in the liver. These may show cystic characteristics.
choledochal cyst A congenital, cystic structure arising from the biliary tree, often in association with abdominal pain and jaundice.
ciliated hepatic foregut cyst A solitary cystic lesion lined with ciliated, pseudo-stratified columnar epithelium.
cystadenocarcinoma A malignant cystic lesion derived from glandular epithelium.
cystadenoma A benign cystic lesion derived from glandular epithelium.
Echinococcus A genus of tapeworms, capable of causing hydatid cysts in humans.
hydatid cyst A cyst formed by the larval form of *Echinococcus*. Often appears as a "mother" cyst with several smaller "daughter" cysts.
microhamartoma A rare, benign lesion of hepatocytes and biliary epithelium encased by a fibrous stroma.
peliosis hepatis A condition associated with blood-filled cavities in the liver. This disease is found mostly in patients with acquired immune deficiency syndrome and anabolic steroid users.
polycystic liver disease A disease characterized by the presence of multiple liver cysts. This condition often occurs in association with autosomal dominant polycystic kidney disease. The condition is inherited in an autosomal dominant pattern.

Hepatic cysts are a common group of disorders that differ in etiology, physical manifestations, and clinical significance. Most cysts occur without symptoms and may be found incidentally by radiological imaging. The majority of cystic lesions are benign and only a small minority will be associated with serious morbidity or mortality. A universally accepted, standardized classification of hepatic cysts is lacking and there is also no consensus regarding the treatment of symptomatic lesions. This article reviews the various etiologies and diagnostic and treatment modalities of hepatic cysts.

BENIGN CYSTIC HEPATIC LESIONS

Simple Cysts

Simple cysts are cystic lesions that do not communicate with the intrahepatic biliary tree. Although generally occurring as solitary lesions, patients may present with multiple cysts. Simple cysts are common lesions with an autopsy prevalence of approximately 1%. The majority of the cysts are less than 1 cm in diameter, but rarely can be large enough to occupy the entire upper abdomen. Simple cysts are principally located in the right lobe of the liver. They are more common in women, with a male to

microhamartoma A rare, benign lesion of hepatocytes and biliary epithelium encased by a fibrous stroma.
peliosis hepatis A condition associated with blood-filled cavities in the liver. This disease is found mostly in patients with acquired immune deficiency syndrome and anabolic steroid users.
polycystic liver disease A disease characterized by the presence of multiple liver cysts. This condition often occurs in association with autosomal dominant polycystic kidney disease. The condition is inherited in an autosomal dominant pattern.

Hepatic cysts are a common group of disorders that differ in etiology, physical manifestations, and clinical significance. Most cysts occur without symptoms and may be found incidentally by radiological imaging. The majority of cystic lesions are benign and only a small minority will be associated with serious morbidity or mortality. A universally accepted, standardized classification of hepatic cysts is lacking and there is also no consensus regarding the treatment of symptomatic lesions. This article reviews the various etiologies and diagnostic and treatment modalities of hepatic cysts.

BENIGN CYSTIC HEPATIC LESIONS

Simple Cysts

Simple cysts are cystic lesions that do not communicate with the intrahepatic biliary tree. Although generally occurring as solitary lesions, patients may present with multiple cysts. Simple cysts are common lesions with an autopsy prevalence of approximately 1%. The majority of the cysts are less than 1 cm in diameter, but rarely can be large enough to occupy the entire upper abdomen. Simple cysts are principally located in the right lobe of the liver. They are more common in women, with a male to

Copyright 2004, Elsevier (USA). All rights reserved.

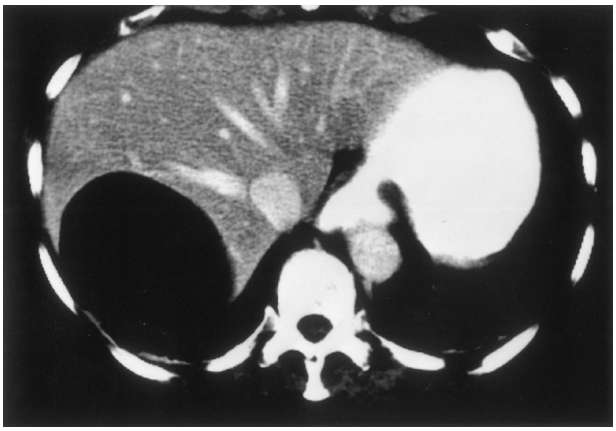

FIGURE 1 CT scan showing a large simple liver cyst. Courtesy of Abraham H. Dachman, M.D.

female ratio of 1 : 5 for asymptomatic cysts and 1 : 9 for symptomatic or complex cysts. Symptomatic cysts tend to present in the fourth and fifth decades of life.

Small cysts are usually asymptomatic and found incidentally on radiologic studies. Larger cysts tend to cause symptoms such as abdominal fullness or pain and nausea, due to compression of adjacent intra-abdominal structures. Physical examination of these patients generally reveals a palpable right upper quadrant mass. Laboratory examination is almost always normal unless the cyst impinges on the biliary tree and gives evidence of obstructive jaundice. Larger lesions may cause atrophy of the adjacent hepatic tissue with compensatory hypertrophy of the other lobe. Hemorrhage into the cyst, bacterial superinfection, torsion, or biliary obstruction can be seen with larger cysts. There is no convincing evidence of neoplastic transformation from simple cysts.

The most useful radiologic modality may be ultrasound, with simple cysts appearing as unilocular, thin-walled (less than 1 cm), anechoic, fluid-filled lesions with posterior acoustic enhancement. Computerized tomography (CT) scan shows well-demarcated, non-enhancing lesions of fluid density (see Fig. 1). If intracystic hemorrhage has occurred, septations may be visible, making diagnosis more complicated. Magnetic resonance imaging (MRI) of simple cysts reveals well-defined, water-attenuation lesions that do not enhance with gadolinium. T2-weighted images reveal a high level of enhancement, whereas the level of enhancement in T1 images is low.

Histologic assessment is rarely necessary for diagnosis. Needle aspiration reveals sterile fluid ranging from clear to brown in color. Cytologic examination of the fluid does not reveal any cellular atypia or dysplasia. On pathologic sections, the cysts demonstrate a single layer of cuboidal or columnar epithelium without mesenchymal stroma or cellular atypia. They are usually surrounded by three layers of dense fibrous tissue.

Asymptomatic cysts do not require any treatment, but periodic ultrasonic monitoring of larger lesions may be prudent to ensure stability of size. If the cyst remains stable for 2 to 3 years, further monitoring is probably unnecessary. If the lesions increase in size, alternate diagnoses such as cystadenoma or cystadenocarcinoma should be considered and surgical intervention may be indicated.

Patients with symptomatic cysts should be considered for treatment. Percutaneous needle drainage with or without injection of sclerosants may provide immediate relief, but has been associated with a high failure rate and rapid recurrence. Internal drainage via cystgastrostomy or cystjejunostomy can be performed via upper endoscopy with or without the aid of endoscopic ultrasound. Surgical unroofing of the cyst has been associated with low recurrence rates and few complications. A laparoscopic approach has been shown to be as effective as the open approach and obviates the need for a large abdominal incision. Recurrence and morbidity rates are less than 15% and this has become the intervention of choice for accessible lesions. Hepatic resection, including lobectomy, is generally reserved for large symptomatic lesions refractory to other treatments.

Cystadenomas

Cystadenomas are rare cystic lesions that occur within the liver parenchyma, extrahepatic bile ducts, or gallbladder. Cystadenomas are more prevalent in women. More than 60% present in patients over 40 years of age. These lesions can reach up to 15 cm in diameter.

Most cystadenomas are asymptomatic and are incidental findings on abdominal imaging studies. When present, the most common clinical manifestations are abdominal fullness, a palpable upper abdominal mass, abdominal pain or discomfort, and anorexia. Biliary obstruction is an uncommon complication. The most significant complication is malignant transformation, occurring in up to 15% of patients.

Ultrasound imaging reveals a well-defined cystic lesion with or without septations, often with slight irregularities of the cyst wall. CT scanning reveals a low-attenuation, uni- or multilocular cystic mass, often with septations, and a thickened and/or irregular cyst wall. MRI reveals a fluid-containing, multiloculated mass with homogenous low signal

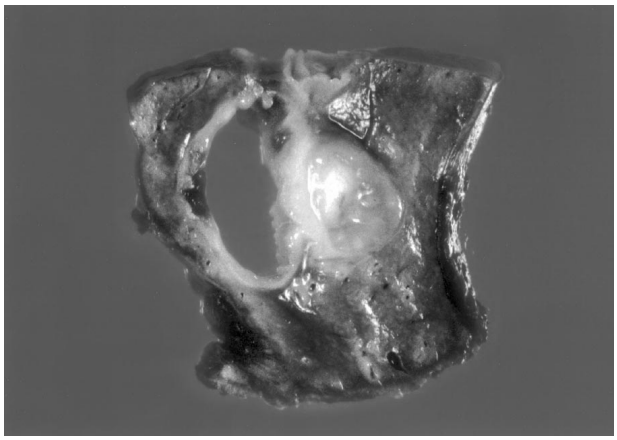

FIGURE 2 Gross liver specimen showing a cross-sectional view of a hepatic cystadenoma. The white rim of tissue lining the cyst cavity is composed of mesenchymal stroma. Courtesy of John Hart, M.D.

intensity on T1-weighted images and high signal intensity on T2-weighted images.

Radiologic studies cannot always differentiate cystadenomas from cystadenocarcinomas; thus, the definitive diagnosis of a cystadenoma requires histology. Gross pathologic examination typically reveals a multilocular cystic lesion with a smooth external surface. The wall is usually thick with a smooth internal lining (see Fig. 2) and the lesions often contain blood or dark brown liquid. Histologically, the cysts are lined by biliary-appearing mucous-producing cuboidal or columnar epithelium. The lining of the cyst is often surrounded by a dense mesenchymal fibrous stroma and a loose collagenous layer. Cystadenomas surrounded by a more cellular (and less fibrous) stroma may be a subtype with less associated risk of malignancy.

Due to the high rate of malignant degeneration and the high rates of recurrence with incomplete resection or needle aspiration, therapy almost exclusively involves complete surgical resection. The excision of the cystadenoma is accomplished by enucleating the lesion from the surrounding liver parenchyma.

Polycystic Liver Disease

Liver cysts can occur in association with autosomal dominant polycystic kidney disease (ADPKD). The incidence increases with age and worsening renal dysfunction. The incidence of polycystic liver disease is similar between the sexes, but the presence of massive cysts is almost exclusively observed in multiparous females. This may be due to sensitivity of the cysts to female hormones, a fact supported by the observation of cyst enlargement in certain patients receiving oral contraceptives or postmenopausal hormone replacement therapy.

The pathogenesis of ADPKD appears to involve a generalized defect in epithelial cell differentiation and/or extracellular matrix function. The liver lesions are derived from biliary epithelium. In addition to renal, hepatic, and pancreatic cysts, afflicted patients may have cerebral aneurysms, cardiac valvular disease, colonic diverticuli, and abdominal or inguinal hernias. Most patients are asymptomatic with preserved hepatic function, but some patients may present with abdominal pain from distension of the liver capsule or compression of adjacent structures. Acute pain suggests the possibility of cyst infection, hemorrhage, rupture, or torsion.

Radiologic (see Fig. 3) and histologic characteristics of the lesions are similar to those of simple cysts, with much larger numbers of cysts visualized.

Treatment should be reserved for symptomatic patients. Varying degrees of success have been reported with partial hepatectomy, but surgical intervention should be performed only at centers with experience in hepatic resection. Orthotopic or living-related liver transplantation has been performed as definitive therapy in patients with disease not amenable to local resection. The limited availability of donor organs and the preserved liver function in patients with ADPKD have made this intervention somewhat controversial.

Cavernous Hemangiomas

Cavernous hemangiomas are benign blood vessel tumors of the liver that may appear cystic in nature.

FIGURE 3 CT scan showing polycystic liver disease. Note the multiple simple cysts of varying sizes throughout both hepatic lobes.

They represent the most common benign hepatic tumors, with an autopsy incidence of 5–7%. The lesions appear to be equally divided among the sexes, but larger, symptomatic lesions tend to occur in women. The cysts are usually solitary and tend to involve the right lobe. However, 20% may involve both lobes. Size ranges from several millimeters to 45 cm in diameter.

Symptoms are more common in elderly patients with larger (greater than 4 cm) lesions. Symptoms include abdominal fullness, pain, nausea, and vomiting. Examination may reveal abdominal distension or a mass. Rare complications can include rupture, hemorrhage, or Kasabach-Merritt syndrome (consumptive coagulopathy within the hemangioma presenting as disseminated intravascular coagulopathy). There is no evidence of malignant transformation of hemangiomas.

Ultrasound demonstrates a well-defined hyperechoic mass. CT shows a mass with contrast accumulation spreading from the periphery to the center of the lesion. MRI is extremely useful, demonstrating a hyperintense signal on T2-weighted images (light bulb sign). Tagged red cell scanning shows initial hypoperfusion followed by gradual increase of the tracer uptake.

Pathologic examination should come from surgical specimens as biopsy is contraindicated due to the extremely vascular nature of these tumors. Grossly, the lesions are blue to purple in color and very vascular. Histology reveals large, dilated channels lined by vascular endothelium. A variable amount of surrounding fibrous tissue is present.

Treatment is necessary only for symptomatic patients. Wedge resection and lobectomy are the treatments of choice. Radiation therapy or arterial embolization may be useful as temporizing measures in patients with acute bleeding or Kasabach-Merritt syndrome.

Miscellaneous Benign Cysts

Ciliated Hepatic Foregut Cysts

This rare, benign condition presents as a solitary hepatic cyst lined with ciliated, pseudo-stratified columnar epithelium surrounded by subepithelial connective tissue, a smooth muscle layer, and an outer fibrous capsule. Only 60 cases have been reported, with cyst sizes ranging from 0.4 to 9.0 cm. These cysts are found more commonly in men and occur more frequently in the left lobe. Malignant transformation has not been reported and the clinical significance is restricted to differentiating ciliated hepatic foregut cysts from other lesions with malignant potential.

Microhamartomas (von Meyenberg Complexes)

Microhamartomas are rare lesions presenting in young children. They may occasionally be cystic in nature. They tend to occur in males. The presentation is that of a painless right upper quadrant mass. Imaging techniques demonstrate a multiloculated cystic lesion, predominantly in the right hepatic lobe. Histology reveals hepatocytes and biliary channels trapped in a variable cellular and fibrous stroma. Treatment is generally not necessary due to the benign nature of these lesions. For symptomatic patients, surgical excision is curative.

Peliosis Hepatis

Peliosis hepatis is a rare condition characterized by blood-filled cavities in the hepatic parenchyma. This condition is most commonly associated with anabolic steroid use. Peliosis also occurs in human immunodeficiency virus (HIV)-positive patients infected with *Bartonella henselae*. Peliosis is generally asymptomatic, with no evidence of malignant degeneration. Treatment, although inconsistently effective, targets the likely cause. In cases associated with anabolic steroid use, discontinuation of these agents has been shown to cause disease regression. In HIV-positive patients, peliosis may respond to prolonged courses of erythromycin or doxycycline.

Miscellaneous

Glands adjacent to the biliary tree can expand and present as periductal cysts. In patients with prolonged cholestasis, biliary cysts can form. Blood-filled cysts can develop as a result of trauma, most commonly after a liver biopsy. Duodenal duplication cysts, extremely rare embryologic abnormalities involving duplication of the duodenal lumen, can present as cystic lesions in the hepatic parenchyma.

MALIGNANT CYSTIC HEPATIC LESIONS

Cystadenocarcinoma

Cystadenocarcinomas likely arise from the malignant transformation of cystadenomas (see above). These lesions occur in the hepatic parenchyma, but have not been found arising from the extrahepatic biliary tree. Although they have been reported in patients as young as 30 years of age, this tumor is generally found in the elderly.

The presenting symptoms are similar to those seen with a cystadenoma (i.e., abdominal pain, mass). However, acute worsening of the symptoms associated with a rapid increase in size of a previously stable lesion is suggestive of malignant transformation.

Radiologically, cystadenomas and cystadenocarcinomas appear similar on ultrasound and CT. Both reveal multilocular, septated cystic lesions.

The differentiation between cystadenoma and cystadenocarcinoma requires histologic examination. Preoperative diagnosis is difficult, as needle aspiration carries the risk of peritoneal seeding of tumor. On pathologic examination, cystadenocarcinomas have a thicker cyst wall than cystadenomas and may have tissue extruding from the internal cyst lining. Histologically, cellular atypia, increased cellular proliferation, and malignant changes are typically found in the inner epithelial lining.

If cystadenocarcinoma is suspected, complete excision by segmental liver resection is the treatment of choice. Enucleation of the cyst, as performed for cystadenoma, is not acceptable, as there is an increased risk of recurrence. Nonsurgical treatments such as radiation or chemotherapy are unproven and thus not recommended.

Cystadenocarcinomas may invade locally and metastasize distantly, but may be curable with complete excision. The prognosis is generally better than that associated with cholangiocarcinoma.

Liver Metastases

The liver is a common site of metastasis for many abdominal and pelvic neoplasms. Rarely, metastatic lesions may outgrow their blood supply, resulting in central necrosis, which may appear as cystic lesions on radiologic studies. The primary lesions include colorectal, ovarian, pancreatic, kidney, and neuroendocrine tumors. Segmental resection of accessible metastases is the only curative intervention, but there must be no involvement of the hepatic artery, portal vein, or major bile ducts, and there must be sufficient postresection functional hepatic reserve. Although laparoscopy may identify occult metastases obviating the need for laparotomy, a clinical risk score involving five factors (lymph node positivity, relapse-free interval <12 months, >1 hepatic metastases on preoperative imaging, serum CEA (carcinoembryonic antigen, a serologic colon cancer marker) >200 ng/ml within 1 month of surgery, and any metastasis >5 cm) has been suggested to predict nonresectability in metastatic colon cancer. Only 12% of patients with a score ≤ 2 had occult metastases on laparoscopy versus 42% of those with a score >2. Five-year survival after resection of hepatic metastasis is 24–38% in most studies. However, fewer than 10% of patients with hepatic metastasis are candidates for curative resection at the time of presentation. Other alternatives for liver metastases, regardless of the primary tumor, include local tumor ablation with injection of ethanol or acetic acid, intraoperative cryotherapy, percutaneous hyperthermic coagulation, radiofrequency or microwave ablation, and hepatic intra-arterial and systemic chemotherapy.

Primary Squamous Cell Carcinoma

Several reports have been published describing the development of primary squamous cell carcinoma within solitary congenital hepatic cysts lined with stratified squamous epithelium. The prognosis appears poor despite surgical resection due to local recurrence. The number of published cases remains small and no formal trials of therapy have been conducted.

CHOLEDOCHAL CYSTS AND CAROLI'S DISEASE

Choledochal cysts are congenital cystic dilatations of the intra- and extrahepatic biliary tree. A system of classification based on morphology has been well accepted (see Fig. 4). Class I choledochal cysts, defined as segmental or diffuse fusiform dilatations of the extrahepatic biliary tree, account for 80 to 90% of cases. Class II cysts are true choledochal diverticuli, class III consists

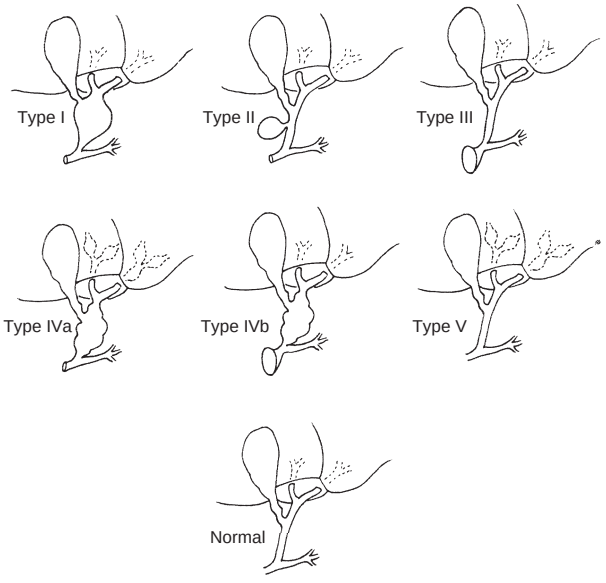

FIGURE 4 Subtypes of choledochal cysts including Caroli's disease. Courtesy of Kenneth D. Chi, M.D.

of dilatations of the intraduodenal common bile duct, and class IV is made up of either multiple intra- and extrahepatic cysts (subtype IVa) or just multiple extrahepatic cysts (subtype IVb). Caroli's disease (Class V) consists of cystic dilatations of the intrahepatic ductal system.

The incidence of choledochal cysts varies geographically, with approximately 1 : 100,000–150,000 in Western countries and up to 1 : 10,000 in Japan. Although choledochal cysts have been documented at all ages, 60–80% of cases present before the age of 10 years. Females are more commonly affected with choledochal cysts, whereas Caroli's disease occurs more commonly in males. Neither of these conditions is familial.

Patients often present in infancy with the classic triad of pain, jaundice, and a palpable abdominal mass. Other symptoms include cholestatic jaundice, acholic stools, hepatomegaly, vomiting, irritability, and failure to thrive. Portal hypertension and ascites may also be evident on presentation, especially in Caroli's disease patients with associated congenital hepatic fibrosis. Adult patients tend to present with epigastric pain or intermittent fever and jaundice. Only approximately 20% of adult patients will present with the classic symptom triad. Complications of choledochal cysts include biliary obstruction, stone formation, cholangitis, hepatic abscess, biliary perforation, pancreatitis, and malignant degeneration. The risk of cholangiocarcinoma correlates with duration of disease. The risk is approximately 1% in the first decade of life, 6–7% in the second decade, and 14% in successive decades. The prognosis of these malignancies is extremely poor.

The diagnosis of choledochal cysts is made by ultrasonography, which reveals the cystic dilations of the bile ducts. Percutaneous cholangiography transhepatic (PTC) or endoscopic retrograde cholangiopancreatography (ERCP) can define the site of biliary origin and the extent of both extra- and intrahepatic disease. PTC and ERCP can also reveal an anomalous arrangement of the pancreaticobiliary junction, which occurs in up to 40% of cases.

On pathologic examination, the cysts are composed of a fibrous wall, with or without a lining of columnar epithelium. Calculi frequently develop within the dilated bile ducts. Liver biopsy may reveal portal tract edema and fibrosis in early disease or biliary cirrhosis with or without carcinoma of the cyst wall in older patients.

Due to a 20-fold increased risk of malignancy in the cystic lesions, the preferred method of treatment is surgical excision of the cyst and reconstruction of the extrahepatic biliary tree, usually with a Roux-en-Y hepaticojejunostomy or choledochojejunostomy for biliary drainage. Cholecystectomy should also be performed due to the subsequent risk of gallbladder cancer. Recurrent cholangitis, stone formation, pancreatitis, and malignancy anywhere along the remaining pancreaticobiliary tree may develop many years after reconstruction, necessitating long-term follow-up. Hepatic resection is indicated for disease limited to a single lobe. Simple decompression and internal drainage are reserved for inoperable cases or as temporizing therapy prior to surgery. Ursodeoxycholic acid therapy may be effective in dissolving intrahepatic stones. Liver transplantation is a therapeutic option in patients with frequent complications, in patients with extensive disease that precludes other surgical alternatives, and in patients with Caroli's disease.

INFECTIOUS/PARASTIC HEPATIC CYSTIC LESIONS

Echinococcal/Hyatid Cysts

Echinococcal disease is caused by the metacestode stage of the tapeworm, *Echinococcus*, family Taeniidae. There are four species that cause disease in human. *E. granulosus* and *E. multilocularis* are the most common, causing cystic and alveolar disease, respectively. *E. vogeli* and *E. oligarthrus* are rarely associated with disease in humans.

Humans are an incidental host and do not play a role in the biologic cycle of the organism (see Fig. 5). Therefore, human to human infection does not occur. Inter- and intraspecies differences exist in regards to geographical distributions and hosts. The adult tapeworm is usually found in the intestinal tract of the canine host acquired by ingestion of sheep viscera infected with hydatid cysts. Scoleces adhere to the dog's intestine and become adult taenia, which shed eggs into the intestinal lumen. The eggs are expelled in the feces and are ingested by sheep, cattle, or rodents or directly contaminate the environment. Humans are usually infected by ingestion of contaminated vegetables or by direct contact with an infected pet through fecal–oral contact. The pathophysiology in humans is similar to that of the typical intermediate host, with formation of hyatid cysts, typically in the liver.

Approximately 50% of hydatid cysts occur in asymptomatic patients and many more are found incidentally at autopsy. The average age at diagnosis is 36 years. The right lobe is affected in 60–85% of cases. The cysts typically grow at a rate of 1 to 5 cm per year. Symptoms

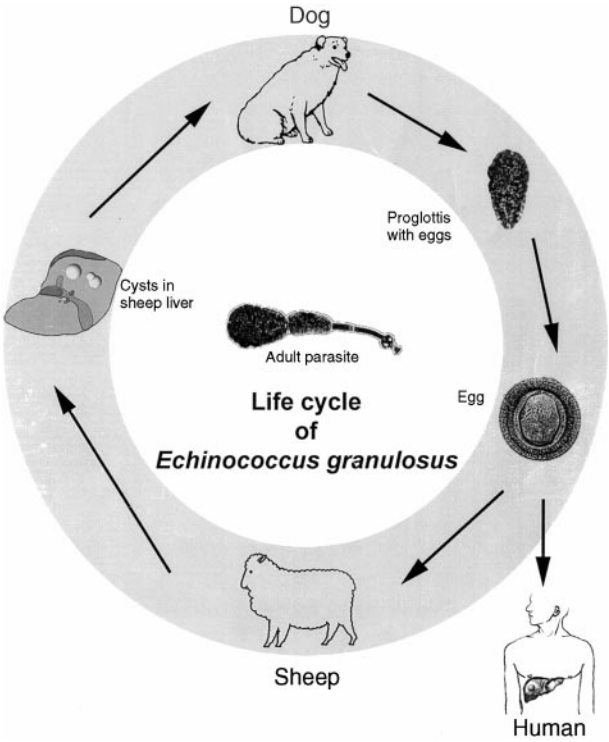

FIGURE 5 The life cycle of *Echinococcus*. Courtesy of Kenneth D. Chi, M.D.

of abdominal fullness, right upper quadrant pain, nausea, and vomiting typically occur when cysts reach 10 cm or more in diameter. Clinical features are due to mass effect on adjacent organs, obstruction of blood or lymphatic flow, or complications such as rupture or bacterial superinfection.

Diagnosis is made by a combination of radiologic and serologic studies. The hyatid cysts may appear as calcified cystic lesions on plain radiograph, whereas the ultrasound appearance is that of an anechoic, smooth, round cyst, similar in appearance to simple cysts. A flattened or elliptical shape, detachment of the germinal layer from the cyst wall (the "water lily" sign), or calcifications within the cyst wall suggest an inactive lesion. When daughter cysts are present, characteristic internal septations are also visible on ultrasound or CT imaging. "Hyatid sand," consisting of scoleces and hooklets of protoscoleces, may also be visualized, particularly if the patient shifts position during imaging. CT has been reported to be more sensitive than ultrasound in diagnosis (95–100% versus 90–95%, respectively).

Many serologic tests have been used to aid in the diagnosis of echinococcal infection. Immunoglobulin G enzyme-linked immunosorbent assay and hemagglutination assays have sensitivities of 80–90%. Immunoblot or antigen gel diffusion assays are more specific and may be used for confirmation.

Diagnostic aspiration or biopsy carries the risk of cyst rupture and anaphylaxis, or secondary spread of infection, and should be reserved for situations when other diagnostic methods are inconclusive. Aspiration should be performed only under CT or ultrasound guidance. Grossly, the cysts are thick-walled lesions often containing smaller, thin-walled daughter cysts (see Fig. 6). Microscopically, a cyst with possible calcifications in the wall is seen. The cyst contains cellular debris and occasionally viable scoleces.

Surgery is the treatment of choice in patients who can tolerate the operation and who have accessible cysts (approximately 90% of patients). Techniques include removal of the intact cyst, aspiration and cyst excision or external drainage, and partial hepatectomy. The instillation of protoscolicidal agents has not been definitively shown to reduce recurrence risk and may cause sclerosing cholangitis or pancreatitis if communication exists between the cyst and the biliary tree. Mebendazole or albendazole should be administered at least 4 days before surgery and for 1 (albendazole) to 3 (mebendazole) months afterward.

In poor surgical candidates, patients with multiple cysts, or patients with cyst recurrence, percutaneous aspiration/instillation of a protoscolicidal agent/reaspiration (PAIR) may be used as a therapeutic option. The procedure involves ultrasound-guided aspiration of the cyst fluid, followed by instillation of a scolicidal agent. The remaining cystic contents are then removed. PAIR has been shown to be effective in 70–99% of cases. Medical therapy alone can be considered in patients who cannot tolerate surgical or PAIR interventions. Although mebendazole or albendazole may be associated

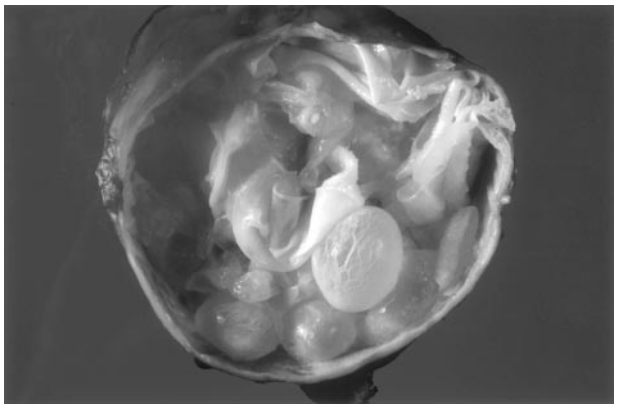

FIGURE 6 Gross specimen of a hydatid cyst filled with multiple daughter cysts. Courtesy of John Hart, M.D.

with shrinkage of the lesions in 50% of cases, cure occurs in less than 30% of patients.

Hepatic Abscesses

Liver abscesses may cavitate and form cystic lesions due to infection with gas-forming organisms or ameba.

SUMMARY

Cystic lesions of the liver are increasingly being diagnosed. Clinical and radiologic characteristics can help differentiate benign from malignant conditions. Needle aspiration and histology are generally not required for diagnosis of simple cysts. Complex, symptomatic, or enlarging lesions require further evaluation. The treatment for such lesions is generally surgical; however, percutaneous and endoscopic approaches are available.

Liver Disease, Pregnancy and

J. EILEEN HAY
Mayo Clinic and Foundation

acute fatty liver of pregnancy Acute liver failure due to microvesicular fatty infiltration of hepatocytes in the third trimester of pregnancy.

HELLP syndrome Triad of hemolysis, elevated liver tests, and low platelet count in the third trimester of pregnancy.

hyperemesis gravidarum Intractable vomiting in the first trimester of pregnancy.

intrahepatic cholestasis of pregnancy Pruritus and liver dysfunction in the second half of pregnancy.

preeclampsia triad of hypertension, edema, and proteinuria in the third trimester of pregnancy.

Pregnancy is an altered physiologic state associated with many hemodynamic and metabolic adaptations to support the placenta and fetus. Although most pregnant women remain healthy, pathophysiologic changes can occur, including five unique liver diseases seen only in the pregnant or postpartum patient. These pregnancy-associated liver diseases have characteristic clinical features and timing of onset in relation to pregnancy. Hyperemesis gravidarum is intractable nausea and vomiting in the first trimester; intrahepatic cholestasis of pregnancy, a disease of pruritus and abnormal liver tests, occurs in the second half of pregnancy; and preeclampsia and its complications of HELLP (hemolysis, elevated liver tests, and low platelets) syndrome and acute fatty liver of pregnancy are third-trimester diseases.

INTRODUCTION

Any liver disease, acute or chronic, occurring in young adult women may also occur coincidentally in pregnancy. Viral hepatitis is a common cause of jaundice in pregnancy and hepatitis A, hepatitis B, and hepatitis C occur with the same frequency and with the same clinical features as in nonpregnant individuals, with pregnancy and the viral hepatitis having little effect on each other. Gallstones are common, particularly in multiparous patients, but fortunately they are rarely symptomatic with biliary colic, pancreatitis,

TABLE I Incidence and Clinical Features of Liver Diseases Unique to Pregnancy

Disease	Incidence (per 1000 pregnancies)	Trimester	Risk factors
Hyperemesis gravidarum	2–10	1st	Multiparity, adolescent mother, twins, hydatiform mole
Intrahepatic cholestasis of pregnancy	1 (USA)	2nd and 3rd	Family history
Preeclampsia with liver dysfunction	1–6	3rd	
HELLP syndrome	1–6	3rd	Older mother, multiparity, preeclampsia
Acute fatty liver of pregnancy	0.05–1	3rd	Primigravida, twins, preeclampsia

or cholecystitis. Pregnancy in the patient with cirrhosis and/or portal hypertension is rare and guidelines for management are sparse; the main maternal risk is variceal bleeding.

This article will be limited to discussion of the five liver diseases unique to pregnancy. The incidence and etiology of the pregnancy-associated liver diseases will be discussed, followed by a description of the clinical features and management of each of these disorders (Tables I and II).

INCIDENCE

A recent prospective population study in the United Kingdom found that, of 4377 deliveries, 3% of patients had liver dysfunction, with elevations of transaminases (84%), bilirubin (17%), and bile acids (14%). Surprisingly, 80% of these patients had pregnancy-associated disorders and only 12% (0.4% of the total population) had coincidental or preexisting hepatobiliary problems; sepsis and postpartum problems contributed in approximately one-third of affected patients.

Nausea and vomiting are very common in pregnancy but the overall reported incidence of hyperemesis gravidarum is 2–10 per 1000 pregnancies with high transaminase levels in 25–50% of patients. Intrahepatic cholestasis of pregnancy (ICP) is a worldwide disease with striking geographical variations. In the United States, it occurs in 0.1% of pregnancies, with jaundice in 20% of cases.

The preeclampsia-associated liver diseases are preeclampsia itself, the HELLP (hemolysis, elevated liver tests, and low platelets) syndrome, and acute fatty liver of pregnancy (AFLP). Preeclampsia occurs in 5–10% of pregnancies and, although liver involvement is considered uncommon, it was the commonest cause of liver dysfunction in pregnancy (1.4% of all deliveries) in a recent prospective study. In 2–12% of cases of severe preeclampsia (0.1–0.6% of all pregnancies), this is further complicated by the HELLP syndrome. The most severe of the pregnancy-associated liver diseases, AFLP, is the least common in most studies, reportedly occurring in 0.005% of pregnancies but its incidence was considerably higher in the recent prospective study.

TABLE II Management of Liver Diseases Unique to Pregnancy

Disease	Hospitalization	Fetal management	Maternal management
Hyperemesis gravidarum	Yes	Routine	Intravenous hydration Antiemetics ? High-dose steroids
Intrahepatic cholestasis	No	Fetal monitoring, delivery <35 weeks	UDCA ? Cholestyramine ? Steroids
Preeclampsia with liver dysfunction	Yes	Immediate delivery	Antihypertensives Seizure prophylaxis
HELLP syndrome	Yes	Immediate delivery	Treatment for preeclampsia CT abdomen Blood/blood products ? Plasmapheresis/OLT
Acute fatty liver of pregnancy	Yes	Immediate delivery	Supportive care for liver failure ? OLT

ETIOLOGY

The etiologies of the liver diseases unique to pregnancy remain obscure but new knowledge is emerging, particularly about ICP and AFLP. The pathophysiology of hyperemesis gravidarum is complex, with evidence for hormonal (elevated estrogen levels, transient hyperthyroidism, and elevated chorionic gonadotropin) and immunologic abnormalities; the role of psychological factors remains poorly defined. The etiology of ICP is probably multifactorial. The geographic and seasonal variability, the potential role of dietary factors such as selenium, and the 45–70% recurrence rate in multiparous patients clearly suggest the importance of exogenous factors. Female sex hormones are of pathogenic importance, perhaps by a genetically abnormal or exaggerated hepatic metabolic response to the physiologic increase in estrogens during pregnancy. Patients with ICP have abnormalities in progesterone metabolism and exogenous progesterone is the only proven exogenous precipitant of ICP. The familial cases and high ethnic variations strongly suggest a genetic predisposition to ICP. Mothers with ICP who are heterozygous, with homozygous babies, for genetic abnormalities in biliary (canalicular) transport proteins have been identified; these abnormalities are responsible for the rare group of diseases known as the progressive familial intrahepatic cholestasis syndromes. Abnormalities in placental bile acid transport systems and/or high circulating bile acid levels with vasospasm of the placental vessels may contribute to fetal loss in ICP.

Preeclampsia is associated with generalized endothelial dysfunction. In the HELLP syndrome, microangiopathic hemolytic anemia causes periportal hemorrhage, necrosis, and fibrin deposition in the liver. With increasing severity, areas of infarction enlarge and hemorrhage dissects from zone 1 diffusely to involve the whole lobule, leading to widespread necrosis, large hematomas, capsular tears, and hepatic rupture.

In AFLP, acute hepatic failure is due to microvesicular fatty infiltration of hepatocytes, perhaps due to abnormalities in intramitochondrial fatty acid oxidation (FAO). FAO helps to meet the increased metabolic demands of pregnancy but is reduced in later pregnancy even as metabolic demands are increasing, especially with preeclampsia. Some babies of AFLP mothers are homozygous for deficiencies in enzymes necessary for normal FAO, the best characterized being LCHAD (long-chain 3-hydroxyacyl-coenzyme A dehydrogenase) deficiency. Maternal heterozygosity, with fetal homozygosity, for deficiency of an enzyme essential for the normal metabolism of fatty acids may overwhelm the increased demands of FAO in pregnancy and cause AFLP.

CLINICAL FEATURES AND MANAGEMENT

Hyperemesis Gravidarum

Clinical Features and Diagnosis

Hyperemesis gravidarum (HG) is intractable vomiting of such severity as to necessitate intravenous hydration. HG occurs in the first trimester of pregnancy, typically between 4 and 10 weeks of gestation, with risk factors being adolescent pregnancy, multiparity, twins, and hydatiform mole. Patients become severely dehydrated and may lose $>5\%$ of prepregnancy weight. High transaminase levels (up to a 20-fold increase) occur in 25–50% of cases and occasionally patients have mild jaundice. A clinical diagnosis is made based on the severity and timing of vomiting; mild to moderate vomiting in pregnancy does not cause liver dysfunction. Viral hepatitis must be considered but liver biopsy is necessary only to exclude other serious diagnoses.

Management

Hospitalization is necessary for hydration and, in severe cases, parenteral nutrition. Symptomatic therapy with antihistamines is safe and successful in many patients; oral ginger root extract or pyridoxine (vitamin B6) may occasionally give relief. Short-term, high-dose steroids may be effective in refractory cases.

Intrahepatic Cholestasis of Pregnancy

Clinical Features and Diagnosis

ICP is characterized by severe, generalized pruritus and liver dysfunction in the second half of pregnancy, typically at 25–32 weeks of gestation, in a patient with no other signs of liver disease; it disappears after delivery, to recur in subsequent pregnancies. Maternal distress can be great and skin excoriations are obvious. Jaundice will follow the pruritus in 10–25% of patients but rarely occurs without pruritus. Severe cholestasis may be complicated by steatorrhea and malabsorption of fat-soluble vitamins.

Mild to 20-fold elevations of transaminases occur but bilirubin remains <5 mg/dl. With placental production, alkaline phosphatase is of little diagnostic value in pregnancy and the most specific and sensitive diagnostic marker of ICP is a serum bile acid level that

is always elevated, up to 100 times above normal, and which may correlate with fetal risk. Generally, in a primigravida, a presumptive clinical diagnosis is made based on typical clinical features, consistent biochemical changes, and no evidence of obstructive gallstone disease, viral hepatitis, or other skin condition; the diagnosis is confirmed by rapid postpartum resolution. A liver biopsy is needed only to exclude more serious liver disease.

Management

Maternal management is symptomatic relief of pruritus. Three small trials have shown that ursodeoxycholic acid (UDCA) is safe and effective at doses of 600–1200 mg/day with symptomatic relief, biochemical improvement, and perhaps improved fetal outcome. Higher doses of UDCA (up to 2 g/day) have been shown to improve the bile acid profile in both mothers and babies—hopefully a benefit to improve fetal outcome. Cholestyramine may be used for symptomatic relief but does not affect the cholestasis. Dexamethasone (12 mg/day for 7 days), by suppressing fetoplacental estrogen production, may give symptomatic relief and it promotes fetal lung maturity to allow early delivery of the baby. No other agents are of proven efficacy for maternal relief in ICP. Therapy with vitamin K may be required at the time of delivery.

ICP results in a high-risk pregnancy for the fetus with premature deliveries, perinatal deaths, and fetal distress. Fetal monitoring for chronic placental insufficiency is necessary but will not prevent intrauterine deaths from acute anoxic injury. Careful obstetric intervention will improve fetal prognosis and early delivery is recommended by 35 weeks or earlier, as soon as there is fetal lung maturity. Whether maternal UDCA therapy will improve fetal outcome remains to be proven.

Symptoms of ICP will resolve by 4 weeks postpartum but will recur in 45–70% of subsequent pregnancies. Rare familial cases of apparent ICP have persisted after delivery with eventual progression to fibrosis and cirrhosis.

Preeclampsia

Preeclampsia is the triad of hypertension, edema, and proteinuria in the third trimester of pregnancy and, if severe, right upper abdominal pain and tenderness and mild jaundice (bilirubin < 5 mg/dl) may develop. Transaminases are elevated, from mild to 20-fold elevations. Hepatic involvement in preeclampsia signifies severe disease but requires no therapy other than that for the preeclampsia; the patient must be stabilized and then immediate delivery effected to avoid eclampsia, hepatic rupture, or necrosis.

HELLP Syndrome

Clinical Features and Diagnostic Criteria

The typical patient with HELLP syndrome is the older, multiparous patient who presents between 27 and 36 weeks of gestation. Most, but not all, have preeclampsia with hypertension, edema, and weight gain. The most common presenting symptoms are epigastric or right upper quadrant pain and tenderness, nausea and vomiting, a flu-like illness, and headache. Jaundice is uncommon (5%). Early diagnosis and management are essential to reduce maternal and fetal mortality.

Diagnosis requires the presence of all three of the following criteria: (1) hemolysis with an abnormal blood smear, an elevated lactate dehydrogenase (> 600 U/liter), and an increase in indirect bilirubin; (2) an aspartate aminotransferase level of > 70 U/liter (up to 20-fold elevation); and (3) a platelet count of $< 100{,}000 \times 10^6$/liter or $< 100 \times 10^9$/liter and, in severe cases, $< 50{,}000$. Coagulation is usually normal but occasionally disseminated intravascular coagulation (DIC) occurs. Bilirubin is usually < 5 mg/dl. Computed tomography of the liver is indicated to detect hepatic rupture, subcapsular hematomas, intraparenchymal hemorrhage, or infarction.

Management
