Expeditious management is required for optimal maternal and fetal outcomes. Treatment of hypertension and seizure prophylaxis is implemented. Severe cases will require full obstetric, surgical, and intensive care facilities and transfer to a tertiary referral center is essential. Delivery is the only definitive therapy and should be effected immediately near term or with fetal lung maturity. Uncomplicated vaginal delivery can be allowed to proceed but many patients require a cesarean section. Blood or blood products are required for hypovolemia, anemia, or coagulopathy, and broad-spectrum antibiotics are given. Management remote from term is more controversial. In severe cases, delivery must proceed despite the fetal risk but occasionally in milder cases at < 34 weeks, high-dose glucocorticoids are given to improve fetal lung maturity and to prolong the pregnancy.

Large subcapsular hematomas and diffuse intrahepatic hemorrhage without rupture are managed with close hemodynamic monitoring in an intensive care unit, correction of coagulopathy, availability of

large volumes of blood/blood products, and immediate intervention for hemodynamic instability or rupture. Exogenous trauma such as abdominal palpation, convulsions, emesis, and unnecessary transportation should be avoided. Liver rupture is rare but life-threatening, and rapid, aggressive medical management and immediate surgery are essential for survival.

In most cases, HELLP syndrome will rapidly resolve within 5 days of delivery with normalization of platelet counts but some patients have persisting thrombocytopenia, hemolysis, worsening hyperbilirubinemia, and impaired renal function. Life-threatening complications persisting for >72 h after delivery are usually taken as an indication for plasmapheresis or plasma exchange but if there is no response, liver transplantation must be considered. Unfortunately, life-threatening maternal complications are common and include DIC, abruptio placentae, acute renal failure, pulmonary edema, and rarely acute respiratory distress syndrome, hepatic failure, or hepatic rupture. The risk of recurrence of HELLP in subsequent pregnancies is poorly established but with subsequent pregnancies, these patients have an increased risk of preeclampsia, preterm delivery, intrauterine growth retardation, and abruptio placentae.

Acute Fatty Liver of Pregnancy

Clinical Features and Diagnosis

Many patients with AFLP are primigravidae, especially with twin pregnancies. The commonest time of presentation is 36 weeks, but it can occur at any time in the third trimester and in the postpartum period. The typical patient has 1–2 weeks of anorexia, nausea, vomiting, and right upper quadrant pain and is ill-looking with jaundice, hypertension (50% of patients have preeclampsia), edema, ascites, a small liver, and hepatic encephalopathy.

Transaminases are often 10-fold elevated but can vary from near normal to 1000 U/liter. Other typical abnormalities are anemia, a high white blood cell count, a normal to low platelet count, abnormal protime, activated partial thromboplastin and decreased fibrinogen with or without DIC, metabolic acidosis, renal dysfunction (often progressing to oliguric renal failure), hypoglycemia, high ammonia, and often biochemical pancreatitis. Liver biopsy is rarely indicated for management but is essential for a definitive diagnosis of AFLP; it shows microvesicular, and infrequently macrovesicular, fatty infiltration, most prominent in zone 3. Occasionally, in the severely ill third-trimester patient, it is difficult to differentiate between HELLP syndrome and AFLP and in some patients these conditions may overlap. Fortunately, delivery of the baby and supportive care for the mother are required in both conditions.

Management

AFLP must be diagnosed quickly with immediate termination of pregnancy and intensive supportive care for the mother until liver function recovers. Transfer to a center with intensive care and liver transplant facilities should ideally be effected. If conditions are favorable, rapid controlled vaginal delivery with fetal monitoring is probably safest but often a cesarean section is performed with blood products to maintain an international normalized ratio of <1.5 and a platelet count of $>50{,}000 \times 10^6$/liter during and after delivery and with prophylactic antibiotics. With correction of the coagulopathy, epidural anesthesia is probably the best choice and will allow better ongoing assessment of the patient's level of consciousness.

Liver tests and encephalopathy will start to improve after 2–3 days but intensive supportive care is needed to manage the many complications, particularly infections and bleeding complications, of fulminant hepatic failure until this recovery occurs over days or many weeks. There is no specific effective therapy for AFLP. Liver transplantation has a very limited role here because of the great potential for recovery with delivery but should be considered in patients whose clinical course continues to deteriorate with advancing fulminant hepatic failure after the first 1–2 days postpartum without signs of hepatic regeneration.

Many patients have no further pregnancies after the devastating illness of AFLP, either by choice or from complications of the illness, but AFLP rarely recurs in subsequent pregnancies. Because LCHAD deficiency is present in many of these infants, later neonatal problems may occur.

Liver Failure, Pediatric

PHILIP ROSENTHAL
University of California, San Francisco

acute-on-chronic liver failure Refers to an individual with chronic liver disease who decompensates as a result of an intercurrent infection or as the result of progressive liver disease.

fulminant liver failure Acute hepatitis occurring within 2–8 weeks of the onset of illness in the absence of preexisting liver disease, complicated by hepatic encephalopathy, massive hepatic necrosis, and a prolonged prothrombin time.

subfulminant liver failure Acute hepatitis accompanied by encephalopathy that begins after 2 weeks, but within 8–12 weeks from the presentation of jaundice.

Fulminant liver failure is a rare but devastating sequel of hepatic injury. It is defined as an acute hepatitis occurring within 2–8 weeks of the onset of illness in the absence of preexisting liver disease, complicated by hepatic encephalopathy, massive hepatic necrosis on histologic examination of the liver, and a prolonged prothrombin time. In spite of advances in medical therapy and intensive care, the mortality rate in the literature ranges between 40 and 80% and is often related to complications of cerebral edema, hypoglycemia, sepsis, gastrointestinal bleeding, and acute renal failure. Liver transplantation currently is the only definitive treatment for those who do not spontaneously recover, and early recognition may allow for stabilization of the patient prior to transfer to a liver transplant center.

INTRODUCTION

In assessing fulminant liver failure, the time of onset of encephalopathy is an important prognostic factor. Severe acute hepatitis consists of hepatic injury accompanied by jaundice and coagulopathy without encephalopathy and typically has an excellent prognosis. Fulminant liver failure consists of severe acute hepatitis with hepatic encephalopathy occurring within 2 weeks of the onset of jaundice. Survival is only about 40% without liver transplantation. Subfulminant liver failure consists of acute hepatitis accompanied by encephalopathy that begins after 2 weeks, but within 8–12 weeks from the presentation of jaundice. Subfulminant hepatitis has a poor prognosis.

Often, the term "liver failure" is used to define the status of an individual with chronic liver disease who

decompensates as a result of an intercurrent infection or as the result of progressive liver disease. This is better defined as acute-on-chronic liver failure. It is critically important that definitions are clear so that there is no misunderstanding regarding the disorder under discussion here, i.e., fulminant or acute liver failure.

ETIOLOGY

A list of potential etiologies of acute liver failure is presented in Table I. Etiologies are often age dependent. Although the cause of acute liver failure is unknown in over half of pediatric cases; in known cases, drug-induced hepatic injury and hepatotrophic viral infections are the most commonly recognized causes in the United States. Hepatitis A and hepatitis B viral infections are the most common infectious causes in all age groups beyond the neonatal period.

In the neonate, the differential diagnosis of liver failure includes infectious, metabolic, ischemic, and perfusion disorders. Infectious etiologies include herpesvirus, echovirus, adenovirus, and hepatitis B. Inborn errors of metabolism presenting as acute liver failure in the neonate include hereditary fructose intolerance, galactosemia, tyrosinemia type I, urea cycle defects, inborn errors of bile acid synthesis, and neonatal hemochromatosis. Ischemic and perfusion defects may be the result of congenital heart disease, cardiac surgery, myocarditis, or severe asphyxia. In infants or toddlers, drug and toxin ingestion, including seizure medications (valproate), antituberculin drugs (isoniazid), acetaminophen, and poison mushrooms (*Amanita*), must be considered. Additionally, infants and children may be exposed to hepatitis A from siblings or day care. Hereditary fructose intolerance may present with liver failure after the introduction of sucrose- and/or fructose-containing formulas or solid foods (fruits/ vegetables) into the diet.

In older children and adolescents, besides infection, drugs, toxins, and perfusion defects, Wilson's disease must be considered in the differential diagnosis. In the appropriate adolescent female, acute fatty liver of pregnancy and fatty acid oxidation defects can be seen. Autoimmune hepatitis with or without a hemolytic anemia may be present. Rarely, malignancy (hepatoblastoma, leukemia, non-Hodgkin lymphoma), radiation, and hyperthermia may result in acute liver failure.

Reye's syndrome is associated with microvesicular fat on liver biopsy, encephalopathy, elevated serum aminotransferase levels, and prolonged prothrombin time, usually arising during convalescence from a viral syndrome such as influenza or varicella. The incidence of Reye's syndrome in recent years has significantly diminished with the reduced use of aspirin for fever control in children and improved recognition and diagnosis of fatty acid oxidation defects that may exhibit similar findings.

It is becoming increasingly apparent that some herbal preparations may also result in acute liver failure and a careful history that includes herbal remedy ingestion must be sought.

PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The hallmarks of acute liver failure are the acute onset of jaundice, biochemical evidence of elevated serum

TABLE I Potential Etiologies of Acute Liver Failure in Children[a]

Cause	Examples
Infection	Hepatitis A or B, hepatitis B with hepatitis D super- or coinfection, hepatitis E, non-A–G hepatitis, cytomegalovirus, varicella-zoster virus, adenovirus, yellow fever, Q-fever
Drugs	
Dose-dependent	Acetaminophen, haloalkanes
Idiosyncratic	Isoniazid, dilantin, valproate, phenytoin, propylthiouracil, penicillin, tetracyclines, sulfonamides, amiodarone, ketoconazole, nonsteroidal antiinflammatory drugs
Synergistic drug reactions	Alcohol and acetaminophen, isoniazid + rifampicin, bactrim, barbiturates + acetaminophen, amoxacillin + clauvulinic acid
Metabolic disorders	Wilson's disease, acute fatty liver of pregnancy, galactosemia, tyrosinemia, errors of fatty acid metabolism
Toxins	*Amanita phalloides*, industrial solvents, carbon tetrachloride, herbal medicines
Systemic disorders	Autoimmune hepatitis, malignancy, hyperthermia, sepsis
Miscellaneous	Budd–Chiari syndrome, portal vein thrombosis, indeterminate

aminotransferase levels, prolonged prothrombin time, and encephalopathy in a previously healthy patient. Initial symptoms may be nonspecific, such as jaundice, nausea, vomiting, and abdominal pain. A careful medical history focusing on a history of ingestion (accidental or intentional), medications, mushroom picking, recreational drugs, blood transfusions, immunizations (particularly hepatitis A and B vaccines), and travel must be sought. An accurate acetaminophen history should include the amount and interval of doses, carefully identifying all acetaminophen derivatives because many combination medications include acetaminophen as a component. On occasion, parents have mistakenly substituted acetaminophen infant drops for the children's elixir, resulting in a significant overdose. In infants, a previous hypoglycemic event, developmental delay, or history of seizures may suggest a metabolic disorder. Rarely, in adolescents, acute liver failure secondary to Wilson's disease may be preceded by neuropsychiatric manifestations.

On physical examination, the child is usually jaundiced and icteric. There may or may not be hepatomegaly. The remainder of the physical exam may be noncontributory. There may be occasional petechiae or bruises attributable to the coagulopathy. A careful assessment of neurological status is imperative but is often a challenge in the young child. The grading scale utilized by the Pediatric Acute Liver Failure Study Group is presented in Table II as a means of evaluating and scoring the degree of encephalopathy.

Biochemical features of acute liver failure include marked elevations in serum aminotransferases (aspartate transaminase, alanine transaminase), total and direct-reacting bilirubins, and prolongation of the prothrombin time. Although the serum aminotransferase levels may rise into the thousands (units/liter), the peak value and rate of decline are not predictive of outcome. The most frequently observed electrolyte disturbances are hyponatremia, hypokalemia, hypocalcemia, and hypomagnesemia. Due to a combination of liver glycogen dysregulation, and central nervous system and multiorgan dysfunction, hypoglycemia is frequently observed. More commonly accompanying non-A—non-G hepatitis is an aplastic anemia. Wilson's disease may present with a constellation of laboratory findings, including a Coombs-negative hemolytic anemia, low serum alkaline phosphatase level, and hyperuricemia. Serum copper values are often markedly elevated. Serum ceruloplasmin levels classically are decreased in Wilson's disease. However, a normal serum ceruloplasmin does not rule out Wilson's disease, and analysis of 24-hour urinary copper excretion a may

TABLE II Encephalopathy Staging Criteria (Pediatric Acute Liver Failure Study Group)[a]

Stage	Clinical	Asterixis/reflexes	Neurologic signs	EEG changes
0	None	None/normal	Psychological testing only	Normal
I	Confused, mood changes, altered sleep habits, loss of spatial orientation, forgetful	None/normal	Tremor, apraxia, impaired handwriting	Normal or diffuse slowing to theta rhythm, triphasic waves
II	Drowsy, inappropriate behavior, decreased inhibitions	None/hyperreflexic	Dysarthria, ataxia	Abnormal generalized slowing, triphasic waves
III	Stuporous obeys simple commands	None/hyperreflexia, upgoing toes (+ Babinski)	Rigidity	Abnormal generalized slowing, triphasic waves
IV	Comatose, arouses with painful stimuli (IVa), or no response (IVb)	Absent	Decerebrate of decorticate	Abnormal, very slow delta activity
For younger children				
Early (I and II)	Inconsolable crying, sleep reversal, inattention to task	Unreliable/normal or hyperreflexic	Untestable	
Middle (III)	Somnolence, stupor, combativeness	Unreliable/ hyperreflexic	Most likely untestable	
Late (IV)	Comatose, arouses with painful stimuli (IVa), or no response (IVb)	Absent	Decerebrate or decorticate	

[a] Adapted with permission from Perkin (2003), Acute liver failure *In* "Pediatric Hospital Medicine: Textbook of Inpatient Management." Copyright Lippincott Williams & Wilkins.

be necessary. If autoimmune hepatitis is suspected, autoimmune markers including antinuclear antibody, anti-smooth-muscle antibody, anticardiolipin, anti-liver–kidney microsomal antibody, and antimitochondrial antibody should be obtained. A reversed albumin/globulin serum protein ratio may also be suggestive of autoimmune disease.

THERAPY

Initial management should focus on stabilization and support to allow for possible recovery or liver transplantation if necessary. All patients with severe acute hepatitis who progress to any stage of encephalopathy should be managed in an intensive care unit. Early referral to a liver transplant center is imperative for all children whose condition is not improving. Room noise should be kept to a minimum and room lighting should be used sparingly to avoid agitating the child. Significant morbidity and mortality may result from the complications of acute liver failure even if the liver spontaneously recovers. Venous access is mandatory. An arterial line should be considered if the child's condition is deteriorating and blood gas analysis is necessary prior to intubation and monitoring of ventilatory support. A nasogastric tube may be required to monitor for gastric bleeding and for administration of medications. A urinary catheter may be placed to monitor fluid status and renal function. If available, the patient's bed should have a built-in scale that enables weighing the patient with minimal disturbance. Frequent scheduled repositioning and involvement of a specialized skin care team especially in the obtunded or comatose patient should avoid bedsores and decubitus ulcers.

Medical management of acute liver failure must be multidisciplinary because of the complexity of the disease and its potential progression to multiorgan failure, characterized by increased cardiac output, peripheral vasodilatation, respiratory distress, and renal failure. Useful laboratory tests include a complete blood count with differential and platelet count, and levels of serum electrolytes, blood urea nitrogen, creatinine, calcium, magnesium, phosphorus, blood sugar, alanine transaminase, aspartate transaminase, alkaline phosphatase, γ-glutamyl transferase, total and direct-reacting bilirubins, prothrombin and partial thomboplastin times, international normalized ratio (INR), amylase, lipase, and serum ammonia. If the history is suggestive, a toxicology screen, acetaminophen, or aspirin levels should be obtained. Hepatitis serologies, including antihepatitis A virus immunoglobulin M (IgM), hepatitis B surface antigen, antihepatitis B core antibody (IgM), and antihepatitis C virus, should be acquired. Culture specimens (blood, urine, stool) should be sent to the lab. Prothrombin times (a measure of vitamin K-dependent clotting factors synthesized by the liver) or INRs are often the most useful laboratory parameters to follow serial progression of the patient's condition. Obviously, administration of fresh frozen plasma or clotting factors will negate the usefulness of serial prothrombin time values. Thus, the judicious use of fresh frozen plasma and clotting factors is mandatory in these patients and is reserved for the presence of active bleeding. If the prothrombin time is prolonged, a trial of intravenous vitamin K daily for 3 consecutive days should be undertaken. Giving the dose intravenously eliminates the possibility of poor intestinal absorption of this fat-soluble vitamin in a patient who is cholestatic. Improvement in the prothrombin time suggests viable hepatocytes capable of synthesizing clotting factors and having the potential for regeneration and recovery, whereas no improvement or a continued prolongation of the prothrombin time is an indication of a poor prognosis.

Because electrolyte and acid–base disturbances frequently occur in acute liver failure, fluid management and electrolyte replacement and supplementation must be meticulously monitored. Fluid management requires a balance to avoid fluid overload and dehydration as multiorgan failure develops. Renal failure can occur in the face of pulmonary edema and peripheral vascular collapse. Cerebral edema and intracranial hypertension necessitate careful fluid administration to avoid intravascular space expansion and exacerbation of cerebral edema.

Nutritional support in acute liver failure is difficult. Hypoglycemia occurs frequently, necessitating intravenous dextrose infusion. Amino acids should be restricted in the initial management of acute liver failure to avoid an excess nitrogen load. However, to prevent a catabolic state, limited protein supplementation (0.5–1 g/kg/day) by day 3 of illness may be considered. The type of proteins and amino acids may influence hepatic encephalopathy. α-Keto analogues of amino acids are transaminated in the intestinal mucosa into amino acids without supplying additional nitrogen. Limited studies suggest that ketoacids are efficiently converted to amino acids and converted into protein while maintaining nitrogen balance. Branched-chain amino acid solutions administered parenterally have also been studied with inconclusive results. Their high expense with limited effectiveness suggests they be restricted at present to investigational protocols.

An abdominal ultrasound with Doppler interrogation is useful to evaluate anatomic or vascular etiologies.

Unless the patient has clinical evidence suggesting cerebral edema, computed tomographic examination of the head is not useful in the evaluation of hepatic encephalopathy.

N-Acetylcysteine should be administered to any patient suspected of toxic acetaminophen ingestion to replenish glutathione stores. Most effective within 12 hours of ingestion, it has demonstrated effects up to 36 hours after the initial overdose. The published acetaminophen level nomogram is useful only in guiding the treatment for a one-time single overdose and does not predict outcome in chronic ingestion cases. Adolescent medicine/psychiatric consultation is imperative if the overdose was intentional or represented a suicidal threat and should be obtained prior to the patient progressing into coma, because this assessment may be crucial in determining the appropriateness of liver transplant.

The cause of hepatic encephalopathy is multifactorial. Current theory includes the accumulation of neurotoxic and neuroactive substances. Although most are poorly defined, hyperammonemia has been associated with acute liver failure-induced encephalopathy. Limiting protein intake to $\leq$1 g/kg/day may decrease colonic bacterial ammonia production and allow the compromised liver to metabolize the protein load. Lactulose, a nonabsorbable carbohydrate, acts as a cathartic to induce diarrhea and ammonia removal via the intestinal tract, and it acidifies the colon to trap ammonia (NH_3) by converting it to NH_4^+ in the gut, promoting ammonia excretion. Oral neomycin has been advocated as a relatively nonabsorbable antibiotic to rid the colon of its ammonia-producing bacterial flora. Unfortunately, chronic oral administration of neomycin may result in its absorption, allowing oto- and nephrotoxicity, which may outweigh any possible benefit. All sedating drugs, even if the child is combative, are to be avoided because most are predominantly metabolized via the liver and their administration may confound the mental status examination. Restraints may be necessary to protect the comatose child from self-injury. Acid suppression with histamine-2 (H2) blockers or proton pump inhibitors is indicated as prophylaxis for gastrointestinal bleeding.

Cerebral edema and brain herniation are the most frequent complications leading to death in acute liver failure. The pathophysiology is unclear and treatment is controversial. Intensive care unit admission, transfer to a liver transplant center, and listing for liver transplantation should be instituted early in the course to optimize outcomes. Cerebral edema must be managed aggressively. Neurologic physical examination may not be sensitive enough for detecting increased intracranial pressure, so clinical suspicion must be maintained. Early signs and symptoms of cerebral edema include systolic hypertension and increased muscle tone. Headache, vomiting, and papilledema are present inconsistently. If progressive, cerebral edema will be associated with decerebrate posturing, hyperventilation, myoclonus, seizures, trismus, and opisthotonos. Although computed axial tomography may not be sensitive for detecting early cerebral edema, its use may be warranted to rule out intracranial bleeding. Intracranial pressure monitoring is required in comatose patients and in those with neurologic deterioration. Several types of devices are available. Intraventricular monitors are accurate and precise, but suffer from complications, especially bleeding. Epidural monitors are the safest but are often inaccurate. Subdural placement of monitors has intermediate risk and relatively accurate readings. All intracranial pressure monitors increase the risk for infection.

Increased intracranial pressure management includes use of hyperventilation, minimal stimulation, head elevation to 30°, maintenance of hemodynamic stability, and mannitol infusion. Steroid administration has not been found beneficial and should be avoided. Attention to avoidance of rapid fluid boluses or aggressive correction of electrolyte imbalances that can aggravate the situation is important. The goal is to maintain cerebral perfusion pressure (the difference between mean arterial pressure and intracranial pressure) above 50 torr. This usually requires maintaining the intracranial pressure in children in the normal range (10–15 torr).

Mechanical hyperventilation lowers intracranial pressure but does not improve patient morbidity. Between 20 and 60 torr, cerebral blood flow is linearly related to the partial pressure of blood carbon dioxide. Lowering carbon dioxide content to 25–30 torr maximizes cerebral vascular constriction and reduces blood flow. This vascular effect progressively diminishes after 6 hours of therapy, although the clinical response may last for a few days. Hyperventilating the patient by increasing tidal volume may raise positive end expiratory pressure and restrict venous return. This may occur especially if there is pulmonary edema. Increased positive end expiratory pressure also reduces diastolic filling volume and may reduce cerebral perfusion pressure.

In patients without renal failure, mannitol infusions have an 80% response rate and may improve survival. Serum osmolality must be monitored frequently and maintained in the range of 300–320 mOsm. Mannitol should not be given if serum osmolality is over 320 mOsm, if renal failure ensues, or if oliguria and a rising serum osmolality develop simultaneously.

Repeated mannitol infusions may reverse the osmotic gradient. Mannitol should be discontinued if the intracranial pressure does not respond after the first few boluses.

Renal failure occurs in up to half of patients with acute liver failure, often due to hepatorenal syndrome. Hepatorenal syndrome is the unexplained development of reversible renal failure in both acute and chronic liver disease, characterized by azotemia, oliguria, low urinary sodium excretion (< 10 mEq/day), and an increased urine:serum osmolality ratio in the absence of active urinary sediment. Attention should be paid to diminished cardiac output and blood pooling from peripheral vasodilatation as possible etiologic factors for poor renal perfusion. Adequate urine output can be maintained with judicious use of loop diuretics and low-dose dopamine infusion. Depleted intravascular volume can be corrected with blood components or volume expanders. Because plasma albumin is invariably low, salt-poor albumin solutions may be preferred to carbohydrate-based volume expanders. If oliguria develops, hemodialysis/hemofiltration may be required to maintain optimal fluid volume and serum osmolality. Fluid restriction must be used if renal failure is established. Sodium and potassium losses should be estimated and replaced appropriately. Hyponatremia should not be replaced by use of hypertonic saline unless a hyponatremic seizure occurs. Excess free water may be removed by dialysis and will resolve the hyponatremia problem without altering the total body sodium content.

Pulmonary complications occur frequently in acute liver failure patients. These patients have a predisposition to low pressure pulmonary edema and development of adult respiratory distress syndrome. Pulmonary edema is observed in about 40% of acute liver failure patients. It is believed to result from pulmonary capillary changes that cause increased permeability. Management is supportive. Continuous pulse oximetry, frequent arterial blood gas measurements, administration of supplemental oxygen, and use of mechanical ventilation are all appropriate. Sedative and paralytic agents may be required to ensure tolerance of mechanical ventilation. These need to be used sparingly if they will alter neurologic evaluation, and they may have prolonged effects due to longer half-lives from decreased hepatic metabolism and renal excretion. Further, the neurologically depressed patient is at risk for the development of aspiration pneumonia.

Infection plays a serious threat to the patient with acute liver failure. It places the patient at risk for sepsis and is a contraindication to liver transplantation. Bacterial infections of either the respiratory or the urinary tract are prevalent. Organisms frequently seen include *Staphylococcus* spp., *Streptococcus* spp., and gram-negative rods. Iatrogenic sources of infection must also be considered because these patients often have indwelling lines and urinary catheters. Despite the high rates of infection, prophylactic antibiotic administration is not advocated. However, a low threshold for starting antibiotics should be used because the usual presentation of infection with fever and leukocytosis may be absent. Surveillance cultures for bacteria and fungi from blood, urine, sputum, and open wounds should be routine. Ascitic fluid should be cultured if present. High-dose broad-spectrum antibiotics should be started at the first sign of infection, with coverage narrowed as soon as a specific organism is identified.

OUTCOME

In general, acute liver failure is associated with significant morbidity and mortality. Fortunately, it is a rare disorder in children. Spontaneous recovery is unusual except for prompt treatment of acetaminophen overdose in young children. Intensive care support and liver transplantation are crucial for the management of these critically ill children, necessitating early referral to transplant centers. The shortage of donor organs continues to influence survival for children with fulminant hepatic failure. Improved outcomes may be obtained by the use of living-related transplants, split-liver transplants, and auxiliary transplants in selected patients. Experimental therapies, including the use of bioartificial liver support and hepatocyte transplantation, hold promise in providing temporary hepatic support, allowing the native liver to repair, recover, and regenerate, thereby reducing complications and avoiding transplantation and lifelong immunosuppression.

Unfortunately, there are several major limitations to attempts to better define and develop therapeutic regimens for severe, acute liver failure. Acute liver failure has varying etiologies (viral, drug, toxin, etc.) and thus may actually be several different conditions. There is no clear understanding of the pathophysiology of the disease, making it difficult to develop specific treatment strategies. There is no single marker of liver dysfunction allowing for stratification of hepatic injury. Relatively few individuals with acute liver failure are seen at a single institution. Progression of the disease is rapid and little time is available to initiate therapy. Therefore, multicenter collaborative trials, such as those of the Pediatric Acute Liver Failure Study Group, are imperative so that standardized data collection and management protocols can be utilized to define and

improve therapies for children with this devastating diagnosis.

LIVER-ASSIST DEVICES

The development of an "artificial" liver system capable of supporting liver functions in patients with liver failure has been in preparation for over four decades. Recent work has focused on the use of mammalian hepatocytes to provide metabolic assistance to the failing liver. Several extracorporeal hepatocyte liver-assist systems have been reported in a small number of pilot clinical trials. One such device was utilized successfully in the care of a 10-year-old child with fulminant liver failure as a bridge to liver transplant. A large, randomized controlled trial in adults utilizing porcine hepatocytes in a hollow-fiber cartridge (Circe Biomedical, HepatAssist 2000) showed encouraging results, but the design of the study was such that it failed to demonstrate statistical significance. A recent systematic review of artificial and bioartificial support systems for acute and acute-on-chronic liver failure has suggested that artificial support systems reduce mortality in acute-on-chronic liver failure compared with standard medical therapy. Artificial and bioartificial support systems do not appear to affect mortality in acute liver failure.

SUMMARY

Acute liver failure is a dramatic syndrome in which previously healthy children rapidly lose hepatic function, develop encephalopathy, and become critically ill. In spite of liver transplantation, many patients die due to complications of the disease or because of a lack of timely donors. Because acute liver failure occurs infrequently, no single center has a large enough experience to conduct important clinical studies to investigate natural history or treatment. Investigations by the Pediatric Acute Liver Failure Study Group should define patient demographics, presenting symptoms, clinical course, suspected etiology, and outcome of children with acute liver failure. This important data collection registry should eventually aid in refining our understanding of the etiology, management, and treatment of this devastating disorder in children.

cold ischemia Technique to slow the metabolism of an organ in order to reduce oxygen consumption; used in the transplant setting and during organ harvesting and preservation.

intermittent clamping Strategy to prevent ischemic injury by interrupting long ischemic insults with multiple short intervals of reperfusion.

ischemic preconditioning Regimen used to prime an organ against subsequent long ischemic insults; consists of a short period of ischemia followed by a brief interval of reperfusion prior to the prolonged ischemic insult.

warm ischemia Interruption of inflow of blood and oxygen during liver surgery, shock, and trauma; occurs at normothermic (body) temperature.

Ischemia reperfusion injuries in the liver have important implications in a number of clinical settings, including transplantation, liver resection, trauma, and shock. Ischemia reperfusion injury occurs in two main forms, cold ischemic injury (occurring during organ preservation) and warm ischemic injury (occurring during liver surgery, shock, and trauma). The mechanisms of injury are complex, and only very few protective strategies are currently applied in routine clinical practice.

INTRODUCTION

Injuries to the liver caused by prolonged periods of interrupted blood flow or low-level oxygen delivery are important in many clinical situations. Lack of insight into the mechanisms associated with these types of injuries has significantly hampered the development of hepatic surgery and transplantation. Over the past two decades, efforts have been invested in the search for protective strategies, and important discoveries have been made over the past few years. In this article, the current literature on the mechanisms of ischemic injury in the liver is summarized and novel protective approaches are discussed.

Hepatic ischemia/reperfusion (I/Rp) injury can be divided into two types: (1) warm (normothermic) I/Rp, which occurs during liver resection, trauma, various forms of shock, and transplantation, and (2) cold I/Rp injury, which occurs in the transplant setting during the period of organ preservation at 1°−4°C. Although several mechanisms of injury appear to share common pathways, recent evidence suggests important differences between warm and cold I/Rp.

WARM (NORMOTHERMIC) ISCHEMIA

Warm ischemia injury is common during liver surgery, trauma, and transplantation. For example, ischemia is intentionally achieved during major liver resections by occluding hepatic arterial inflow (Pringle maneuver) during the time of transsection of the liver parenchyma, to prevent bleeding. Ischemia is tolerated only for a period of about 1 hour in normal livers and about 30 minutes in cirrhotic livers, and the duration of ischemia correlates with the degree of reperfusion injury.

Many studies have shown that death of endothelial cells and hepatocytes does not occur during the period of ischemia but rather during subsequent reperfusion. Furthermore, accumulating evidence suggests that cell injury occurs by apoptosis (programmed cell death), which, unlike necrosis, is an active and energy-requiring form of cell death. Some investigators, however, suggest that necrosis, rather than apoptosis, is the major cause of cell death in the ischemic liver. The reason for this ongoing controversy might be related to the fact that the distinction between apoptosis and necrosis is not always clear. There are shared pathways, common features, and transitions from apoptotic pathways to necrosis. In addition, differences in the energy status and ATP levels (e.g., starved vs. fed condition) might be critical to induce a switch from apoptotic to necrotic forms of cell death. Nevertheless, active apoptotic mediators have been well documented in the ischemic liver, mainly after reperfusion.

The balance between pro and antiapoptotic mediators prevents and regulates death in healthy cells. In the setting of I/Rp, this tightly regulated "survival" balance is severely disturbed in favor of cell death. Recent advances in our understanding of several mediators of

 Copyright 2004, Elsevier (USA). All rights reserved.

apoptosis have enabled new insights into the mechanisms of injury in the ischemic liver. For example, apoptotic cell death is initiated by binding of tumor necrosis factor α (TNFα) to the specific receptor, TNF-R1, on the cell membrane of hepatocytes in a mouse model of normothermic I/Rp injury (Fig. 1). The apoptotic signal is then transferred into the cell, where the specific protease caspase-8 is activated. This initial step is followed by the activation of a cascade of various proteases and other cellular events. First, a protein that is a BH3-interacting death domain (BID) agonist is activated and translocates to the mitochondria, inducing the release of cytochrome C, which binds to the apotosis protease-activating factor-1 (APAF-1). This compound activates caspase-9 with subsequent activation of caspase-3, the "executioner" caspase. This process leads to DNA fragmentation and cell death. Due to the presence of inactive proforms of the specific apoptotic proteases, signal transduction does not depend on protein synthesis and can occur rather quickly. In this process, the mitochondria act as amplifiers of the deadly signal, allowing even weak signals to have deleterious effects.

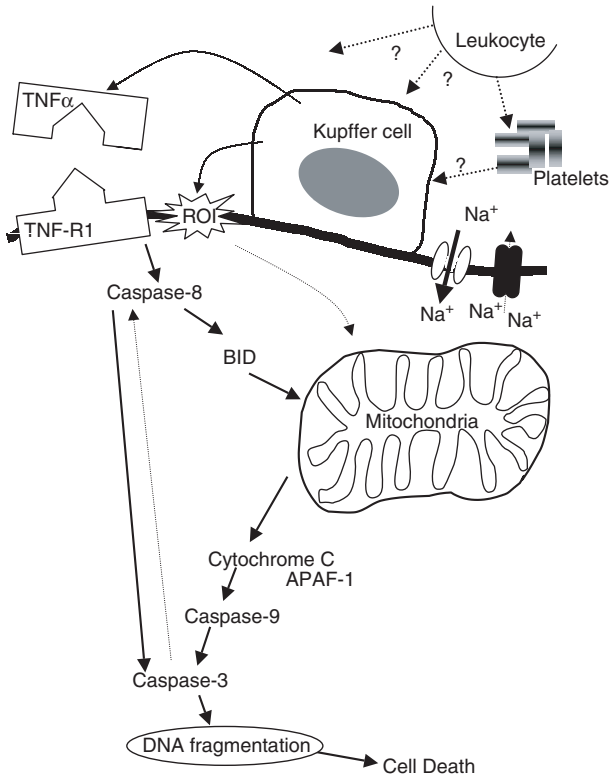

FIGURE 1 Several mechanisms of normothermic ischemic injury have been postulated to date, including tumor necrosis factor α (TNFα)-mediated apoptosis, dysregulation of ion distribution, and generation of reactive oxygen intermediates (ROI). The mechanisms of injury appear to involve multiple cell systems and pathways. APAF-1, Apotosis protease-activating factor-1; BID, BH3-interacting death domain agonist.

The activation of Kupffer cells also contributes to I/Rp injury in the liver. Activated Kupffer cells release a variety of potentially harmful mediators, including TNFα and reactive oxygen species. In high concentrations, oxygen radicals induce peroxidation of lipids, an effect that leads to membranous dysfunction and favors cell death. The release of highly reactive radicals might be critical for initiation of apoptotic cell death after ischemia, inasmuch as several cell types, including hepatocytes, are resistant to TNFα alone. From this perspective, oxidative stress might act as a sensitizer for the deleterious effect of TNF signaling.

Prolonged hypoxic conditions are associated with an impaired energy status within cells, which has severe consequences for the regulation of cellular pH and cell volume. The ATP-dependent efflux of Na^+ through Na^+,K^+-ATPase as well as the impaired function of Na^+/H^+ exchangers and Na^+/HCO_3^- cotransporters lead to acidification of the cytosol and cell swelling. However, the link between these disturbances of ion distribution, cell swelling, and simultaneously ongoing apoptotic processes remains unclear.

Ischemia in the Diseased Liver

Chronic liver diseases such as steatosis and cirrhosis are associated with increased sensitivity to ischemia and hypoxia. Although mild steatosis (< 30%) has little impact on the results of liver resection and transplantation, severe steatosis (> 60%) is associated with an increased risk of liver failure after surgery. We recently hypothesized that the devastating effects of ischemia on the fatty liver are due to a dysfunction in the apoptotic pathway and to a predominant necrotic form of cell death. We used a model of Zucker rats, which develop severe steatosis at the age of 8 weeks due to overeating. After 1 hour of hepatic ischemia, there was an associated dramatic increase in liver injury (e.g., serum transaminases) and impaired survival. However, markers of apoptosis [caspase-8 and caspase-3 activity, cytochrome C release, and terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling (TUNEL) staining] were decreased compared to lean animals, suggesting a low apoptotic activity level. Morphological analysis of a hematoxylin/eosin-stained biopsy revealed massive coagulative necrosis in fatty animals, whereas apoptosis was predominant in lean animals.

Although the increased sensitivity of the cirrhotic liver to warm or cold ischemia has been well described, the underlying mechanisms of cell injury are still

unknown. Future studies in animal models are needed to further identify mechanisms and to develop effective protective strategies in cirrhosis.

Protective Strategies

Many strategies to protect against warm ischemic injury have been proposed in various animal models, but only two, intermittent clamping and ischemic preconditioning, have finally made the transition into clinical practice. Intermittent clamping consists of multiple cycles of short intervals of ischemia (10–30 minutes) and reperfusion (5–15 minutes) (Fig. 2b). The protocol for ischemic preconditioning consists of a single brief ischemic interval (10 minutes) followed by a short period of reperfusion (10–15 minutes) prior to the prolonged ischemic interval (Fig. 2c). We have recently evaluated protection conferred by these two approaches using a mouse model of prolonged hepatic ischemia. We found that protection was similar for ischemic insults of up to 75 minutes, whereas intermittent clamping was more effective for ischemic intervals of 120 minutes. Ischemic preconditioning appears preferable in most cases because it avoids the blood loss that occurs during the multiple periods of reperfusion inherent to intermittent clamping. In addition, a great majority of cases require an ischemic interval shorter than 60 minutes, and protection appears comparable in ischemic preconditioning and intermittent clamping.

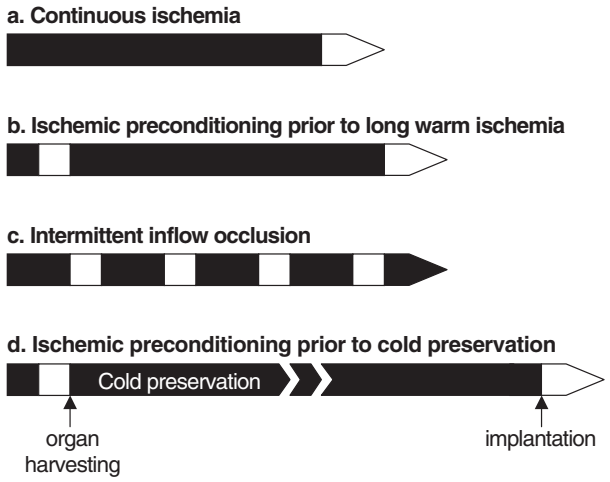

FIGURE 2 Several surgical strategies exist to overcome the negative effects of (a) prolonged ischemia (■) and reperfusion (□). To overcome warm ischemic injuries, options include ischemic preconditioning (b) and intermittent inflow occlusion (c). Experimental studies suggest that normothermic ischemic preconditioning prior to hypothermic preservation also protects against cold ischemic injuries (d).

The mechanisms of the biologic adaptation to ischemia initiated by ischemic preconditioning are still poorly understood. Several mediators have been suggested to be involved in these protective pathways, including adenosine, nitric oxide, oxygen radicals, protein kinases, ATPases, and prostaglandins. We have recently shown that preconditioning causes a downregulation of the apoptotic pathway following ischemia. Better understanding of these protective pathways may lead to the design of specific protective interventions by pharmacological means. Such approaches are appealing because the negative effects of preconditioning due to the short period of ischemia would be avoided (e.g., a possible decrease in ATP levels).

COLD ISCHEMIA

Liver transplantation has experienced a dramatic success over the past 15 years and has become the treatment of choice for patients with end-stage liver disease. Although major progress has been made in several areas of transplantation, such as selection of recipients and immunosuppression, ischemic injury remains an important limiting factor in some aspects of the procedure. During the various phases of transplantation, the liver graft is exposed to different types of ischemic stress, including normothermic ischemia prior or during harvesting, cold ischemia (at 1°–4°C) during the period of preservation, and rewarming during graft implantation (Fig. 2d).

It is currently believed that nonparenchymal cells (i.e., sinusoidal endothelial cells) are the major targets of cold ischemic injury (cold preservation). In contrast to sinusoidal endothelial cells (SECs), parenchymal liver cells (hepatocytes) remain morphologically well preserved even after extended periods of cold preservation. It is thought that later injuries to the hepatocytes are a consequence of nonparenchymal injury, the final demonstration of this relationship is not yet available.

Injuries due to low-temperature preservation are different from warm ischemic injuries in many aspects. The main feature of warm ischemia injury is massive and early (3–6 hours) apoptosis of hepatocytes after reperfusion. In contrast, cold storage is associated with diffuse SEC damage within 30–60 minutes of reperfusion, but hepatocytes are mostly preserved. The degree of SEC injury correlates with functional impairment of the graft following transplantation. The SEC injury is characterized by alteration of the extracellular matrix and cytoskeleton and detachment and rounding of endothelial cells. We have observed that similar processes also occur during the early

stage of angiogenesis. Angiogenesis is a fundamental process during wound healing, tissue collateralization, and neoplasia and occurs as a result of low oxygen tension. The manifestations of angiogenesis consist of cytoskeletal and extracellular matrix changes by matrix metalloproteinases, resulting in endothelial cell detachment, rounding, and, finally, proliferation. We have recently demonstrated that inhibition of antiangiogenic protease inhibitors (such as minocycline, interferon, and fumagillin) is able to prevent SEC detachment during cold ischemia, reducing preservation injury. Several recent reports point to matrix metalloproteinases (MMPs) as having critical roles in the mechanisms of SEC detachment during cold hepatic preservation. MMPs are important contributors to angiogenesis.

On reperfusion of the cold preserved graft, SECs undergo apoptosis, with subsequent DNA fragmentation and cell death. The strong correlation between the degree of apoptosis and graft viability suggests that SEC apoptosis is a critical process of cold ischemic injury. Although a number of intracellular mediators of apoptosis are known, the data regarding the initiating extracellular processes are scarce. Experimental studies have shown that platelets are sequestered in the ischemic liver after reperfusion and contribute to organ injury. In addition, strong evidence suggests a pivotal role of leukocytes in the mechanisms of cell death during reperfusion after cold ischemia. Sindram *et al*. have recently demonstrated that the action of platelets and leukocytes is not independent but rather is synergistic in nature. Jaeschke has shown that oxygen free radicals and proteases are involved in blood cell-mediated killing of hepatocytes. Neutralization of oxygen species may represent a promising approach to minimize preservation injury. Further studies are needed to detail how the signal from platelets and leukocytes is transferred into the cell, causing endothelial cell apoptosis.

Protective Strategies

Development of cold preservation solution by the University of Wisconsin (UW) in the mid-1980s was a breakthrough in liver transplantation, allowing safe organ preservation for up to 24–30 hours. The solution was empirically developed and contains a cocktail of substances such as lactobionate, raffinose, phosphate buffer, glutathione, colloids (hydroxyethyl starch), and various ions. Despite no definitive understanding of how the ingredients confer protection, the UW solution still remains the most widely used preservation solution. Other solutions, such as Eurocollins (with high glucose content and very high osmolarity) or Celsior (with mannitol, glutamate, and histidine buffer), have never gained wide acceptance among liver transplant surgeons.

As in the warm ischemic liver, ischemic preconditioning is potentially an effective approach to prevent preservation injury in the transplant setting. Although the impact on the outcome of clinical transplantation is not known, protection has been demonstrated in animal models and some pathways of protection have been identified. Several mechanisms appear to be similar to those of the normothermic setting, including involvement of adenosine or protein kinases. We have recently demonstrated that a moderate burst of oxygen radicals during the brief period of ischemic injury might be critical in triggering defense mechanisms. However, prospective randomized studies are needed to determine the clinical benefit and applicability of ischemic preconditioning in liver transplantation.

CONCLUSION

Ischemia and reperfusion injuries remain important in liver surgery, transplantation, and various forms of shock. Although some injurious mechanisms (e.g., apoptotic cell death) are common to the two types of ischemia injury—normothermic (warm) and cold (organ preservation)—critical differences exist, such as the resistance of hepatocytes to cold ischemic injury. Better understanding of the underlying mechanism of injury and some protective strategies, such as ischemic preconditioning, may lead to the discovery of innovative and effective protocols to prevent injury.

INR (International Normalized Ratio) A test that measures clotting impairment.

The first successful liver transplant was performed by Thomas Starzl at the University of Colorado in 1967. The patient lived approximately 1 year before dying of recurrence of the hepatocellular carcinoma for which she was transplanted. In the ensuing years, the mortality rate for patients undergoing liver transplant remained high, due to the complexity of the procedure and the lack of drugs that could selectively work against rejection without creating a state of overwhelming immunosuppression and associated life-threatening infections. In 1979, with the introduction of cyclosporine, a more selective calcineurin inhibitor, results following liver transplantation began to improve. At a 1983 National Institutes of Health consensus conference, it was declared that liver transplantation was the procedure of choice for patients with end-stage liver disease and should no longer be considered experimental.

INDICATIONS AND CONTRAINDICATIONS

The common causes of liver disease in children and adults are shown in Table I. Liver disease can be chronic or acute. Indications for transplantation in patients with chronic liver disease are the complications of end-stage liver disease, such as poor synthetic function, intractable ascites, encephalopathy, and hepatorenal syndrome. TABLE I Common Causes of Liver Disease in Children and Adults

Chronic liver disease	**Acute fulminant hepatic failure**
Hepatitis B	Viral hepatitis
Hepatitis C	Drug-induced (e.g., halothane, sulfonamides)
Alcoholic cirrhosis	Metabolic liver disease (e.g., Wilson's disease, Reyes' syndrome)
Autoimmune disease	**Inborn errors of metabolism**
Biliary atresia	Glycogen storage disease
Primary biliary cirrhosis	α1-Antitrypsin disease
Primary sclerosing cholangitis	Wilson's disease
Cryptogenic cirrhosis	**Primary hepatic malignancies**
Budd–Chiari syndrome	Hepatoma with or without cirrhosis
Veno-occlusive disease	

end-stage liver disease but may also be seen in patients with chronic inflammation (e.g., hepatitis B or hematomochrosis) in the absence of cirrhosis. Transplant may be the treatment of choice in patients with unresectable hepatocellular carcinoma.

Acute liver failure is the new onset of liver disease with poor synthetic function and encephalopathy in a patient who 12 weeks previously had normal liver function. In patients with acute liver failure, transplant is necessary before the patient develops cerebral edema.

Prioritizing Patients on the Transplant Waiting List

The disparity between the number of organ donors and the number of patients waiting for transplants makes necessary the very difficult task of determining who should be given priority when a liver becomes available. The United Network for Organ Sharing has recently adopted a new scoring system for determining waiting list priority, based on the Model for End-Stage Liver Disease (MELD). MELD is an objective scoring system based on creatinine, bilirubin, and tests of coagulation (INR) that predicts which patients are more likely to die within 3 months without a transplant. The maximum MELD score is 40; the higher the score, the worse the prognosis is. Under the previous system, priority for transplant was based in part on the amount of time patients had spent on the waiting list. The impact of waiting time could therefore be detrimental to very sick patients who were referred to the transplant center late in the course of their disease. In an attempt to reduce the number of patients dying on the waiting list and to minimize the impact of "waiting time," patients are now prioritized according to their MELD score. Time spent on the list is used only among patients with the same MELD score.

Patients with hepatocellular carcinoma are particularly disadvantaged by the long waits for organs, because while they wait, their tumors may grow to a point that renders them ineligible for transplant. Tumor patients who are at a high risk for disease progression but who are still likely to have good outcomes with transplantation are given increasingly higher MELD scores, so they can be transplanted in a timely fashion.

One of the arguments against MELD is that it does not predict (and was not meant to predict) peri-transplant survival. The question that will remain unanswered until results of the new system can be studied is whether transplants will now be performed mainly in very ill candidates with poorer posttransplant survival.

Transplantation in Patients with Tumors

Before the development of advanced radiological techniques that could reveal small cancers during the pretransplant workup, tumors were often discovered after transplant in the explanted liver. Long-term outcomes in patients with incidental tumors were no different than outcomes in patients without incidental tumors and recurrent tumors were rare. It is now believed that transplantation in patients with tumors ≤ 3 cm is associated with an extremely low recurrence rate. Furthermore, transplantation in patients with either a single tumor < 5 cm or up to three tumors < 3 cm, without evidence of major vascular invasion or extrahepatic disease, is associated with excellent results.

Transplantation for Metabolic Problems

Infrequently, liver transplant is recommended for patients with essentially normal livers who have enzyme deficiencies that may be cured by transplant. Examples of such disorders include familial amyloidosis and oxaluria.

Transplantation for Alcoholic Liver Disease

Patients with end-stage liver disease secondary to alcoholic abuse undergo a rigorous evaluation. Patients are considered for transplant if they have a history of abstinence (most programs use 6 months as a minimum), have developed insight into their disease, maintain good family support systems, and have entered some sort of Alcoholics Anonymous or rehabilitation program. The recidivism rate after transplant is reported

to be approximately 20%; long-term survival, however, is good.

TYPES OF TRANSPLANTS

Transplants from Cadaveric Donors

The most common liver transplant is the orthotopic cadaveric transplant, in which a whole cadaveric liver with the suprahepatic and infrahepatic cava is transplanted into a recipient. What makes a good cadaveric liver? To be worthy of initial consideration, a cadaveric liver donor must only be ABO-compatible and somewhat size-matched to the recipient (i.e., a liver from a 200 lb. male is unlikely to fit into a 98 lb. female with a shrunken liver). HLA matching and crossmatching are not necessary. Other important factors in the evaluation of a potential cadaveric donor are the donor's past medical history (including history of alcoholism, diabetes, and cholesterol), length of hospital stay, and need for pressors after the declaration of brain death. Weight is important, because fatty livers do not function well. Liver function tests must be performed to evaluate damage to the liver. Viral studies are performed to rule out hepatitis C, hepatitis B, and human immunodeficiency virus (HIV).

The only absolute contraindication to use of a cadaveric donor liver is positive serology for HIV or hepatitis B surface antigen. A history of active or recent cancer in the donor (other than primary brain malignancies, which rarely metastasize to the liver) is also generally a contraindication. Livers from donors with poor liver function tests or with significant amounts of macrovesicular fat in their livers do not tolerate ischemia and do not function well. Although age is not an absolute contraindication to donation, and some centers transplant livers from donors as old as 80 years, livers from older donors do not tolerate long cold or warm ischemic times.

In children, whole cadaveric livers are often too large and the left lateral segment or left lobe alone may be transplanted. The reduction of the liver is performed *ex vivo*. The liver is kept in a basin of ice and saline to prevent rewarming while it is cut down to the right size. It is now recognized that if the left lateral segment or left lobe of a cadaveric liver is used for a child, careful splitting of the liver, with close attention to the blood supply of both sides, permits the right lobe to be used for transplantation in an adult patient. More recently, these "splits" are being performed *in vivo*, during the donor operation, so that cold and warm ischemia times are minimized.

Transplants from Living Donors

Living donor transplants in pediatric patients were first reported by Raia in Brazil in 1989 and by Broelsch in Chicago in 1991. Before the introduction of living donor liver transplants, mortality among children waiting for liver transplants was very high because small cadaver organs were extremely scarce. With the use of left lateral segments from living donors, mortality among children on the waiting list fell dramatically.

More recently, with persistent shortages of cadaver organs and continuing increases in waiting list mortality among adult transplant candidates, left lobes and right lobes have been taken from living donors for transplantation into adult recipients. The use of the left lobe was initially thought to be more desirable, as it was the smaller of the two sides and thus safer for the donor. Results with left lobe transplants were not as good, however, in part because left lobe transplants are technically more difficult but mainly because left lobes were inadequate for recipients with severe liver disease and portal hypertension. Right lobe transplants from living donors have therefore become the more viable option.

Not all recipients are good candidates for living donor donation, however. Patients with severe portal hypertension or renal failure or patients who are very ill need a full-size graft. On the other hand, it is particularly reasonable to consider living donor transplants for patients who might not receive an organ in a timely fashion under the present allocation system, such as those with larger tumors or those with poor quality of life but without corresponding poor liver function tests.

Any individual over the age of 18 can be considered for living donation. Potential living donors undergo careful screening and intensive evaluation of their general health as well as cardiac, pulmonary, and renal function. They are also evaluated for the presence of any unknown liver disease. Imaging studies (i.e., computed tomography scans, magnetic resonance imaging, and, when necessary, angiography) are performed to evaluate liver size (both right and left lobes) and arterial and venous anatomy. Donors with any significant co-morbidity or with inadequate liver volume to sustain either the recipient or themselves after resection are ruled out as candidates. They are also evaluated for their psychological ability to understand the risks and benefits of the procedure and for their desire to donate without coercion. The morbidity to the donor includes bile leaks from the cut surface, wound infection, small bowel obstruction, postoperative pain, and 8–12 weeks of disability. There is a small but very real risk of mortality to the donor (approximately 1/350).

COMPLICATIONS AND SIDE EFFECTS

Early Posttransplant Complications

Primary nonfunction is the term used to describe a situation in which a transplanted liver does not function and the patient needs to be urgently retransplanted. Primary nonfunction is diagnosed by increasingly elevated liver function tests and bilirubin, failure of the coagulapathy to normalize, and poor bile production. Renal failure and hemodynamic instability may also occur. Retransplantation is the only treatment.

Poor early graft function is diagnosed when the liver does not initially function well, with elevated liver function tests and coagulopathy for the first few days posttransplant. Poor early graft function resolves without long-term sequelae in the liver.

Technical complications are also seen early after transplant. Hepatic artery thrombosis occurs in approximately 4% of cases. Hepatic artery thrombosis (HAT) can cause abnormal liver function tests but is usually detected due to biliary complications. As the blood supply of the bile ducts is dependent on the artery, early HAT usually results in bile leaks secondary to necrosis of the anastomosis. Other complications may include liver abscesses and, rarely, liver failure. Most centers perform duplex ultrasonography on postoperative day 1 to screen for HAT. Early diagnosis before secondary complications occur can allow for successful surgical reconstruction of the artery and salvage of the liver. Late hepatic artery thrombosis (occurring more than 30 days posttransplant) usually results in bile duct strictures and retransplant is often required.

Portal vein thrombosis is a much less common but more devastating early posttransplant complication. The portal vein supplies 75% of the blood flow to the liver. Acute thrombosis results in liver necrosis, massive ascites, and hemodynamic instability. Rapid diagnosis may occasionally allow for surgical repair. More often, retransplantation is urgently needed.

Possible posttransplant complications also include bile leaks from the biliary anastomosis (which may or may not be associated with HAT).

Side Effects of Immunosuppression

The goal of immunosuppression is to prevent rejection of the transplanted organ. At the same time, immunosuppressive medications must be carefully and individually titrated to minimize side effects. Fortunately, as the interval from transplantation lengthens, most patients require less and less immunosuppression to maintain their freedom from rejection.

Immunosuppression has many major side effects. Immunosuppressive drugs in general make patients more vulnerable to infectious complications and certain malignancies. Steroids are well known to predispose patients to diabetes, hypertension, osteoporosis, and weight gain. Cyclosporine and tacrolimus, two of the mainstays of transplant immunosuppression, can cause hypertension, diabetes, neurotoxicity, nephrotoxicity, and decreased bone density.

In a study at the Mount Sinai Medical Center, Sheiner *et al.* examined 88 liver transplant recipients who had survived at least 5 years after their transplant and compared results from these patients with U. S. population statistics. After controlling for confounding variables, they found that hypertension and diabetes were significantly more prevalent in liver transplant recipients. Furthermore, more than 60% of the study patients had hypertension, making it the most common medical condition in the long-term transplant survivors. Half the patients with hypertension required more than one medication to control it.

Numerous authors have observed that transplant recipients have increased prevalences of impaired glucose tolerance and overt diabetes. In the Mount Sinai study, nearly 18% of the long-term survivors became diabetic. Almost 50% of the long-term survivors were moderately to severely obese, which may also have contributed to the increased prevalence of diabetes.

Weight gain and hypercholesterolemia have been well described in association with immunosuppressive therapy. Both conditions, common in the general public, were also common in the transplant recipients. Forty-eight percent were obese by standard criteria, compared to 33% of the general population. Although steroids may be a major risk factor for weight gain and hypercholesterolemia early after transplant, Sheiner *et al.* found that even long after transplant, when steroid doses were low, weight gain and high cholesterol levels persisted.

Despite the apparently high prevalence of obesity and hypercholesterolemia, however, the prevalence of heart disease in the liver transplant patients was not statistically different from that in the general population. This finding is in contrast to the accelerated atheromatous disease, associated with premature death, that has been reported in long-term survivors of heart and renal transplant.

Both steroids and cyclosporine are known to cause bone loss. Glucocorticoids directly suppress osteoblast function, inhibit intestinal calcium absorption, and stimulate renal calcium excretion. In heart transplant patients, cyclosporine was found to induce high bone

turnover. The Mount Sinai study patients were not screened for bone loss; osteoporosis was diagnosed only after symptoms became evident (i.e., back pain with radiological evidence of bone loss or compression fracture). Even without formal screening, there was a higher prevalence of fractures in female liver recipients than in the general population.

The association of peptic ulcers with corticosteroids was first reported more than 50 years ago. Researchers who have reported an increase in ulcer disease in transplant recipients have suggested that anti-ulcer prophylaxis be routine. There is evidence that the risk of ulcers may be greatly increased when certain medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), are taken with steroids. Liver transplant recipients are generally advised not to take NSAIDS, but mainly because of the associated nephrotoxicity.

Chronic immunosuppression can also cause renal toxicity and renal failure. In liver recipients followed for more than 2 years posttransplant, researchers in Sydney found elevated serum creatinine levels, but no patient required dialysis or renal transplantation. Among 68 pediatric heart recipients from Pittsburgh who survived >5 years, 2 required renal transplant. Results were similar in Mount Sinai's long-term survivors. Although creatinine clearance rates were generally lower after transplant, only 4 of 88 patients developed chronic renal failure requiring hemodialysis. It must be remembered, however, that the patients had already survived 5 years and were probably a particularly good risk group.

Finally, Mount Sinai analyzed the incidence of cancer in all their liver recipients (not just the 5-year survivors) to see whether malignancies were a significant source of early death. In fact, most patients who developed a malignancy went on to survive >5 years. Reported cancer incidences in transplant patients range from 4 to 18%, with the incidence apparently related to the duration of immunosuppression exposure. The most common malignancies in the Mount Sinai population were non-Hodgkin's lymphoma and nonmelanotic skin cancers. The incidences of these were similar to those reported in the general transplant literature.

The increased incidence of certain *de novo* malignancies (i.e., non-Hodgkin's lymphoma and nonmelanotic skin cancers) in transplant patients and their association with immunosuppression is well known. Direct mutagenic effects of the immunosuppressive drugs, length of exposure to these drugs, and/or decreased immune surveillance (allowing activation or proliferation of oncogenic viruses) may be responsible.

RECURRENT DISEASE AFTER TRANSPLANT

Hepatitis C

Hepatitis C virus is now the major cause of end-stage liver disease leading to transplantation. Unfortunately, hepatitis C recurs in the new liver. Although most studies have yet to show a difference in survival between patients transplanted for hepatitis C and those transplanted for other diseases, recurrent disease is a major source of morbidity and mortality after transplant.

Given the impact of recurrent disease not only on survival but on quality of life as well, it is important to look at ways to prevent or diminish the severity of recurrent disease. Treatment of recurrent hepatitis C after transplant with interferon has not been shown to be effective. Newer approaches, such as combination therapy with interferon and ribavirin or pegylated interferon, may yield better response rates but in the author's experience has not been well tolerated and the long-term effect is still unknown.

Perhaps, until better antiviral medications become available, the effects of immunosuppressive agents should be examined more closely and immunosuppression regimens should be tailored to reduce the risk of recurrent hepatitis C. It is has become increasingly clear that immunosuppression, especially steroids, plays a role in the recurrence of hepatitis C. Furthermore, augmented immunosuppression for treatment of rejection has been shown to be a particular risk factor for recurrence. Given that steroids seem to be the main culprit in recurrence of hepatitis C, the goal of transplant immunosuppression in hepatitis C patients may be the rapid withdrawal of steroids or steroid-free immunosuppression. Some centers have begun to study the use of induction immunosuppression with the rapid withdrawal of steroids in their hepatitis C population.

Hepatitis B

Results after transplantation for hepatitis B were initially poor due to recurrent hepatitis in the allograft. In fact, it was thought that patients who were DNA positive or E antigen (Ag) positive were at particularly high risk for poor transplant outcomes and these patients were generally excluded from candidacy. Eventually, however, it became apparent that passive immunization with monthly infusions of hepatitis B immunoglobulin (HBIg) improves survival, with recurrence rates ranging from 5 to 30% (recurrence is reportedly increased in the high-risk patients mentioned above). Lamivudine may be used in conjunction with

HBIg or as a rescue for patients who recur despite prophylaxis. Adefovir, a newer antiviral agent, may provide further improvement in long-term results but is still in clinical trials.

Autoimmune Hepatitis

Autoimmune hepatitis is another disease that can recur in the liver allograft despite immunosuppression. Although steroid withdrawal after transplant is generally considered beneficial, it has been suggested that steroids may need to be maintained in patients transplanted for autoimmune hepatitis, to prevent recurrence. Recurrence is treated with steroids and/or azathioprine or 6-mercaptopurine. Retransplant for recurrent autoimmune hepatitis has been necessary in a small proportion of patients.

Primary Biliary Cirrhosis and Primary Sclerosing Cholangitis

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are primary cholestatic disorders of the liver. Both diseases can recur after transplant. Biliary strictures from ischemia might mimic PSC, however, and chronic rejection might mimic PBC, making the diagnosis of recurrent disease more difficult.

THE FUTURE OF LIVER TRANSPLANTATION

Further advances in immunosuppression and in tolerization will help improve the results of transplantation while decreasing the risk of side effects from long-term immunosuppression.

Improvement in the treatment of hepatitis C, prevention of recurrent disease, and development of an effective immunoprophylaxis are necessary. Further refinements in the techniques of living donor surgery, as well as educational programs to increase public awareness of the importance and value of organ donation, will also be important.

Liver, Anatomy

CHEN LIU AND JAMES M. CRAWFORD
University of Florida College of Medicine

bile canaliculus Minute canal between the abutting hepatocytes; passes bile from hepatocyte to the biliary system.
bile duct Structure that passes bile from the liver to the gallbladder or to the duodenum.
canals of Hering Structures lined by both cholangiocytes and hepatocytes; the most peripheral portion of the biliary system.
cholangiocyte Epithelial cell that lines the bile ducts.
Glisson's capsule External capsule of the liver.
hepatic acinus Triangular hepatic parenchymal mass with a terminal hepatic vein at the apex and portal venous channels at the base.
hepatocyte Polygonal epithelial parenchymal cells of the liver.
Kupffer cell Hepatic macrophage that presents in the lumen of hepatic sinusoids.
portal tract (portal triads) Structures composed of bile duct, hepatic artery, and portal vein, embedded within connective tissue.
sinusoid Channel between the hepatic cords.
space of Disse Region between the sinusoidal side of the hepatocytes and the sinusoidal wall.
stellate cell Located in the space of Disse; has long cytoplasmic processes.

The liver is the single largest organ in the human body. It serves as the primary regulatory site for metabolism, processing nutrients entering via the splanchnic circulation for controlled distribution to extrahepatic tissues via the systemic circulation. It synthesizes essential circulating proteins, including albumin and selected clotting factors, and is a major processor of circulating proteins such as lipoproteins. It is responsible for the detoxification of many endogenous and exogenous substances, including bilirubin and xenobiotics. In addition to urinary secretion, hepatic secretion of bile constitutes the other major route for elimination of waste substances, including cholesterol, bilirubin pigments, copper, and amphiphilic xenobiotics. The liver may also be critical in modulating the immune system through its resident macrophages and lymphocytes. The anatomic structure of the liver is well suited for these functions: it receives almost the entirety of blood derived from the intestines as well as a component of systemic arterial blood, has an extensive perfusion bed for contact of blood with hepatic cells, and then delivers its effluent to the inferior vena cava.

LIVER DEVELOPMENT

The liver is derived from the endodermal lining of the most distal portion of the foregut during the third to fourth weeks of gestation, arising as a diverticular bud off the ventral portion of the foregut. The proliferating epithelial cells in this diverticulum, termed hepatoblasts, invade the immediately adjacent septum transversum, a mesenchymal plate that separates the thoracic cavity from the abdominal cavity. The hepatoblasts form cohesive cords and plates within the mesenchyme of the septum transversum, coincident with the ingrowth of a network of vascular tributaries derived from the vitelline vein and a second vascular system derived from the hepatic artery. These vascular networks run in parallel and are invested with a mesenchyme, forming the so-called portal tracts of the liver. The terminal vascular channels run between the hepatoblast cords, forming sinusoids; scattered mesenchymal cells grow between the endothelial cells of the sinusoids and the hepatic cords to form the connective tissue cellular components of the hepatic sinusoid.

The foregut diverticulum also develops a patent luminal channel that will become the extrahepatic biliary tree. Within the liver, two layers of hepatoblasts immediately adjacent to the mesenchyme of the portal tracts mature into a cuboidal biliary-type epithelial layer. This paired epithelial layer is circumferential around the portal tract mesenchyme, and is termed the "limiting plate." This circumferential architecture reorganizes into a series of ductular channels that tether the parenchyma to mature bile ducts running along the axis of the portal tract. The mature portal tract is then achieved, containing portal vein, hepatic artery, and bile duct (Fig. 1). This pattern of maturation moves from the hilum outward and continues after birth; the biliary channels are at all times in continuity with the lumen of the developing extrahepatic biliary tree.

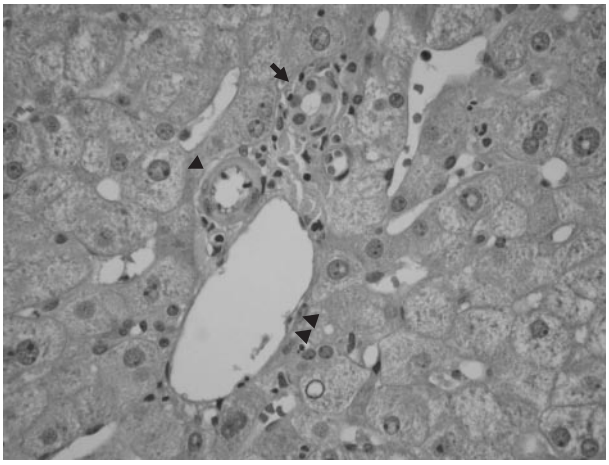

FIGURE 1 Micrograph of normal liver. The portal tract contains portal vein (double arrowheads), hepatic artery (single arrowhead), and bile duct (arrow).

The primordial liver separates from the septum transversum, leaving behind a mesenchymal remnant that will become the diaphragm. As the redundant major vessels of the embryonal circulation reorganize into the mature abdominal vascular system, the fetal liver receives some vascular supply from the umbilical vein through a vitelline vein remnant, while also receiving blood from the portal vein and hepatic artery. Most of the umbilical vein blood enters directly into the inferior vena cava through the short ductus venosus in the liver hilar area. At the time of birth, the mature hepatic circulation is achieved through closure of the ductus venosus and atrophy of the vitelline vein to produce the nonpatent falciform ligament connecting the hilum of the liver to the umbilicus.

The developing liver is an important metabolic center in the developing fetus; as the largest organ, it represents 10% of the fetal weight, falling to around 5% of body weight at the time of birth. The liver is also the main hematopoietic organ in fetal life, with hematopoietic elements constituting half of the liver mass at midterm, falling to almost zero at term. Although the hepatic organization and development begin in the third week of gestation, the functional and architectural maturation is not complete at birth and continues well into the postnatal period. The liver doubles in size in the first year of life alone; full maturation of the liver is not achieved until about 15 years of age.

GROSS ANATOMY

The liver is situated in the right hypochondrium and epigastric regions under the rib cage and extends from the right fifth intercostal space at the midclavicular line to just below the costal margin. The mean weight of the liver in the adult man and woman is 1800 g and 1400 g, respectively. It accounts for approximately 1.8–3.1% of body weight in adults. The liver is wedge shaped and is covered by Glisson's capsule (hepatic capsule), which is composed of the visceral peritoneum (a mesothelial epithelial layer), and an underlying shallow network of connective tissue. From Glisson's capsule, fibrous septa project inward into the hepatic parenchyma to a depth of about 0.5 cm. The superior convexity of the liver is not completely invested with peritoneum; a reflection of peritoneum onto the diaphragm produces a triangular "bare spot" on the most superior portion of the liver. The inferior surface of the liver has a deep concave recess with a central hilus, referred to as the liver hilum, or "porta hepatis," where major blood vessels, bile ducts, lymphatic vessels, and nerve trunks enter or leave the liver. To the right of the hilum is the gallbladder fossa, a concavity in which lies the gallbladder.

The liver is connected to the diaphragm and abdominal cavity by five ligaments. The anterior falciform ligament is a crescentic fold of peritoneum extending from the diaphragm to the umbilicus. The round ligament (ligamentum teres) is the fibrous remnant of the vitelline vein, forming the inferior border of the falciform ligament. The superior coronary ligament is composed of the peritoneal reflections onto the diaphragm. The right and left triangular ligaments are the respective lateral borders of the coronary ligament. Hence, the liver is held in place only by ligaments to the diaphragm and anterior abdominal wall, and by vasculature to the inferior vena cava posteriorly, and through the hilum to the posterior abdominal wall inferiorly. Mobilization of the liver during surgery is therefore readily accomplished.

The midline falciform ligament divides the liver into the historical right and left lobes. The protuberant caudate lobe projects posteriorly between the sulcus for the inferior vena cava and the fissure for the ligamentum venosus. The quadrate lobe lies inferiorly between the gallbladder fossa and the fissure for the round ligament.

VASCULAR ANATOMY

Liver anatomy is better defined by its vascular beds. In 1897, Cantlie noted that the right and left portal veins fed the right and left lobes, divided along a plane several centimeters right of midline, extending anterior to posterior from the gallbladder fossa to the vena cava. This plane is referred to as Cantlie's line, and constitutes the watershed between the right and left hepatic

circulations. Couinaud further described the functional anatomy of the liver and demonstrated that the vascular distribution network further divided the liver into four sectors and eight segments. By this nomenclature, the liver is divided by vertical and oblique planes, or scissurae, defined by branches of the three main hepatic veins, and a vertical plane separating the right and left portal vein branches. These four sectors are further divided by the transverse scissura into eight segments, named clockwise in the frontal plane, with the segment I corresponding to the caudate lobe; the quadrate lobe is viewed as part of the right lobe. Each segment is an independent functional unit supplied by a single vascular trunk containing both portal vein and hepatic artery branches. These anatomic subdivisions define the dissection planes for partial hepatic resections.

The liver receives approximately 25% of the cardiac output. Venous blood containing nutrients from the gastrointestinal tract is brought to the liver by the hepatic portal vein, which accounts for 75% of the liver blood supply. The hepatic artery branches off the celiac artery and provides 25% of hepatic blood. Branches of the portal vein and hepatic artery ramify within progressively smaller portal tracts, ending in terminal portal veins and terminal hepatic arteries. The volume of liver parenchyma supplied by terminal vasculature is on the order of 2 to 3 mm^3, giving rise to so-called microarchitectural units. Detailed structural studies have shown that there are between 18 and 20 orders of branches of portal tract circulation, producing an estimated 400,000 to 500,000 microarchitectural units in the adult liver.

The portal veins give rise to small venous channels that branch off at many points along the ramification of the portal vein system; these channels penetrate the liver parenchyma as the primary blood supply to sinusoids. The hepatic artery supplies the mesenchymal stroma of portal tracts, the peribiliary vascular plexus, the vasa vasorum of major blood vessels (including the vasa vasorum of major hepatic veins), and Glisson's capsule. Postcapillary blood from these distributions may enter the portal vein, the parenchyma directly, or the hepatic veins. Arterial blood may also supply sinusoids directly, although this does not appear to be a major component of arterial blood flow in humans.

Regardless of how portal vein and hepatic arterial blood reaches the parenchyma, blood percolates through the sinusoidal network to collect within terminal hepatic veins. The terminal hepatic veins collect into a conducting hepatic venous system, which drains ultimately into three major hepatic venous branches: right, middle, and left hepatic veins. The left and middle hepatic veins often join together, forming a common trunk before entering the inferior vena cava. There are also variable short venous segments that drain the posterior surface of the liver directly into the inferior vena cava.

BILE DUCTS

Bile is secreted by hepatocytes into bile canaliculi, small channels between abutting hepatocytes delineated along their length by tight junctions between hepatocytes. Bile canaliculi ramify throughout the hepatic parenchyma, depositing bile within the most peripheral portion of the biliary tree, the canals of Hering. Each canal of Hering is a "trough"-like channel bounded on one side by bile duct epithelial cells (cholangiocytes) and on the other by hepatocytes. Canals of Hering may lie circumferentially along the interface of the hepatocellular parenchyma and portal tract mesenchyme, or may penetrate the parenchyma to up to one-third the distance to the terminal hepatic vein. From a fluid dynamic standpoint, the canal of Hering provides a broad entry point for flow of bile from bile canaliculi into the biliary tree.

Canals of Hering connect to bile ductules, circular channels fully surrounded by cholangiocytes and a basement membrane. Ductules are the bridges between canals of Hering and the terminal bile ducts within portal tracts. In keeping with the variable canal of Hering anatomy, bile ductules may have both intraportal and short intraparenchymal segments. Terminal bile ducts collect ductular bile and convey it downstream to conducting bile ducts, and finally to the hepatic hilum for drainage into the gut through the extrahepatic biliary tree.

Terminal and conducting bile ducts run in parallel with hepatic arteries in a 1 : 1 relationship. The diameter of the bile duct (measured from basement membrane to basement membrane) is essentially equal to the diameter of the companion hepatic artery along most of the intrahepatic portal tree; the largest bile ducts are accompanied by multiple smaller hepatic artery branches. Hence, identification of hepatic arteries without companion bile ducts is indication of bile duct loss; a very helpful sign in assessing microscopic liver damage.

LYMPHATIC SYSTEM

Lymphatic vessels are abundant in portal tracts and are thought to begin as blind-ended channels in the terminal portal tracts. Extrasinusoidal fluid from the parenchyma draining retrograde into the portal tract mesenchyme collects in these lymphatics. Lymph travels downstream through a rich plexus of lymphatic

channels in the portal tree, converging around the major hepatic arteries, bile ducts, and portal vein to form 12 to 15 lymph vessels draining at the portal hilum. From there, lymph flows to the foraminal node at the epiploic foramen, the superior aortic nodes, and the ipsilateral aortic nodes. The lymph ultimately drains into the cisterna chyli superior to the celiac artery root, and then to the thoracic duct. Lymph collecting in lymphatics of Glisson's capsule drains either via hilar lymphatics or posteriorly and superiorly into lymphatics exiting along the hepatic veins and the inferior vena cava.

INNERVATION

The liver is innervated by both sympathetic and parasympathetic nerve fibers. They both contribute to the perivascular nerve plexus within the portal tree. Innervation of hepatocytes and sinusoids is relatively sparse and not uniform between lobules. Both sympathetic and parasympathetic nerve fibers influence hepatic metabolic activity, and play a role in regulating fluid secretion by cholangiocytes lining the biliary tree. This regulation may not be essential for normal liver function, because the transplanted liver apparently functions in the absence of regenerated nerve fibers. However, neural regulation may play a critical role in modulating cellular proliferation following hepatic injury, raising questions about the biology of liver damage following hepatic transplantation.

MICROSCOPIC ANATOMY

Microscopic Organization

Unlike the prototype nephron in the kidney, the liver does not have a defined smallest, structurally distinct, "self-sufficient" unit. Because terminal hepatic veins lie roughly 1 mm from portal tracts on several sides, nineteenth century microscopists viewed the liver "lobule" as having portal tracts at the periphery of a hexagon and terminal hepatic veins at the center. This classic lobule enables reference to parenchyma that is "centrilobular," "midzonal," and "periportal," a terminology that is well established in current practice.

In 1954, Rappaport demonstrated that blood flow from the penetrating venous channels flowed along parallel sinusoids to converge on the terminal hepatic veins, thereby defining a triangular hepatic "acinus" as having penetrating portal venous channels at the base and a terminal hepatic vein at the apex. The parenchyma of the hepatic acinus is divided into three zones, zone 1 being the closest to the vascular supply and hence best oxygenated, zone 3 abutting the terminal hepatic venule, and zone 2 being intermediate. This zonation is of considerable metabolic consequence, because a lobular gradient exists for oxygenation and solute content of sinusoidal blood and for the activity of many hepatocellular enzymes. This is called "zonation," or the "lobular gradient." Many forms of hepatic injury exhibit a zonal distribution, owing to variable exposure and susceptibility to injury of hepatocytes along the sinusoid. These microanatomic concepts have continued to undergo refinement, including efforts to define hepatic microanatomy on the basis of biliary drainage. The key concept is that hepatocytes along the sinusoids are not uniform, but behave variably on the basis of their position along the lobular gradient.

Microscopic Structure

The hepatic parenchyma is organized into cribriform, anastomosing sheets or plates of hepatocytes, seen in two-dimensional histologic sections as cords of cells (Fig. 1). The hepatocyte cords immediately abutting the portal tract are referred to as the limiting plate, forming a discontinuous rim around the mesenchyme of the portal tract. Between the hepatocyte cords is the sinusoid, conducting blood from the penetrating venous channels of the portal vein and hepatic arterial system to terminal hepatic venules. Hepatocytes are thus bathed on two sides by well-mixed portal venous and hepatic arterial blood.

Sinusoids are lined by a unique fenestrated endothelium that lacks a basement membrane. This is unlike any other vascular bed in the body. The absence of a perfusion barrier permits free exchange of plasma proteins with the perisinusoidal space, and hence with hepatocytes. This is the so-called space of Disse, between the sinusoidal endothelium and hepatocytes. Instead of a basement membrane, delicate connective tissue fibers traverse the space of Disse.

Hepatocytes

Hepatocytes constitute 80% of the cell population of the liver. There are approximately 100 billion of hepatocytes in an adult liver. An individual hepatocyte is a polygonal epithelial cell approximately 25 μm in diameter. The nucleus is centrally located and contains conspicuous nucleoli (Fig. 2). With increasing age, up to 20% of hepatocytes are binucleated and tetraploid. The hepatocyte is a polarized cell consisting of two functionally specialized membrane domains—the basolateral domain, which faces the perisinusoidal space of Disse and the lateral region between adjacent hepatocytes, and the apical domain, which forms the bile canaliculus midway between adjacent hepatocytes. Tight junctions

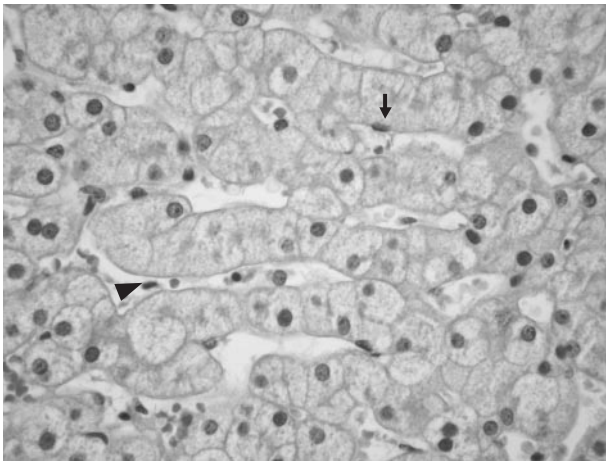

FIGURE 2 Micrograph of normal hepatocytes. The hepatocytes form hepatic cords and the sinusoids are lined with endothelial cells (arrow) and Kupffer cells (arrowhead).

separate the bile canaliculus from the lateral space between hepatocytes, thereby constraining bile to flow within the canalicular space. The basolateral domain constitutes about 88% of the hepatocyte plasma membrane surface, and the apical domain about 12%. The basolateral domain is occupied by transport and endocytic/exocytic events pertaining to exchange with sinusoidal plasma. The apical domain is responsible for the secretion of bile.

The hepatocellular cytoplasm contains numerous organelles, including rough endoplasmic reticulum (RER), smooth endoplasmic reticulum (SER), Golgi complexes, mitochondria, lysosomes, and peroxisomes. The RER is mostly involved in synthesis of membrane proteins or soluble proteins for extracellular secretion. The SER is rich in enzymes for drug metabolism, biosynthesis of cholesterol and conversion of cholesterol to bile acids, and the cytochrome P450 enzyme system. The Golgi complex of hepatocytes, located in the vicinity of the bile canaliculus, is necessary for processing of membrane proteins and secretory proteins prior to final targeting, including terminal glycosylation, and also plays a role in synthesis of very-low-density lipoproteins. There are approximately 1000 mitochondria in an individual hepatocyte, constituting between 13 and 20% of the cytoplasmic volume. Mitochondria are a major metabolic compartment, including the tricarboxylic acid cycle, fatty acid oxidation, and half of the urea cycle. They provide the essential oxidative energy for hepatic metabolism. Mitochondria are much smaller and more numerous in hepatocytes of acinar zone 3 compared to those in zone 1. Lysosomes in the hepatocyte are responsible for degradation of endocytosed proteins and are capable of discharging their contents into bile as a normal mechanism for eliminating some substances such as copper. Lysosomes can accumulate lipofuscin as a long-term by-product of autophagy, ferritin in iron-overload states, copper in Wilson disease, and lipids in a number of lysosomal storage disorders. There are approximately 300 to 600 peroxisomes in an individual hepatocyte. Peroxisomes contain oxidases and catalases and are responsible for 20% of hepatocellular oxygen consumption. Omega oxidation of long-chain fatty acids also occurs in peroxisomes.

The cytosol of the hepatocyte is occupied 80% on a volume basis by the aforementioned organelles. The remainder is a dense fluid containing cytosolic enzymes and a dynamic three-dimensional network of cytoskeletal proteins forming microfilaments, intermediate filaments, and microtubules. Each cytoskeletal element exists in a depolymerized and a polymerized state. Intermediate filaments are composed predominantly of cytokeratins 8 and 18, and are relatively stable; almost all microfilament protein is polymerized. In contrast, microfilaments and microtubules are highly dynamic structures, with rapid exchange of protein subunits between solubilized and polymerized states. The proportion of polymerized microfilaments and microtubules, and their location and polarity, are dictated on a moment-to-moment basis by the needs of the hepatocyte.

Hepatic Stellate Cells

Hepatic stellate cells lie within the space of Disse, and have extensions that wrap around the sinusoidal channel or extend into the lateral space between hepatocytes. Under normal conditions, they are scattered within the space of Disse and contain lipid droplets rich in vitamin A. They contain contractile filaments and are capable of regulating vascular tone within the sinusoid. They produce the delicate extracellular matrix of the space of Disse and secrete growth factors such as hepatic growth factor (HGF) or insulin-like growth factor-2 to regulate hepatocyte regeneration. When hepatic injury occurs, stellate cells are activated and rapidly proliferate, losing their lipid droplets in the process. In their activated state, they lay down abundant extracellular matrix and render the space of Disse fibrotic and relatively impermeant to plasma proteins. Activation of stellate cells is a major contributor to the development of liver cirrhosis.

Kupffer Cells

Scattered Kupffer cells of the monocyte–phagocyte system are attached to the luminal side of the endothelial cells (Fig. 2). These cells are the major macrophages of

the hepatic corpus and clear particulate matter and bacterial endotoxin from the splanchnic circulation. Hence, they are a major "filter" for intestinal blood before it enters the systemic circulation. Kupffer cells are a major source of cytokines in inflammatory states such as hepatitis, influencing in particular inflammatory injury of the subjacent sinusoidal endothelium and hepatocytes. Kupffer cells have an irregular stellate shape with bean-shaped nuclei. The cytoplasm of Kupffer cells often contains vacuoles and granular aggregates of ceroid pigments. The cells can actively proliferate in response to many inflammatory stimuli, including viral infections.

Lymphocytes

Liver-associated lymphocytes are abundantly present in the liver. It is estimated that there are approximately 1×10^{10} lymphoid cells in a normal human liver. So-called pit cells are present in the space of Disse; portal tracts also normally contain lymphocytes. Hepatic lymphocytes are heterogeneous in terms of the molecular markers on the cell surface. Natural killer (NK) cells and T lymphocytes are present in the liver cell population. Lymphocyte apoptosis is high in the liver, prompting the hypothesis that T lymphocytes are normally cleared by the liver and undergo apoptosis. The liver thus may be an important immunoregulatory organ through its selective removal of T lymphocytes from the circulation. The details of the physiological function of liver-associated lymphocytes are still unclear.

Bile Duct Epithelial Cells

The epithelium of the biliary tree, including the canals of Hering, is a continuous layer of tightly coupled cells, the so-called bile duct epithelial cells, or cholangiocytes. The smaller bile ducts are lined by cuboidal cells. The larger bile ducts are lined by columnar cells and may include goblet cells. Bile duct epithelial cells have prominent Golgi complexes, numerous cytoplasmic vesicles, and short luminal microvilli. Bile duct epithelial cells rest on a basement membrane and the biliary channel is highly impermeable to fluid leakage under normal conditions. The nuclei of the bile duct epithelial cells are located near the basement membrane. Bile duct epithelial cells are responsible for regulated secretion of approximately 30 to 40% of the volume of bile as a bicarbonate-rich fluid, and hence are significant modifiers of hepatic bile en route to the alimentary tract. Bile acids may be absorbed by the biliary epithelium, and so there is opportunity for intrahepatic recirculation of bile acids. This may be of value when the biliary tree is obstructed, allowing removal of bile acids from bile for redirection to urinary secretion.

CONCLUSION

Although the macroscopic anatomy of the liver is somewhat mundane, the microscopic anatomy is uniquely suited for its specialized physiologic functions: serving as a major metabolic organ for the entire body, synthesizing and secreting a critical set of plasma proteins, processing circulating plasma proteins, clearing noxious matter from the splanchnic circulation, and elimination of waste products via biliary secretion. It is small wonder that only the brain and kidneys receive more blood flow than the liver, and that the liver is a major producer of body heat.

fibroblast growth factors Proteins expressed by the cardiac mesoderm; extracellular signals for inducing liver progenitor cells.

homeobox Segment of nucleic acid base pairs that is conserved in genes involved in controlling the development of an organ or structure that produces factors that control gene expression.

phrygian cap Congenital gallbladder anatomical abnormality, resulting in a conical cap shape (the traditional ancient Phrygian headgear) at the gallbladder tip.

Obtaining genetic knowledge about the development and morphogenesis of the liver has been a challenging topic. Because the functions of the liver are essential to life, and many developmental mutations are lethal to the embryo. Despite the challenges, progress has been made on the molecular and cellular mechanisms of liver development. Transcription factors and signal transducers play an important role in the development of hepatoblasts from endodermal progenitor cells and in their continued growth and differentiation into hepatocytes and cholangiocytes. Abnormalities of these events may lead to developmental disorders of the liver, its vasculature, or the biliary system.

DEVELOPMENT OF THE LIVER PARENCHYMA

Functions of the liver include processing nutrients delivered by the vitelline umbilical vein or portal vein, synthesizing critical blood metabolites and serum proteins, detoxification, and supporting hematopoiesis during gestation. The liver develops from an outgrowth from the ventral foregut endoderm during the third week of intrauterine life and the biliary system originates from further outpouching of the liver bud. Early development can be divided into three stages that involve differentiation of the progenitor cells into hepatoblasts, growth of hepatoblasts, and ultimately morphogenesis of the liver.

Embryology and Gene Regulation

Early liver development starts with formation and patterning of the endoderm. The ventral endoderm differentiates into thyroid, lung, liver, and pancreas and the dorsal endoderm differentiates into pancreas and intestines (Fig. 1). The events leading to differentiation of the ventral endoderm to hepatoblasts, then the liver bud, and eventually a formed liver are due to liver specific transcriptional programs and external signaling events originating from the cardiac mesoderm. The *forkhead box A* (*FoxA*) genes are highly regulated and control gut development throughout the animal kingdom. Fox A proteins regulate almost all liver-specific genes as well as a number of genes specific to the lung and pancreas. These proteins have a 110-amino-acid DNA-binding domain and regulate gene transcription. In addition to the FoxA proteins, a subclass of the GATA zinc finger transcription factors is important for liver-specific gene expression (e.g., albumin).

Model systems have demonstrated that the cardiogenic mesoderm, which is transiently adjacent to the prospective hepatic endoderm, provides critical extracellular signals for inducing liver progenitor cells (Fig. 1). The cardiac mesoderm expresses a minimum of

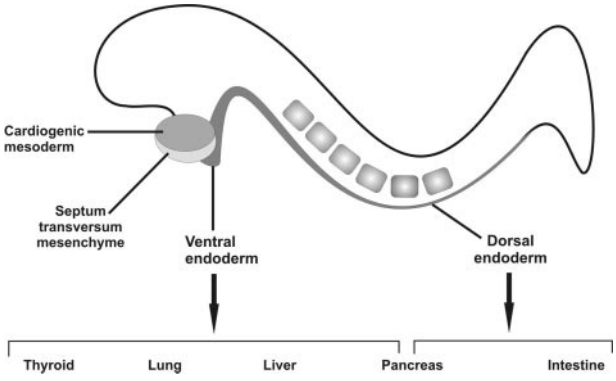

FIGURE 1 Formation and patterning of the mouse endoderm into the visceral organs at the sixth somite stage (approx. 8.25 days of gestation). The cardiogenic mesoderm sends extracellular signals to the ventral endoderm and promotes formation of the liver bud. Without the cardiogenic mesoderm, the endoderm differentiates into pancreatic tissue by default. The septum transversum initiates formation of separate body chambers and eventually forms the diaphragm.

 Copyright 2004, Elsevier (USA). All rights reserved.

three different fibroblast growth factor (FGF) proteins and the ventral endoderm expresses at least two of the four FGF receptors. Inhibitory FGF signaling blocks hepatic induction by the cardiogenic mesoderm whereas FGF treatment of endoderm explants induces early hepatic gene expression. These events occur at the seven- to eight-somite stage of the mouse embryo (approximately 8.3 days of gestation). The septum transversum mesenchyme also plays a signaling role by expressing bone morphogenetic proteins 2 and 4 (transforming growth factor-β family) before and during the induction of hepatoblasts within the endoderm. Without these signaling events, the ventral foregut endoderm differentiates by default into pancreatic tissue.

Another major step in liver development is the organization of hepatoblasts within the endoderm into a liver bud. Two genes, the hematopoietically expressed and Prospero-related homeoboxes, *Hex* and *Prox 1*, which encode transcriptional regulatory proteins, are required for early steps in liver bud development. Extracellular matrix proteins that interact with β1 integrin receptors also play a role in forming the liver bud, which occurs at day 9 to 10 of embryonic gestation in the mouse. By day 14.5, the liver becomes a large vascularized hematopoietic organ; this development does not occur if a septum transversum homeobox gene, *Hlx*, is knocked out. This indicates that soluble factors originating from the septum transversum are critical for developing the hematopoietic component of the embryonic liver.

Developmental Anomalies

Abnormalities of these early events can lead to anomalous development of the liver bud. Lobulation can be affected, leading to accessory lobes such as a supradiaphragmatic lobe or ectopic liver tissue (mesentery, or surface of the gall bladder, spleen, or adrenals). The right lobe can be abnormally enlarged (Reidel's lobe) and foregut diverticula can give rise to simple hepatic foregut cysts. However, most hepatic cysts are associated with abnormalities of the bile ducts.

DEVELOPMENT OF THE BILIARY SYSTEM

Embryology and Gene Regulation

A diverticulum (pars cystica) arises from the caudal surface of the liver bud and develops into the gallbladder, cystic, and extrahepatic bile duct. This is initially a solid cord, which develops a lumen. The adjacent parenchyma forms the developing biliary ductal epithelium and this structure migrates into the liver, following the branches of the portal vein during the sixth week of human fetal development. The hepatic artery also migrates into the liver along the portal vein. The forkhead transcription factor (Foxf1) expressed in the septum transversum mesenchyme is thought to play an important role in biliary morphogenesis. In addition, hepatocyte nuclear factors (Hnf6 and Hnf1 β) play a role in regulating hepatoblast differentiation into biliary cells. Perturbations in these transcription and signaling events can lead to defects in the biliary tree.

Developmental Anomalies

Anomalies of the biliary tract occur in 10−20% of the population. Anomalies include atresia, hypoplasia, or dilatation. Extrahepatic biliary atresia is the most frequent major anomaly and occurs in 1/10,000 live births. Although it usually presents during the first month of life, the process originates during the fifth week of fetal development. The cause is unknown but may involve perinatal viral infections. Patients with biliary atresia usually have persistent inflammation of the intrahepatic biliary tree, suggesting that the atresia may reflect a dynamic process of the entire hepatobiliary system. A hepatoportoenterostomy procedure of Kasai is the treatment of choice and has the best results when performed within 8 weeks postnatally. The short-term benefit of this surgery is decompression and biliary drainage to forestall the rapid onset of cirrhosis and sustain growth until a liver transplant can be done.

Cystic lesions are the result of developmental dilatations of the bile duct and can be either intrahepatic or extrahepatic, segmental or diffuse, and can involve the large or small bile ducts. Dilatation of the common bile duct leads to choledochal cysts, which are usually extrahepatic, but may sometimes extend into the liver. Their pathogenesis remains uncertain. Diverticulae of the common bile duct or dilatation of the intraduodenal portion of the common duct (choledochocele) can also occur.

Hepatocytes along branches of the portal vein form a biliary ductal plate that gives rise to the bile canaliculi. Error in remodeling of the embryonic ductal plate leads to fibropolycystic disorders of the biliary system. For example, Caroli's disease is an autosomal recessive condition with saccular dilatation of several segments of the large intrahepatic bile ducts. Saccular dilatation of small bile ducts can also occur with fibrosis (congenital

hepatic fibrosis) and with cystic changes in the collecting ducts of the kidney (autosomal recessive polycystic kidney disease). The gene for polycystic kidney and hepatic disease 1 (*PKHD1*), located on chromosome 6p21.1–p12, has been linked to classical forms of this disorder. Caroli's syndrome involves dilatations of the large intrahepatic bile ducts, with fibrosis and/or renal involvement. Autosomal dominant polycystic kidney disease can be also associated with liver cystic lesions, which may or may not communicate with the biliary system.

Intrahepatic biliary hypoplasia, another disorder of infancy or early childhood, involves an absence or decrease in the number of interlobular bile ducts or ductules, but the hepatic artery and portal vein maintain a normal size. The pathogenesis remains obscure. Accessory bile ducts are rare and usually are an extension of the right hepatic bile duct. Cholecystohepatic ducts are seen due to persistence of fetal connections between the liver and the gall bladder. They are usually associated with atresia of the right and left hepatic duct. Although the genetic defects explaining these biliary abnormalities remain unknown, Hnf6-null homozygous mice show an absence of the gall bladder. Other abnormalities of the gall bladder include duplication, oversized gallbladder, diverticula, or a phrygian cap. The anatomic location of the gallbladder may also vary (Fig. 2).

DEVELOPMENT OF HEPATIC VASCULATURE

Embryology and the Role of Endothelial Cells

Increasing evidence supports a critical role for endothelial cells during early development of the liver. This includes a role for angioblasts, which invade the septum transversum coincident with hepatocyte proliferation. Vascular endothelial growth factor (VEGF) signaling plays an important role in endothelial cell–hepatocyte interactions. During embryonic development, the portal vein originates from the paired vitelline veins and the hepatic artery originates from the celiac trunk.

Developmental Anomalies

Complete atresia or malformations in the shape, size, and number of the portal veins have been reported and can produce portal hypertension. Other congenital defects include clusters of dilated vessels within the periportal region and dilated portal veins, large or multiple hepatic arteries, or arterioportal anastomoses.

CONCLUSION

Much remains to be discovered about the regulation of hepatogenesis and development of the liver and biliary

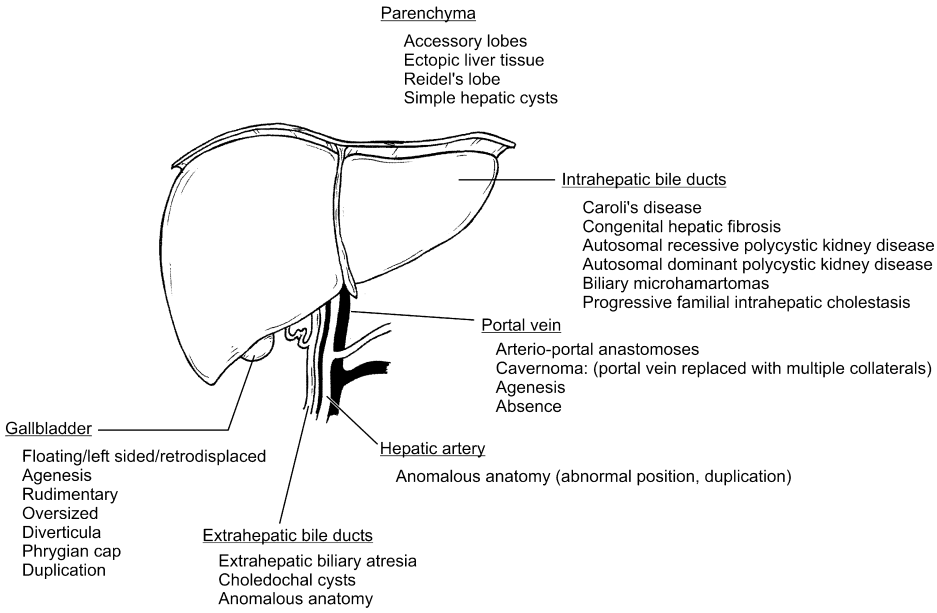

FIGURE 2 Developmental disorders of the liver arising from defects in various stages of liver development. The genetic or developmental explanations for most of these disorders remain unknown.

tree. However, studies in model systems are now making the long list of developmental defects seem more rational (Fig. 2).

Liver Disease, Pregnancy and

J. EILEEN HAY
Mayo Clinic and Foundation

acute fatty liver of pregnancy Acute liver failure due to microvesicular fatty infiltration of hepatocytes in the third trimester of pregnancy.

HELLP syndrome Triad of hemolysis, elevated liver tests, and low platelet count in the third trimester of pregnancy.

hyperemesis gravidarum Intractable vomiting in the first trimester of pregnancy.

intrahepatic cholestasis of pregnancy Pruritus and liver dysfunction in the second half of pregnancy.

preeclampsia triad of hypertension, edema, and proteinuria in the third trimester of pregnancy.

Pregnancy is an altered physiologic state associated with many hemodynamic and metabolic adaptations to support the placenta and fetus. Although most pregnant women remain healthy, pathophysiologic changes can occur, including five unique liver diseases seen only in the pregnant or postpartum patient. These pregnancy-associated liver diseases have characteristic clinical features and timing of onset in relation to pregnancy. Hyperemesis gravidarum is intractable nausea and vomiting in the first trimester; intrahepatic cholestasis of pregnancy, a disease of pruritus and abnormal liver tests, occurs in the second half of pregnancy; and preeclampsia and its complications of HELLP (hemolysis, elevated liver tests, and low platelets) syndrome and acute fatty liver of pregnancy are third-trimester diseases.

INTRODUCTION

Any liver disease, acute or chronic, occurring in young adult women may also occur coincidentally in pregnancy. Viral hepatitis is a common cause of jaundice in pregnancy and hepatitis A, hepatitis B, and hepatitis C occur with the same frequency and with the same clinical features as in nonpregnant individuals, with pregnancy and the viral hepatitis having little effect on each other. Gallstones are common, particularly in multiparous patients, but fortunately they are rarely symptomatic with biliary colic, pancreatitis,

Lower Gastrointestinal Bleeding and Severe Hematochezia

GUSTAVO A. MACHICADO AND DENNIS M. JENSEN
University of California, Los Angeles and Veteran's Administration Greater Los Angeles Healthcare System

angioma Arteriovenous malformation or proliferation, with or without dilation, of the blood vessels.
coagulopathy Disorder affecting the coagulability of the blood.
hematemesis Vomiting of blood, either red, clotted, or coffee-ground appearance.
hematochezia Passage of bloody stools, in contradistinction to melena (tarry stools).
hematocrit Percentage of the blood sample volume occupied by cells.
ischemia Low blood flow to the gut with tissue injury, either due to mechanical obstruction of the blood supply or reduction in local perfusion.
lower gastrointestinal Pertaining to the colon.
shock (hypovolemic) Caused by a reduction in the intravascular volume of blood, as from hemorrhage or dehydration.
stigmata (of recent hemorrhage) Endoscopically visible signs of recent hemorrhage such as active bleeding, adherent clot, or visible vessel.
thrombocytopenia Reduction in the number of platelets in the circulating blood.
upper gastrointestinal Pertaining to the esophagus, stomach, or duodenum.
varices (varix) Dilated veins (vein) in the esophagus and/or stomach related to portal hypertension.

Hematochezia is defined as passage of red blood or clots per rectum. It may be associated with diarrhea or pain, but often is painless. Hematochezia is a common reason for adults both young and old to present for medical attention. The approach to the diagnosis and treatment depends on the acuteness and severity of the hemorrhage. Patients with recurrent or severe hematochezia, with hypovolemia, or with severe anemia causing symptoms usually require hospitalization. Some with very severe blood loss or comorbid medical or surgical problems should be considered for intensive care unit management. Those patients with severe anemia and slower bleeding may also need to be hospitalized for blood transfusions and evaluation. The type and timing of diagnostic and therapeutic interventions will also be dictated by the severity of the hemorrhage.

INITIAL EVALUATION

Patients with presumed lower gastrointestinal (LGI) bleeding may present for medical attention with severe, persistent hematochezia and hypotension or shock. The majority of patients with this type of presentation have colonic sources of bleeding but some have upper gastrointestinal (UGI) or small bowel sources (Fig. 1). More commonly, the presentation of colonic bleeding is with recurrent bouts of self-limited hematochezia or with stools positive for occult blood with or without anemia.

The initial management of patients who present with severe hematochezia is similar to that of any patient presenting with severe bleeding from any source. Initial resuscitation efforts for patients presenting in shock (hypotension, tachycardia, and obvious intravascular volume depletion) include intensive care unit monitoring, adequate intravenous access, and vigorous volume replacement. If anemia is significant and/or the patient has severe or symptomatic heart, pulmonary, or vascular disease, transfusion of packed red blood cells (RBCs) is recommended. For patients with coagulopathies such as hypoprothrombinemia, administration of fresh frozen plasma

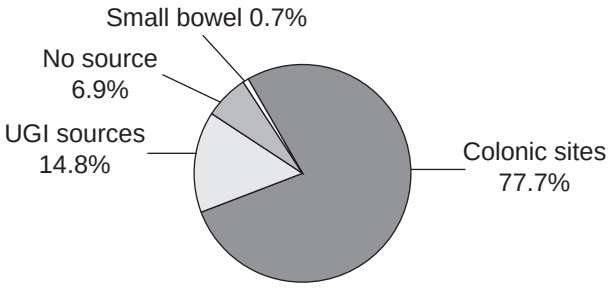

FIGURE 1 The distribution of bleeding sites for 291 consecutive patients (from the CURE Hemostasis Research Group study) with severe hematochezia, hospitalized and evaluated with urgent colonoscopy, anoscopy, panendoscopy, and/or push enteroscopy. UGI, Upper gastrointestinal.

TABLE I Resuscitation and Management of Patients with Severe Hematochezia

Establish one or preferably two large-bore intravenous lines
Assess intravenous volume and replace vigorously
Evaluate degree of blood loss and replace with packed red blood cells
Evaluate coagulation and correct with fresh frozen plasma, platelets, and/or desmopressin acetate
Place a nasogastric tube to check for a possible upper gastrointestinal source—blood or bile
Treat comorbid conditions

is indicated in cases of severe or ongoing hematochezia. Those with ongoing hematochezia and thrombocytopenia or severe renal insufficiency may require transfusions of platelets or desmopressin acetate (DDAVP). Table I summarizes resuscitation and initial management of patients with severe hematochezia.

A careful medical history and physical examination may yield important clues about the potential source of GI hemorrhage. A history of cirrhosis might suggest esophageal or gastric varices or angiomas of the gut. Severe chronic renal disease on hemodialysis could indicate angiomas. Severe heart disease can be associated with colonic angiomas or intestinal ischemia. A history of peptic ulcer disease, diverticulosis, inflammatory bowel disease, or internal hemorrhoids might direct the physician to these diagnoses as the potential bleeding site. Similarly, a history of crampy abdominal pain, anorexia, diarrhea, or fever with hematochezia may indicate a diagnosis of inflammatory bowel disease, ischemic bowel disease, or infectious colitis. A malignancy should be considered with weight loss, anorexia, constipation, or a change in bowel habits with anemia and hematochezia. A careful medical history should include questions about all medications the patient ingested recently, because many over-the-counter (OTC) and prescription drugs may cause or be associated with acute or chronic GI bleeding. Specifically, patients should be queried about recent use of aspirin or nonsteroidal antiinflammatory agents (NSAIDs), which commonly cause GI ulcerations and hemorrhage or aggravate bleeding from preexisting GI lesions. Anticoagulants or gingko may also aggravate GI bleeding from gut lesions.

DIAGNOSTIC APPROACH TO SEVERE HEMATOCHEZIA

Initial Management

While patients with severe hematochezia and anemia or hypotension are being resuscitated, the initial evaluation should include the passage of a nasogastric (NG) tube and gastric lavage to exclude the possibility of upper gastrointestinal (UGI) bleeding in patients without hematemesis. If bile is obtained in the presence of ongoing hematochezia, there is continuity with the duodenum and an upper gastrointestinal lesion is unlikely as the source of the hematochezia unless the bleeding is intermittent. When only clear fluid is obtained and no bile is present, continuity with the duodenum is not ascertained and the study should be regarded nondiagnostic. If there is evidence of blood (red or dark blood, clots, or coffee-ground appearing) in the NG aspirate, then an esophagogastroduodenoscopy (EGD) is indicated to exclude the possibility that a lesion in the upper gastrointestinal tract is responsible for the hematochezia (Fig. 1). Selected patients with suspected rectal lesions (such as internal hemorrhoids, fissures, or proctocolitis) should be given enemas and have urgent flexible sigmoidoscopy and anoscopy with a slotted anoscope before purge and urgent colonoscopy. Table I provides other general recommendations about the acute management of patients with severe hematochezia.

Urgent Colonoscopy

The CURE Hemostasis Group advocates an urgent approach to the diagnosis and treatment of patients with severe hematochezia similar to that currently used for patients with severe UGI hemorrhage. While resuscitating the patient, the approach is to purge the colon of clots, blood, and stool with a balanced electrolyte solution. Then, an urgent colonoscopy is performed for diagnosis and, if necessary, colonoscopic hemostasis during the same examination. This approach has dramatically changed the diagnosis, treatment, and cost of management of patients with severe hematochezia hospitalized in the CURE group institutions.

A polyethylene glycol (PEG)-based purge (Golytely or Colyte) is the commercially available preparation now utilized as preparation for urgent colonoscopy. If there is no evidence of UGI bleeding and the patient already has a nasogastric tube in place, the solution is administered via the tube. Alternatively, some patients can drink enough purge solution at a rapid enough rate (e.g., 1 liter every 30–45 minutes) to effectively prepare their colons. Metoclopramide (Reglan, 10 mg) is administered intravenously 10–15 minutes prior to starting the purge for its prokinetic and antiemetic effects. A liter of purge solution (Golytely or Colyte) is administered or drunk every 30–45 minutes until the rectal effluent is clear of blood, clots, and particulate matter. Usually 6–10 liters over 3–6 hours is needed to accomplish

TABLE II Colon Preparation Prior to Urgent Colonoscopy in Patients with Severe Hematochezia

Give metoclopramide (Reglan) if no contraindications, 10 mg intravenously or intramuscularly 5–30 minutes prior to starting purge
Give a polyethylene glycol-based purge for colonoscopy (Nulytely or Colyte) orally or via nasogastric tube at 1 liter every 30–45 minutes until effluent is clear of clots, stool, and blood—usually 6–10 liters required over 3–6 hours
In patients with tense ascites, perform therapeutic paracentesis to prevent respiratory compromise during colonoscopy
If patient is in congestive heart failure, treat with intravenous diurectics; if in renal failure, use concurrent hemodialysis

this goal. Following this, an urgent colonoscopy is performed at the bedside or in an in-patient endoscopy unit, while monitoring the patient.

Patients who have congestive heart failure often require diuresis during or after colonic purge. Similarly, patients with chronic renal failure who are on dialysis usually require hemodialysis during or just after the bowel preparation, because 10–20% fluid absorption is expected during the rapid purge in such patients. During colonic purge, volume overload is common with these and other severe comorbid conditions, such as end-stage liver disease with large-volume ascites. Table II provides general recommendations on this method of bowel preparation.

Results for Urgent Colonoscopy

The CURE group recently prospectively studied 291 consecutive patients who were hospitalized because of severe hematochezia. Patients who had ongoing, severe hematochezia and those who appeared to stop bleeding after hospitalization were included in this study. All patients had NG aspiration and lavage, purging of the colon and performance of urgent colonoscopy, and/or performance of upper endoscopy (or enteroscopy) for positive NG lavage or if the colonoscopy was negative.

A specific diagnosis was made by either stigmata of recent hemorrhage on the lesion (such as active bleeding, nonbleeding visible vessel, or adherent clot) at endoscopic examination or the identification of a GI lesion without stigmata, but in the absence of other significant GI lesions that might have caused the hemorrhage. A colonic bleeding site was found in 77.7% of patients admitted with hematochezia, an UGI source was present in 14.8%, a small bowel source was found in 0.7%, and no source could be found in 6.9% (see Fig. 1).

A variety of lesions were found in patients bleeding from a colonic site (77.7%). The three most common diagnoses were diverticulosis, internal hemorrhoids, and ischemic colitis. Table III lists these and other frequent colonic diagnoses.

Red Cell Scanning

Technetium-labeled red blood cell (RBC) scans can be useful to localize the bleeding site in patients with severe hematochezia. Early RBC scans (e.g., baseline and up to 1–4 hours only) are recommended in selected patients with severe, ongoing hematochezia. Selected patients include those with recurrent GI bleeding that has defied diagnosis by urgent colonoscopy, enteroscopy, and anoscopy; hospitalized patients who have ongoing severe hematochezia during colonic purging; and patients with severe ongoing hematochezia for whom a visceral angiogram is being considered.

The advantages of RBC scanning are that it can be performed while the patient is undergoing resuscitative efforts and purging. Although RBC scanning requires active bleeding to show extravasation into the gut, it is reported to be positive with a bleeding rate as low as 0.1 ml/min. In addition, the scanning can be repeated because the labeled RBCs remain in the circulation at least 24 hours. There are also disadvantages of RBC scanning. In most patients, the scans will be negative because patients have stopped bleeding before the scan is done. Another major disadvantage is limited ability to establish the location of small bowel lesions, when scans are read as positive, particularly delayed scans (after 4 hours). If the RBC scan is positive, a confirmatory test such as colonoscopy, push enteroscopy, angiography, or intraoperative enteroscopy is recommended to identify the precise location of the hemorrhage and clarify the nature of the bleeding lesion. Empiric surgical resection is not recommended based on the results of

TABLE III Colonic Sources of Severe Hematochezia[a]

Diagnosis	Colonic source (%)
Diverticulosis	29.6
Internal hemorrhoids	14.2
Ischemic colitis	12.4
Solitary rectal ulcers	9.2
Ulcerative or other colitis	8.8
Delayed post polypectomy ulcer	8.0
Colon angiomas	5.7
Colon polyp or cancer	6.2
Other lower gastrointestinal	7.0

[a] Expressed as the percent of all colonic sources of severe hematochezia. From the CURE Hemostasis Research Group Study (Jensen, 2001; Kovacs *et al.*, 2001). $N = 291$ total severe hematochezia patients.

a RBC scan alone, because localization is often poor, especially with delayed scans (more than 4 hours) that are positive. Whereas early scans (less than 4 hours after baseline) have been reported to be helpful for localization (positive yields more than 75% at surgery), delayed scans have not proved reliable for localization (yield less than 40% at surgery).

Emergency Visceral Angiography

Visceral angiography may be useful in the diagnosis and localization of bleeding sites in patients with severe or ongoing hematochezia. Its diagnostic yield has been reported to be from 12 to 69% in patients with presumed active bleeding. Angiography may also identify nonbleeding lesions such as angiomas or tumors. An advantage is that angiography can be performed without a bowel preparation or during bowel preparation. Skilled angiographers can also treat bleeding lesions by selective embolization. The disadvantages of angiography are that critically ill patients have to be transported to the radiology department for the procedure. High blood flow ($\sim$0.5 ml/minute) is also required to see extravasation into the gut lumen, and this high bleeding rate is unusual for colonic lesions. The contrast agent may cause serious complications, particularly in the elderly, such as volume overload or renal insufficiency. Emergency angiography is recommended in severely bleeding patients when urgent anoscopy, colonoscopy, and enteroscopy have failed to yield a diagnosis and there is continued or recurrent bleeding. Screening of these patients first with a RBC scan may increase the yield of angiography, if only those with positive early scans are selected for emergency angiography.

DIAGNOSTIC APPROACH TO LESS SEVERE BLEEDING

Most patients who present with self-limited hematochezia or occult blood positive stools and anemia can be managed as outpatients. The exceptions are those who present with severe comorbid conditions and symptoms (such as angina pectoris or dizziness) or signs of the severe anemia (such as hypotension, syncope, or shock). These patients usually require hospitalization and RBC blood transfusions. Patients with severe comorbid conditions such as heart disease or renal disease may also require concomitant diuresis or dialysis, during intravascular volume repletion or transfusion. Patients with slow GI bleeding who do not require RBC transfusions can be managed with iron supplements and outpatient evaluations.

ENDOSCOPIC DIAGNOSIS AND TREATMENT OF BLEEDING COLONIC LESIONS

Diverticular Hemorrhage

Diverticulosis is the most frequent colonic lesion responsible for severe hematochezia. Patients with diverticular hemorrhage do not present with slow GI hemorrhage, anemia, and Hemoccult positive stools. Instead, they present with overt bleeding and usually with hematochezia. Diverticulosis was diagnosed as the cause of hematochezia in 24.1% of all patients admitted with severe hematochezia in a recent study. In the study, the majority of patients had colonic diverticulosis, because they were over 65 years of age and diverticulosis is common in the elderly. However, for all patients with diverticulosis of the colon admitted with severe hematochezia, more than 50% were found to have bleeding from nondiverticular colonic, sources. These were reported as "incidental diverticulosis." If an urgent colonoscopy after good colonic preparation had not been performed, many of these nondiverticular lesions would have been missed or overlooked because stigmata of colonic hemorrhages tend to disappear in 1–3 days. "Definitive diverticular bleeding" was diagnosed when there were stigmata of recent hemorrhages (active bleeding, a nonbleeding visible vessel, or an adherent clot) in a diverticulum on urgent colonoscopy. Adequate colonic cleansing with the purge and target water-jet irrigation facilitated identification of stigmata of hemorrhages during colonoscopy. "Presumptive diverticular hemorrhage" was diagnosed when only colonic diverticulosis and no other potential bleeding lesions were found on colonoscopy, anoscopy, and enteroscopy (see Fig. 2).

Thirty-four patients with definitive diverticular hemorrhages have been studied to compare medical-surgical with medical-colonoscopic management. Seventeen patients received medical-surgical treatment in an initial observational study to define the natural history of definitive diverticular hemorrhage. In a subsequent study of definitive diverticular bleeding, 17 patients had medical treatment and hemostasis at the time the stigmata were diagnosed at urgent colonoscopy. Both groups of definitive diverticular bleeds were comparable in terms of age, comorbid conditions, recent aspirin and/or NSAID ingestion, and blood transfusion requirements prior to colonoscopy. Patients in the medical-surgical cohort of the study underwent emergency colonoscopy for diagnosis but did not receive any colonoscopic treatment. Medical-colonoscopic treated patients also underwent

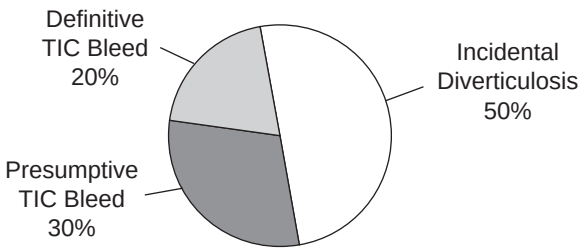

FIGURE 2 Prevalence of incidental diverticulosis and presumptive and definitive diverticular hemorrhage (56 patients with diverticulosis and severe hematochezia in a study by the CURE Hemostasis Group). The types of diverticular hemorrhage are designated in patients with severe hematochezia, evaluated by urgent colonoscopy, after colonic purge. Definitive diverticular hemorrhage is finding a stigma of recent hemorrhage (active bleeding, nonbleeding visible vessel, or adherent clot) on or in a single diverticulum, resistant to target water irrigation and suctioning. Presumptive diverticular hemorrhage is diagnosed when only colonic diverticulosis (without stigmata of hemorrhage) and no other potential bleeding lesions are found on colonoscopy, anoscopy, and push enteroscopy. Incidental diverticulosis refers to patients with colonic diverticulosis, but some other definitive source of hemorrhage is found on urgent colonoscopy, anoscopy, endoscopy, or push enteroscopy.

emergency colonoscopic treatment for stigmata of hemorrhage (active bleeding, adherent clot, or a nonbleeding visible vessel). Colonoscopic treatment consisted of epinephrine injection, bipolar cautery, or both. For both cohorts of patients, the diverticulum with the stigmata of hemorrhage was tattooed with India ink to facilitate localization at surgery or retreatment. After the urgent colonoscopy, ongoing or recurrent hemorrhage that required transfusions of two or more units of packed red blood cells was observed in 53% of the medical-surgical treated patients, in contrast to 6% of the medical-colonoscopic treated group. Severe bleeding requiring transfusion with more than three units of packed red blood cells and subsequently requiring surgery was seen in 35% of the medical-surgical group in contrast to 6% of the medical-colonoscopic treated group. No complications were seen from colonoscopic treatment of bleeding diverticulosis. The median time to hospital discharge was 5 days for the medical-surgical group and 2 days for the medical-colonoscopic group (see Table IV). None of the patients in either group had recurrent bleeding on long-term (mean 36 months) followup. In contrast, patients with "presumed diverticular hemorrhage" had a recurrent bleeding rate of 5.7% during a mean of 36 months of followup. This is in contrast to surgical series that report 38–50% recurrent bleeding rates during 3–5 months of followup.

Colonic Angiomas

Colonic angiomas are also referred to as telangiectasia, arteriovenous malformations, or angiodysplasia. These lesions may occur sporadically or can be part of a congenital syndrome such as hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu syndrome). The etiology of sporadic colonic angiomas is unknown. However, they have been observed to occur with increased frequency with advanced age and in patients with severe heart disease (particularly valvular heart disease), chronic renal insufficiency, cirrhosis of the liver, and collagen vascular disorders.

In a previous prospective study of 100 patients who were hospitalized with very severe, persistent hematochezia, 30% were found to be bleeding from colonic angiomas. All of these patients were elderly and most had severe comorbid conditions, such as heart, renal, or liver disease. In contrast, in a subsequent prospective study of 291 patients hospitalized with either self-limited hematochezia or ongoing hematochezia, colon angiomas were diagnosed as the cause of hemorrhage in 4.7%. Another prospective study of patients with hemorrhage from colonic angiomas included 100 consecutive patients. Approximately 75% presented with anemia, Hemoccult positive stools, and self-limited hematochezia. In contrast, 25% had severe hematochezia requiring resuscitation and transfusions. These were hospitalized and had urgent colonoscopy. Angiomas varied in size from 1 to 30 mm, but a majority were smaller than 10 mm and could be coagulated easily via colonoscopy. The most common location was the right colon: the cecum and ascending colon accounted for 72%. A less common location for angiomas was the left colon (the descending and sigmoid colon accounted for 22%).

The CURE group randomized 100 patients with bleeding from colonic angiomas for hemostasis at

TABLE IV Outcomes of Treatments of 34 Consecutive Patients with Definitive Diverticular Hemorrhage[a]

	Med-Surg ($N = 17$)	Med-Colon ($N = 17$)
Endoscopic hemostasis	0	17 (100%)
Additional bleeding	9 (53%)	1 (6%)*
Severe bleeding	6 (35%)	1 (6%)*
Emergency surgery	6 (35%)	1 (6%)*
Median time to discharge after colonoscopy (days)	5	2
Complications	2 (12%)	0

[a] From Jensen (2000, 2001). *$P < 0.05$.

colonoscopy with either bipolar coagulation or heater probe. Both coagulation devices have been shown to be equally effective for the treatment of GI angiomas. In these patients, the clinical course significantly improved after, compared to before, colonoscopic hemostasis in terms of recurrent bouts of hemorrhage, need for blood transfusions, and serum hemoglobins. Complications occurred in 5.7%. Two patients developed postcoagulation syndrome and recovered with medical therapy alone and four others developed delayed bleeding due to ulcers at the coagulated site. Two of the latter patients with severe coagulopathies required surgery for control of recurrent colonic bleeding. No colonic perforations occurred in this group, although perforations have been reported by other groups who have treated colonic angiomas with other coagulation devices, such as monopolar probes or lasers, and also in those patients who had repeat coagulation at the same site with heater probe or bipolar coagulation.

Colonic Carcinomas, Polyps, and Postpolypectomy Bleeds

Patients with colonic cancers or polyps usually present with occult gastrointestinal bleeding and anemia and rarely with gross hematochezia. In a prospective study of 100 patients with severe, persistent hematochezia, urgent colonoscopy revealed ulcerated cancer or polyps in 9% of patients. In a second series of 291 patients admitted for hematochezia, ulcerated polyps or cancers were found in 5.2%. Bleeding from ulcerated cancers or polyps usually does not involve arterial bleeding but rather tends to be oozing bleeding. Endoscopic control of such bleeding can usually be achieved with the injection of 1 : 10,000 epinephrine with or without bipolar probe coagulation in the case of cancers. During the same colonoscopy, lesions are biopsied to obtain a histologic diagnosis. Subsequently, surgical resection is recommended. In contrast, bleeding polyps can usually be removed with a polypectomy snare and electrocautery. For large sessile polyps that are not amenable to complete endoscopic removal, hemostasis and biopsy are recommended to establish a histologic diagnosis, prior to consideration for surgical resection.

Significant bleeding can occur immediately after a polypectomy and this is usually due to ineffective or inadequate coagulation of the vessels within the polyp stalk. If bleeding occurs immediately following polypectomy, hemorrhage can be arrested with the same polypectomy snare by resnaring the stalk and applying pressure with or without electrocautery. If resnaring is not feasible, the area can be injected with epinephrine and subsequently cauterized with bipolar or heater probe, but other devices, such as the endoloop or hemoclips, have also been used.

Delayed hemorrhage occurs due to the coagulum sloughing off the polyp stalk, or the polypectomy base in the case of sessile polyps. In the series of 291 patients with severe hematochezia, postpolypectomy delayed bleeding accounted for 8.0% of colonic diagnoses. Most reported rates of postpolypectomy bleeding are less than 6%. In the original series of patients with severe hematochezia, this diagnosis was not reported. With the colonoscopy initiatives for colorectal cancer screening in the past 5 years, this is now the sixth leading colonic cause of severe hematochezia (see Table III). Delayed bleeding in the patients discussed here occurred a median of 9 days (range 2−73) postpolypectomy. The mean size of the index polyps was 20 mm. Ulcers with a mean size of 11 mm were found in the patients who presented with delayed postpolypectomy hemorrhage and underwent emergency colonoscopy following a bowel purge. Active bleeding was present in 23%, nonbleeding visible vessel was present in 23%, adherent clot was present in 38%, a flat spot was present in 8%, and clean ulcer was present in 8%. The majority (92%) of the patients achieved complete hemostasis with epinephrine injection and cautery. Only one patient rebled. Endoscopic treatment of these lesions was effective and safe.

Internal Hemorrhoids

Internal hemorrhoids are the most common lesion causing self-limited rectal bleeding in ambulatory adults. Rarely, internal hemorrhoids cause persistent bleeding needing emergency hemostasis. In the original series of 100 patients with severe, persistent hematochezia, internal hemorrhoids were the bleeding site in less than 4%. Often, a simple slotted anoscopy examination at the bedside will yield the diagnosis, obviating the need for urgent colonoscopy. Several effective methods can be used to control bleeding from internal hemorrhoids without surgery. In one randomized study, bipolar probe and heater probe coagulation were reported to be equally effective in controlling bleeding from internal hemorrhoids in a randomized study of patients who had failed medical therapy. Internal hemorrhoid banding has also been used successfully for many years. Endoscopic banding is commonly used after urgent colonoscopy, when internal hemorrhoids are diagnosed as the bleeding site, because of the effectiveness of this technique. Injection sclerotherapy has also been used in the past with a variety of sclerosants for the treatment of internal hemorrhoids. Complications such as thrombosis, infection, ulceration, or delayed

bleeding are reported for all these techniques of internal hemorrhoid hemostasis. However, complication rates are low and most physicians and patients favor this approach over surgical hemorrhoidectomy.

Lupus Erythematosus

SALAHUDDIN KAZI
University of Texas Southwestern Medical Center, Dallas

antinuclear antibodies (ANAs) Autoantibodies that are directed against nuclear antigens and measured by indirect immunofluorescence. Specific ANAs are directed against DNA, histones, components of the spliceosome (Sm, RNP, Ro, and La), and other nuclear antigens (centromere, topoisomerase I).

drug-induced lupus erythematosus A distinct form of lupus caused by sustained exposure to certain drugs (procainamide, phenytoin, and isoniazid are the commonest) associated with the production of anti-histone antibodies and clinically with fever, arthralgia, myalgia, rash, and serositis and the absence of renal or central nervous system involvement.

major histocompatibility complex The genetic region on the short arm of chromosome 6 encoding groups of highly polymorphic surface proteins that are expressed on the surface of all living cells and that are important in antigen presentation and shaping of the immune repertoire.

Lupus erythematosus is a complex multisystem autoimmune disorder characterized by inflammation in many organ systems and by the formation of distinct autoantibodies often associated with specific end-organ involvement. There is considerable phenotypic heterogeneity accounting for a wide spectrum of disease expression ranging from mild to life-threatening forms of this disease.

CLASSIFICATION

Several interrelated and overlapping clinical disease subsets of lupus erythematosus (LE) are recognized. Historically, LE was first described as a cutaneous disease and in many patients LE is exclusively a cutaneous disease. Systemic lupus erythematosus (SLE) is the classic systemic form of the disease, typically with some combination of cutaneous, musculoskeletal, hematologic, and renal involvement. Drug-induced lupus erythematosus is a distinct form of the disease associated with the production of anti-histone antibodies and clinically with fever, arthralgia, myalgia, rash, and serositis as well as the absence of renal or central nervous system involvement.

EPIDEMIOLOGY

SLE is a relatively uncommon disease with an incidence of approximately 5 per 100,000 per year and prevalence of between 25 and 50 per 100,000. Certain racial groups are at increased risk for SLE and include African Americans and African Caribbean individuals. The peak incidence is between 15 and 45 years of age. There is a striking female predominance with a female : male ratio of 9 : 1. Twin studies indicate that SLE is predominantly a genetic disease, although several extrinsic triggers have been implicated. These include ultraviolet light, hair products, smoking, estrogens, and viral agents like Epstein-Barr virus and hepatitis C virus (HCV).

ETIOLOGY AND PATHOGENESIS

SLE appears to be a multigenic disease resulting from complex interactions between susceptibility genes and environmental factors resulting in the generation and persistence of an autoimmune state with subsequent destructive inflammatory events. It is useful to conceptualize the pathogenesis of SLE as a set of preclinical events occurring in a genetically predisposed individual characterized by the induction and expansion of autoimmunity followed by immune-mediated injury causing clinically recognizable disease.

The genes conferring susceptibility to SLE include certain allelic major histocompatibility complex molecules and several other immunoregulatory genes that have been partially identified. Acting in concert with other factors, these genes lead to the development of autoreactive T cells, followed by an expansion phase that is characterized by considerable clonal expansion of B and T cells that recognize self-antigens. Once mature, high-affinity autoantibodies form and have access to autoantigen and immune-mediated injury ensues, resulting in clinical forms of this disease. It is very likely that cell-mediated processes are also involved but their role in SLE pathogenesis is less well understood.

CLINICAL FEATURES

General

Fatigue is the commonest feature of SLE, sometimes reflecting disease activity, but equally prevalent even when the disease is inactive when it can represent the effects of depression, stress, fibromyalgia, or medication side effects. Fever is also a common feature of disease and is typically episodic. Constant fever is more suggestive of infection. Weight loss may precede the diagnosis of SLE, whereas weight gain may be the result of steroid therapy.

Cutaneous

The most characteristic skin lesion associated with lupus is the diffuse, macular, erythematous facial eruption in a malar distribution, also known as the "butterfly" rash. It is referred to as acute LE, since it is associated with active SLE. Other less common but equally distinct cutaneous lesions include chronic cutaneous LE (discoid LE) and subacute cutaneous LE, both of which may also occur in patients without systemic features.

Musculoskeletal

Though exceedingly common, arthritis associated with SLE is usually mild and not associated with the development of deformities. It may be migratory and most often involves the hand joints. Myalgia is common but true myositis is rare.

Renal

The majority of patients with SLE have renal involvement, often subclinical. In 50–75% of patients, this will become clinically apparent in a few years after disease onset. Renal disease appears to be the result of immune complex damage and in some cases is associated with elevated anti-DNA antibody titers and low levels of complement proteins C3 and C4. There are six different histologic patterns described in patients with SLE in whom renal biopsy is performed: normal (type I), mesangial (type II), focal proliferative (type III), diffuse proliferative (type IV), membranous (type V), and sclerosing (type VI). Although some of these histologic lesions are associated with distinct clinic syndromes, there is substantial overlap and histologic transition over time. Type IV disease is both the commonest and severest form of lupus nephritis.

Hematologic

All three cell lines are affected in patients with SLE. Leukopenia is common, but rarely is clinically significant. Autoimmune hemolytic anemia is seen in a small number of patients with SLE, with most patients who are anemic exhibiting an anemia of chronic disease. Mild thrombocytopenia is common; occasionally it is severe. Anti-phospholipid antibodies directed against a variety of clotting factors occur in up to one-third of SLE patients and may cause a prolongation in the activated partial thromboplastin time (lupus anticoagulant).

Gastrointestinal

Most gastrointestinal symptoms in SLE are related to medication-related side effects [nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, immunomodulators]. SLE has also been associated with direct involvement of the gastrointestinal tract. Oral ulcers are exceedingly common. Dysphagia is less common and often multifactorial (most often related to hypomotility). Vasculitis of mesenteric vessels is a rare but serious complication of SLE. It may present with an acute abdomen or may have an insidious onset. Complications include bowel necrosis and perforation. Bland mesenteric thrombosis may occur secondary to a hypercoagulable state associated with anti-phospholipid antibodies. Pancreatitis is seen in up to 8% of patients with SLE. It is occasionally secondary to mesenteric vasculitis. Liver disease in SLE is frequent. Lupoid hepatitis refers to an antinuclear antibody (ANA)-positive autoimmune hepatitis, most often associated with anti-smooth muscle antibodies and sometimes with anti-mitochondrial antibodies as well (which are rare in SLE). In contrast, the term "lupus hepatitis" is increasingly employed to refer to an autoimmune hepatitis occurring in patients with SLE. It has been associated with antibodies to ribosomal P antigen and typically occurs in patients with clinically overt SLE. Protein-losing enteropathy is an uncommon clinical feature of SLE.

Other

Neurologic disease is very common in SLE and most often presents as neuropathy, mononeuritis multiplex, meningitis, cerebritis, neurocognitive dysfunction, seizures, and stroke syndromes. Headaches are a relatively common complaint and are often not an indicator of underlying disease activity. Pulmonary manifestations include pleuritis, pleural effusions, pneumonitis, interstitial lung disease, pulmonary hypertension, and alveolar hemorrhage. Myocarditis, pericarditis, valve abnormalities, and coronary arteritis can all occur in patients with SLE.

DIAGNOSIS

Classic SLE can be readily diagnosed when a patient from a high-risk epidemiologic group (for example, young African American women) presents with the typical constellation of symptoms and signs. Diagnostic difficulties arise when the disease occurs in low-risk epidemiologic groups (such as, children or older males) or when it presents with involvement of just a few organ systems. Chronic human immunodeficiency virus and hepatitis C virus infection can phenotypically mimic SLE. Criteria have been developed for the classification of SLE by an expert consensus panel. Although the criteria were devised to create uniformity in clinical studies, the criteria are frequently used to diagnose SLE (see Table I). ANA testing in SLE is widely performed but suffers from low specificity while maintaining high sensitivity. The rational use of ANA testing is dependent on generating clinical pretest probabilities of SLE and avoiding ANA testing when the clinical probability of SLE is low. Though less sensitive, anti-DNA and anti-Sm antibodies are considered specific for SLE.

TABLE I The ACR 1982 Revised Criteria for the Classification of Systemic Lupus Erythematosus

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, reported in patient history or observed by physician
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
Arthritis	Nonerosive arthritis involving 2 or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	(1) Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion OR (2) Pericarditis—documented by ECG or rub or evidence of pericardial effusion
Renal disorder	(1) Persistent proteinuria >0.5 g per day or $>3+$ if quantitation not performed OR (2) Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	(1) Seizures—in the absence of offending drugs or known metabolic disorder derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance OR (2) Psychosis—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance
Hematologic disorder	(1) Hemolytic anemia with reticulocytosis OR (2) Leukopenia— $<4000/mm^3$ total on 2 or more occasions OR (3) Lymphopenia— $<1500/mm^3$ on 2 or more occasions OR (4) Thrombocytopenia— $<100{,}000/mm^3$ in the absence of offending drugs
Immunologic disorder	(1) Anti-DNA: antibody to native DNA in abnormal titer OR (2) Anti-Sm: presence of antibody to Sm nuclear antigen OR (3) Positive finding of antiphospholipid antibodies based on (i) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (ii) a positive test result for lupus anticoagulant using a standard method, or (iii) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescence treponemal antibody absorption test
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

Note. The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation. Criterion 10 (Immunologic disorder) was updated in 1997. Sensitivity and specificity 96%. Data taken from Tan *et al*. (1982) and Hochberg (1997).

THERAPY AND PROGNOSIS

SLE is marked by substantial clinical heterogeneity with resulting variations in natural history and prognosis. Patients from lower socioeconomic backgrounds, African Americans, and those with renal disease have a worse prognosis. Therapy is thus dependent on an accurate assessment of organ involvement and disease activity. Overall, the outlook for SLE has improved remarkably over the past 50 years with an improvement in 10-year survival from 40 to $>90\%$.

Treatment involves the consideration of general issues such as photoprotection, nutrition, cardiovascular risk factor modification, osteoporosis prevention, infection control, exercise, and pregnancy counseling as well as therapies directed at specific organ systems. NSAIDs are employed for treating arthritis, antimalarial drugs (principally hydroxychloroquine) are useful in managing cutaneous and joint disease, and corticosteroids are reserved for major organ system involvement. Intravenous pulse cyclophosphamide is the treatment of choice for proliferative lupus nephritis. Azathioprine is often employed as a first-line steroid-sparing agent. Newer therapeutic approaches are focusing on interrupting immune cell–cell signaling mechanisms.

Lymph, Lymphatics, and Lymph Flow

PATRICK TSO AND RONALD JANDACEK
University of Cincinnati Medical Center

alkaline phosphatase Enzyme (pH optimum 9.5–10.5) that hydrolyzes many orthophosphoric monoesters and serves as an important component of intracellular pH buffering.

chylomicrons Large, spherical lipoproteins made exclusively by the small intestine; their major function is to transport from the enterocytes to the lymph the large amount of dietary fat absorbed by the small intestine.

cirrhosis Degenerative disease of the liver that results in damage to hepatic parenchymal cells and decreased blood flow to the liver; characterized by the development of fibroids and nodes.

diamine oxidase Enzyme (also known as amine oxidase or histaminase) secreted by enterocytes; plays an important role in the breakdown of histamine and polyamines.

hepatic lymph hepatic lymph Derived from the perisinusoidal space, or space of Disse, it is through these channels that fluid and proteins are drained from the liver.

lipid absorption Process by which lipids are digested, mainly in the intestinal lumen, where they are absorbed by enterocytes and then packaged and secreted as chylomicrons into the lymph. Bile salt plays a critical role in the absorption. A concentrated form of energy, lipids are composed of a number of classes of compounds that are insoluble in water but soluble in organic solvents; triacylglycerols and triglycerides are the most abundant of all dietary lipids.

lymph Fluid that is collected from the tissues throughout the body and transported via the lymphatic vessels to the venous blood.

small intestine Consists of the duodenum, jejunum, and ileum and is where most digestion and absorption of nutrients takes place.

Lymphatic vessels, composed of countless microvessels of endothelial tubing, form an interconnected system that collects and transports fluids from the tissue of various organs in the body and channels them into the venous blood circulation. The gastrointestinal tract has the most extensive lymphatic system, which is essential to the absorption and digestion of nutrients and of some gastrointestinal hormones by the small intestine and their eventual transport to the general circulation via enterocyte processing. To a certain degree, lymphatics are involved in every pathological process.

ANATOMICAL CONSIDERATIONS

The historical aspects of knowledge about the gastrointestinal lymphatic system have been described in an excellent book written by Dr. James A. Barrowman in 1978. The formation of lymph begins in the lamina propria (interstitial compartment) of the small intestine. This interstitial compartment is best viewed as a complex noncellular matrix that supports the cells as well as the capillaries and lacteals. The main components of the interstitial matrix are bundles of collagen fibers and glycosaminoglycan chains, which are mechanically entangled and cross-linked, producing a gel-like structure. Hyaluronic acid, the main interstitial glycosaminoglycan, is a polymer of *N*-acetylglucosamine and glycuronic acid; it has a molecular weight that varies from a few thousand to several million. The anionic nature of hyaluronic acid causes pockets of negative charge within the gel matrix. The rate of diffusion of water and water-soluble molecules across the interstitial matrix (also called the hydraulic conductivity) depends mostly on the degree of hydration of the matrix. For example, doubling of the interstitial volume (therefore hydration) is believed to increase the hydraulic conductance more than a thousandfold. The interstitial matrix probably undergoes continuous modification, especially during periods when the matrix is markedly expanded (hydrated), e.g., during fat absorption. For instance, hyaluronic acid, which can be found in thoracic duct lymph, increases markedly during the absorption of fat.

Initial lymphatic vessels (lacteals), fine vessels found in the villus, range between 100 and 500 nm in length. They have only a single layer of endothelial cells with a fragmented basement membrane. The endothelial cells of the initial lymphatic vessel are joined together quite variably. For instance, they can be joined together by tight junctions, or there may be gaps between endothelial cells. As shown in Fig. 1, the gap between endothelial cells of the lacteals allows the chylomicrons to enter the lacteal. Three-dimensional reconstruction from electron micrographs show a special type of open junction formed by processes of

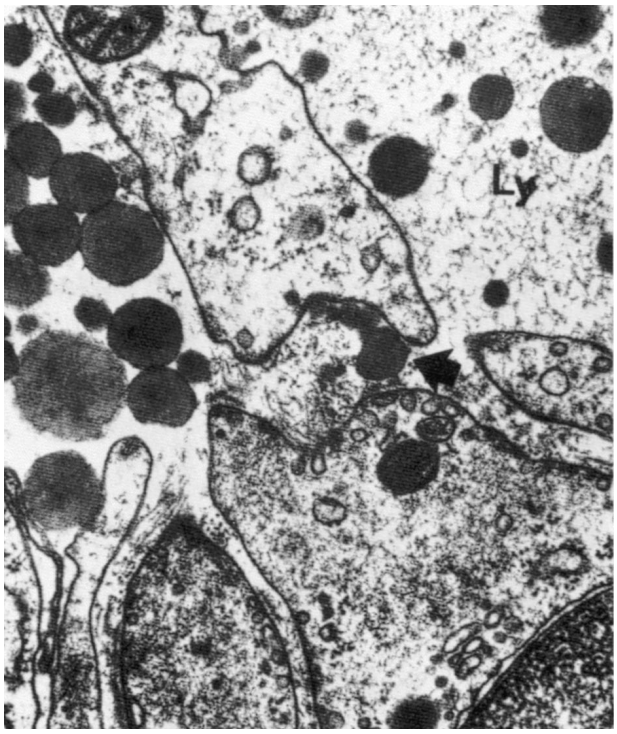

FIGURE 1 Chylomicrons produced by enterocytes entering lymphatic vessels (Ly) by moving through gaps (arrow) that develop between cytoplasmic extensions of the endothelial lining of the vessel.

lymphatic endothelium that enclose channels from the interstitial matrix (interstitium) to the lymphatic lumen along the length of the initial lymphatics.

The fine lymphatic vessels merge progressively, forming collecting vessels that transport the lymph to the main intestinal lymph duct, the cisterna chyli, and the thoracic duct. The thoracic duct then carries the lymph, which enters the general circulation by emptying into the subclavian vein. Valves are present in the main intestinal lymph duct and the thoracic duct. Although not well studied, a number of papers have reported innervation of the lymph vessels by sensory fibers.

FORMATION OF GASTROINTESTINAL LYMPH

In the small intestine, unlike most other organs, the source of fluids, electrolytes, peptides, and lipoproteins is the capillary filtrate and the intestinal absorption and secretion by enterocytes that line the intestinal epithelium. Various factors affect lymph flow as a result of changes in filtration of fluids and solutes from the capillaries. Plasma fluids, electrolytes, and proteins cross the capillary to diffuse through the interstitium and return to the circulation through the lymph. Because the plasma filtrate contributes to lymph flow, factors that affect the filtration of fluid from the capillaries also affect lymph flow. For example, in portal hypertension (elevation of venous pressure), enhanced intestinal lymph flow occurs as a result of the increase in transcapillary hydrostatic pressure gradient. In contrast, reduced hydrostatic pressure occurs during arterial hypotension (i.e., hemorrhage), which leads to reduction in lymph flow. It can also be predicted that a reduction in plasma protein concentration (hypoproteinemia) increases lymph flow by a reduction in the transcapillary oncotic pressure gradient (as explained by the Starling force equation). The lymph-to-plasma ratio, which is inversely proportional to the size of the protein, is another important factor regulating the amount of protein filtered from the capillaries. The bigger the protein, the less the amount that is filtered from the capillaries to the interstitium. For total protein, however, the lymph-to-plasma ratio is between 0.5 and 0.65.

The small intestine absorbs a large amount of fluid and solutes (especially sodium) from the intestinal lumen daily. This absorbed fluid expands the interstitial space, thereby increasing the interstitial pressure. This increase in interstitial pressure causes fluid to move from the interstitium to the initial lymphatics. Thus, the lymphatic system plays an important role in fluid absorption from the small intestine to the general circulation.

The liver also contributes to the lymph flow in the thoracic duct. Although no direct anatomical evidence is available to trace the origin of hepatic lymph, it is generally believed that hepatic lymph is formed at the space of Disse. The permeability of the endothelial lining of the liver sinusoids, unlike that of the small intestine, is very porous, allowing most proteins to travel through with little difficulty. Consequently, the protein concentration in liver lymph is almost as high as the protein concentration in the circulating blood. The protein in liver lymph is composed of protein filtered from blood and protein produced by the liver. Hepatic lymph flow increases dramatically with liver cirrhosis.

The Transport of Lipids in Lymph

Dietary lipid, chiefly triglyceride, undergoes hydrolysis in the small intestinal lumen to form 2-monoglycerides and fatty acids. The reaction is catalyzed by pancreatic lipase. After triglyceride digestion products are taken up by enterocytes, they are resynthesized to form triglycerides. These triglyceride lipid

droplets are then coated with phospholipids and apolipoproteins to form triglyceride-rich lipoproteins. The small intestine secretes both very-low-density lipoproteins (during fasting) and chylomicrons (during active fat absorption). Chylomicrons are richer in triglyceride and much larger compared to very-low-density lipoproteins (100–200 nm versus 50–80 nm). Using electron microscopy, enterocytes secrete chylomicrons by exocytosis. The interstitium is resistant to chylomicron movement. Therefore, the increased hydration of the interstitial matrix and the resulting increase in lymph flow are believed to facilitate chylomicron movement across the interstitial matrix and into the initial lymphatics. Chylomicrons are not only important in the transport of dietary fats by the small intestine, but they are also vehicles for the transport of fat-soluble vitamins and drugs. For instance, it has been demonstrated that *p*-aminosalicylic acid, tetracycline, and the highly lipophilic antimalarial, halofantrine, are transported in lymph. There is tremendous interest from the pharmaceutical industry in studying drug delivery via the lymphatic route.

Gastrointestinal Hormones in Lymph

In addition to transporting macromolecules, lymph is also a potential avenue by which gastrointestinal hormones enter the general circulation. The presence of gastrointestinal hormones in lymph has been documented previously by bioassays and radioimmunoassays of the gastrointestinal hormones. However, the relative importance of the lymphatic route versus the portal route in the transport of gastrointestinal hormones remains to be explored.

Lymphatic Transport of Proteins

As with lymph from other regions of the body, plasma provides the greatest source of proteins to intestinal lymph. There are, however, proteins in intestinal lymph derived from the small intestine. Apolipoproteins A-I, A-IV, and B48, the major apolipoproteins associated with lymph lipoproteins, are derived from the small intestine. The intestine is a major source of circulating apolipoproteins A-I and A-IV. The intestinal lymph also contains a number of enzymes secreted by enterocytes. For instance, enterocytes secrete alkaline phosphatase, which is associated with surfactant-like particles that appear in lymph during fat absorption. There is a linear relationship between the amount of fat and the amount of alkaline phosphatase in lymph. Another enzyme secreted by enterocytes is diamine oxidase (histaminase). It plays an important role in the breakdown of histamine and polyamines.

A major component of the lymphoid system, the gastrointestinal-associated lymphoid tissue (GALT), is located in the gastrointestinal tract. The GALT consists of three components: (1) Peyer's patches, (2) intraepithelial lymphocytes, and (3) plasma cells and lymphocytes in the lamina propria. The plasma cells secrete immunoglobulin A (IgA). Transported in lymph, the concentration of IgA is significantly higher in lymph than in blood.

The Transport of Xenobiotics in Lymph

In general, the degree of lipophilicity of foreign substances appears to determine the route of transport of these compounds from the small intestine, and the more lipid-soluble compounds tend to favor the lymphatic route. Clearly, the importance of lymphatic transport of xenobiotics rests on the fact that the liver is bypassed, thus allowing extensive systemic distribution of the compound. However, the small intestinal epithelial cells have the capacity to carry out both phase I and phase II reactions. Therefore, they can convert the absorbed lipophilic compounds to more hydrophilic compounds and direct more polar metabolites to the portal route. Lymphatic transport of numerous xenobiotics, including benzo[*a*]pyrene, 7,12-dimethylbenzanthracene, polychlorinated biphenyls, and dichlorodiphenyltrichloroethane (DDT), has been demonstrated. For this reason, the intestinal lymphatic transport of lipophilic toxic xenobiotics is of considerable interest, particularly as related to their potential role in cancer development.

PATHOPHYSIOLOGY OF GASTROINTESTINAL LYMPHATICS

To some extent, lymphatics are involved in every pathological process. One important example is their role in the dissemination of epithelial malignant tumors that arise in the gut and its associated structures. The role of disordered lymphatic function in the pathogenesis of selected gastrointestinal diseases is considered in the following discussions.

Primary Intestinal Lymphangiectasia

This disorder is thought to result from congenital structural abnormalities in the lymphatics of the intestinal wall or its mesenteries, causing impaired drainage of the mucosal initial lymphatics. Chylous effusions in the pleural or peritoneal cavity are often associated with intestinal lymphangiectasia. The central lymphatics of the intestinal villi are dilated and filled with protein and

chylomicron-rich lymph; the villi are clubbed as a result of mucosal edema. Gastrointestinal symptoms are generally mild, though abdominal pain, nausea, vomiting, and diarrhea with steatorrhea can occur. Severe protein depletion can lead to hypoproteinemic edema, causing impaired growth in children.

Primary intestinal lymphangiectasia is diagnosed by protein-losing enteropathy and mucosal biopsy. It can be treated in several ways: (1) by resection, if only a short segment of small intestine is affected, (2) by lymphovenous anastomosis, to correct the localized anomaly, and (3) by reduction in dietary long-chain triglycerides. This last treatment reduces the lipid required for transport by the lymphatics and reduces intestinal lymph formation, because fat feeding is a powerful intestinal lymphagogue (an agent that promotes lymph formation).

Secondary Intestinal Lymphangiectasia

Secondary intestinal lymphangiectasia is caused by any pathological process that obstructs major lymph trunks from draining the intestine. Crohn's disease, which involves the intestine or mesentery, is an example of this pathological condition. Chronic pancreatitis is another example and is caused by inflammation of the retroperitoneal tissues. Whipple's disease displays a moderate degree of secondary intestinal lymphangiectasia and results from the infiltration of lymph nodes with periodic acid Schiff (PAS)-positive macrophages. Cirrhotic patients with enteric loss of plasma proteins exhibit intestinal lymphangiectasia in small intestinal biopsies.

Inflammatory Bowel Disease

Edema is a prominent histopathological feature of all forms of inflammatory bowel disease. The pathogenesis of edema is complex. There is evidence that capillary permeability is enhanced as a result of local liberation of chemical mediators of inflammation such as histamine, serotonin, bradykinin, and other such substances. Bacterial endotoxins may also produce enhanced vascular permeability to protein, as may oxygen free radicals derived from leukocyte activity.

The extent to which abnormalities of lymphatic drainage play a part in edema of the intestine in inflammatory bowel disease is unclear. In Crohn's disease, there is lymphatic dilatation in all layers of the bowel wall, notably in the submucosa. It is suggested that an element of lymphatic obstruction from inflammatory changes in adjacent tissues and lymph nodes may be involved. Additionally, a defect in the function of intestinal lymphatic vessels may occur in Crohn's disease.

Acute Pancreatitis

Gross edema of the gland occurs in both acute interstitial (edematous) pancreatitis and necrotizing (hemorrhagic) pancreatitis. Distended lymphatics can usually be observed by morphological examination. It is unlikely that lymphatic obstruction plays a primary role in the pathogenesis of acute pancreatitis, but some evidence suggests that lymphatic obstruction may aggravate the autodigestive process by allowing toxic products to accumulate in the tissue. For instance, obstruction of lymph flow in experimental acute pancreatitis in animals increases the inflammatory process.

Chyluria

Chyluria results from situations in which a major lymph trunk communicates with the urinary tract. Patients with chyluria have afforded investigators the opportunity to study the human intestinal lymph lipoprotein and apoprotein spectrum.

Lymphocytes

RODNEY NEWBERRY
Washington University School of Medicine, St. Louis, Missouri

antigen Any molecule that can specifically bind to an antibody.
antigen-presenting cells Have the ability to internalize protein antigens, process them into peptides, and present these peptides on their surface in association with MHC II molecules. The primary antigen-presenting cells are dendritic cells, macrophages, and B lymphocytes.
B cell receptors Molecules present on B lymphocytes; contain cell surface immunoglobulin specific for antigen.
cytokines Small soluble proteins made by cells; can affect the behavior of other cells.
cytotoxins Proteins produced by cytotoxic T lymphocytes; participate in the destruction of target cells.
immunoglobulin Protein (antibody) produced by plasma cells; has the ability to bind specific antigen.
intraepithelial lymphocyte compartment Collection of T lymphocytes and NK cells interspersed between the intestinal epithelial cells.
lamina propria lymphocyte compartment Collection of bone marrow-derived cells (including lymphocytes and antigen-presenting cells) dispersed throughout the stroma, supporting the intestinal villi.
major histocompatibility complex molecules Polymorphic cell surface glycoproteins with the ability to bind peptide antigens and to stimulate T lymphocytes bearing receptors specific for these antigen/glycoprotein complexes.
Peyer's patches Organized lymphoid structures located on the antimesenteric border of the small intestine; contain lymphocytes and antigen-presenting cells and are important for the induction of immune responses against antigens from the intestinal lumen.
poly-Ig receptor Polymeric immunoglobulin receptor located on the basolateral surface of epithelial cells; binds polymeric immunoglobulins (IgA and IgM) and plays a critical role in transporting IgA produced by plasma cells in the lamina propria to the intestinal lumen.
T cell receptors Complexes on the surface of T lymphocytes; contain a disulfide-linked heterodimer of either α and β chains or γ and δ chains and are responsible for the recognition by T lymphocytes of specific antigen/major histocompatibility glycoprotein complexes.

The immune response can grossly be divided into innate and adaptive responses, which interact effectively in a complex series of coordinated events to protect higher organisms from invading pathogens. The innate immune response is important early in immune-mediated events, is present in individuals at all times, and does not increase in magnitude on repeated exposure to pathogens, whereas the adaptive or acquired immune response is directed at specific antigens, increases in magnitude with repeated exposure to those antigens, and results in immunological memory. The roles lymphocytes play in the immune response encompass a spectrum covering both innate and adaptive immune responses. Cell lineages include B lymphocytes, T lymphocytes, and natural killer cells. The B and T lymphocytes bear antigen-specific receptors and are the primary effector cells responsible for adaptive immune responses; conversely, natural killer cells lack antigen-specific receptors and play a role in innate immune responses.

INTRODUCTION

Lymphocytes are bone marrow-derived cell lineages arising from a common lymphoid progenitor (Table I). In general, lymphocytes can be classified by cell surface receptors and by the specific immune functions attributed to each cell type. In this scheme, understanding how lymphocytes are classified is fundamental to assigning a function for lymphocytes in the immune response. Lymphocytes circulate freely throughout the body and perform their functions in concert with other immunologically relevant cells and factors. An in-depth understanding of lymphocyte function requires understanding how lymphocytes circulate, interact with other cells, and perform their effector functions; although this is beyond the scope of this article, lymphocytes and their classification and function will be discussed within the structural framework of their functions in the immune response.

NATURAL KILLER CELLS

Natural killer (NK) cells, in contrast to B cells and T cells, lack antigen-specific receptors and play a role in the innate immune response. NK cells are functionally

Important in innate immune responses	Important in adaptive immune responses	Important in adaptive immune responses

defined by their ability to kill tumor cell lines without prior immunization. The mechanism by which NK cells kill their targets is similar to that of cytotoxic T lymphocytes. Cytotoxic granules are released by NK cells onto the surface of the target cell, penetrating the target cell membrane and resulting in programmed cell death of the target. NK cells bear two classes of receptors, activating receptors and inhibitory receptors. Inhibitory receptors recognize "normal" self major histocompatibility complex (MHC) class I molecules, expressed on all nucleated cells, and thus inhibit the killing of self when normal self MHC I is expressed. Activating receptors recognize a variety of ligands present on infected or malignant cells. NK cell function requires the expression of activating ligands by target cells as well as decreased or abnormal expression of self MHC I, thus allowing NK cells to receive an activating signal in the absence of an inhibitory signal. NK cell function can be enhanced by exposure to some cytokines, in particular interferon γ (IFNγ) and interleukin-12 (IL-12) produced by macrophages early in the immune response. Therefore, NK cells are a key component of the early (innate) immune response and are crucial for removal of abnormal and/or infected cells. The variety, repertoire, and restriction of the inhibitory and activating receptors on NK cells are not well understood and provide an area of active investigation.

COMMON PROPERTIES OF B AND T LYMPHOCYTES

In comparison to other cell types in the body, and to other cell types in the immune system specifically, B and T lymphocytes share many unique properties. The B and T lymphocytes are the cornerstones of the adaptive immune response, which is remarkable for its diversity, specificity, and memory. These characteristics are primarily due to the unique B and T lymphocyte surface receptors, the B cell receptor (BCR) and the T cell receptor (TCR). These receptors are generated by gene rearrangement of somatic DNA during the development of each B or T lymphocyte. This process results in the generation of billions of B and T lymphocytes, each expressing a unique receptor with its individual antigen specificity. Importantly, B and T lymphocytes express multiple copies of a single rearranged receptor on their surface, allowing them to recognize exclusively a single antigen. The development and function of lymphocytes are determined by signals received through these receptors. Through these unique antigen-specific receptors, B and T lymphocytes have the ability to respond to a diverse repertoire of antigens in a very specific way. The B and T lymphocytes also share the property of clonal expansion. When mature B and T lymphocytes encounter antigens specific for their receptors, in the appropriate environment, they respond and divide multiple times to produce clonal populations of lymphocytes expressing the same receptor. This clonal population has the ability to produce an augmented immune response on reexposure to the same antigen, and thus forms the basis for immunological memory, the principle behind vaccination.

B LYMPHOCYTES

The B lymphocytes recognize native antigen via their BCR and can participate in the immune response at multiple levels; however, one function unique to B lymphocytes is their differentiation into plasma cells, which produce secreted immunoglobulin, or antibody. After activation of mature B lymphocytes by ligation of the BCR by specific antigen, B lymphocytes may undergo additional rearrangement of their somatic DNA and differentiate into plasma cells to produce different classes, or isotypes, of immunoglobulins (IgA, IgM, IgG, IgE, and IgD). The various isotypes of immunoglobulins produced retain the antigen specificity of the progenitor B lymphocyte, although different isotypes of immunoglobulin perform distinct functions in the immune response. A prime example of these distinct functions is the role luminal IgA plays in protecting the host from invading pathogens at mucosal surfaces. In addition

TABLE II Properties of B-1 and B-2 B lymphocytes

B-1 B lymphocytes	B-2 B lymphocytes
Self-renewing from the peritoneal and pleural cavity	Renewed from the bone marrow
Spontaneous immunoglobulin production	Low or no spontaneous immunoglobulin production
Do not require cognate T lymphocyte interactions for differentiation into plasma cells	Require cognate T lymphocyte interaction for differentiation into plasma cells
Little or no somatic hypermutation	Somatic hypermutation to produce high-affinity antibody
Little or no memory response	Strong memory response
Contribute to fecal immunoglobulin production	Contribute to fecal immunoglobulin reproduction

to this unique effector function, B lymphocytes may also act as antigen-presenting cells (APCs), which, in association with class II MHC on their cell surface, present antigen to responding T cells.

The B lymphocytes can be divided into two categories, B-1 and B-2 B lymphocytes (Table II), which can be distinguished by the expression of cell surface molecules. Although both B-1 and B-2 B lymphocytes can differentiate into antibody-producing plasma cells, the pathways they take to achieve this state differ. B-2 B lymphocytes require cognate T lymphocyte interactions in order to differentiate optimally into antibody-producing plasma cells. The optimal differentiation of these B cells into high-affinity antibody-producing plasma cells is also dependent on the presence of organized lymphoid structures. These structures facilitate somatic hypermutation, a process in which B lymphocytes modify the genetic coding of the hypervariable region of the immunoglobulin gene responsible for binding antigen. This allows the development and selection of B lymphocytes expressing immunoglobulin genes with high affinity for a specific antigen. Mature B-2 B lymphocytes are continually produced by the bone marrow and circulate throughout the body.

In contrast to B-2 B lymphocytes, B-1 lymphocytes arise from a self renewing pool located primarily in the peritoneal and, to a lesser extent, pleural cavities. In comparison to B-2 B lymphocytes, B-1 B lymphocytes express a restricted repertoire of BCR, and do not require cognate T lymphocyte interactions for their differentiation into plasma cells, although they can benefit from cytokines produced by T lymphocytes. B-1 B lymphocytes do not undergo the process of somatic hypermutation and therefore are not optimal producers of high-affinity antibodies. In addition, B-1 B lymphocytes do not display a strong memory response. Collectively, these observations suggest that B-1 B lymphocytes may play a role in the nonadaptive (innate) phase of the immune response.

T LYMPHOCYTES

αβ and γδ T Lymphocytes

The T lymphocytes can be categorized by the chains comprising their TCR. The TCR present on the surface of T lymphocytes is a heterodimer composed of either α and β chains or γ and δ chains, thus dividing T lymphocytes into two distinct categories, αβ T lymphocytes and γδ T lymphocytes. The γδ T lymphocytes are preferentially enriched at some mucosal surfaces and bind antigen in association with nonclassical MHC molecules. The TCR repertoire of γδ T lymphocytes is more restricted when compared with the TCR repertoire of αβ T lymphocytes. The function of γδ T lymphocytes is poorly understood, and they are felt to represent a more primitive form of the adaptive immune response.

T Lymphocytes Recognize Antigen in the Context of MHC

In contrast to B lymphocytes, which recognize native antigen via the BCR, T lymphocytes recognize antigen peptides bound to specialized cell surface glycoproteins, MHC molecules. There are two classes of MHC molecules with different patterns of expression. Class I MHC, or MHC I, is expressed on all nucleated cells in higher organisms, whereas MHC II expression is primarily restricted to APCs. In contrast to B lymphocytes, T lymphocytes undergo maturation and selection in the thymus. During this time, T lymphocytes with gene rearrangements that produce a functional TCR with the ability to bind self MHC complexes on stromal cells in the thymus are either positively or negatively selected. Only T lymphocytes bearing TCRs binding self MHC with the appropriate affinity are positively selected. The T lymphocytes expressing TCRs binding self MHC with high affinity represent self-reactive T lymphocytes and are eliminated, as are T lymphocytes

TABLE III Properties of CD4 and CD8 T Lymphocytes

CD4+ (helper) T lymphocytes	CD8+ (cytotoxic) T lymphocytes
Undergo selection and maturation in the thymus	Undergo selection and maturation in the thymus
Recognize antigen in association with MHC II expressed on antigen-presenting cells	Recognize antigen in association with MHC I expressed on nucleated cells
Major effector functions mediated by the production of cytokines	Major effector functions mediated by the release of cytotoxins
Mediate a variety of effects, depending on the profile of cytokines produced	Kill cellular targets

bearing TCRs lacking the ability to bind self MHC, because these thymocytes will be unable to respond to antigen presented by self MHC-bearing antigen-presenting cells. This process generates a diverse population of T lymphocytes with the capacity to recognize antigens in association with self MHC.

CD4 (Helper) and CD8 (Cytotoxic) T Lymphocytes

The T lymphocytes may be further classified by their expression of the CD4 and CD8 coreceptors (Table III). The CD4 coreceptor facilitates interactions between the TCR and the class II MHC expressed on APCs, and the CD8 coreceptor facilitates interactions between the TCR and the class I MHC expressed on nucleated cells. Thus, T lymphocytes expressing the CD4 coreceptor can recognize antigens only in the context of self MHC II, and are appropriately named "helper" T lymphocytes, based on their function. T Lymphocytes expressing the CD8 coreceptor can recognize antigens only in the context of self MHC I and are thus named "cytotoxic" T lymphocytes, based on their function.

The T lymphocytes produce two classes of effector molecules, cytotoxins and cytokines. Cytotoxins are primarily produced by CD8 T lymphocytes responding to antigens presented in association with self MHC I. On the recognition of antigen/MHC complexes by the ligation of the TCR, CD8+ T lymphocytes release lytic granules, resulting in the death of their targets. In this way CD8+ T lymphocytes selectively eliminate infected or damaged target cells.

Although both CD4 and CD8 T lymphocytes produce cytokines, cytokines are the primary mechanism by which CD4 T lymphocytes mediate their effects. Previously activated CD4 T lymphocytes produce specific patterns of cytokines on reactivation, resulting in phenotypic patterns of immune responses. For example, one pattern of cytokine expression by CD4 T lymphocytes may facilitate immunoglobulin class switch by B lymphocytes and their subsequent differentiation into plasma cells, whereas another pattern of cytokine expression may promote proinflammatory cell-mediated immune responses. The production of specific patterns of cytokines is reproducible once a CD4 T lymphocyte has fully differentiated, and thus the pattern of cytokines produced by differentiated CD4 T lymphocytes is a means to further subdivide these T lymphocytes into functional groups, or subsets. The factors directing the differentiation of CD4 T lymphocytes into the different subsets are at least partially dependent on the cytokine milieu present when an undifferentiated, or naive, T lymphocyte first encounters antigen and MHC. Thus, although CD4 T lymphocytes are primary effectors of the acquired immune response, they can promote a spectrum of phenotypic responses, including tolerance, humoral (antibody-mediated) immune responses, and proinflammatory cellular immune responses.

LYMPHOCYTE FUNCTIONS RELEVANT TO THE GASTROINTESTINAL TRACT

Lymphocyte Location in the Gastrointestinal Tract

The gastrointestinal tract contains the largest number of lymphocytes in the body. These lymphocytes are distributed throughout the gastrointestinal tract in three phenotypically and physically distinct compartments: the Peyer's patches (PPs), the lamina propria lymphocyte (LPL) compartment, and the intraepithelial lymphocyte (IEL) compartment (Fig. 1).

Peyer's patches are organized lymphoid structures located on the antimesenteric border of the small intestine. These structures resemble lymph nodes in architecture and composition, however they lack afferent lymphatics and sample luminal antigens via specialized antigen-transporting cells known as microfold cells (M cells), which are located in the overlying follicle-associated epithelium. Peyer's patches contain predominantly B-2 B lymphocytes and some αβ T lymphocytes. The organization of the Peyer's patches allows optimal interactions of B lymphocytes, T lymphocytes, and

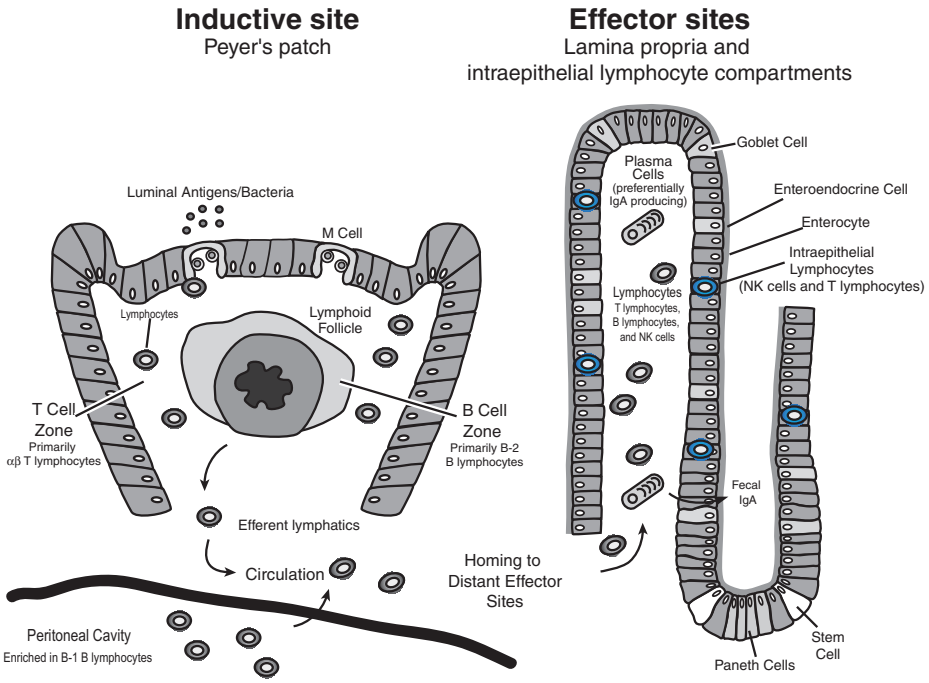

FIGURE 1 Distribution of lymphocytes in the gastrointestinal tract.

APCs for the induction of immune responses. Thus, Peyer's patches are thought to be the site of induction of intestinal immune responses. In the colon, lymphoid nodules, which are structures with an architecture similar to that of the Peyer's patch, are felt to perform analogous functions.

The lamina propria is a loosely organized lymphoid compartment within the supporting stroma of the intestine. The composition of the bone marrow-derived cells within the lamina propria resembles that of the Peyer's patch; in addition, the lamina propria contains a population of NK cells. However, in contrast to the Peyer's patch, a majority of lymphocytes within the lamina propria have a phenotype consistent with previous activation. The lamina propria is the major effector compartment for the intestinal immune response, containing a majority of plasma cells responsible for fecal immunoglobulin production, and is the site of mononuclear cell infiltration and inappropriate inflammatory responses in intestinal inflammatory disorders.

The IEL compartment contains T lymphocytes and NK cells, interspersed among the intestinal epithelial cells. In contrast to more classic lymphoid structures, an increased proportion of T lymphocytes in the IEL compartment bear the γδ TCR and the CD8αα isoform of the CD8 coreceptor, which have been associated with extrathymic T lymphocyte development. The function of intraepithelial lymphocytes is poorly understood.

Homing

The mucosal immune system in general, and the intestine specifically, have a unique ability to transmit antigen-specific immune responses selectively between distant mucosal surfaces. The mechanism allowing these coordinated immune responses is lymphocyte homing, a series of events in which lymphocytes activated by specific antigen at a mucosal surface selectively migrate to and reside in a distant mucosal surface to perform their effector function. Lymphocyte homing to the intestine is a multistep process involving antigen-specific activation of lymphocytes, resulting in the selective migration of these lymphocytes to their effector sites, the LPL and IEL compartments (Fig. 1). Homing is at least partially dependent on induced expression of cell surface molecules (integrins) by lymphocytes in the Peyer's patch. Integrins bind specific receptors on specialized venules in the lamina propria, thus allowing lymphocytes activated in the Peyer's patch to cross these venules and reside in the lamina propria. This multistep process allows for the coordinated transmission of antigen-specific responses between distant mucosal surfaces.

Fecal Immunoglobulin Production

A primary function of the intestinal immune system is the production of fecal immunoglobulin, which is

important for protection against invading organisms at mucosal surfaces. The events resulting in the production of fecal immunoglobulin are complex and involve the activation, migration, and differentiation of both B-1 and B-2 B lymphocytes (Fig. 1). B-1 B-lymphocytes contributing to the pool of plasma cells that produce fecal immunoglobulin arise primarily from the peritoneal cavity and migrate to the intestinal lamina propria to perform their effector function. These B-1 B-lymphocytes undergo differentiation into plasma cells during their migration or shortly after their arrival in the intestinal lamina propria. In contrast, B-2 B-lymphocytes contributing to the pool of plasma cells that produce fecal immunoglobulin arise from organized lymphoid structures and differentiate into plasma cells after their arrival in the intestinal lamina propria. Therefore, understanding the regulation of fecal immunoglobulin production requires accounting for factors inducing the migration and differentiation of two phenotypically and physically distinct subsets of B lymphocytes.

Fecal immunoglobulin is predominantly of the IgA isotype and to a lesser extent of the IgM isotype. Mechanistically, this arises for two reasons: (1) the need for antibody to cross the intestinal epithelium to enter the intestinal lumen and (2) the preference for lamina propria plasma cells to produce immunoglobulin of the IgA isotype. Antibody of the IgA isotype can be formed as monomers or dimers held together by a polypeptide, the J chain. Monomeric IgA is predominant in the serum whereas dimeric IgA predominates in intestinal secretions. Dimeric IgA produced by plasma cells in the intestinal lamina propria has the ability to bind a polymeric immunoglobulin (poly-Ig) receptor on the basolateral surface of intestinal epithelial cells. Binding the poly-Ig receptor allows for the uptake and transport of dimeric IgA across the epithelium into the intestinal lumen. IgM is a pentameric immunoglobulin with the ability to bind the polymeric Ig receptor as well, and therefore IgM may also be transported across the intestinal epithelium into the intestinal lumen. The preponderance of IgA-producing plasma cells in the intestinal lamina propria and the preferential production of dimeric IgA by these plasma cells contribute to making IgA the most abundant immunoglobulin isotype in the intestinal lumen.

CONCLUSION

Lymphocytes are cells comprising B lymphocytes, T lymphocytes, and natural killer cells, all lineages arising from a common lymphoid progenitor in the bone marrow. Lymphocytes circulate throughout the body and perform a wide variety of effector functions in both the early (innate) and late (adaptive) phases of the immune response. In general, lymphocytes can be subclassified into cell types by their expression of cell surface molecules, and by specific immune functions assigned to these cell types. Lymphocytes play a prominent role in host defense and are specifically responsible for carrying out coordinated immune responses between mucosal surfaces and for the production of fecal immunoglobulin. An in-depth understanding of lymphocyte function requires understanding how lymphocytes mature, differentiate into effector cells, and interact with other cells, both bone marrow derived and non-bone marrow derived.

Lymphomas

HYUN SIL KIM
University of California, San Diego

enteropathy-associated T-cell lymphoma (EATL) A clinically aggressive tumor typically seen in patients with a long history of celiac disease. Unlike other gastrointestinal lymphomas, EALT is a T-cell lymphoma derived from the intestinal intraepithelial T-cell population.

mucosa-associated lymphoid tissue (MALT) lymphoma A low-grade primary B-cell gastric lymphoma associated with *Helicobacter pylori* infection; a MALT-like organization of the stomach is induced by chronic gastric inflammation and development of lymphoma.

The gastrointestinal tract is the most common site of extranodal primary lymphoma involvement. The non-Hodgkin's lymphoma is the predominant variety, usually involving the stomach and small intestine, as primary colonic lymphoma constitutes <10% of all gastrointestinal lymphomas. Primary intestinal Hodgkin's lymphoma is relatively rare. Patients who have immunologic disorders, such as collagen vascular disease, congenital immune deficiency syndromes, and acquired immunodeficiency syndrome, have an increased risk of developing gastrointestinal lymphomas. In addition, organ-transplanted patients who have received immunosuppressive agents are at risk of developing lymphomas of the intestine.

NON-HODGKIN'S LYMPHOMA

The majority of intestinal lymphomas are of the non-Hodgkin's type and, except for enteropathy-associated T-cell lymphoma, the B-cell variety predominates. These B-cell lymphomas are categorized according to their histological features: diffuse large cell or small noncleaved cell lymphomas. The stomach is often the most common site of primary lymphoma in Western countries and is seen in 50–80% of cases, followed by the small intestine (10–30%) and the colon (<10%).

Clinical Features

The initial presenting symptoms depend on the site and the extent of lymphomatous involvement, but usually patients will have nonspecific abdominal pain/cramps, weight loss, malaise, abdominal distension, malabsorption, or anemia. Intestinal perforation can also occur, particularly in small intestinal lymphomas. Other complications, such as intussuception and obstruction, have also been reported. Physical examination may be normal, but often abdominal distension or mass may be detected along with occult blood in the stool. Along with history and physical examination, the diagnostic workup usually includes endoscopies for a diagnosis and to obtain tissue specimens, abdominal and pelvic computed tomography, and barium studies of the upper and lower gastrointestinal (GI) tract for localization. Endoscopically, intestinal lymphomas have varied appearances and may present as multifocal ulcerations with irregular margins, nodules, large masses, or diffuse mucosal thickening with loss of normal intestinal folds.

Disease Course

The important considerations for the staging of lymphomas include tumor histology, extraintestinal lymph node involvement, extent of metastasis, and size of the tumor. Poor prognostic features include advanced stage, aggressive tumor growth, tumor mass >7 cm, invasion through the intestinal wall, unresectability, and bcl-2 oncogene rearrangement. The 2-year survival rate is ~80% for the early stage lymphomas, but in the advanced stage, the survival rate decreases to <30%.

Treatment

The therapy for intestinal lymphoma depends on the stage of the disease. Surgical debulking is recommended for patients with high tumor burden followed by chemotherapy and/or radiotherapy to improve survival, even for patients with stage IV disease. Surgical interventions have shown survival benefits, particularly in patients with obstructive tumors and in those who are at high risk of tumor perforation or massive hemorrhage. Since curative resection has been difficult to achieve, especially for the advanced aggressive tumor, a combined treatment plan with surgery, chemotherapy,

 Copyright 2004, Elsevier (USA). All rights reserved.

and radiotherapy has most often been utilized. The most commonly used chemotherapeutic agents for intestinal lymphoma are cyclophosphamide, doxorubicin, prednisone, methotrexate, vincristine, and bleomycin, which are used as a combination treatment. For those patients who demonstrate a complete response to chemotherapy, the predicted 4-year survival rate is 80–85%.

Lymphomas in Human Immunodeficiency Virus

In patients with human immunodeficiency virus infection, the non-Hodgkin's lymphoma of the intestine is the second most common extranodal site affected and has been known to occur in approximately 10% of patients. The majority of these B-cell lymphomas are of a highly aggressive, immunoblastic type. In addition to vague abdominal symptoms, some patients have presented with entero-colonic fistulas and bowel perforation. Epstein–Barr virus, human herpesvirus 8, and Kaposi's sarcoma-associated herpesvirus have been associated with intestinal lymphomas in acquired immunodeficiency syndrome. Treatment options are similar to those for other non-Hodgkin's lymphomas, and surgical debulking procedures, chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone to name a few), and radiation therapy have all been used with variable success. Successful treatment and response depend on the stage of the lymphoma and other prognostic factors, such as tumor histology and cytogenetic abnormalities.

MUCOSA-ASSOCIATED LYMPHOID TISSUE-TYPE LYMPHOMA

Of the primary gastric lymphomas, mucosa-associated lymphoid tissue (MALT) lymphoma has been of a particular interest due to its indolent clinical course and the causative agent that is associated with this type of lymphoma. *Helicobacter pylori* is a multiflagellate microaerophilic bacterium that colonizes the stomach and has been correlated with the induction of gastritis and peptic ulcer disease. In addition, *H. pylori* is associated with low-grade B-cell gastric MALT lymphoma in 80–90% of cases. Low gastric pH is an important aspect of the host defense system against bacterial infection in the stomach; however, *H. pylori* produces urease, which is active at low pH and produces ammonium, which creates a neutral environment where the bacteria can live and multiply. Although the exact pathogenesis of MALT lymphoma from *H. pylori* infection has not been defined, the bacterial infection clearly exerts a strong antigenic stimulus on the host immune response and a prolonged, chronic *H. pylori* infection most likely induces a malignant transformation of activated B cells.

In healthy individuals, MALT is found mostly in the terminal ileum—Peyer's patches being a prime example of this type of organized lymphoid follicle—but MALT lymphoid follicles do not exist in the stomach. However, in the setting of *H. pylori* infection, gastric MALT formation has been demonstrated consistently in all gastric tissues examined and the organism itself has been shown to be an important driving force in the stimulation of tumor-infiltrating lymphocytes. Due to its association with gastric MALT lymphoma and gastric cancer, *H. pylori* is now considered an infectious carcinogen.

Patients with MALT lymphoma will have clinical symptoms similar to those with peptic ulcer disease or gastritis, which include epigastric pain, nausea, dyspepsia, and bleeding. Endoscopy of the stomach may show gastritis, ulceration, or erosion. Since the antrum and distal body are common sites of *H. pylori* infection, gastric MALT lymphomas occur mostly at these sites, although any area of the stomach can be affected. Histologically, the structure of the MALT lymphoma resembles Peyer's patches and displays diffuse reactive polymorphic lymphoid follicles, which are notable for small- to medium-sized B cells infiltrating the epithelium in low-grade MALT lymphoma. Characteristic lymphoepithelial lesions with invasion of the epithelium by neoplastic B cells, or centrocytes, are prominent histologic features and immunohistologic staining of these lesions with pan-B-cell antibodies will be positive. Unlike other nodal B-cell lymphomas, MALT lymphoma has different genotypes and is characteristically negative for *bcl*-2 oncogene rearrangement. It has also been reported that trisomy 3 occurs in >60% cases of low-grade MALT lymphoma. One genetic defect, t(11;18) (q21;q21), has been observed to occur specifically in MALT lymphomas and this particular translocation defect was seen in approximately 65% of patients who do not respond to *H. pylori* eradication.

For the treatment of low-grade MALT lymphoma, eradication of *H. pylori* with various combinations of antibiotics has been shown to induce clinical remission in 70–90% of cases. Zithromycin, ampicillin, flagyl, and tetracycline along with acid suppressive agents have been commonly used for *H. pylori* treatment. Although MALT lymphoma is an indolent tumor and responds well to antibiotics for tumor regression, high-grade MALT lymphoma generally does not respond to the standard *H. pylori* therapy. Combinations of chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone, radiotherapy, and (or) gastric resection

have shown various survival rates ranging from 50 to 100% in those patients who did not respond to anti-*H. pylori* treatment.

ENTEROPATHY-ASSOCIATED T-CELL LYMPHOMA

In a subset of patients with a long history of celiac disease, enteropathy-associated T-cell lymphoma (EATL) has been observed. In contrast to the majority of primary intestinal lymphomas, which are of B-cell origin, EATL is strictly a T-cell lymphoma. As a complication of the disease, EATL is typically seen in the fifth decade of life and can occur even in the setting of a strict compliance with a gluten-free diet. Patients can present with abdominal pain, diarrhea, weight loss, and anemia and symptoms may resemble those with recurrent or refractory celiac disease.

The most common site of EATL involvement is the jejunum and EATL can be multifocal. Endoscopically, mucosal ulcerations of the small intestine may be observed. Immunohistologic studies of the bowel specimens from EATL demonstrate clonal rearrangements of the T-cell receptor in $>90\%$ of the tumors examined and, in some patients, showed identical T-cell receptor gene arrangements in the tumor and in the adjacent diseased intestine. Thus, EATL is believed to arise from a clonal transformation of inflammatory intestinal intraepithelial T cells into malignant lymphoma. The exact mechanism of development of enteropathy-associated T-cell lymphoma from chronic enteropathy due to gluten intolerance is unknown, although some studies have linked Epstein-Barr virus infection with the development of EATL in patients with celiac disease.

Generally, EATL follows a highly aggressive clinical course and carries a poor prognosis. One study has reported a 5-year survival of $<10\%$ with $\sim 50\%$ mortality rate within 6 months of diagnosis. Therefore, although current chemotherapeutic regimens and surgical intervention have shown some success, early clinical suspicion and detection in patients with long-standing celiac disease who develop diarrhea and other symptoms are strongly recommended.

Lynch Syndrome/Hereditary Non-Polyposis Colorectal Cancer (HNPCC)

C. RICHARD BOLAND
Baylor University Medical Center, Dallas

DNA mismatch repair system Group of proteins that recognize and correct errors made by DNA polymerase during DNA replication.
germ-line mutation Parentally inherited mutation that is present in every cell of the body.
human Mut S homologue 2 Mismatch repair gene.
microsatellite Short, repetitive DNA sequence; repeats consist most commonly of mononucleotide repeats (A_n, G_n, etc.), dinucleotide repeats ($[Ca_n]$), trinucleotide repeats, or occasionally tetranucleotide or pentanucleotide repeats. Poly(A) or dinucleotide repeats are, by far, the most common of these. These repetitive sequences are highly prone to insertion or deletion mutations during DNA replication, and require DNA mismatch repair activity for faithful replication.
microsatellite instability Mutational signature in which ubiquitous errors are seen in repetitive DNA sequences as a consequence of losing mismatch repair activity.
somatic mutation Acquired mutation in a non-germ-line tissue.

Lynch syndrome is one of the familial, genetic forms of colorectal cancer. It is inherited as an autosomal dominant disease caused by a germ-line mutation in one of the genes involved in DNA mismatch. Historically, the disease has also been called hereditary non-polyposis colorectal cancer to distinguish it from the far less common, but phenotypically more distinctive disease, familial adenomatous polyposis. Familial adenomatous polyposis is characterized by hundreds to thousands of premalignant adenomatous polyps, which antedate the onset of cancer. In Lynch syndrome, the number of antecedent adenomas is relatively small, but these are prone to rapid conversion into cancers. Thus, Lynch syndrome is characterized by some precursor polyps, but not florid polyposis, and a very high risk for cancers of the colorectum and other sites.

INTRODUCTION

Colorectal cancer is a very common and highly lethal disease that affects approximately 150,000 Americans each year. Approximately one-third of these patients will succumb to this disease; however, the outcome is highly dependent on the stage of disease at the time of diagnosis. Diagnosis of the disease in stage 1 or 2 can lead to a cure in 80–95% of the cases.

Familial clusters of cancer occurring in young people raise the possibility of Lynch syndrome. The diagnosis is first suspected on clinical grounds when the "Amsterdam criteria" are met. These consist of a family with at least three members with a characteristic cancer of this disease (see later), one of whom is a first-degree relative of the other two, in which one person has developed cancer at age 50 or less, and familial adenomatous polyposis (FAP) has been ruled out. About 2–3% of all colorectal cancers are thought to be Lynch syndrome on the basis of a germ-line mutation in a DNA mismatch repair (MMR) gene. The actual number of cancers that are caused by germ-line mutations in a DNA MMR gene is probably higher than currently appreciated, because the current technologies can identify mutations only half the time, even in well-characterized families. When a definitive diagnosis can be made by finding a germ-line mutation in a DNA MMR gene, the disease can be called Lynch syndrome. Other names historically associated with this disease include cancer family syndrome and site-specific hereditary colon cancer. These terms are misleading because they imply that the colon is the exclusive organ at risk for cancer, which is not the case.

CLINICAL MANIFESTATIONS

The average age to develop a sporadic colon cancer in the United States is approximately 69 years. In the setting of Lynch syndrome, the average age is approximately 40–45 years. Patients with Lynch syndrome are at risk for cancer of several different organs; however, not every organ is at increased risk for cancer. The lifetime risk for any cancer by age 70 in this disease is estimated to be 91% for men and 69% for women. The lifetime risk of colon cancer is approximately 70% for men and 30% for women. Women with Lynch syndrome have a 40% lifetime risk of developing endometrial cancer. There are substantially increased risks for cancers of the stomach, small intestine, ovaries,

 Copyright 2004, Elsevier (USA). All rights reserved.

renal pelvis, ureter, pancreas, central nervous system, and hepatobiliary system. However, there is no increased risk for cancers of the lung or breast, for example. The premorbid phenotype is, with some exceptions, normal for carriers of a mutant DNA MMR gene. The premier feature of the disease is the sharp increase in cancer risk and the earlier age of onset of disease compared with the sporadic forms. In general, these cancers develop about 25 years earlier than would be expected for sporadic disease. Approximately 75% of sporadic colon cancers occur distal to the splenic flexure, most occurring in the sigmoid colon and rectum. In Lynch syndrome, 60–70% of colon cancers occur proximal to the splenic flexure. The biological basis of the proximal predilection is unknown.

Lynch syndrome colon cancers have a tendency to be associated with certain unique pathological features. These colon cancers have a tendency to appear poorly differentiated or medullary and to be mucinous, and a very high proportion is diploid or near-diploid. Some of these tumors show an intense Crohn-like reaction with a large number of tumor-infiltrating lymphocytes. Although none of these features is present in the majority of colon cancers, one or more of the features will be present often enough that an experienced pathologist can be suspicious of Lynch syndrome in a young patient with a proximal colon cancer that has these pathological features. The colons of patients with Lynch syndrome are not characterized by diffuse polyposis; however, there is an excess number of adenomatous polyps in young people with Lynch syndrome. The available data suggest that these benign polyps progress to malignancy at an accelerated rate compared to sporadic polyps. Thus, accelerated progression of the disease is thought to be a key clinical characteristic, which dictates the management as well. A study of patients with Lynch syndrome at a median age of 42 years found an incidence of adenomatous polyps of 30%; 18% of the patients had proximal colonic adenomas and 20% had multiple colonic adenomas. By contrast, control age-matched patients had an overall incidence of adenomatous polyps of 11%, in which 1% were proximal, and 4% of patients had multiple polyps. Additionally, there is a striking increase in polyps with advancing age as seen in Lynch syndrome patients compared with sporadic patients.

THE GENETIC BASIS OF LYNCH SYNDROME

The DNA MMR system consists of a group of proteins that cooperate to recognize and repair errors made in the DNA sequence during replication; some of these genes are linked to Lynch syndrome (see Table I). Two of the genes, *human Mut L homologue 2* and *human Mut L homologue 6* (*hMSH2* and *hMLH1*), are the "major" DNA MMR genes. The proteins coded by these genes will heterodimerize with a homologous protein, hMSH6 and hPMS2, respectively, to form working protein complexes that will both recognize mismatched DNA during its replication and lead to excision of that region followed by resynthesis, which repairs the error. hMSH2 + hMSH6 is the principal heterodimer that recognizes single base-pair mismatches and short "loop-outs" in the DNA that occasionally occur during an attempt to replicate a repetitive sequence. When the DNA polymerase encounters a mononucleotide repeat or a dinucleotide repeat, a small proportion of these, perhaps 1 in 100 to 1 in 1000, suffer a deletion of one or more repetitive elements in the newly synthesized strand, and the nascent double-stranded DNA will have a loop-out on the template strand. If not corrected, the daughter DNA strand will be shorter by one repeat element after the next round of replication. The DNA MMR system recognizes these errors, and corrects them.

The hMSH2 protein can alternatively heterodimerize with the hMSH3 protein, and this protein pair has specificity that recognizes larger loop-outs than those bound by hMSH2 + hMSH6. Thus, by having diverse proteins within the cell, a broad range of

TABLE I DNA Mismatch Repair Gene Mutations and Lynch Syndrome

Gene	Chromosome	Link with cancer
Common cause		
hMSH2	2p16	40–50% of families meeting Amsterdam criteria
hMLH1	3p21	40–50% of families meeting Amsterdam criteria
hMSH6	2p16	Causes attenuated Lynch syndrome in 8% of familial clusters of colon cancer that do not meet Amsterdam criteria
Less common		
hPMS2	7p22	Uncommon cause; mutations may be homozygous in some families (AR)
hMLH3	14q24.3	Uncommon cause of Lynch syndrome
No apparent link		
hPMS1	2q31	Not found in Lynch syndrome families
hMSH3	5q11–q13	Not found in Lynch syndrome families

replication errors can be recognized. The hMLH1 protein dimerizes with hPMS2 to complete the DNA repair process. The biochemical and biophysical details of this are not completely understood. Two additional proteins, hMLH3 and hPMS1, can also heterodimerize with hMLH1, but again, the functions of these complexes are not entirely understood; presumably, they add to the ability of the system to recognize and repair different types of replication errors.

Lynch syndrome is suspected on the basis of a strong family history in which the Amsterdam criteria are met. In about half of such families, a germ-line mutation can be found in either *hMSH2* or *hMLH1*. The proportion of mutations found in these two genes is approximately equal and depends on "founder effects" in the population. In addition, a small proportion of families with Lynch syndrome will have germ-line mutations in the *hMSH6* gene. However, because *hMSH6* is not absolutely essential for at least partial DNA MMR activity, patients with this mutation have an attenuated form of the disease. In the case of *hMSH6* germ-line mutations, the median age to develop cancer is approximately 60 years and the penetrance for colon cancer is substantially lower, but women are still at a similar risk for endometrial cancer. Thus, germ-line mutations in *hMSH6* have been called "attenuated Lynch syndrome." In one study of familial clusters of colon cancer in which the Amsterdam criteria were not met, over 8% had germ-line mutations in *hMSH6*.

Rare families have germ-line mutations in *hPMS2*; some of these families have homozygous mutations in this gene. It is not clear whether the very small number of families linked to this gene reflect the requirement for homozygous mutations, but if this is the case, it could explain recessive inheritance patterns. Germ-line mutations in *hMLH3* have been found in Lynch syndrome, but these are much less common compared to mutations in *hMSH2* or *hMLH1*. Individuals who have a germ-line mutation in a critical DNA MMR gene have one mutated and one wild-type copy of the gene. The DNA MMR activity in these cells is normal. A second mutation or other genetic event is required to inactivate the wild-type allele inherited from the unaffected parent. When this occurs, the cell becomes deficient in DNA MMR activity. MMR deficiency is not, per se, sufficient to create a neoplastic phenotype. Loss of DNA MMR activity accelerates the accumulation of mutations occurring throughout the genome, particularly at microsatellite sequences.

Most microsatellite sequences occur in introns or between genes. Mutations in these sequences are thought to be innocuous. However, point mutations can occur in critical genes, and deletion mutations are very likely to occur at microsatellite sequences in the coding regions of genes. Many genes with coding microsatellites have been identified that encode a protein critical to the regulation of the growth of epithelial cells (see Table II). Mutations in these "target genes" mediate the development of neoplasms in the colon, endometrium, and elsewhere. These genes are normal in most tissues but are mutated in the tumors.

A tumor from a patient with Lynch syndrome contains thousands of microsatellite mutations, referred to as microsatellite instability (MSI). (There are hundreds of thousands of these sequences in the genome.) An indirect way to help confirm a suspicion of Lynch syndrome is to determine whether the tumor has MSI. Finding this molecular signature in a tumor indicates that the tumor developed in the absence of DNA MMR activity. About 12–15% of all colorectal cancers have MSI, but only about 25% of these are attributable to Lynch syndrome. The other 75% are due to an acquired silencing of the *hMLH1* gene, by hypermethylation of the gene promoter. When a tumor has MSI, immunohistochemistry can detect hMSH2 and hMLH1 proteins. The absence of expression of one of these two proteins strongly suggests its involvement in causing the disease. The absence of hMSH2 expression almost always indicates Lynch syndrome. However, hMLH1 staining involves additional consideration. It may not be expressed due to the acquired silencing of its gene (which usually occurs in older individuals, making it easier to distinguish from Lynch syndrome). Also, some missense mutations in hMLH1 inactivate the protein, but do not abrogate its immunoreactivity.

Some complexity in genotype–phenotype relationships has been found. The simultaneous presence of a common and otherwise innocuous polymorphism in the cyclin D1 gene is associated with a median onset of cancer 10 years younger in some kindreds with *hMSH2* mutations, creating a more virulent situation. Germ-line mutations in the *hMSH6* gene lead to a more attenuated form of the disease, with lower penetrance, later onset, and a slight modification of target organs that develop cancer. Some patients have additional skin lesions, including multiple sebaceous neoplasms and keratoacanthomas; this is referred to as the Muir–Torre syndrome and is usually associated with germ-line mutations in the *hMSH2* gene.

MANAGEMENT OF LYNCH SYNDROME

Managing families with Lynch syndrome is a multidisciplinary undertaking. First, such families are identified by obtaining a family history; the diagnosis is confirmed with a blood test (commercially available) for a

TABLE II Target Genes of Microsatellite Instability

Repeat sequence: A10
- *TGFβ2R* (regulates colonic cell growth)

germ-line mutation. Before patients have blood drawn for genetic testing, they should be evaluated by a genetic counselor, to ensure that they understand all of the implications of testing before the blood is drawn. Genetic counseling can be performed successfully by interviewing several family members at once; however, it may be wise to counsel members individually, because, in some cases, patients may elect not to be tested. It is not universally guaranteed that patients carrying a germ-line mutation in one of these genes will not suffer discrimination when attempting to obtain health or life insurance.

Genetic testing for germ-line mutations in the DNA MMR genes is successful in only 50% of well-characterized families. The family member most likely on a clinical basis to be a true carrier of the mutation should be tested. A positive test in this person can be used to make or exclude the diagnosis in other members of that family. A negative test is useful only once the index case is characterized. Otherwise, negative genetic tests cannot be interpreted, because it is not possible to distinguish between a mutation not being present and one that is simply not detectable.

Patients with Lynch syndrome who develop invasive colon cancers should undergo surgical resection. If surgery is to be undertaken, a subtotal colectomy is preferred over more localized surgeries to remove as much at-risk colon as possible. It is not necessary to remove the rectum in such patients, which makes the treatment more acceptable to most individuals. The rectal segment must be examined on a regular basis thereafter. Some patients may inquire about a prophylactic colectomy should they be a gene carrier. This is an acceptable approach; however, careful intensive surveillance colonoscopy may obviate the necessity for colonic resection.

Patients with advanced (stage 3 or 4) colorectal cancer should be offered chemotherapy. Interestingly, loss of the DNA MMR activity *in vitro* confers resistance to many chemotherapeutic agents. However, empirically, patients with Lynch syndrome have a better survival rate than do patients with sporadic disease, and those given adjuvant chemotherapy have a better response than is seen in the sporadic situation. Moreover, because patients are typically younger when they present with the disease, they characteristically tolerate the treatment well.

When a germ-line mutation is found in an individual who has not yet developed a colorectal cancer, colonoscopy should be performed every 1−2 years. One clinical study indicated that performance of a colonoscopy every 3 years significantly reduced the mortality due to colorectal cancer. Performing colonoscopy with careful inspection for tiny adenomas

and removing all such lesions may prevent the development of cancer, and surveillance is also likely to detect earlier stage cancers. It is not known whether the benefits of annual colonoscopy outweigh the potential hazards of such repetitive surveillance, so the optimal surveillance interval is still debatable.

Patients with Lynch syndrome are at increased risk for cancer of the endometrium and ovaries. Surveillance of these organs is not as effective in preventing invasive cancer compared to colonoscopic surveillance in reducing colorectal cancer. Thus, women with Lynch syndrome should be encouraged to have their uterus and ovaries removed once they have completed their childbearing.

Lynch syndrome patients have fourfold increase in gastric cancer, and the median onset of disease is approximately 56 years. It is not known whether surveillance endoscopic examinations will be of benefit in preventing death due to gastric cancer. This disease does not develop through an adenoma–carcinoma sequence, so there is no apparent benefit by periodic examination to remove premalignant lesions. Likewise, no preventive strategies have been reported to be useful in preventing death due to cancers of the small intestine, urinary tract, pancreas, or brain. Periodic history and physical examination and prompt attention to new symptoms are all that can be offered. Finally, it is not known whether aspirin or other nonsteroidal antiinflammatory drugs will prevent this disease or alter the natural history of patients with Lynch syndrome.

gadolinium chelate Magnetic resonance imaging intravenous contrast agent consisting of a complex of an organic ligand and a lanthanide metal.
in-phase gradient echo Magnetic resonance pulse sequence in which signals from lipid and water are additive.
opposed-phase gradient echo Magnetic resonance pulse sequence in which signals from lipid and water are subtractive. Used to demonstrate the presence of lipid.
pulse sequence Technical parameters consisting of a set of radiofrequency pulses, magnetic gradient pulses, and the time intervals between pulses used to create the image and image contrast on magnetic resonance images.
short tau inversion recovery (STIR) Magnetic resonance pulse sequence in which T1- and T2-dependent contrasts are additive and signal from fat is suppressed.
susceptibility Ratio of the intensity of magnetization induced in a substance to the intensity of the magnetic field to which the substance is exposed.
T1 weighted Magnetic resonance pulse sequence designed to distinguish tissues with differing T1 relaxation times.
T2 weighted Magnetic resonance pulse sequence designed to distinguish tissues with differing T2 relaxation times.

Objectives of liver, biliary, and pancreatic imaging with magnetic resonance include screening for the presence of disease, characterization of lesions, anatomic localization, evaluation of interval change during the course of treatment, and assessment of vascular anatomy and patency. Magnetic resonance imaging offers excellent soft tissue contrast, versatility, multiplanar capability, and the possibility of a comprehensive exam that can obviate the need for other studies. In clinical practice, magnetic resonance imaging may be utilized as a primary diagnostic imaging exam or as a problem solver when other imaging studies are inconclusive.

INTRODUCTION

Because of the versatility and complexity of magnetic resonance imaging (MRI), exams must be tailored for specific clinical indications. Routine MRI examinations are designed to utilize different techniques to maximize tissue contrast and characterize tissue composition. The basic pulse sequences include a T1-weighted sequence, a T2-weighted sequence, and dynamic contrast-enhanced T1-weighted sequences. Tissues are described according to their signal intensity on the different sequences. For instance, fluid will demonstrate hyperintensity on T2-weighted sequences and hypointensity on T1-weighted sequences. Adipose tissue will demonstrate hyperintensity on T1-weighted sequences. A signal from lipid may be eliminated with a variety of fat-suppression techniques.

LIVER

Technique

In general, a hepatic MRI exam consists of the following pulse sequences:

1. T2 weighted or short tau inversion recovery (STIR).
2. In-phase and opposed-phase breath-hold T1-weighted gradient echo (GRE).
3. Dynamic gadolinium-chelate-enhanced breath-hold fat-suppressed T1-weighted gradient echo obtained during the arterial dominant, portal venous, and equilibrium phases. Three-dimensional volume acquisitions permit multiplanar reconstruction, volumetric renderings, and MR angiograms (MRAs), which may be useful for diagnosis and surgical planning.
4. Additional pulse sequences may used for specific indications.

Specialized "liver specific" intravenous contrast agents, such as various forms of superparamagnetic iron oxide (SPIO) particles and mangafodipir trisodium, may improve the detection and characterization of some liver tumors.

Diffuse Liver Disease

Fatty Infiltration

Diffuse fatty infiltration, or hepatic steatosis, is a common condition characterized by accumulation of lipid within hepatocytes. The most common causes include alcohol, obesity, diabetes mellitus, and malnutrition. Although fatty infiltration is a benign condition, a subset of patients may a progress to a hepatitis-like

 Copyright 2004, Elsevier (USA). All rights reserved.

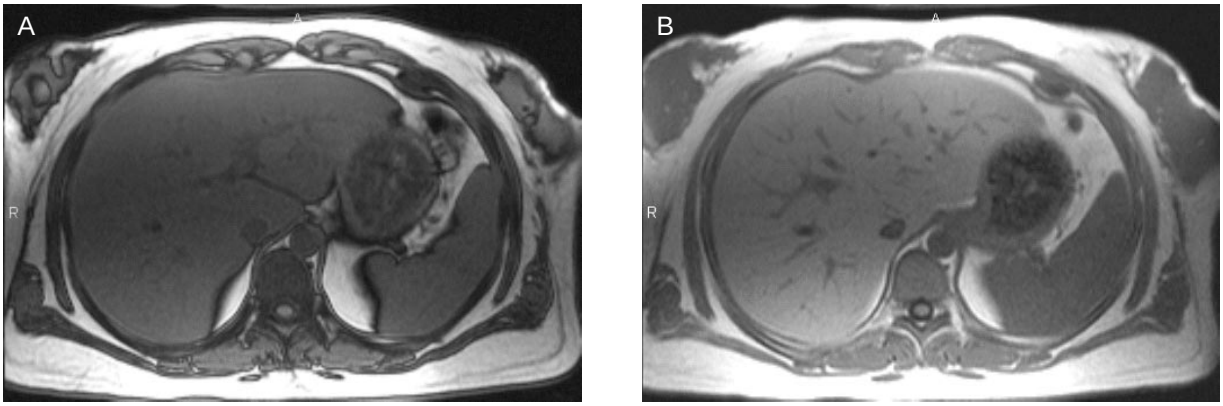

FIGURE 1 Opposed-phase (A) gradient echo image, showing a decrease in liver signal compared with in-phase image (B), which is diagnostic of diffuse fatty infiltration.

picture and ultimately cirrhosis. Consequently, MRI may play a role in establishing the diagnosis as well as in monitoring patients for complications.

Diffuse fatty infiltration is diagnosed by the loss of liver signal on opposed-phase images, compared to that on in-phase ones (Fig. 1). Focal forms of fatty infiltration, which can simulate a tumor on computed tomography (CT) or ultrasound, can be readily distinguished from a mass lesion on MRI by the absence of associated mass effect and the demonstration of lipid using chemical shift techniques.

Iron Deposition

MRI characteristics of iron deposition rely on the magnetic susceptibility effects of iron, resulting in loss of signal intensity on MR images with certain pulse sequences (Fig. 2). Primary or hereditary hemochromatosis is an autosomal recessive disorder exhibiting incomplete penetrance. Commonly involved organs include the liver, pancreas, myocardium, pituitary gland, and synovium. In the liver, the iron is deposited in hepatocytes. Untreated, patients may develop cirrhosis and liver failure. MRI clarifies the distribution of iron deposition within the body and monitors for the progression of complications. MRI can demonstrate the findings of cirrhosis and development of hepatocellular carcinoma. It is not uncommon for hemochromatosis to be diagnosed initially by MRI performed for unrelated reasons.

Hemosiderosis occurs secondary to dyserythropoiesis or transfusional iron overload states. Excess iron accumulates in the reticuloendothelial system, including the spleen, bone marrow, and Kupffer cells in the liver.

Cirrhosis

Cirrhosis is a chronic diffuse liver disease characterized by hepatic regeneration and fibrosis. The most common causes include alcohol abuse, chronic viral hepatitis, hemochromatosis, autoimmune chronic hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, and drug toxicity. MRI can be used to establish the diagnosis and monitor for the development of complications, including ascites, varices, portal vein thrombosis, and hepatocellular carcinoma.

Although the morphologic changes in cirrhosis are quite variable, depending on the etiology, early cirrhosis may include "central atrophy" characterized by enlargement of the hilar periportal space and expansion of the major interlobar fissure and gallbladder fossa. As cirrhosis progresses, morphologic changes include nodularity of the surface contour and parenchyma secondary to regenerative nodules and proliferating hepatocytes surrounded by fibrous septa (Fig. 3).

Regenerative nodules have characteristic features on MRI that usually allow confident distinction from hepatocellular carcinoma. Most commonly, they are isointense with other background nodules on both T1-weighted and T2-weighted images. Occasionally, they may be hyperintense on T1-weighted images and

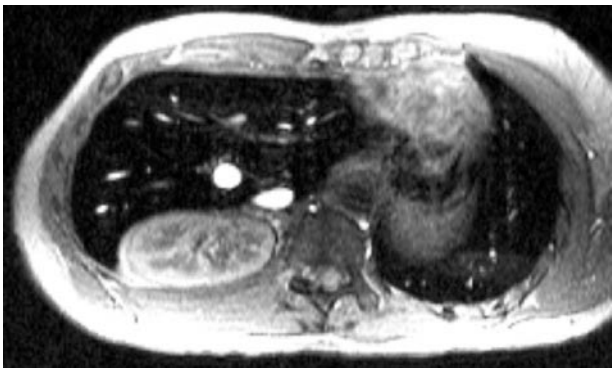

FIGURE 2 T2-weighted image, showing extremely dark liver due to iron overload.

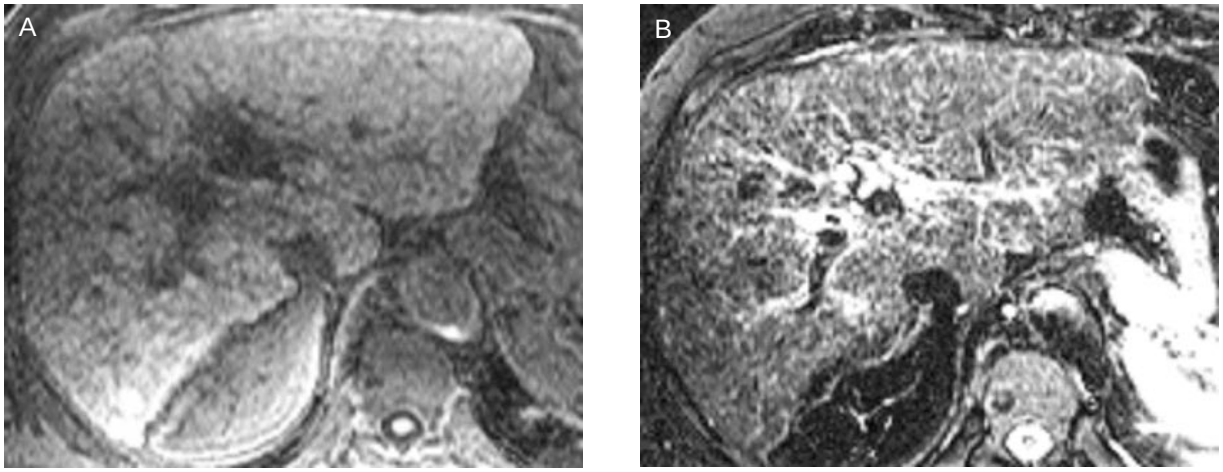

FIGURE 3 T1-weighted (A) and T2-weighted (B) images, showing nodular contour of a cirrhotic liver containing innumerable regenerative nodules.

hypointense on T2-weighted images. However, unlike hepatocellular carcinoma, they are rarely hyperintense on T2-weighted images with the exception of those that occur in the setting of chronic Budd–Chiari syndrome. Some regenerative nodules contain iron and demonstrate low signal intensity on all nonenhanced sequences. However, these benign siderotic regenerative nodules cannot be reliably differentiated from iron-containing dysplastic nodules, which may be premalignant lesions. Because regenerative nodules invariably have a portal venous blood supply with minimal contribution from the hepatic artery, they rarely enhance more than background liver during the hepatic arterial phase of gadolinium-enhanced study.

Another manifestation of cirrhosis, which may mimic a mass lesion, is confluent hepatic fibrosis. On MRI, confluent hepatic fibrosis may be isointense or hypointense on T1-weighted images and hyperintense on T2-weighted images. The contrast enhancement pattern is variable. The presence of capsular retraction from volume loss and scarring helps differentiate this process from a hepatoma (Fig. 4).

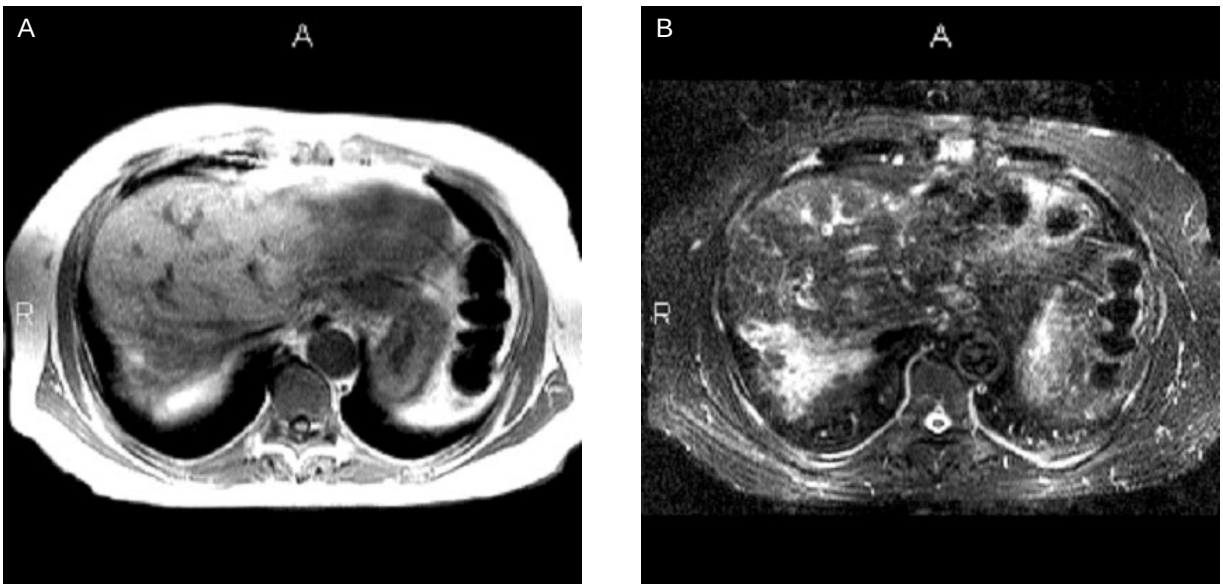

FIGURE 4 T1-weighted (A) and fat-suppressed T2-weighted (B) images of a liver with cirrhosis secondary to sclerosing cholangitis, showing liver capsule retraction adjacent to an area of confluent hepatic fibrosis in the posterior segment of the right lobe.

Focal Liver Disease

Cavernous Hemangioma

Cavernous hemangiomas are the most common benign hepatic neoplasm. They are often discovered incidentally with no clinical consequences. On MRI, cavernous hemangiomas are well-defined round or lobulated lesions. They are usually hypointense on T1-weighted sequences and very hyperintense on T2-weighted sequences, approaching the signal characteristics of fluid. The contrast-enhanced features of cavernous hemangiomas differentiate them from hypervascular or cystic malignant neoplasms. Most commonly, cavernous hemangiomas demonstrate peripheral nodular enhancement with progressive centripetal filling in. In some cavernous hemangiomas smaller than 1.5 cm, immediate homogeneous enhancement may be observed. In larger cavernous hemangiomas, the central portion may not enhance owing to fibrosis, thrombosis, or calcification.

Hepatic Cyst

Hepatic cysts are common benign lesions that occur in 2–10% of the population. They may be solitary or multiple and range in size from a few millimeters to several centimeters. Hepatic cysts are usually discovered incidentally and have no malignant potential. On MRI, they are well-defined round or oval lesions with thin, almost imperceptible walls. Simple cysts are very hypointense on T1-weighted sequences and very hyperintense on T2-weighted sequences, corresponding to the signal characteristics of fluid. Additionally, simple cysts demonstrate no internal architecture and no gadolinium contrast enhancement. Biliary hamartoma may be indistinguishable from simple hepatic cysts but are also benign entities.

Hepatic Abscess

Hepatic abscesses may result from bacterial, fungal, or parasitic infection. In the United States, bacterial abscesses are most common. Worldwide, however, parasitic abscesses, in particular, are most common. On MRI, hepatic abscesses have nonspecific imaging characteristics. In the appropriate clinical setting, multiple lesions demonstrating hyperintensity on T2-weighted images with perilesional edema and rim enhancement are suggestive of abscesses.

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is the second most common benign hepatic neoplasm. It is believed to result from a hyperplastic response to a preexisting vascular malformation. FNHs contain disorganized nodules of hepatocytes and Kupffer cells that are separated by small bile ducts lacking communication with the normal biliary tree. FNHs are usually solitary and less than 5 cm in diameter. They are most often found in women.

MRI characteristics of FNH include isointensity or slight hypointensity compared with normal hepatic parenchyma on the T1-weighted sequences and slight hyperintensity or isointensity on the T2-weighted sequences (Fig. 5). FNH is usually homogeneous in signal intensity with the exception of the central scar. The central scar is hypointense to the lesion and surrounding liver on the T1-weighted sequences (T1-Ws) and hyperintense on the T2-weighted sequences.

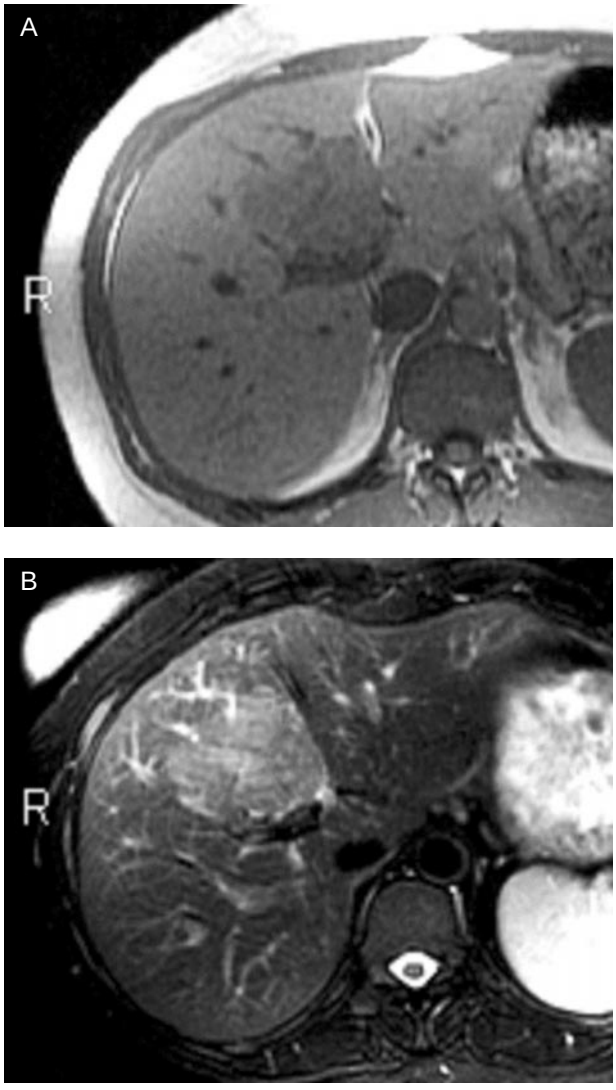

FIGURE 5 Characteristic MRI appearance of focal nodular hyperplasia that is slightly hypointense on the T1-weighted image (A) and slightly hyperintense on the T2-weighted image (B).

Following gadolinium chelate administration, the lesion demonstrates marked homogeneous intense enhancement in the arterial phase, homogeneous washout in the portal venous phase, and isointensity or mild hyperintensity in the portal venous phase. The central scar demonstrates delayed enhancement. Only approximately 40% of FNHs exhibit all of these MRI characteristics and can be definitively characterized with MRI.

Hepatocellular Adenoma

Hepatocellular adenoma is a benign hepatic neoplasm composed of hepatocytes with an absence of normal portal structures. This rare neoplasm is seen in association with oral contraceptive use, anabolic–androgenic steroid use, and glycogen storage disease types I and III. Complications include acute hemorrhage and rare malignant transformation.

On MRI, hepatic adenomas demonstrate heterogeneous signal intensity on T1-weighted and T2-weighted sequences (Fig. 6). On T1-weighted images, foci of hyperintensity may be present from prior hemorrhage. Foci of hypointensity may represent necrosis or calcification. Adenomas commonly contain lipid. With dynamic gadolinium-enhanced imaging, intense heterogeneous arterial phase enhancement is often seen.

Dysplastic Nodules

Dysplastic nodules (DNs) are found in 14–38% of cirrhotic livers and are considered by many to be premalignant lesions. On gross pathological examination, DNs are distinguished from regenerative nodules (RNs) on the basis of size (usually >8 mm), color, texture, or the degree to which they bulge from the cut surface of the liver.

DNs are categorized as low- and high-grade lesions. Histologically, low-grade DNs contain hepatocytes that are minimally abnormal without architectural or cytological atypia. They usually contain portal tracts and hepatic venules and may contain iron or copper. High-grade DNs have cellular and architectural atypia. Some high-grade dysplastic nodules may contain subnodules of overt hepatocellular carcinomas (HCCs), the majority of which are well differentiated.

There is significant overlap in the MRI appearance of DNs and small hepatocellular carcinomas. Most commonly, DNs are hyperintense on T1-Ws and hypointense on T2-Ws (Fig. 7), a pattern that is also present with some small HCCs. Close MRI monitoring of cirrhotic patients who have known DNs is recommended in order to detect changes that may herald transformation into hepatocellular carcinoma.

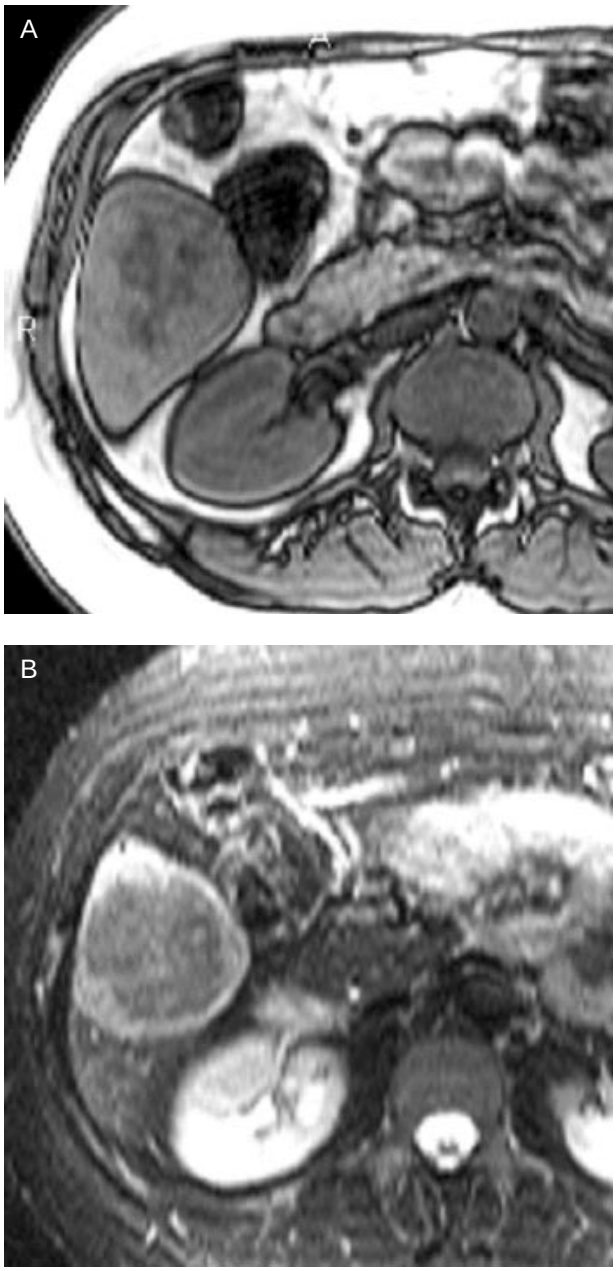

FIGURE 6 Characteristic MRI appearance of hepatocellular adenoma, which demonstrates heterogeneous signal intensity on T1-weighted (A) and T2-weighted sequences (B).

Hepatocellular Carcinoma

Hepatocellular carcinoma is the most common primary hepatic malignancy. It usually occurs in the setting of chronic liver disease and cirrhosis secondary to hepatitis B and C, alcohol abuse, hemochromatosis, and aflatoxin exposure. On MRI, hepatocellular carcinoma may present as a solitary mass, multifocal masses, or a diffusely infiltrating lesion. Vascular invasion is common.

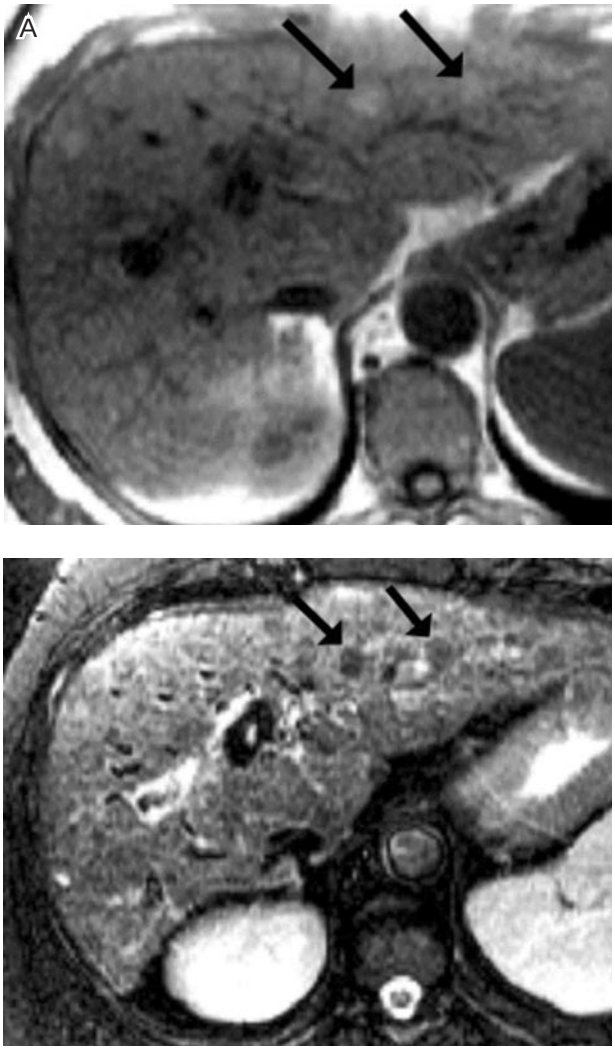

FIGURE 7 Characteristic MRI appearance in a cirrhotic liver of dysplastic nodules (arrows) that are hyperintense on T1-weighted images (A) and hypointense on T2-weighted images (B).

The signal intensity characteristics on T1-weighted and T2-weighted images are highly variable, but they are most commonly moderately hyperintense on T2-weighted images (Fig. 8).

The contrast enhancement pattern is dependent on the degree of tumor differentiation and vascularity. The most common enhancement pattern for small HCCs (<2.0 cm) is diffuse, homogeneous enhancement during the arterial phase with rapid washout during the portal venous phase (Fig. 8). Enhancement of a nodule or a focus within a nodule during the arterial phase favors a diagnosis of hepatocellular carcinoma, because DNs usually have a predominantly portal venous blood supply. Well-differentiated hepatomas demonstrate minimal arterial enhancement that washes out on the portal venous phase. Moderate and poorly differentiated tumors demonstrate marked arterial enhancement. In a cirrhotic liver, any focus of abnormal arterial phase enhancement should be considered a hepatocellular carcinoma until proved otherwise. However, as many as 4% of low-grade DNs and 32% of high-grade DNs may have an arterial blood supply. Thus, enhancement of a hepatic nodule during the arterial phase, once thought to be diagnostic of malignancy, can also occur with DNs.

In one study, triphasic helical CT detected 17% of HCCs 2–10 mm in size, 29% 11–20 mm in size, and 63% that were >20 mm; 8% had a false positive CT. In another study, dynamic contrast-enhanced MRI had an overall sensitivity of 37% for HCCs due to the inability to detect the large number of tumors less than 10 mm in size. However, the sensitivity for detecting HCCs >10 mm was 89%.

Metastasis

On MRI, hepatic metastases often demonstrate hypointensity on T1-weighted images and hyperintensity on T2-weighted images (Fig. 9). Occasionally they are difficult to detect on non-contrast-enhanced images. Hypervascular metastases may be identified only on arterial phase images. On the portal venous phase, metastases may demonstrate inhomogeneous or ring enhancement with early peripheral washout (Fig. 9).

BILIARY SYSTEM

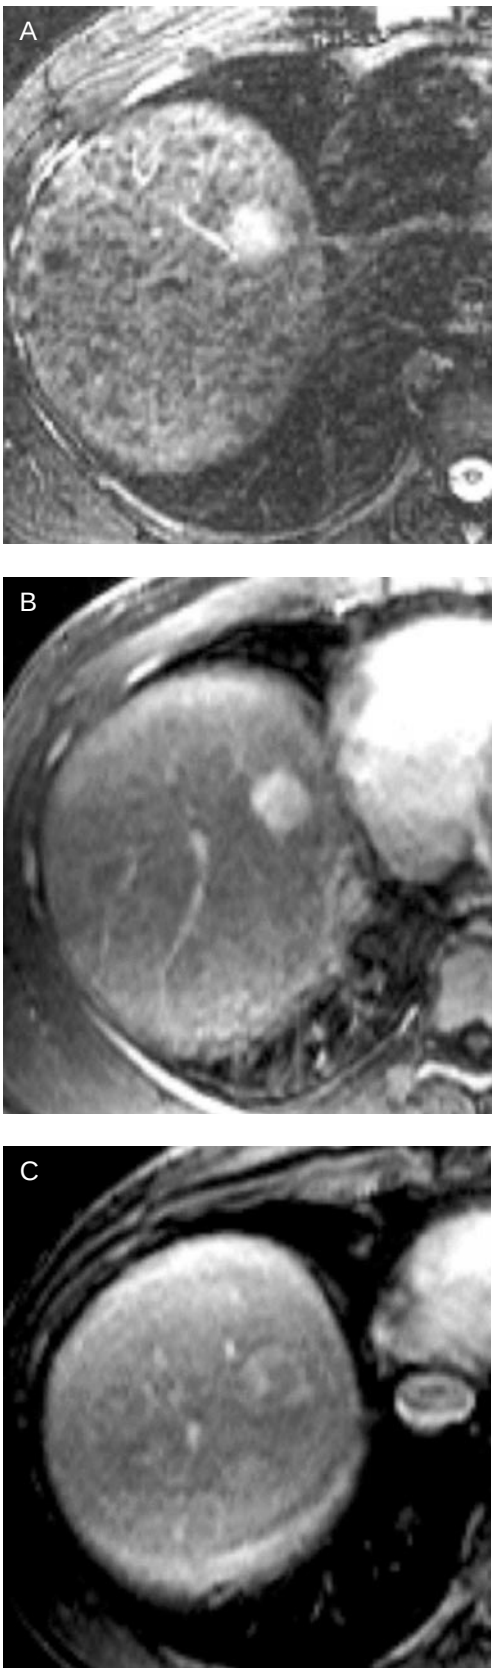
Technique

With MRI, the biliary system is usually evaluated with MR cholangiopancreatography (MRCP). The goal with MRCP is to produce a "hydrogram" in which the entire biliary system is bright due to the presence of bile fluid (Fig. 10). There are numerous techniques for producing T2-weighted images in which fluids are bright. The trade-offs between spatial resolution, image acquisition time, and image quality will determine the preferred technique on a particular scanner.

Cholelithiasis and Choledocholithiasis

Cholelithiasis and choledocholithiasis are common conditions. Although many patients remain asymptomatic, others may develop cholecystitis, pancreatitis, or biliary tract obstruction. Additionally, patients with biliary tract calculi may have a higher risk of developing subsequent cholangiocarcinoma.

MRCP demonstrates the biliary and pancreatic ductal anatomy by using T2-weighted sequences that depict fluid-containing structures as hyperintense.



Consequently, calculi will be seen as intraluminal filling defects. Other causes of filling defects that must be distinguished from calculi include pneumobilia, blood clots, and tumor. Most patients with suspected biliary calculi are adequately evaluated with ultrasound and nuclear medicine studies. However, ultrasound fails to detect many common bile ducts stones in nondilated ducts. MRCP can depict the presence or absence of biliary tract obstruction in 91–100% of cases. For choledocholithiasis, the reported sensitivity is >90% and specificity >94%. MRCP also provides a road map of the biliary tree and a more comprehensive assessment of the extrabiliary structures.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a disease of unknown etiology characterized by inflammation, fibrosis, and destruction of the intrahepatic and extrahepatic biliary tree. Approximately 70% of patients with PSC have inflammatory bowel disease, most commonly ulcerative colitis.

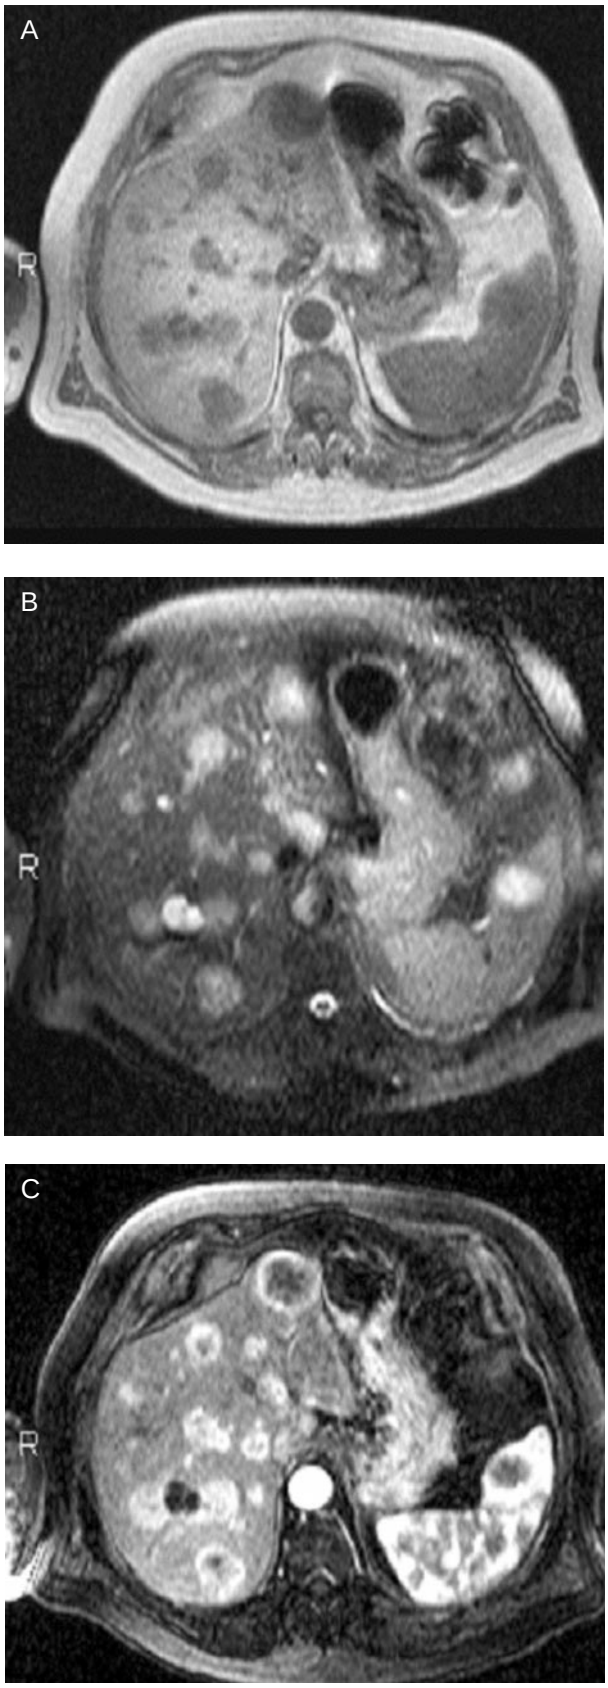
MRCP characteristics of PSC include beading characterized by focal dilatation of the intrahepatic and extrahepatic bile ducts alternating with segmental stenoses (Fig. 11). As the fibrosis progresses, the peripheral bile ducts become obliterated and the biliary tree assumes a characteristic pruned appearance. Contrast-enhanced MRI may demonstrate thickening and enhancement of the bile ducts. The hepatic parenchyma may demonstrate concomitant peripheral patchy areas of atrophy with abnormal signal intensity and enhancement.

As an adjunct imaging modality to endoscopic retrograde cholangiopancreatography (ERCP), MRCP offers several potential advantages. It is noninvasive, can depict the entire biliary tree (even in the presence of strictures and obstruction), and may detect early cholangiocarcinoma.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic autoimmune cholecystic liver disease characterized by the destruction of small intrahepatic bile ducts. It affects predominantly middle-aged women. The diagnosis of PBC is based on a combination of findings, including cholestatic liver enzymes, a positive antimitochondrial

FIGURE 8 MRI appearance of a hepatoma. The short tau inversion recovery image (A) shows a hyperintense mass in the hepatic dome. On the arterial-phase contrast-enhanced image (B), the mass enhances briskly. On the equilibrium-phase image (C), the mass is isointense with the liver, but there is an enhanced capsule.



antibody (AMA) assay, and characteristic liver biopsy findings.

In the early stages, the liver appears normal on MRI. The hallmark of the disease is lymphadenopathy in unusual locations and out of proportion to the degree of liver disease. The presence of the "periportal halo" sign is considered specific for the disease (Fig. 12). This appears as low-signal rounded lesions centered on a portal venous branch, 5–10 mm in size, involving all segments of liver. It corresponds pathologically to the inflammatory process involving portal triads with development of dense infiltrate and mild fibrosis.

Cholangiocarcinoma

Most cholangiocarcinomas are ductal adenocarcinomas that arise from the intra- and extrahepatic bile duct epithelium. Many predisposing conditions have been described, most of which involve preexisting biliary tract disease. Cholangiocarcinomas exhibit several different growth patterns, including polypoid, infiltrative, and exophytic. There is almost always some degree of biliary dilatation, which may be localized in the case of focal intrahepatic disease or generalized if the common hepatic or common bile ducts are involved. The tumors may be hypointense on T1-weighted images and mildly hyperintense on T2-weighted ones, but they are often difficult to identify on non-contrast-enhanced images. Dynamic gadolinium-enhanced imaging may show progressive enhancement of larger tumors. This enhancement may appear and be most conspicuous only on scans delayed for 10–15 minutes.

PANCREAS

Technique

MRI assessment of the pancreas usually includes an evaluation of the pancreatic parenchyma as well as the ductal system using an MRI protocol similar to that for MRI of the liver and the biliary system. Fat-suppressed T1-weighted images followed by dynamic contrast-enhanced fat-suppressed images with thin slices (on the order of 2–3 mm) are particularly useful for diagnosis of pancreatic carcinoma.

Normal Pancreas

Normal pancreatic tissue demonstrates uniform high signal on fat-suppressed T1-weighted images, possibly due to the presence of aqueous protein within the

FIGURE 9 MRI appearance of lung metastases that are hypointense on T1-weighted images (A), hyperintense on T2-weighted images (B), and show ring enhancement (C).

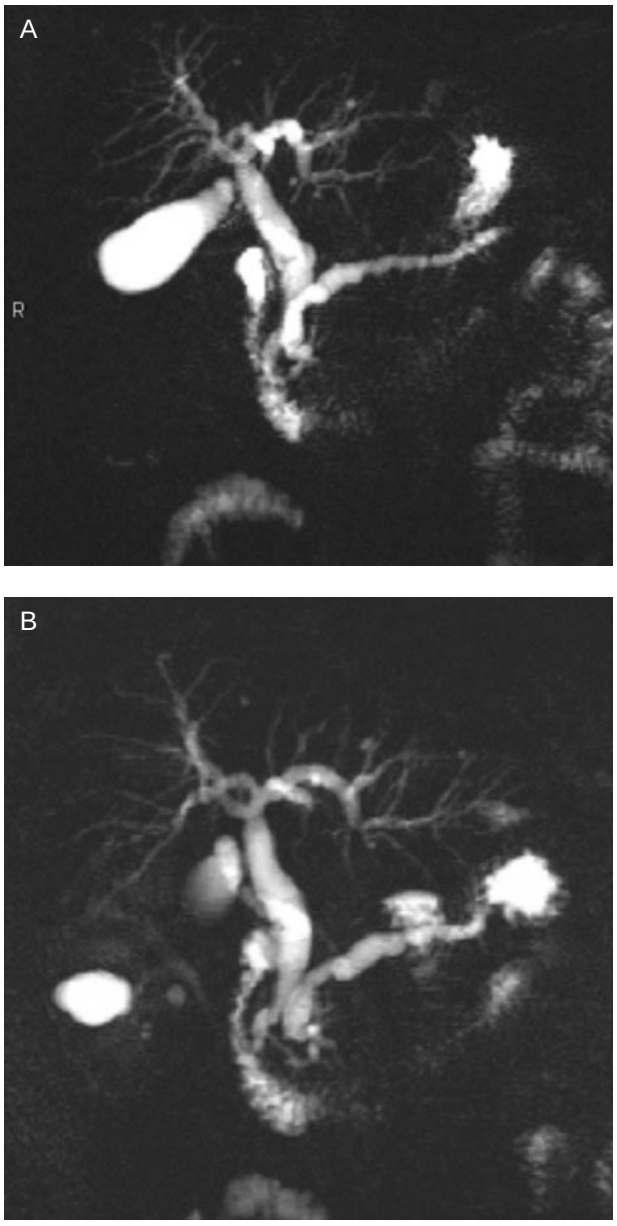


FIGURE 10 MR cholangiopancreatogram in two views (A and B) shows a dilated common bile duct and pancreatic duct secondary to metastatic ovarian carcinoma in the pancreatic head.

acini. Immediately after the administration of gadolinium chelate, there is a uniform parenchymal blush.

Pancreas Divisum

Pancreas divisum is the most common anatomic variant of the pancreas. It results from failure of fusion of the dorsal and ventral pancreatic ducts. The major regions of the pancreas, including the superior–anterior parts of the head, the body, and the tail, are drained by the long dorsal pancreatic duct through the accessory papilla. The inferior–posterior parts of the head and uncinate process are drained by the short ventral pancreatic duct that joins the common bile duct in the ampulla. Although it is usually an incidental finding, pancreas divisum is thought to be a causative factor in some cases of recurrent pancreatitis as a result of a functional obstruction of the minor papilla. Pancreas divisum may be missed with ERCP because the standard procedure opacifies only the ventral duct after cannulation.

On MRCP, pancreas divisum can be diagnosed when a dominant dorsal duct is visualized from body

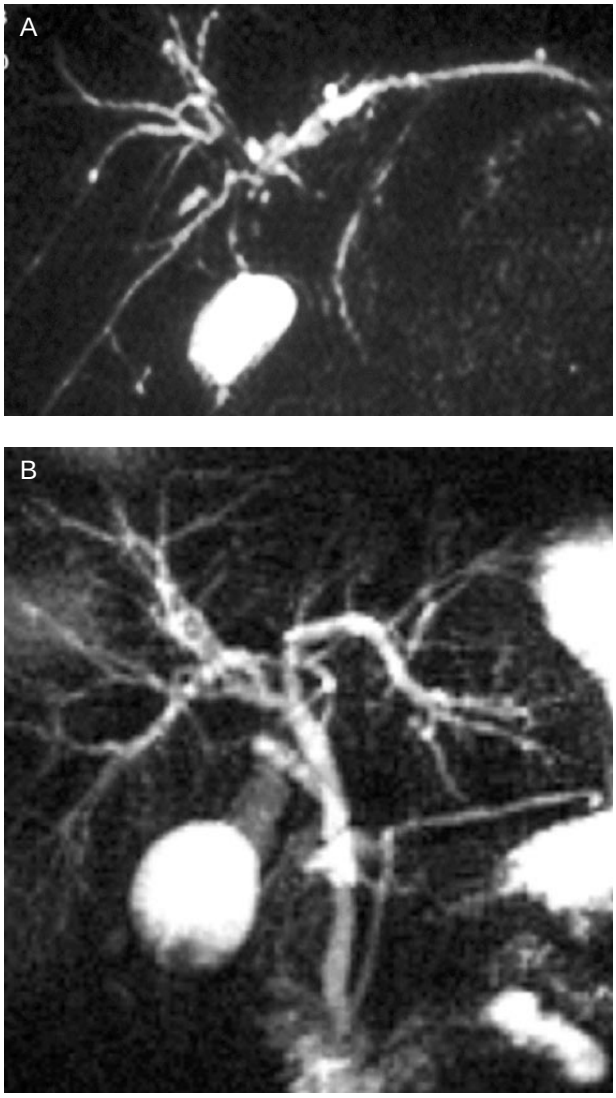

FIGURE 11 MR cholangiopancreatogram in two views (A and B) shows the beaded appearance of intrahepatic bile ducts secondary to alternating dilatation and strictures in primary sclerosing cholangitis.

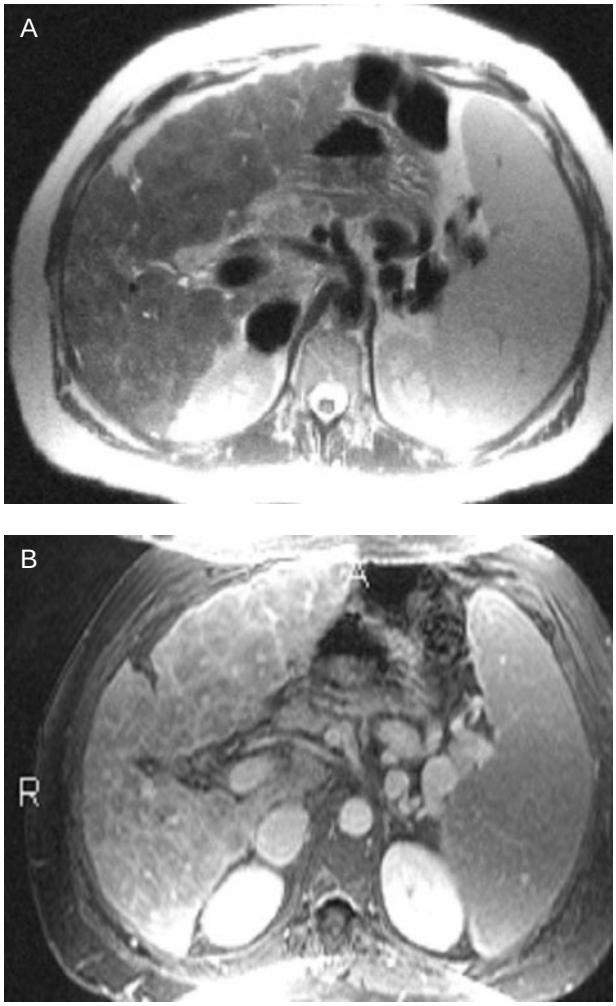

FIGURE 12 T2-weighted (A) and postcontrast fat-suppressed T1-weighted (B) images show a nodular contour and periportal halo sign (low-signal rounded lesions centered on a portal venous branch, 5–10 mm in size, involving all segments of liver) secondary to primary biliary cirrhosis.

to head crossing anterior to the common bile duct (CBD) and draining superiorly and separately from the CBD. Although it is helpful to identify the ventral duct draining separately into the major papilla with the CBD, this finding is not required for a diagnosis.

Pancreatitis

Pancreatitis is an inflammatory disease of the pancreas with acute and chronic clinical presentations. The most common etiologies include alcoholism and cholelithiasis. When diagnostic imaging studies are required, CT scanning remains the study of choice. In those patients unable to receive iodinated contrast and in selected cases in which a biliary etiology is suspected, MRI provides a valuable alternative imaging modality.

In patients with pancreatitis, the pancreas may have a diffuse low signal and decreased contrast enhancement on T1-weighted images. As with CT, contrast-enhanced scans can be used to assess necrosis. A focal form of pancreatitis may mimic a mass. Pancreatic duct dilatation, pseudocysts, and peripancreatic fluid are readily identified on T2-weighted images, and inflammatory pseudocysts are the most common small pancreatic cystic lesions.

Carcinoma

Pancreatic adenocarcinoma is the most common malignant neoplasm of the pancreas. It is also the most common cause of malignant biliary obstruction. Patients typically present with advanced local disease or metastases at the time of diagnosis. Imaging studies assist in making the diagnosis and determining which patients are candidates for surgical intervention.

On MRI, pancreatic adenocarcinomas are typically hypointense compared to normal pancreatic parenchyma on fat-suppressed T1-weighted images, and this may be more apparent immediately after contrast injection (Fig. 13).

The role of imaging is to determine the presence of disease and of local invasion and metastases. The major potential benefits of MRI compared to CT are that it is easier to detect very small non-contour-deforming tumors with MRI, easier to determine if a contour abnormality is due to a tumor or an anatomic variant, and it is easier to detect and characterize concomitant liver lesions. MRI is also useful in patients who have diminished renal function or iodine contrast allergy. CT and MRI are considered equivalent for the assessment of vascular invasion and adenopathy, and both have limitations in the detection of peritoneal and liver metastases. In most patients, there is no demonstrable advantage of MRI compared to high-quality CT for the detection or staging of pancreatic neoplasms.

Pancreatic Cystic Tumors

Pancreatic cystic tumors are classified into benign microcystic adenomas and mucinous cystic neoplasms that may be potentially malignant or malignant. Microcystic adenomas (formerly called serous cystadenoma) are well-defined, lobulated cystic neoplasms containing numerous small cysts, often having a honeycombed appearance. Each cyst measures less than 2 cm in diameter. The presence of a central stellate scar is a characteristic feature. On dynamic contrast-enhanced sequences, this scar demonstrates delayed contrast

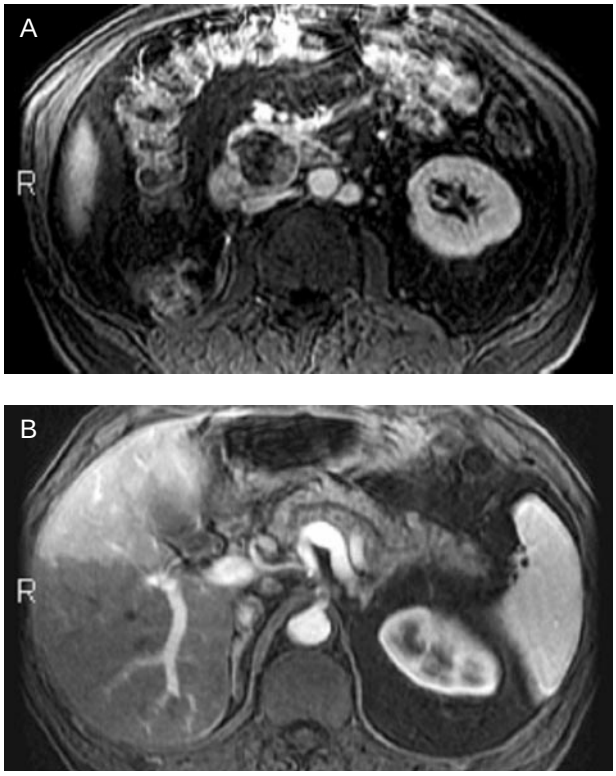

FIGURE 13 Fat-suppressed arterial-phase contrast-enhanced images, showing a pancreatic head carcinoma (A) with proximal pancreatic duct dilatation (B).

enhancement. Central calcifications may be seen on CT but are usually not appreciated on MRI.

Mucinous cystic neoplasms (formerly called mucinous cystadenoma and cystadenocarcinoma) are thick-walled, unilocular or multilocular neoplasms containing a small number of cysts measuring greater than 2 cm in diameter. Features of malignant transformation include the presence of solid nodular enhancing components within the cysts as well as adjacent vascular encasement or occlusion. They usually occur in the pancreatic tail, most commonly in middle aged women. In many cases, it is impossible to reliably differentiate between microcystic and mucinous cystic neoplasms on the basis of imaging features alone.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms (IPMNs) have been designated in the literature under various names, including mucinous duct ectasia, mucin-producing tumor of the pancreas, intraductal mucin-hypersecreting neoplasm of the pancreas, mucus-hypersecreting tumor of the pancreas, mucus cell hypertrophy, nonpapillary hyperplasia, and papillary hyperplasia. An IPMN is characterized by epithelial proliferation in the main pancreatic duct or its major tributaries or both, with focal or diffuse mucinous transformation of the ductal epithelium. The changes can range from cellular atypia without malignancy to carcinoma-*in-situ*. When the mucin production is extensive, there is cystic dilatation of the duct, which can result in the appearance of a cystic mass on MRI. An IPMN is considered to be a premalignant lesion, and malignant transformation ranges from a dilated pancreatic duct without a stricture or mass to papillary projections into the duct lumen.

When symptoms are present, patients may present with recurrent attacks of pancreatitis, presumably secondary to intermittent obstruction of the pancreatic duct either by polypoid tumor or inspissated mucus. Currently, most IPMNs are found incidentally on abdominal MRI or CT exams. On endoscopic examination, a gaping ampulla extruding mucus is a pathognomonic finding. IPMNs differ from mucinous cystic neoplasms in that the latter are thought to result form the mucinous neoplastic transformation of the epithelium lining parenchymal ductules, whereas IPMNs arise in the main or intermediate-size ducts, most commonly in the head or uncinate. Mucinous cystic neoplasms rarely communicate with the main duct, and when they do it is in the form of a fistula.

ERCP establishes the diagnosis of IPMN by demonstrating a bulging papilla with mucinous extrusion and communication of the lesion with the pancreatic ductal system. Although ERCP remains the diagnostic imaging modality of choice, MRCP may yield sufficient diagnostic information in some patients unsuitable for ERCP or when technically difficult cases arise from the inability to opacify the pancreatic ductal system secondary to excessive mucin production or a patulous papilla.

On MRI, IPMNs demonstrate low signal intensity on T1-weighted images and high signal intensity on T2-weighted images secondary to mucinous contents (Fig. 14). Communication with the pancreatic ductal system is highly suggestive of the diagnosis.

Pancreatic Islet Cell Tumor

Pancreatic islet cell tumors develop from the amine precursor uptake and decarboxylation cell line and may be functioning or nonfunctioning. The most common tumors, in order of frequency, are insulinoma, gastrinoma, and nonfunctioning islet cell tumor.

On MRI, insulinomas are usually less than 2 cm in diameter. These tumors are commonly hypointense on fat-suppressed T1-weighted images and hyperintense on T2-weighted sequences. Because these tumors are often hypervascular, they may be best seen on the

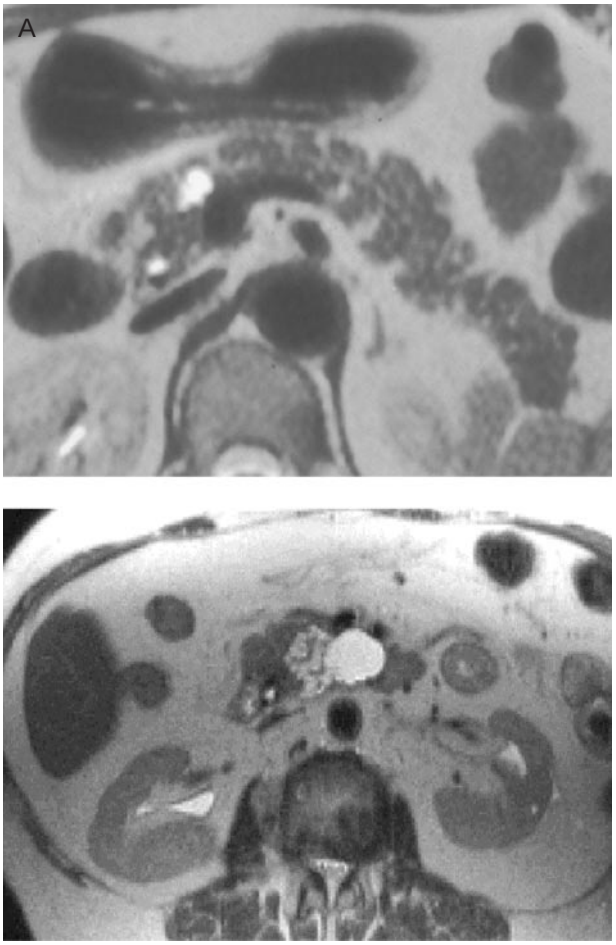

FIGURE 14 T2-weighted images, showing side branch intraductal papillary mucinous neoplasms with no main duct dilatation in two patients.

arterial phase of the dynamic contrast-enhanced sequences. Gastrinomas and nonfunctioning islet cell tumors share imaging features with insulinomas but typically present as larger tumors with a higher incidence of metastases.

Functional Studies

Occasionally, the pancreatic duct, particularly its tail and side branches, is difficult to visualize and characterize on MRCP. This can result in false positive examinations. Intravenous secretin can ameliorate this problem. In healthy subjects, secretin induces pancreatic fluid secretion and is followed by duodenal filling. The fluid secretion results in a transient increase in the main pancreatic duct caliber, improving its visualization. Side branches are not usually depicted in healthy subjects.

Dynamic secretin-stimulated MR pancreatography can also be useful for diagnosing pancreatic papillary stenosis or dysfunction and for detecting reduced pancreatic exocrine reserve. In patients with chronic pancreatitis, there may be reduced duodenal filling due to a decrease in pancreatic exocrine reserve. Acinar filling during dynamic secretin MR pancreatography may be a specific but insensitive finding of early pancreatitis.

SUMMARY

MRI is a versatile diagnostic tool that can be used to diagnose and evaluate a wide spectrum of diseases of the liver, biliary system, and pancreas.

Malabsorption

CHARLES M. MANSBACH
University of Tennessee and Veterans Administration Medical Center, Memphis

enterocytes Mature absorptive cells that line the villi of the small intestine.
malabsorption Failure to digest and absorb dietary nutrients.
sprue A word anglicized by Patrick Manson in 1880 from the Dutch *sprouw*, meaning "thrush"; used in seventeenth-century Europe to describe a diarrheal disorder with oral aphthous ulcerations.
steatorrhea Increased fat in stool due to malabsorption.

When considering malabsorption, most people think of the malabsorption of dietary fat, or steatorrhea. It should be realized that humans also commonly malabsorb carbohydrates, especially lactose-containing foods, and less commonly, specific metals (calcium or iron) and vitamins (the fat-soluble vitamins or vitamin B_{12}). All of these dietary components play a role in nutrition and disease. Although ideas of nutrition with respect to heart disease or dietary vitamin requirements change over time, what does not change is the body's built-in ability to absorb almost all of what we eat under normal conditions.

BRIEF OVERVIEW OF FAT ABSORPTION

Humans normally absorb 95% of their dietary fat intake. Truly remarkable levels of intake can be achieved without overloading the system. For example, because of their caloric density, fat-laden foods are carried by Arctic explorers, who may consume up to 500 g of fat per day without malabsorption. The normal American diet contains 100–150 g of fat per day. Although fat is absorbed efficiently, cholesterol is not. Only about half of the cholesterol that is eaten is absorbed.

The absorption of dietary fat is quite complex, with the primary reason being the water insolubility of the lipid. Fat does not interact with water and if it is not processed to do so, it will be excreted, with only small amounts being absorbed. The chemical structure of fat, as triacylglycerol (TAG), can be graphically visualized as having the shape of the letter E, with the glycerol backbone forming the vertical part of the E and the three fatty acids (FAs), which are attached to glycerol in ester linkages, appearing as the horizontal lines. Digestion of TAG starts in the stomach with the gastric enzyme lipase and progresses further in the duodenum, where the lipid interacts with pancreatic lipase. The end product of this is monoacylglycerol (MAG), which can be visualized as the middle FA attached to the glycerol backbone, and two FAs. These products, which can interact with water, are absorbed. The rapidity of absorption is enhanced greatly by the presence of bile salts, which are excreted from the gallbladder, where they are stored after their synthesis in the liver. Both gallbladder contraction and the elaboration of pancreatic lipase are under the control of the hormone cholecystokinin. Specialized cells localized to the duodenum sample duodenal luminal contents and secrete this hormone. The absorbed FAs and MAGs are resynthesized to TAG in the intestinal absorptive cell and are packaged in a chylomicron (the major lipid transport lipoprotein of the intestines), which is ultimately secreted into the lymph and then into the circulation.

THE CAUSE OF DIARRHEA IN STEATORRHEA

Normally, humans produce 100 to 200 g of stool per day. Anything over 250 g per day is considered diarrhea. There are there reasons for the diarrhea in patients who malabsorb lipid: (1) The malabsorption of fat is usually, but not always, associated with the malabsorption of carbohydrates and proteins as well. These osmotically active particles enter the colon and require the colon to secrete water to maintain equivalent osmolality. (2) FAs entering the colon cause water and salts to be excreted rather than absorbed because they induce Cl^--driven water excretion. (3) Ricinoleic acid, the active laxative in castor oil (glyceryl triricinoleate), is 12-hydroxy stearate. Oleic acid, a common FA constituent of fat, is easily converted to 10-hydroxy stearate by bacterial hydroxylation of the double bond at the 9–10 position of oleate.

DISEASES CAUSING MALABSORPTION

Celiac Sprue

Celiac sprue, a relatively common genetically and immunologically based disease, has a prevalence rate of $\approx 1:200$. Most patients have either the DQ2 or DQ8 human leukocyte antigen (HLA) haplotype, which will interact with the inciting dietary protein, gliadin, found in wheat, rye, and barley, to cause the disease. Gliadin is an unusual protein in that 30% or more of the protein is made up of glutamine residues and there are large amounts of proline as well. The peptide component of gliadin that appears to be the proximal causative agent has been discovered by hypothesizing that the inciting gliadin peptide would resist the normal proteolysis occurring in the intestine. This turns out to be a peptide composed of 33 amino acids. The peptide resists hydrolysis because of its prolyl residues, which are known to resist proteolysis by gastro/pancreatic peptidases. This peptide interacts with tissue transglutaminase, the autoantigen of celiac patients, and its incubation with intestinal T cells from celiac patients causes their induction.

Classically, celiac sprue causes steatorrhea, weight loss, and abdominal cramps. Currently, more subtle signs of the disease are recognized as common presenting symptoms. These may be unexplained osteoporosis due to vitamin D deficiency and/or calcium malabsorption, iron deficiency without intestinal blood loss, or easy bruising associated with vitamin K depletion. The disease is also associated with other autoimmune disorders, such as type 1 diabetes or Hashimoto's thyroiditis.

Causes of Fat Malabsorption in Celiac Sprue

There are multiple causes of fat malabsorption in celiac disease. Because the condition induces enlargement of the intestinal crypts, both vertically and horizontally, there is an increase in salt and water secretion from the crypts, the normal site of such secretion. Normally, flow out of the crypts is sensed by the tips of the villi that are further up the villus than the crypts. These mature villus cells are the sites of normal salt and water absorption. In celiac disease, the villus tip cells are relatively immature, resulting in impaired absorption. The result is that the intestine is in a secretory rather than in the normal absorptive state. The resulting increase in salt and water in the lumen of the intestine reduces the concentration of bile salts in the lumen. In order to function properly in the solubilization of the products of TAG hydrolysis, bile salts must self-associate to form micelles. This is concentration dependent and does not begin in humans until bile salt concentrations exceed 1.8 m*M*. A concentration of 10 m*M* bile salts is seen postprandially in normal persons. Therefore, a reduction of bile salt concentration by dilution would have a greater effect on bile salt micelle formation than what would have been predicted by the reduction in bile salt concentration alone.

Because of villus atrophy, there is a reduction in the surface area of the intestine. This is magnified by the fact that the microvilli, which jut out into the intestinal lumen from the surface of the absorptive cells, also become atrophic. The microvillus surface area forms the majority of the total surface area of the intestines. This results in a reduction of the total surface available for nutrient absorption.

Another reason for fat malabsorption in celiac sprue is that the endocrine cells in the duodenum, which release cholecystokinin (CCK), become dysfunctional or atrophic. Normal stimuli to CCK release, such as essential amino acids, result in a reduced amount of hormone production in celiac sprue. However, if intravenous CCK is given to these patients, their gallbladder contracts normally, showing that the defect is not in CCK receptors in the gallbladder. A reduction in CCK in the duodenal mucosa can be demonstrated directly. This results in a further reduction of bile salt concentration in the intestinal lumen and a reduction of lipase and proteolytic enzymes released by the pancreas in response to a meal as well.

Finally, the cells at the intestinal surface are more immature than normal in celiac sprue. This results in the impaired processing of absorbed lipids and likely a reduction in the absorption of amino acids, peptides, and carbohydrates that depend on specific active transporters found in mature enterocytes for their normal uptake.

Other Malabsorbed Nutrients in Celiac Sprue

Because celiac sprue affects the most proximal intestine the most severely, vitamins and nutrients that are absorbed in this area of the gut can be malabsorbed even when the overall absorption of fat is not. Fat absorption can occur more distally in the less affected part of the bowel because adequate absorption does not require specialized transporters. For this reason, calcium, iron, and/or folate may be malabsorbed in the absence of steatorrhea. By contrast, vitamin B_{12}, which is absorbed in the distal ileum, is usually absorbed normally in celiac sprue patients. The fat-soluble vitamins, A, D, E, and K, may be malabsorbed due either to an insufficient concentration of bile salts in the gut lumen or to a reduction in the products

of TAG hydrolysis that aid in the absorption of the vitamins.

Diagnosis of Celiac Sprue

The classic way to diagnose celiac sprue is by intestinal biopsy. This is not always easy because of the possibility of poorly oriented tissue or other problems, leading to either a false positive or a missed diagnosis in the hands of an inexperienced pathologist. At best, because there are no specific pathologic characteristics of celiac sprue on biopsy, the pathologist can only state that the tissue is consistent with a diagnosis of celiac disease. Two new blood tests, antitissue transglutaminase and antiendomysial antibodies, are now available and both appear to have few false positives and false negatives. When suspicion is high that the patient has celiac sprue, such as with a primary member of a family known to have the disease, a positive blood test is all that should be required. As more experience is acquired with the blood tests, it is likely that a positive biopsy result will become a lesser part of the diagnosis and that it will be reserved for those patients who do not respond to the gluten exclusion diet or who have other specialized issues. Some patients have a dermatological condition, dermatitis herpetiformis, a pruritic herpetic-like lesion appearing most commonly over extensor surfaces.

The diagnosis is not secured until the patient responds to a gluten exclusion diet. It is no longer current practice to challenge patients with gluten to see if they reacquire symptoms. Usually, however, the patient will assume after a period of time that they are cured and will have a dietary indiscretion. Eating gluten will rapidly cause the recrudescence of symptoms. In young children, eating gluten after a period of abstention can cause an illness similar to serum sickness, which can be quite severe.

Treatment of Celiac Sprue

Because the dietary cause of the celiac sprue is known, treatment is directed toward removal of gluten from the diet. All patients with celiac sprue respond to a diet devoid of wheat, rye, and barley. Oats are usually excluded as well until the patient has a response to the diet. Symptomatic improvement is usually seen within 2 weeks, but histologic improvement of the intestinal mucosa takes much longer and may never completely revert to normal. If symptomatic improvement does not occur, the most likely problem is dietary indiscretion. The labels of all food bought at grocery stores must be read carefully to exclude the introduction of gluten-containing material such as stabilizers or other nonspecific components used in foodstuffs such as ice cream. If the diet is correct, then the nonresponsive patient may have pancreatic insufficiency or stasis syndrome with bacterial overgrowth. If these are ruled out, the patient may have ulcerative ileojejunitis, collagenous sprue, or α chain disease, all of which are not responsive to gluten exclusion.

Stasis Syndrome

Diseases and Conditions Associated with Stasis Syndrome

Stasis syndrome, or blind-loop syndrome, is caused by the lack of forward propulsion of intestinal contents. In this environment, bacteria proliferate, causing damage to enterocytes. Diseases that reduce intestinal propulsion, such as scleroderma and diabetes, or idiopathic problems can cause stasis. Other potential causes are small bowel diverticulosis, in which bacteria proliferate within the diverticulae, which then seed the intestinal luminal contents. Narcotics, which slow intestinal propulsion, do not cause symptomatic stasis syndrome. The proton pump inhibitors, which reduce gastric acid production, also increase small bowel bacterial content, but likewise do not cause symptoms.

Pathophysiology of Stasis Syndrome

The proliferating bacteria in stasis syndrome release glycosidases, which digest some of the protective glycosides from the surface of the enterocytes. Proteases and pancreatic phospholipase, which are plentiful in the intestinal lumen, are then postulated to gain access to the cell interior. This results in damage to the enterocyte that can be seen at the electron microscopic level as dilated endoplasmic reticulum (ER), a sign of cellular distress. Impaired lipid absorption is suggested by the finding that the endoplasmic reticulum is engorged with prechylomicrons, with few chylomicrons in the Golgi. This suggests a blockade in the normal movement of chylomicrons from the ER to the Golgi. A modest steatorrhea may result. Albumin is also thought to leak into the bowel in the stasis syndrome, resulting in protein-losing enteropathy and a reduction in serum albumin concentrations. Although there is bacterially caused deconjugation of bile salts, with a resultant increase in bile salt pK_a that leads to bile salt protonation passive absorption, the potential reduction in intestinal luminal bile salt concentration is minimal, and normal amounts of hydrolyzed lipids are found in the aqueous phase of intestinal contents. Because of bacterial folate synthesis, folate levels are usually increased in the serum of these patients. Vitamin B_{12} levels may be low due to the binding of B_{12} to the surface of the bacteria, its metabolism by

the bacteria to inactive metabolites, and the utilization of B_{12} by the bacteria for their own metabolism.

Diagnosis

The diagnosis of stasis syndrome can be suspected in patients who have multiple diverticulae as seen on small-bowel follow-through X rays or who are shown to have a Billroth II anastomosis with an enlarged afferent loop. Establishing the diagnosis is more difficult. The classical way is to collect intestinal luminal fluid for quantitative bacterial counts, especially anaerobic bacteria. Counts greater than 10^5/ml anaerobic bacteria suggest the diagnosis. Bile acid deconjugation can be documented in fluid collected from the upper intestine by separating the bile salts using thin layer chromatography. Although a modest steatorrhea may be seen, this is a nonspecific finding.

Treatment

Treatment is directed toward ridding the bowel of anaerobic bacteria. This can be done using antibiotics such as tetracycline, which are given for 3 weeks at 1 g/day and then treatment is stopped. The patient is observed and retreated if required. Some patients will need to be on chronic antibiotic therapy for the least number of days per month that will reduce symptoms. Surgical revision of a blocked afferent loop or removal of small bowel diverticulae, if feasible, can be helpful as well.

Chronic Pancreatitis and Pancreatic Insufficiency

Diseases Associated with Pancreatic Insufficiency

Chronic pancreatitis is the condition that most frequently leads to pancreatic insufficiency. A diagnosis of pancreatic insufficiency requires showing that the pancreas is dysfunctional at the exocrine or endocrine level. Because of the great functional reserve of the pancreas, it takes 90–95% glandular destruction before the resulting lipase deficiency leads to steatorrhea.

By far the most common cause of pancreatic insufficiency in the United States is alcoholic pancreatitis. Minor amounts of pancreatic insufficiency are caused by cystic fibrosis or hereditary pancreatitis. Painless pancreatitis leading to pancreatic insufficiency is well described. Not all diseases that cause acute pancreatitis are associated with the development of chronic pancreatitis, however. For example, biliary pancreatitis never leads to the chronic form of the disease.

Symptoms of Chronic Pancreatitis

Symptoms are related to the development of either exocrine or endocrine insufficiency or both. In the case of exocrine insufficiency, steatorrhea may be marked, with up to 70% of ingested fat excreted. That there is not more is due to the action of gastric lipase. The amount of fat may be so great that oil droplets ooze from the rectum. The weight of the stool is not as great as one would expect for the amount of lipid in the stool because there is poor hydrolysis of proteins and (to a lesser extent) carbohydrates, leading to fewer osmotically active particles in the stool. Endocrine insufficiency manifests by the development of diabetes. This type of diabetes usually requires insulin, but not as much as in type 1 diabetes, because there is no immunological component. The side effects associated with diabetes, such as renal failure or neurological problems, are rarely seen in pancreatogenous diabetes for unclear reasons. A possibility is the reduced life span of these patients following diagnosis, compared to patients with type 1 diabetes.

Diagnosis

Chronic pancreatitis can be diagnosed by the observation of calcifications in the pancreas either by standard X ray, computed tomography (CT) scan, or ultrasound. A dilated pancreatic duct at CT scan is also helpful. In general, however, the diagnosis is not made until late in the course. The most sensitive test is the pancreatic secretin test, in which the hormone secretin is injected intravenously and pancreatic juice is collected by a tube placed in the duodenum. The volume of fluid and its bicarbonate concentration are measured. More than 70% of the gland must be destroyed before the test becomes abnormal. In Europe, similar studies are performed after a Lundth test meal. An abnormally low serum trypsinogen is also an indicator of chronic pancreatitis.

Treatment

The simplest treatment is for the diabetic complication of chronic pancreatitis, for which insulin is usually required rather than oral medication. Treating the steatorrhea is more difficult. The major problem is that the enzymes that are given orally are in part acid inactivated in the stomach. It is estimated that only 10% of these are still active in the duodenum. Some preparations, such as Viokase, are given as active enzymes in a capsule form. Others, such as Creon, have the active enzymes embedded in a resin so that the active enzymes are not released until the pH of the surrounding luminal fluid is more alkaline. Combining enzyme therapy with a proton pump inhibitor is another way of preserving enzyme

activity. Despite these steps, it is rare to completely reverse the steatorrhea of chronic pancreatitis. The associated pain experienced by patients with chronic pancreatitis is a therapeutic dilemma if medications for pain relief, i.e., narcotics, are supplied to persons with an addictive personality. For this reason, narcotics should not be used, especially over the long term. Milder analgesics such as acetaminophen are more appropriate. An occasional patient can be helped by giving Viokase, with the theory being that the active enzymes reduce pancreatic secretion by hydrolyzing cholecystokinin-releasing peptide, which controls pancreatic secretion in a feedback loop fashion.

Cholestasis

Cause and Physiological Effects

Because bile salts play an important role in the efficient absorption of lipids and are required for the absorption of fat-soluble vitamins, any process that limits the delivery of bile salts to the intestinal lumen in response to a meal reduces the effectiveness of bile salts in the absorption process. This would include conditions that are localized to the liver, such as intrahepatic cholestasis, or obstruction of the extrahepatic bile ducts, as in pancreatic cancer or gallstones. Because extrahepatic conditions that obstruct bile flow are usually dealt with by relieving the obstruction (failure to do so usually leads to the death of the patient within a short period of time), the physiological effects of a reduction in bile salt delivery to the intestine in terms of lipid or vitamin absorption are usually only seen in patients with intrahepatic cholestasis. For example, in primary biliary cirrhosis, in which there is failure to excrete bile salts before the development of cirrhosis, osteoporosis due to impaired vitamin D absorption may be seen. The steatorrhea found under these conditions is not severe, usually in the range of 10 to 20 g of fat per day.

Treatment

Treatment is directed at the disease causing the bile flow restriction. If the problem is extrahepatic, the treatment is usually surgical; if intrahepatic, treatment depends on the cause. For example, some drugs cause intrahepatic cholestasis that is relieved on removal of the drug. Primary biliary cirrhosis is helped by the administration of ursodesoxycholic acid.

Whipple's Disease

Description and Pathophysiology

Whipple's disease, a relatively rare condition affecting mostly middle-aged men, is invariably fatal if not detected and treated. It is caused by the bacterium *Tropherema whippelii*. Symptoms usually start with multiple joint pains and swelling, which may occur years before the more localizing symptoms of fever, steatorrhea, lymph node swelling, and weight loss. Other organs can be involved, including the heart or the brain. The neurological symptoms, which can be ocular or a progressive dementia, are particularly insidious because they are usually irreversible. Neurological symptoms may occur after antibiotic treatment for Whipple's disease if the antibiotic used does not cross the blood–brain barrier.

Tropherema whippelii is able to exist in macrophages for many years, both in the intestine and in draining lymph nodes. The lymph nodes may become blocked, resulting in impaired lymph flow from the intestinal villi. This leads to swollen, clublike villus structures and dilated lymphatics that can be seen at both the light and electron microscopic levels. Rarely, the mucosa can become flattened and the biopsy may be confused with celiac sprue. The lymphatic blockade leads to a reduction in the ability of the intestine to transport chylomicrons to the thoracic duct. Because there are other mechanisms of transporting lipid into the body besides the normally used lymphatic system, the amount of steatorrhea seen in this condition is modest, at 20 to 25 g of fat per day.

Diagnosis

A small bowel biopsy is the usual way that the condition is diagnosed. Once the condition is suspected and a biopsy is obtained, the biopsy results are usually straightforward. The striking finding is that the lamina propria is packed with macrophages, which have enlarged regions of cytoplasm with a foamy appearance. With periodic acid–Schiff (PAS) stain, the macrophages are stained a bright red due to the numerous bacteria contained within them. Some of these bacteria can be seen with electron microscopy to be dividing, a sign that the bacteria are alive and proliferating. In patients who are HIV positive and have the AIDS complex, PAS-positive macrophages can also be found due to the presence of *Mycobacterium avium-intracellulare*. These organisms can be distinguished from *T. whippelii* on electron microscopy because of differences in morphology.

Treatment

The current treatment of choice is sulfamethoxazole–trimethoprim (SM–TM). This antibiotic eradicates *T. whippelii* in the intestines and elsewhere in the body. Importantly, SM–TM crosses the blood– brain barrier and attacks the bacteria in the central nervous system (CNS). Rarely, patients treated with SM–TM

will develop CNS symptoms. Treatment should be given for 1 year. If an antibiotic that does not cross the blood–brain barrier is chosen, CNS symptoms may occur 1 to 3 years later, even though other systemic or intestinal symptoms have cleared. In patients who have been followed for long periods (up to 25 years) and who have become asymptomatic, PAS-positive macrophages can still be seen in the intestine, although at a greatly reduced number over that which was originally present.

Intestinal Ischemia

Presentation and Diagnosis

There are three levels of intestinal ischemia. The first is intestinal angina, in which the patient experiences upper abdominal, usually severe, crampy pain associated with meals. The pain is so severe that the patient begins to eat progressively less, resulting in weight loss. The weight loss may be extensive. Early in the course, when the patient is eating well, steatorrhea may occur as a result of poor intestinal perfusion and oxygenation. Ultrasonic Doppler evaluation of the three arteries supplying the small intestine, i.e., the celiac, the superior mesenteric, and the inferior mesenteric arteries, should show reduced flow in at least two of the three arteries. This is usually followed by an aortogram, in which radio-opaque dye is injected into the aorta to outline the lumens of the three arteries. To substantiate the diagnosis, there must be significant obstruction of at least two of the three arteries. The second level of ischemia is mucosal infarction and the third level is infarction of the entire thickness of the gut. In either case, steatorrhea does not result because the patient is too sick to eat.

Treatment

Treatment is surgical, either bypassing or endarterectomizing the obstructed arteries.

Zollinger–Ellison Syndrome

Presentation and Diagnosis

Zollinger–Ellison syndrome is caused by a tumor that elaborates the hormone gastrin. Gastrin drives the stomach to produce large amounts of acid, with the result that patients usually present with a severe peptic ulcer, a perforated ulcer, or an ulcer that bleeds. The tumor is discovered on investigation because of the unusual location of the ulcer (for example in the distal duodenum) or because of the persistent recurrence of the ulcer after therapy. Occasionally, diarrhea with malabsorption is seen. This is due to the acidic environment of the duodenum, where a pH of 1.5 can be found. This pH irreversibly denatures lipase, with the result that the patient is rendered essentially lipase insufficient.

The diagnosis is made by measuring gastrin in the serum; if the results are inconclusive, the hormone secretin is given intravenously and the gastrin response in the serum is followed. If gastrin rises to a level of 200 pg/ml or more above fasting levels, the patient is likely to have the Zollinger–Ellison syndrome.

Treatment

With the advent of proton pump inhibitors, symptomatic relief is available. The objective is to reduce gastric acid output to 10 mEq H^+/hour or less; below 10 mEq/hour, ulceration seems not to occur. Approximately 60% of the tumors are malignant at the outset and they are slow growing. If the tumor can be shown to be localized, surgical resection is an option.

Systemic Mastocytosis

Symptoms, Diagnosis, and Treatment

Systemic mastocytosis is manifested by tan to brown macules (urticaria pigmentosa) distributed over the trunk and extremities. The hallmark of the disease is the raising of a pruritic wheal on trauma to the skin, caused by mast cell release of histamine. This is a condition in which mast cells may proliferate in the skin, bone marrow, liver, spleen, lymph nodes, and intestine. The cause of the malabsorption in this condition is not known, but may be related to histamine release and overproduction of gastric acid. The diagnosis is suggested by the classic skin lesions but occasionally submucosal nodules can be seen on barium X ray of the small intestine. A small bowel biopsy shows dilated villi packed with eosinophils. Urinary levels of a metabolite of prostaglandin D2 are increased. Treatment is nonspecific. Disodium cromoglycate may be helpful in relieving the intestinal symptoms.

Giardiasis

Symptoms, Diagnosis, and Treatment

Giardia lamblia is a common parasitic contaminant of drinking water in various parts of the world, including the United States. A famous outbreak occurred in Aspen, Colorado due to cross-contamination of the freshwater line with the sewage line. *Giardia* also commonly contaminates freshwater streams because of infected beavers. Symptoms are usually abdominal distension, crampy abdominal pain, excessive flatus, diarrhea, and, less often, steatorrhea. There is no known cause for the steatorrhea. The diagnosis is made by finding cysts in the stool or, more accurately, trophs in the

duodenal contents or next to the surface of the duodenum on a biopsy. When cysts or trophs are found, treatment is a 10-day course of metronidazole. Antibiotic resistance is rare.

Short Bowel Syndrome

Diagnosis and Treatment

Short bowel syndrome is usually the result of surgical resection of the bowel. The extent of the resection can be estimated from a small bowel follow-through examination (a barium X-ray study). Alternatively, the amount of bowel removed at surgery may have been recorded and the records may be available. Malabsorption occurs because of the reduction in bowel surface area. Malabsorption is usually worse with distal resections because of the lack of ileal absorption of bile acids. Further, the ileum adapts to the absence of the jejunum, but the jejunum does not adapt to the absence of the ileum. By adaptation, it is meant that the intestinal villi become enlarged and elongated.

Treatment is difficult, but predigested meals using casein hydrolysates may be helpful. The protein hydrolysates are preferred over the crystalline amino acid preparations because di- and tripeptides are better absorbed than are single amino acids. A low-fat diet is usually best. Patients can also be given a small amount of oil prior to a meal; this is thought to slow intestinal transit of food, thus prolonging contact time between the food and the intestinal absorptive cells.

Lactose Intolerance

Symptoms, Diagnosis, and Treatment

Lactose intolerance is one of the commonest forms of intestinal "malfunction." In most mammals, loose stools occur if milk is ingested after weaning. In humans, this is also true for 90% of Asians, for 70% of African Americans, and for many tribes in Africa, with symptoms usually occurring at age 7 to 9 years. People of northern European descent and a few tribes in Africa retain the ability to drink milk throughout their lives without ill affect.

Symptoms of lactase insufficiency usually are abdominal cramps, flatus, and acidic loose stools shortly after milk ingestion. The milk sugar, lactose, must be split into its component monosaccharides, glucose and galactose, by the enzyme, lactase, which is present at the surface of intestinal absorptive cells. The decrease in lactase activity at weaning is a programmed enzymatic depletion, because feeding milk continuously does not change the developmental stage at which lactose becomes malabsorbed. The malabsorbed lactose enters the colon, where bacteria can digest the sugar and produce short-chain fatty acids. Treatment is either avoiding milk or foods containing dairy products, or treating milk prior to drinking with lactose-containing bacteria (Lactaid) or live bacteria containing lactase, such as Lactinex granules.

Mallory–Weiss Tear

BRYAN T. GREEN
Duke University Medical Center

angiography The radiographic visualization of blood vessels following introduction of contrast material.
gastrointestinal endoscopy Visual inspection of the lumen of the gastrointestinal tract by means of an endoscope passed through the mouth, anus, or ostomy.
hematemesis The vomiting of blood.
hematochezia The passage of red blood and/or clots from the rectum.
hemostasis The arrest of bleeding.
Mallory–Weiss tear Linear, nonperforating mucosal tear at or near the gastroesophageal junction.
melena The passage of black, tarry stools due to altered blood.
retching A strong involuntary effort to vomit.
upper gastrointestinal bleeding Blood loss from any portion of the digestive tract proximal to the ligament of Trietz (fourth portion of the duodenum).

Mallory–Weiss tears are linear, nonperforating mucosal tears near the gastroesophageal junction, classically induced by retching. They usually involve the gastric mucosa of the cardia but may involve the esophageal mucosa. They account for 5–15% of all cases of upper gastrointestinal bleeding. Although bleeding will stop spontaneously in the majority of cases, some cases will require therapeutic intervention.

CLINICAL FEATURES

Associated Conditions

In 1929, Mallory and Weiss described a syndrome of hematemesis and gastric hemorrhage that followed a long and intense alcoholic debauch. Early descriptions of the Mallory–Weiss syndrome emphasized the association with chronic and/or binge alcohol use and persistent vomiting, retching, and increased abdominal pressure. Although these features are present in many cases, numerous patients lack them. Conditions predisposing to Mallory–Weiss tears may be broadly grouped in two categories: conditions that produce increased intra-abdominal pressure and conditions that weaken the gastroesophageal (GE) junction. Mallory–Weiss tears have been produced by numerous conditions that increase intra-abdominal pressure, including the following: retching, nausea, vomiting, prolonged or paroxysmal coughing, hiccups, straining efforts, status asthmaticus, seizures, blunt abdominal trauma, and cardiac resuscitation. Conditions that weaken the GE junction include hiatus hernia and esophagitis. Nonsteroidal anti-inflammatory agent use is a risk factor, likely due to the adverse effect on platelet function. Portal hypertension is also associated with Mallory–Weiss tears and its presence portends a poor prognosis.

Iatrogenic Causes

Mallory–Weiss tears are uncommon during upper gastrointestinal (GI) endoscopy but are reported to occur in 0.07 to 0.4% of procedures. They have occurred in all types of upper GI endoscopy including standard esophogastroduodenoscopy, endoscopic retrograde cholangiopancreatography, percutaneous endoscopic gastrostomy tube placement, pneumatic balloon dilation, and standard dilation. They are induced by either direct trauma or more commonly retching and/or struggling during the procedure. The use of large-caliber or side-viewing endoscopes may be a risk factor. Mallory–Weiss tears induced during endoscopy typically have a benign course with spontaneous resolution of bleeding and only rarely require blood transfusion. If bleeding persists, the standard treatment modalities may be utilized.

Nasogastric and nasoduodenal tubes have been reported to produce Mallory–Weiss tears, usually due to retching while the tube is being placed. Polyethylene glycol electrolyte lavage solution ingestion to prepare the bowel for colonoscopy has been reported to produce Mallory–Weiss tears due to the vomiting it may induce, but such incidents are rare.

Clinical Presentation

Mallory–Weiss tears typically present with hematemesis (vomiting blood), classically after the patient has had several nonbloody episodes of emesis. The hematemesis may be frank red blood, suggesting an acute tear, or resemble coffee grounds, suggesting blood that has been altered while in the stomach for

 Copyright 2004, Elsevier (USA). All rights reserved.

several hours. Up to one-half of patients may have hematemesis on first emesis. Anticedent nausea, vomiting, retching, regurgitation, or abdominal pain is present in over one-half of patients. Less commonly, patients may have no hematemesis but pass melena (dark black tarry stools). Rarely, Mallory–Weiss tears may cause hematochezia (red, bloody bowel movements). This indicates a very rapidly bleeding lesion and predicts a poor outcome. One-third of patients will have hemodynamic instability at presentation, particularly those who present with hematochezia.

MANAGEMENT

Diagnosis

Mallory–Weiss tears were initially diagnosed either at surgery or autopsy but the advent of flexible endoscopy has made gastrointestinal endoscopy the gold standard for diagnosis. Although barium radiographs may occasionally be diagnostic, their use for this purpose is of historical interest only. Through the endoscope a Mallory–Weiss tear will appear as a linear laceration at or near the GE junction. Often they are seen only when the endoscope is retroflexed and the gastric side of GE junction is carefully inspected. The length of the tear may range from several millimeters to several centimeters, with the majority of lesions measuring near the shorter extreme. Roughly one-third of patients will have either active bleeding or stigmata of recent bleeding (visible vessel, adherent clot, or pigmented protuberance) at the time of endoscopy. These characteristics predict a complicated course (rebleeding, high transfusion requirements, or death) and endoscopic treatment with a variety of means (described below) is recommended. Patients without active bleeding or stigmata of recent bleeding, coagulopathy, portal hypertension, or hemodynamic instability can usually be managed by a brief period of observation.

Treatment

Resuscitation

As with all forms of GI bleeding, initial resuscitation with intravenous fluids and blood transfusion is essential. Anti-emetics should be administered and any coagulopathy corrected. Intravenous histamine 2 receptor antagonists are generally given but their benefit is unproven.

Endoscopy

Roughly one-third of patients with Mallory–Weiss tears will require endoscopic therapy. This is generally performed at the time of diagnosis with the same endoscope. A variety of means have successfully been employed, including electrocoagulation, injection, band ligation, and hemoclipping. Bipolar cautery or heater probe coaptive coagulation was initially used to treat bleeding from ulcers but can be effective at achieving hemostasis and reducing rebleeding rates for Mallory–Weiss tears. A variety of substances have been injected into and around Mallory–Weiss tears to achieve hemostasis. Epinephrine at a concentration of 1:10,000 is most commonly used and has been proven successful. It may be used alone or prior to electrocautery. The combination may be more effective than either agent alone. Injection with 98% alcohol, a sclerosing agent, has also been effective. Endoscopic band ligation and hemoclipping have been successful but are not yet widely used for Mallory–Weiss tears.

Radiology

Angiography with embolization or selective intra-arterial vasopressin infusion is effective when endoscopy fails to achieve hemostasis.

Surgery

Although once the only available treatment, surgery is now rarely required and utilized only when other measures have failed.

OUTCOME

Two-thirds of patients with a Mallory–Weiss tear will not require endoscopic therapy and will heal spontaneously. Blood transfusion is required in roughly one-half of patients. Less than 10% of patients will rebleed during the index hospitalization and usually within 24 h. Hematochezia, hemodynamic instability, portal hypertension, coagulopathy, a low admission hematocrit, and active bleeding or stigmata of recent bleeding are predictors of a complicated course. The mortality of Mallory–Weiss tears approaches 5%.

bacterial translocation Migration of various bacteria from the gastrointestinal mucosal surfaces to local lymphatic vessels and blood vessels.

bioimpedance analysis Using imperceptible electric currents of various frequencies, the resistance and reactivity of body tissues, reflecting total body water, can be used to assess body cell mass and lean body mass indirectly.

body cell mass The actively metabolic component of lean body mass, representing approximately 40% of body mass (weight) and consisting principally of skeletal muscle and visceral organs.

body mass index (BMI) Body weight in kilograms divided by height in meters squared; this index provides a good measure of nutritional states including malnutrition, normal status, overweight, and obesity. The BMI is not gender-specific and is relatively independent of height.

counterregulatory hormones The various hormones of intermediary metabolism, including growth hormone, catecholamines, cortisol, and glucagon, that counter the effects of insulin to lower glucose levels.

creatinine–height index The 24 h urinary excretion of creatinine is an indirect measure of skeletal muscle, which, when related to height and gender, can be used to estimate the degree of protein calorie malnutrition.

kwashiorkor Also known as protein malnutrition, this condition is due to a moderate to severe systemic inflammatory response with some degree of accompanying semistarvation.

lean body mass The fat-free compartment of the body, which contains nitrogen, is termed the lean body mass and makes up approximately 75% of body mass or weight. It includes the body cell mass, the extracellular fluid compartment, and the supporting tissues.

marasmus Also known as protein calorie malnutrition, this condition is primarily due to prolonged periods of inadequate intake of nutrients. It is often seen in the chronically ill with little or no underlying systemic inflammation.

mid-arm muscle circumference (MAMC) This index is derived by measuring the triceps skinfold (TSF) and mid-upper arm circumference (AC) midway between the shoulders and the elbow according to the following formula: $\text{MAMC} = \text{AC} - 3.14 \times (\text{TSF in centimeters})$.

nitrogen balance The net difference between intake of nitrogenous sources of nutrients (i.e., proteins) and nitrogen losses, principally in the urine. Nitrogen intake is estimated by protein intake in grams divided by 6.25. The 24 h urinary urea nitrogen excretion in grams plus 4 is used to estimate nitrogen output. Each gram of nitrogen lost or gained represents 28 to 30 g of lean tissue loss or gain.

subjective global assessment A comprehensive assessment of nutritional status using both objective and subjective clinical findings.

upper arm anthropometry An indirect means of measuring one's fat and muscle mass using triceps and subscapular skin folds (indexes of body fat) and the mid-upper arm circumference (an index of skeletal muscle).

This is the gold standard for body composition analysis, but it is largely a research tool for the investigation of important clinical problems.

Malnutrition remains one of the oldest and most prevalent global challenges for medicine, the scientific community, and public health organizations. The World Health Organization reported in 1999 that approximately one billion humans were either undernourished or malnourished. In many developing countries, where food insecurity and socioeconomic limitations are severe, malnutrition is endemic. It has been estimated that worldwide 40,000 deaths per day are attributable to malnutrition. Until the early 1970s, malnutrition was only clearly recognized in the developing world and during cataclysmic events, such as war, in the developed world. However, a number of surveys in the mid-1970s identified a high prevalence of malnutrition among certain populations in the developed world and even among the more "affluent" adults. This is protein calorie malnutrition (PCM), which is related to underlying illness. Grossly defined as unintentional weight loss of more than 10%, PCM is particularly common among hospitalized patients. Even in the era of modern medicine, malnutrition remains prevalent and is often unrecognized. Surveys comparing hospitalized patients in the 1970s to those in the late 1980s show that despite improved recognition of malnutrition, approximately 50% of surgical and medical patients are still identified as malnourished. No matter what the underlying cause, malnutrition is associated with poorer medical and surgical outcomes (greater risks of postoperative complications and poorer wound healing), longer hospital stays, and increased risk of death. A number of gastrointestinal diseases are associated with malnutrition. Some chronic illnesses, such as inflammatory bowel disease, malabsorptive conditions, and cirrhosis, have easily identified signs of malnutrition, whereas more acute conditions, such as severe pancreatitis, biliary sepsis, and toxic colitis, often have occult malnutrition, where significant losses of lean tissue and associated nutritional derangements commonly occur but are not realized. In order to optimize clinical outcome, it is therefore imperative for all clinicians and especially gastroenterologists to assess all patients and recognize those at risk for malnutrition.

DEFINITION

Malnutrition is a rather broad description of various disorders of poor dietary intake and/or enhanced catabolic losses. It has been used to describe the underfeeding conditions of marasmus and kwashiorkor seen in underdeveloped countries. It has also been applied to the overfeeding condition of obesity in the developed world and increasingly in the developing world. It has also been used to refer to deficiencies of various vitamins and minerals that accompany states of inadequate nutrient intake surrounding illness. This article focuses on states of suboptimal caloric and protein intakes leading to significant weight loss along with physiologic and functional impairments.

Protein Calorie Malnutrition

Protein calorie malnutrition (PCM) is the state of inadequate intake of food (as a source of protein, calories, and other essential nutrients) occurring in the absence of significant inflammation, injury, or another condition that elicits a systemic inflammatory response. This is also known as protein energy malnutrition (see Table I). It ranges from complete deprivation of nonfluid dietary intake (starvation) to a more common state of semistarvation, in which the intake of protein and energy is suboptimal. This has classically been referred to as marasmus. Common clinical conditions in which mainly starvation or semistarvation leads to PCM include anorexia nervosa, severe malabsorptive syndromes, states of gastrointestinal dysmotility, and upper gastrointestinal obstructions (i.e., esophageal strictures).

Protein Malnutrition

A condition that is more commonly encountered in the hospitalized setting is that of hypoalbuminemic malnutrition (also known as protein malnutrition or kwashiorkor). This generally occurs as a consequence of a moderate to severe systemic inflammatory response following acute illness or injury. Although dietary deprivation of protein alone could theoretically lead to the classic condition of kwashiorkor, the hallmark of protein malnutrition seen in the hospitalized patient is that of a systemic inflammatory response (SIR). This SIR reduces dietary intake due to anorexia, enhances

TABLE I Differentiating Features of the Two Major Types of Malnutrition

Protein malnutrition (kwashiorkor)	Protein calorie malnutrition (marasmus)
Develops over weeks	Develops over months
May not have weight loss	Significant weight loss
Due to systemic inflammation and semistarvation	Due to low intake of nutrients
Hypoalbuminemia	Serum albumin is normal
Excess body water	Edema is not a typical feature

catabolic losses of energy and protein stores, and invariably leads to hypoalbuminemia. A moderate systemic inflammatory response is seen with major bleeding, the inflammation seen in conditions such as severe pancreatitis or inflammatory bowel disease, and various systemic infections such as peritonitis or pneumonias. Common clinical conditions that induce a severe systemic inflammatory response include major burns, closed head injury, multiple trauma, and severe sepsis often associated with multiorgan dysfunction.

Although for descriptive purposes, marasmus and kwashiorkor are considered separate entities, in general most states of malnutrition have some element of a systemic inflammatory response. For instance, many patients suffering from chronic diseases such as cirrhosis, renal failure, chronic pancreatitis, and chronic cardiac or pulmonary failure exhibit a persistent, low-grade inflammatory response and are usually malnourished prior to their hospital admission. Meanwhile, others with normal nutritional status on hospital admission, such as those undergoing elective surgeries, can quickly develop protein malnutrition, making them susceptible to postoperative infectious complications.

Cachexia Syndrome

In a number of chronic medical conditions, a third form of malnutrition, known as the cachexia syndrome, develops. This is characterized by severe weight loss (more than 20%). This is usually seen at the end stages of medical diseases such as cirrhosis, renal failure, congestive heart failure, COPD, autoimmune deficiency syndrome, and various forms of malignancies, particularly those involving the upper gastrointestinal tract (esophagus, stomach, and pancreas). In these conditions, a mild to moderate systemic inflammatory response, manifested by the presence of enhanced cytokine production, elevated acute-phase protein levels, and hypoalbuminemia, generally accompanies the severe loss of lean tissue and fat.

METABOLIC RESPONSE TO MALNUTRITION

Body Compartments

To appreciate the physiologic changes occurring in starvation, protein calorie malnutrition, and protein malnutrition, one must have an understanding of normal body composition. Energy provision in the form of ATP, which is the body's means of converting chemical energy to mechanical work, is the net result of the metabolism of three basic fuels: glucose, protein, and fat. The three body compartments where these energy substrates are stored are the body fat, extracellular mass (ECM), and the body cell mass (BCM) (see Table II). The mobilizable pool of protein primarily derives from the BCM (approximately 40% of body mass), consisting of skeletal muscle (75%) and visceral tissues (25%). The visceral tissues include the highly metabolic organs like the liver, which has high energy requirements (i.e., 200 kcal/kg of tissue). The fat compartment is quantitatively the largest storage of energy, but unlike the BCM, it has limited metabolic activity and energy requirements. The ECM is principally a supporting compartment with limited metabolic and energy requirements.

TABLE II Body Compartments

Fat compartment (25%)
Body cell mass (40%)
Skeletal muscle (30%)
Viscera (10%)
Extracellular mass (35%)
Skeleton (10%)
Plasma proteins (5%)
Extracellular fluids (20%)

Physiology of Starvation and Semistarvation

Under normal physiologic conditions, immediately after feeding, insulin secretion is increased in response to absorbed carbohydrates and amino acids. Insulin stimulates the uptake of amino acids and glucose by liver and skeletal muscle, where glucose is stored as glycogen and the amino acids are used for the synthesis of proteins. Once feeding ends, the systemic pool of glucose is gradually reduced. This is paralleled by a fall in circulating insulin levels, a change that leads to: (1) a reduction in glucose uptake by peripheral tissues for energy production and repletion of glycogen stores, (2) an increase in gluconeogenesis and glycogenolysis by the liver to release glucose to the circulation as a fuel, and (3) increases in the oxidation of fatty acids released from adipose tissue. Finally, after an overnight fast, in a period referred to as the postabsorptive state, there is even greater mobilization of the liver glycogen and increased gluconeogenesis (from skeletal muscle release of amino acids) and enhanced fat oxidation, in order to maintain circulating glucose levels. In fact, during the postabsorptive state, fat oxidation is the major source of fuel for energy production.

In pure starvation, in the absence of a systemic inflammatory response, there is a shift over time toward preserving lean tissues by diminishing protein losses. One way such adaptation is achieved is by lowering the body's basal energy expenditure by 25 to 30% through

TABLE III Metabolic Responses to Starvation and Injury

Starvation	Injury and stress
Decreased basal metabolic rate	Increased basal metabolic rate
Increased gluconeogenesis (+)	Increased gluconeogenesis (+++)
Increased glycogenolysis (+)	Increased glycogenolysis (+++)
Increased lipolysis (++)	Increased lipolysis (++)
Increased amino acid breakdown	Increased amino acid breakdown (+++)
Increased free fatty acid use	Increased free fatty acid use
Ketone bodies (++)	Ketone bodies (+)
Low insulin levels	High insulin levels
Counterregulatory hormones (low to normal)	Very high levels of counterregulatory hormones
Typical clinical situations: COPD, chronic liver and renal disease, CHF	Typical clinical situations: trauma, severe sepsis, ARDS, SIRS

Note. COPD, Chronic obstructive pulmonary disease; CHF, Congestive heart failure; ARDS, Acute respiratory distress syndrome; SIRS, Severe inflammatory response syndrome.

changes in thyroid and catecholamine metabolism (see Table III). Meanwhile, as fasting continues beyond 2 to 3 days, the glycogen stores in the liver become completely depleted and almost half of the muscle glycogen is exhausted. The body then relies on the mobilization of amino acids (from skeletal muscle) and glycerol (from fat) to the liver in order to make glucose via gluconeogenesis. This is essential for tissues such as the red blood cells, renal medulla, and peripheral nerves that can use only glucose as fuel. The lowering of insulin, together with a rise of glucagon, further stimulates fatty acid oxidation to produce the ketone bodies acetoacetate and β-hydroxybutyrate. In this condition, called starvation ketosis, ketone bodies become an important source of fuel for skeletal muscle, visceral tissue, and brain. This adaptation diminishes the requirement for peripheral amino acid mobilization by providing an alternate fuel (ketone bodies) for those organs that are not glucose-dependent. In states of semistarvation, intakes of at least 100 g of carbohydrates will prevent starvation ketosis.

Physiologic Response to Injury and Critical Illness

What distinguishes the body's response to injury compared to that of starvation is the activation of the hypothalamic–pituitary–adrenal axis as well as the induced presence of a number of inflammatory mediators (cytokines). Irrespective of the cause of injury (i.e., severe trauma, sepsis, burn, inflammation, infection, or major surgery), there is a sudden increase in systemic cortisol concentrations as stimulated by adrenocorticotropin hormone release from the pituitary gland. Cortisol secretion, partially mediated and enhanced by cytokine production [interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor (TNF)], has principally catabolic effects. Meanwhile, cytokine-mediated resistance to anabolic hormones including insulin, growth hormone, insulin-like growth factor-I, and androgens produces net protein catabolism. The resulting net mobilization of amino acids from skeletal muscles and connective tissue provides circulating substrates for hepatic gluconeogenesis, wound healing, and support of the immune system. Meanwhile, the adrenal medulla and sympathetic nervous system are also stimulated with the systemic inflammatory response, via such triggers as pain, volume depletion, and fever. Survival becomes the priority for the body at the temporary expense of skeletal muscle mass.

In summary, supraphysiologic levels of these counterregulatory hormones lead to the net catabolism of protein, glycogen, and fat, in order to meet the heightened demands of the severe systemic inflammatory response. For the short term (7 to 10 days) in the previously well-nourished host with a mild to moderate degree of systemic inflammation, this trade-off provides a net benefit in terms of morbidity and mortality.

Cytokines and Their Role in Injury

The systemic inflammatory response, whether due to gram-negative sepsis or in response to severe injury or infection, leads to the production of a number of polypeptide mediators that are synthesized by the liver, fixed tissue, and circulating cytokine-producing cells (macrophages, endothelial cells, monocytes, and lymphocytes). Those most studied include the principal proximate cytokines (TNF, IL-1, and IL-6) that result from the activation of innate immunity. Their role in the metabolism of the critically ill is important due to their effects on insulin and counterregulatory hormone

release, as well as their direct effects on amino acid, fat, and glucose metabolism. Insulin is the principal hormone involved in glucose homeostasis, acting to regulate glucose production in the liver and to foster peripheral glucose uptake mainly by skeletal muscle. In normal circumstances, insulin also inhibits lipolysis, proteolysis, and glycogenolysis. However, in critical illness, despite relatively higher levels of insulin, the counterregulatory hormones and other mediators such as IL-1, IL-6, and TNF oppose these inhibitory effects of insulin, resulting in insulin resistance. This affects insulin's ability to reduce hepatic glucose production and to stimulate muscle glucose uptake.

CONSEQUENCES OF MALNUTRITION

In critical illness, the increase in resting energy expenditure is often overcompensated for by a dramatic reduction in activity-related energy expenditure, so that total energy expenditure may be less than in normal healthy individuals of similar body size. However, anorexia generally leads to a negative energy balance, and when combined with reduced activity, increased catabolism, and reduced protein synthetic efficiency, it produces an accelerated loss of body cell mass. After 7 to 10 days of combined semistarvation and moderate inflammatory response in an individual with an initially normal nutritional status, the body's ability to heal wounds and to support immune function begins to be impaired. Such effects are also seen with shorter periods of semistarvation in an individual with either preexisting malnutrition or severe inflammation alone. In such circumstances, likely complications include dysfunction of most aspects of immune function. Such impairments consist of diminished innate immunity, complement and immunoglubulin production, and cellular immunity as well as impairment of various aspects of leukocyte action including chemotaxis, phagocytosis, oxidative burst, and killing function. Other consequences are poor wound healing, as well as reduced performance of cardiac, respiratory, gastrointestinal, and other vital organ function. Indeed, numerous studies have clearly shown increased infectious risk, longer hospital stay, poorer outcome, and increased mortality in patients with significant unintentional weight loss (more than 10%) or significant hypoalbuminemia (<3.0 g/dl) prior to their acute illness.

NUTRITIONAL ASSESSMENT

To identify patients at high risk for protein malnutrition and those with prior protein calorie malnutrition, a systematic and comprehensive nutritional assessment is crucial. Such an assessment begins with a thorough history and physical examination. Through this evaluation, the clinician should be able to estimate the body composition and analyze the pertinent laboratory values, with an effort to compile all of the subjective and objective data required to define the patient's nutritional state.

Clinical History and Physical Examination

A nutritional history should include the patient's recent state of health and current complaints and symptoms related to recent dietary intake, signs of systemic inflammation, and voluntary motor activity. Special attention should be given to any gastrointestinal symptoms, such as nausea, vomiting, diarrhea, and dysphagia, as well as to the patient's dietary and weight history. An unintentional weight loss of approximately 10% in the recent past indicates a significant degree of semistarvation and a mild degree of PCM. Moderate PCM is usually characterized by a 10 to 20% weight loss and severe PCM should be considered when there is weight loss of more than 20% from baseline. Generally, in unintentional weight loss that develops with disease, approximately 50% of the loss is from body fat stores. Prior to hospitalization, if a premorbid weight is not available, the patient's weight can be compared to the established standards of weight in relation to height. A weight of 85% or less of the desirable range for a particular height indicates the likelihood of PCM. Body mass index (BMI), which is weight in kilograms divided by the height in meters squared, is another helpful parameter for diagnosing malnutrition, because it is independent of the patient's gender and height. The normal range is 20 to 25 kg/m^2 and a value less than 18.5 kg/m^2 represents significant PCM. Death from PCM is likely when the BMI falls in the range of 12 to 14 kg/m^2. A BMI of 25 to 30 kg/m^2 is considered to represent overweight and values greater than 30 kg/m^2 indicate the presence of obesity. In two common settings, body weight becomes a less specific marker of malnutrition. First, in many chronically ill patients who have a relative increase of their total body water due to decompensated hepatic, renal, or cardiac function, the increase in weight represents overhydrated lean tissue. Up to one-half of such patients will have severe PCM when assessed by specific measures such as upper arm anthropometry or total body nitrogen. Second, after hospitalization, particularly in critically ill patients, an increase in the total body water is expected due to elevated antinatriuretic and antidiuretic activity characteristic of the systemic inflammatory response related to the increased secretion of aldosterone, vasopressin, and insulin. This

state of overhydration is often compounded by massive volume resuscitation in the most critically ill patients or more commonly by the failure to restrict total fluid intake in the critically ill particularly when it is considered that 1.5 to 2 liters/day is necessary for adequate nutritional support in the absence of increased fluid losses.

Assessments of the Body Compartments

Anthropometry

During starvation alone or with accompanying stress, the contribution of the lean tissue to body weight loss ranges from 25 to 50%, respectively. Although individuals who suffer from more critical illnesses (i.e., closed head injury, multiple trauma, severe sepsis, or major burns) sustain lean tissue to fat loss ratios of 75 : 25, when not fed, their lean tissue and weight loss is usually masked by fluid retention. Simple assessment of body compartments can still be a valuable and an important task in determining an individual's nutritional status. One simple and inexpensive estimation of the body reserves is via upper arm anthropometry, particularly in patients with marasmus and in patients with volume overload states, such as those with chronic hepatic, renal, and cardiac failure. The triceps skinfold (TSF) and subscapular skinfold thickness are generally used as indexes of body fat. Such measurements have fallen out of favor due to their low level of sensitivity, lack of correction for hydration status, and heterogeneity in normal individuals. By themselves, they are not very sensitive, since many healthy individuals have a body fat composition of less than 5%. However, due to their relative simplicity, such measurements should be considered with the intent of identifying the most severely malnourished patients, a group who can certainly benefit from nutritional support. Upper arm anthropometry consists of the measurement of TSF thickness with skinfold calipers (in centimeters), measurement of the mid-arm circumference with a tape, and the calculation of the mid-arm muscle circumference (MAMC) using the following calculation: MAMC (centimeters) = arm circumference $-$ (3.14) $\times$ (TSF in centimeters). MAMC is used to estimate the total skeletal muscle mass. A value of less than the fifth percentile of the normal standard indicates the presence of severe PCM and losses of at least 30% of normal lean tissue.

Creatinine–Height Index

Another means of estimating lean tissue stores, specifically the muscle mass, is by measuring urinary creatinine excretion over a 24 h period. Once normalized for height, this measure is a reasonable index of the skeletal muscle mass, which is the body's largest compartment of actively metabolizing lean tissue, and a good estimate of body cell mass and lean body mass. What makes this a difficult parameter to rely on is the relative inconvenience and frequent inaccuracy of the collection in ambulatory patients. It is also not as reliable in patients with diminished creatinine clearance, with serum creatinine in the range of 4 to 6 mg/dl. Creatinine–height indexes (CHIs) of less than 75% and less than 60% of normal indicate moderate and severe protein depletion, respectively. A CHI of 60% of normal also correlates well with a MAMC below the fifth percentile, again indicating severe PCM.

Other Methods

Methods of total body water measurement, directly using isotope dilution or indirectly by bioimpedance analysis and underwater weighing, are much more accurate means of estimating the lean body mass and body cell mass. These techniques are based on the concept that fat-free body mass (lean body mass) and body water maintain a relatively close and stable relationship, which is true in health but not in disease. One can calculate the fat compartment by subtracting the fat-free body mass from the body weight. The value of these methods of body composition analysis is most evident in patients with marasmus, but they are of little value in patients with chronic cardiac, renal, or hepatic disease with fluid retention or in patients with critical illness leading to distortions in tissue composition. Dual-energy X-ray absorptiometry (DEXA) and total body nitrogen by neutron activation are more recent and more accurate techniques of estimating body compartments. The latter technique is valid even in the critically ill. Despite the accuracy and the sensitivity of DEXA and the neutron activation method, due to their expense and limited availability, as well as lack of a general knowledge of their role among most clinicians, they remain essentially research tools.

Serum Markers

Serum albumin is the most studied and cited value associated with the assessment of nutritional status. It is the most abundant serum protein and quantitatively the largest synthetic product of the liver. A low serum albumin can help differentiate between marasmus and hypoalbuminemic malnutrition (protein malnutrition). In marasmus, the albumin level is always above 3 g/dl and often normal. However, as the sole indicator of nutritional status, albumin is not a very sensitive marker. In fact, with ongoing stress, even with adequate nutritional support, serum albumin levels cannot be restored to normal. A low albumin level is seen in all

conditions of chronic inflammation and levels are severely depressed when the systemic inflammatory response is severe (i.e., major burns, severe sepsis, closed head injury, and multiple trauma). An understanding of the physiology of albumin clarifies these changes. The decline in serum albumin in the setting of injury, stress, and severe infection is due to several forces that are cytokine-mediated: (1) extravasations of the albumin molecule into the extravascular space as a result of an increased capillary permeability, (2) cytokine-induced reduction of hepatic albumin synthesis, (3) an increase in the breakdown of albumin, and (4) a reduction in hepatic production due to low protein intake. In addition, untreated edematous states due to volume overload are almost always manifested with serum albumin levels below normal. And since albumin is a negative acute-phase protein, when abnormally low, it indicates the recent presence of a systemic inflammatory response that also causes a reduction in dietary intake, increased rates of lean tissue catabolism, and reduced rates of protein synthesis. Thus, hypoalbuminemia results as a consequence of the systemic inflammatory response, which then commonly leads to protein calorie malnutrition. Studies have demonstrated a strong association between hypoalbuminemia and increased medical and surgical complications in hospitalized patients and poorer prognosis in outpatients with disease. A low serum albumin is an excellent predictor of morbidity, mortality, and longer hospital stay. Although not a specific index of malnutrition, it is a valuable tool in identifying the group of individuals with the greatest need for nutritional support—those with severe metabolic stress who are likely to have significant loss of lean tissue.

A number of other serum proteins (transferrin, retinol-binding protein, and prealbumin) have been used in the evaluation of malnutrition. Due to their shorter half-lives, they have been studied as potential alternatives to albumin. Like albumin, they are also negative acute-phase proteins; they have not been shown to be superior to albumin as indicators of the systemic inflammatory response. As with albumin, their response to nutritional support is limited until the systemic inflammatory response remits.

FUNCTIONAL TESTS FOR MALNUTRITION

To assess the physiologic and functional consequences of malnutrition and to evaluate the effects of nutritional support, a number of tests have been designed to address this issue on more subjective grounds. Delayed hypersensitivity skin testing can be used to assess cell-mediated immunity, which is often impaired in malnutrition of many varieties, including protein, calorie, iron, zinc, essential fatty acid, vitamin B12, and folate deficiencies. Even though the skin anergy of malnutrition is correctable with nutritional repletion, the multifactorial nature of this type of immune suppression makes skin testing a very insensitive tool. Other functional tests, for instance, hand-grip strength using an ergometer, electrophysiologic studies of the adductor pollicis muscle relaxation, and assessment of respiratory muscle strength, have all been shown to be good indices of nutritional changes due to illness, as well as reasonable predictors of postoperative morbidity. However, the use of such techniques is limited to those individuals who can cooperate and have good cardiopulmonary status and they have not found wide applicability as measures of response to nutritional support.

SUBJECTIVE GLOBAL ASSESSMENT

In an effort to combine all of the objective data along with the clinical and historical elements, an approach termed subjective global assessment (SGA) has been proposed. This systematic approach tries to incorporate the relevant clinical factors influencing the patient's nutritional state. The SGA is a bedside clinical assessment focusing on five areas: severity, duration, and the pattern of weight loss; dietary intake; presence of gastrointestinal symptoms; the individual's functional capacity; and finally, the metabolic demands of the patient's illness. Furthermore, several aspects of the physical examination, such as estimation of the subcutaneous fat and muscle bulk, cutaneous and hair lesions, and the fluid status, are all incorporated in the assessment to finally categorize the patient as being well nourished (category A), moderately malnourished (category B), or severely malnourished (category C). Studies show that the SGA is a reproducible way of categorizing one's nutritional state and it is a more accurate predictor of postoperative complications than serum albumin, anthropometry, creatinine–height index, and many other traditional markers of nutritional status taken individually.

NUTRITIONAL SUPPORT

Due to the prevalence of protein calorie malnutrition in hospitalized patients and the well-documented association between poor nutrition and increased morbidity and mortality, invasive nutritional therapies are

commonly employed in hospitalized patients. In order to identify the patients at risk and to provide appropriate and effective nutritional support, a thorough and early evaluation by a team of physicians and dieticians is crucial. The timing of initiation of nutritional support depends on the patient's nutritional assessment. In the absence of prior malnutrition and with an on-going moderate systemic inflammatory response, initiating invasive feeding 5 to 7 days or, even more conservatively, 7 to 10 days after a period of fasting, if oral intake has not resumed, is a reasonable and well-accepted guide. Those with a poor premorbid nutritional status (i.e., more than 10% weight loss or a BMI of less than 18.5 kg/m^2) and superimposed illness are not as able to mount an adequate inflammatory response. They often have nutritionally related impairment of their protein synthetic capacity and are more prone to organ failure. It is therefore important not to delay nutritional therapy in such individuals and to intervene within the first several days. Although it is even more effective to feed moderately malnourished individuals for 7 days prior to an elective major operative procedure, present-day reality is that early postinjury feeding is generally the rule. On the other hand, those with the most severe injuries, such as multiple trauma, major burns, closed head injury, and severe sepsis, can have lean tissue losses of 600 to 900 g/day and early feeding is essential. In this group of patients, even in the absence of pre-illness weight loss, adjuvant nutritional therapy should be started soon after the acute resuscitation and metabolic issues are resolved. Although many patients with major traumatic or burn injury are not malnourished at the time of presentation, their heightened degree of catabolism and increased metabolic demands quickly lead to severe protein malnutrition.

Thus, the goals of nutritional provision should be to provide adequate amino acids and energy along with essential nutrients, so as to allow optimal protein synthesis for the support of the immune system, wound healing, and vital organ function. The initial goal is to diminish but not to completely reverse protein loss, since this is not possible initially, given the intensity of the systemic inflammatory response and the major reduction in voluntary muscle activity. It is important to keep in mind that, in order to safely provide nutritional support for optimal protein synthesis, energy intake to meet balance is not necessary. Additionally, it should not be the goal of therapy in the first weeks of most injuries, as efforts to match and particularly to exceed the high metabolic energy needs of the injured and the critically ill have not been shown to be beneficial. In fact, they can lead to overfeeding complications such as hyperglycemia, hepatosteatosis, and immune suppression.

Modes of Nutritional Delivery

With a functional gastrointestinal tract, the traditional approach has been to deliver nutritional therapies enterally. Enteral feeding is a more physiologic route; in addition, theoretical reasoning has been used in support of this method. Bacterial translocation, in the absence of lumenal gut content, has been postulated to lead to septic complications. Although bacterial translocation has been demonstrated to be significant in animal models, confirmatory studies in humans have been inconclusive. To date, no studies in human have convincingly shown that such translocation is reduced via enteral feeding or promoted by parenteral nutrition. Although fasting does lead to minor architectural changes in the intestinal mucosa, the gut mucosal barrier in human does not seem to be impaired. Furthermore, in the critically ill and in many postsurgical patients, intolerance of enteral feeding, particularly when feeding into the stomach, is common. Total parenteral nutrition (TPN) is a well-established means of providing nutritional support in such patients and there is no clear evidence that this method has more risks or is less effective than enteral nutrition. Although many clinicians recommend the use of the enteral route versus the parenteral route based on the belief that parenteral nutrition is more likely to produce infectious complications, it appears from a closer review of the literature that many of the complications were more clearly related to overfeeding. When provided appropriately and with care, there are no significant differences between the two different modes of delivery. When it is possible to use enteral feeding to meet nutritional goals, this method is preferred, but TPN exclusively or in combination with enteral feeding should be considered when such goals are not achievable by enteral feeding alone. An added benefit to combination feeding is that such individuals tend to transition to full enteral feeding more quickly than those who are fed exclusively via the parenteral route.

CONCLUSION

Malnutrition in clinical practice is very common and, although it is an independent risk factor for morbidity, when accompanied by disease it can have an even more negative impact on outcome. The recognition of malnutrition requires an understanding of its physiological and functional consequences as well as an appreciation of its effects on body composition. There is a sizable body of suggestive evidence demonstrating that adjuvant nutritional support, when administered adequately, to the right group of patients, and in a timely fashion, can significantly improve outcomes.

Malrotation

ROBERT W. CHANG, STEVEN M. ANDREOLI, AND MORITZ M. ZIEGLER
Children's Hospital Boston

Ladd's bands Peritoneal attachments to an abnormally positioned cecum. They can cause obstruction of the duodenum by extrinsic compression.

short bowel syndrome A spectrum of intestinal malabsorption that occurs after major resection of the small intestine.

volvulus A twisting or displacement of the intestine around a fixed focal point that can cause obstruction and/or strangulation.

Malrotation is defined as an abnormal position of bowel created by a variance in its embryologic development. Normal development of the human intestine includes rotation and fixation of the embryonic midgut. Abnormalities of this process create a spectrum of anomalies, which vary in their clinical significance from asymptomatic presentations to a twist of the midgut (volvulus) and abdominal catastrophe.

INTRODUCTION

Embryologic variation in midgut formation has long been recognized. Calder, in 1752, first described congenital duodenal obstruction due to malrotation. In 1898, Mall described the embryology of abnormal intestinal rotation. Dott, in 1923, correlated embryologic observations with clinical evidence and suggested a surgical treatment for duodenal obstruction. In his landmark article in 1932, Ladd described the surgical procedure that bears his name and remains the gold standard treatment for this condition.

The true incidence of malrotation of the midgut is difficult to determine. The autopsy prevalence may be as high as 0.5 to 1% of the total population, but the incidence in patients with clinical symptoms may be much less. The clinical presentation in the infant may occur in 1 in 6000 live births. Malrotation accounts for

approximately 1 in 25,000 of all hospital admissions. Fifty to 75% of these patients will present with symptoms in the first month of life, with 90% of all patients presenting within the first year of life. Although volvulus and bowel ischemia present more frequently before 1 year of age, they can occur at any age. In the neonatal age group, males predominate in a 2 : 1 ratio, but this difference disappears with age. Sixty-two percent of patients with malrotation have associated gastrointestinal anomalies including intestinal atresia, duodenal web, Meckel's diverticulum, intussusception, Hirschsprung's disease, extrahepatic biliary system anomalies, and gastric volvulus.

EMBRYOLOGY AND DEVELOPMENTAL PATHOLOGY

The primitive gut is initially a tubular structure composed of endoderm. In the human, the intestinal segment that opens ventrally into the yolk sac is defined as the midgut (see Fig. 1). This portion will come to be supplied by the superior mesenteric artery (SMA), which serves as its axis, with the omphalomesenteric duct located at its apex. The primary loop rotates 180° counterclockwise such that the proximal "prearterial" loop lies posterior to the SMA. The cranial section of this limb will become the duodenum and its proximal position is fixed to the right of the SMA. The more distal portion of the prearterial loop becomes fixed to the left of the SMA and becomes the third and fourth portions of the duodenum, attached by the ligament of Treitz to the body wall to the left of the aorta, at or just above the level of the gastric outlet. Thus, the distal portion of the duodenum ultimately completes a 270° turn counterclockwise (Fig. 1).

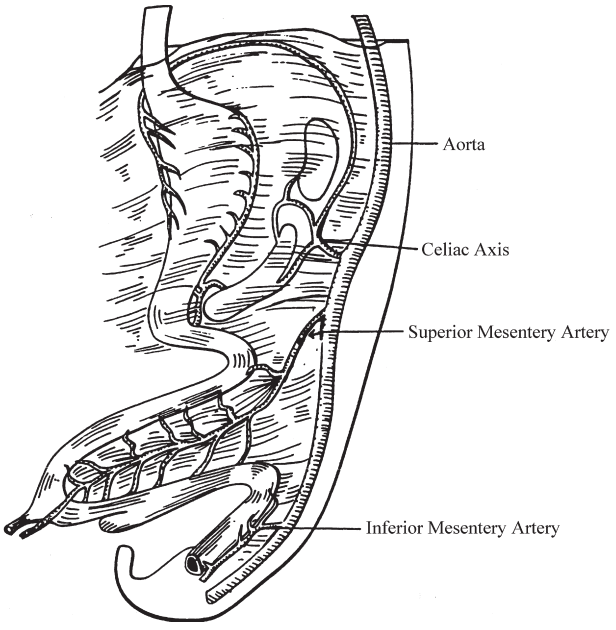

FIGURE 1 The primitive midgut grows to form an intestinal loop and its blood supply is from the superior mesenteric artery. Figure is from the personal collection of M. M. Ziegler.

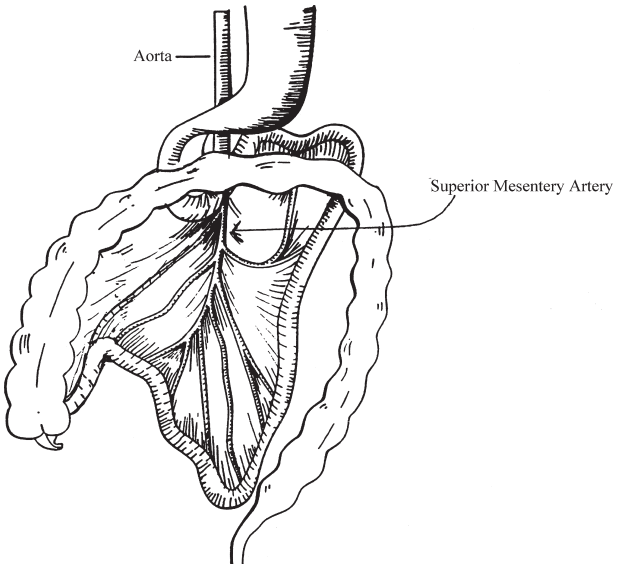

FIGURE 2 The correct anatomical location of the midgut after it rotates 270° counterclockwise around the axis of the superior mesenteric artery. Figure is from the personal collection of M. M. Ziegler.

The jejunum and proximal ileum undergo elongation to eventually form the primary loops of bowel at birth. The postarterial limb of the midgut becomes the terminal ileum, the cecum, and the proximal transverse colon. This segment also rotates 270° counterclockwise but does so anterior to the SMA.

Following the initial growth and rotation phases of the midgut outside of the fetal body stalk, the midgut retracts into the abdominal cavity. The duodenal–jejunal junction will come to lie posterior to the SMA, the small bowel will lie both to the right and to the left of midline, and the cecum and ascending colon will end up anterior to the SMA.

The final step in midgut positioning is fixation to the posterior body wall (see Fig. 2). After reduction into the left abdomen, the cecum descends and is fixed normally in the right iliac fossa. The intestinal mesentery is fixed in an oblique orientation from this point to the left upper quadrant where the ligament of Treitz secures the duodenum. This broad-based fixation is critical for the stability of the intestine and mesentery (Figs. 2 and 3). When considering rotational abnormalities, it is useful

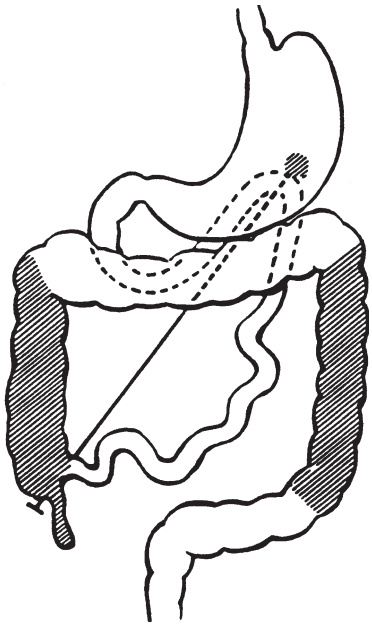

FIGURE 3 The normal attachment of the small bowel mesentery. Its broad base extends from the ligament of Treitz to the cecum. The ascending colon and descending colon are fixed retroperitoneally. Figure is from the personal collection of M. M. Ziegler.

to think of embryologic development in three main stages: herniation, rotation and return, and fixation. Herniation usually commences during the 5th to 10th weeks of gestation. Failure to go beyond this stage results in an omphalocele. Although not usually considered a true malrotation, the embryologic abnormality of intestinal orientation in this entity is a form of nonrotation.

The return of the intestinal contents to the abdomen is usually accomplished during the 10th to 12th weeks and associated abnormalities create a variety of pathologic entities. One form of rotational anomaly (nonrotation) occurs when the gut fails to rotate; that is, the gut turns less than 90° instead of the normal 270°. The distal cecocolic limb enters the abdomen first instead of last. Thus, nonrotation occurs when the duodenum descends inferiorly to the right of the SMA. The small bowel lies to the right and the colon lies on the left. The cecum is located at or near the midline and the small intestine lies to the right of midline. This condition may produce subtle symptoms and volvulus can occur. This variant has been reported in 0.2% of gastrointestinal contrast studies (Fig. 4).

Incomplete rotation is characterized by the arrest of normal rotation at 180° and may cause duodenal obstruction by either extrinsic compression or volvulus. The prearterial segment fails to complete the positioning posteriorly and to the left of the SMA. The cecum comes to lie in the upper abdomen usually to the left of the SMA and posterior wall attachment is accomplished by peritoneal bands, known as Ladd's bands, that can potentially cross and obstruct the duodenum. These bands are derived from embryonic dorsal mesogastrium and usually serve to secure the cecum and mesocolon to the posterior body wall (Fig. 5). As with nonrotation, the resulting narrow vascular pedicle provides an opportunity for volvulus to occur (Fig. 6).

Reverse or mixed rotations are less common forms of malrotation that can be caused by rotational arrest anywhere in midgut development. This creates a wide spectrum of anomalies that range from an incompletely descended cecum to more serious conditions that predispose to volvulus. For example, reverse rotation occurs when there is an abnormal 90° clockwise turn instead of the opposite 270° counterclockwise rotation. The distal limb enters the cavity first and rotates in a counterclockwise manner 180° about the SMA base. The duodenum will then lie in front of the transverse colon, producing a retroarterial tunnel, which may result in vascular or lymphatic occlusion (Fig. 7).

Paraduodenal or mesocolic hernias are a rare group of anomalies that occur when the small bowel is trapped behind the mesocolon as the colon attaches

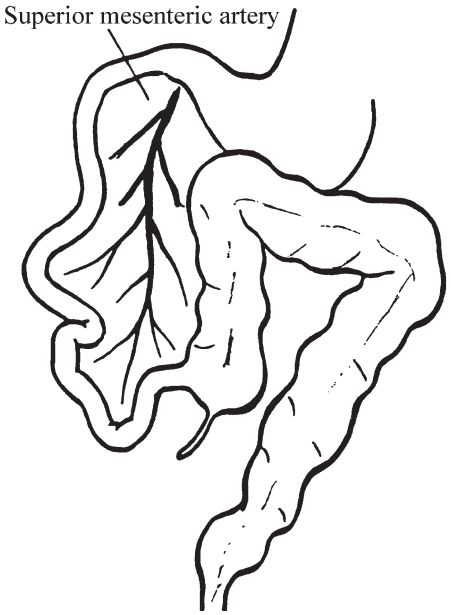

FIGURE 4 Nonrotation. Return of the postarterial segment first leaves the colon on the left and the small intestine on the right. Note that the ileum enters the cecum from the right side. Figure is from the personal collection of M. M. Ziegler.

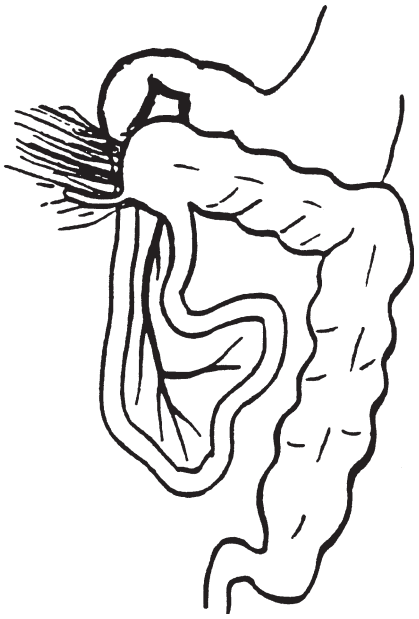

FIGURE 5 Malrotation. Duodenal obstruction can occur from Ladd's bands. Figure is from the personal collection of M. M. Ziegler.

to the retroperitoneum. Failure of proper mesocolic–posterior body wall fixation offers potential space on either side for bowel sequestration and entrapment. Right-sided hernias occur as the prearterial limb fails to rotate around the SMA and is entrapped by the mesocolon of the cecum and ascending colon. A left-sided hernia occurs when the prearterial limb rotates to the left and invaginates the mesocolon of the descending colon. The colon continues its normal positioning and the small bowel becomes encased in a mesenteric sac. As with any hernia, these situations present a potential risk for obstruction, incarceration, and strangulation of the intestine.

Fixation normally begins after the 12th week of gestation. Failure of this process results in a mobile or subhepatic cecum or a retrocecal appendix. The subsequent mesenteric mobility may increase the risk for volvulus.

PRESENTATION AND DIAGNOSIS

The symptoms of malrotation generally result from either partial duodenal obstruction or midgut volvulus. The manner of presentation usually follows an age distribution.

Presentation in the newborn period is usually acute. Bilious emesis is a cardinal manifestation of neonatal intestinal obstruction and demands that malrotation be included in the differential diagnosis. Less common symptoms include coffee ground emesis, distension, pain, and bloody stools. Duodenal obstruction is most often caused by extrinsic compression from Ladd's

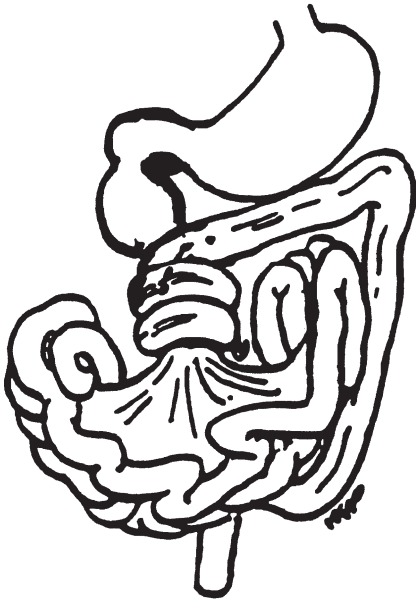

FIGURE 6 Malrotation. Duodenal obstruction can occur from volvulus. Figure is from the personal collection of M. M. Ziegler.

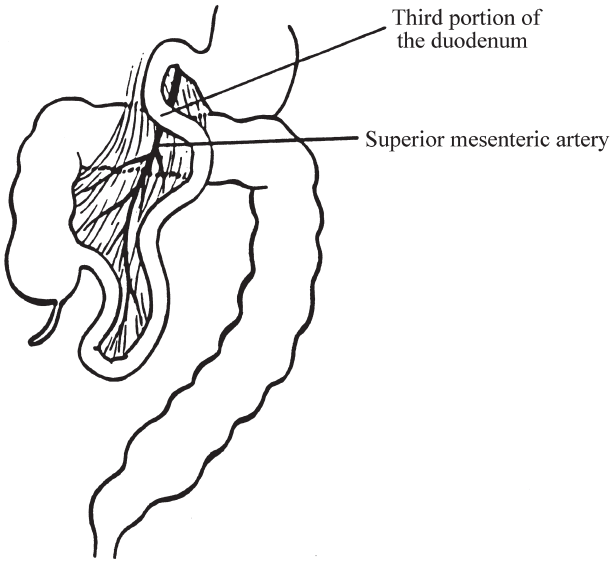

FIGURE 7 Reverse rotation. The duodenum is anterior to the superior mesenteric artery, which in turn is anterior to the transverse colon. Figure is from the personal collection of M. M. Ziegler.

bands. Ladd's bands cross anteriorly and laterally to the descending duodenum; thus, a postampullary site is the typical point of obstruction with characteristic bilious vomiting. There is a low but significant incidence of associated intrinsic duodenal obstruction, which may occur in the form of a web, stenosis, or true atresia. This is seen in 8–12% of patients who undergo operation for malrotation and it should be excluded by either careful inspection or by passage of a trans-lumenal balloon-tipped catheter. The physical examination may be normal in up to 50% of patients. Among older patients, presentations include chronic abdominal pain, weight loss or failure to thrive, chronic pancreatitis, or other relatively nonspecific gastrointestinal complaints. A number of patients present asymptomatically, in which the lesion is discovered incidentally.

The most pressing clinical concern is the presence of SMA pedicle torsion and volvulus. Midgut volvulus is the presentation in approximately half of the patients who come to operation for rotational abnormalities. Guiac-positive stool or hematochezia resulting from mucosal injury is a relatively common early finding. The patient may present *in extremis* and midgut volvulus has the tragic sequelae of bowel necrosis, sepsis, hypotension, acidosis, respiratory failure, and coagulopathy. The outcome for midgut volvulus is time-dependent, which is the reason that all suspected neonatal intestinal obstruction is aggressively diagnosed and treated.

For pediatric intestinal obstruction, the adjunct diagnostic algorithm generally begins with a plain abdominal radiograph. Classic early findings may reveal a nonspecific bowel gas pattern or may show gastric or duodenal distension. The "duodenal triangle," a triangular gas shadow in the right upper quadrant, thought to be the liver edge overlying the duodenum, has been described as a reliable radiologic sign for malrotation. Plain films, however, cannot rule out malrotation and may not distinguish between intrinsic and extrinsic duodenal compression.

The study of choice when malrotation is suspected is the upper gastrointestinal contrast series. Typically, it will show an abnormally located duodenojejunal junction; normally this junction lies to the left of the midline, at the level of the pylorus and fixated posteriorly. In malrotation, the junction is seen lower, more anterior, and in the midline or to the right. The presence of distal contrast will rule out duodenal atresia, but it does not differentiate malrotation from duodenal stenosis or an intrinsic web. Typically, in the presence of volvulus, narrowing of the duodenum will produce signs of torsion or compression, with image descriptors such as "bird beak," "corkscrew," or "coiled" used. Diagnostic uncertainty requires immediate operation.

The use of contrast enemas may define a high, abnormally located cecum and it may help in investigating more distal neonatal intestinal obstruction. It has limited utility in the diagnosis of malrotation.

Other modalities such as ultrasonography, computed tomography, and angiography have shown some efficacy in identifying axial relationships of the SMA pedicle. The typical finding is a reversed anatomic relationship of the SMA and SMV, which in malrotation cases would find the SMA in an aberrant anterior or left position. Angiographic findings of volvulus are described as a "barber pole" sign, due to the whirling of the mesenteric vessels and the dilated SMV with developed, dilated collateral vessels. As with plain films, a normal axial investigation does not rule out malrotation. These studies are helpful in diagnosis, but have no role in the acute setting, especially in the newborn, when time is of the essence. The most prudent diagnostic and therapeutic evaluation may be exploratory laparotomy.

TREATMENT

Neonates and infants who are diagnosed with malrotation require emergent operative management. Prompt evaluation, aggressive resuscitation, and timely preoperative preparation are essential for successful outcomes. The urgent nature of this disease must be stressed to the clinician. If the midgut is found to be unsalvageable at laparotomy, the survival rate falls to 50% and lifelong short bowel syndrome requiring parenteral nutrition is indicated.

The modern operative procedure is still based on the classic description by Ladd and proceeds as follows: abdominal entry is made through a wide transverse supraumbilical incision. Rapid exploration is then carried out with complete evisceration of the midgut. The usual finding at operation is either midgut volvulus or an aberrant location of the cecum and right colon. After the root of the mesentery is inspected, the volvulus, if present, is relieved by counterclockwise rotation of the affected segment (Fig. 8). The bowel may require a period of intraoperative warming and observation to assess viability. Ladd's bands stretching across the duodenum from the right upper quadrant are then divided (Fig. 9). To prevent recurrence, the base of the mesentery is broadened by dividing the peritoneal attachments of the cecum, small bowel mesentery, mesocolon, and duodenum (Fig. 10). The second, third, and fourth parts of the duodenum are then straightened and positioned along the right abdomen. The ileocecal junction is positioned in the left lower quadrant. If the bowel is deemed to be viable, intestinal contents are milked distally to

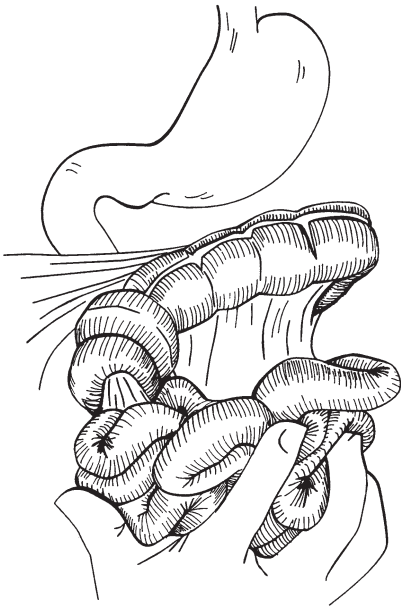

FIGURE 8 Counterclockwise detorsion of midgut volvulus. Figure is from the personal collection of M. M. Ziegler.

assess lumenal patency. An appendectomy is performed before the cecum is placed in the left lower quadrant (Fig. 11). Cecopexy has not been shown to offer any benefit.

Mesocolic hernias are addressed by dividing the lateral peritoneal attachments. Left hernias require mobilization of the inferior mesenteric vein and reduction and closure of the hernia sac. If properly performed, recurrence is rare. The overall incidence of adhesive small bowel obstruction following surgery approaches 10%.

If a limited segment of bowel is necrotic, resection and primary anastomosis is performed. In some cases, the severity of bowel edema prevents primary closure and silo or Gortex closure should be used. After appropriate resuscitation and hydration, a second-look laparotomy is performed in 36–48 h. In tragic situations where most or all of the midgut is necrotic, closure and family discussion should take place before a total enterectomy is performed.

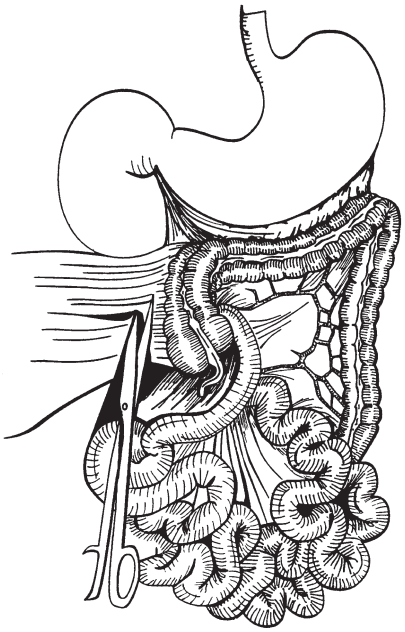

FIGURE 9 Incision of Ladd's bands is critical in order to relieve duodenal obstruction. Figure is from the personal collection of M. M. Ziegler.

OUTCOME AND FUTURE DIRECTION

In Ladd's original report, 8 of 35 patients died and there were no recurrences in the remaining patients (27 of 35). In current practice, the Ladd procedure is the therapy of choice and carries an overall mortality of 3–9%. The mortality rate increases with the presence of intestinal necrosis and prematurity. Eighteen percent of patients with short bowel syndrome had midgut volvulus and subsequent bowel resection as the etiology of their disease.

In patients found to have malrotation as an incidental finding on radiologic studies or at laparotomy for other reasons, a Ladd procedure should be performed. There is no way to accurately predict which patients are at risk for potentially catastrophic volvulus; therefore, early treatment minimizes morbidity and mortality.

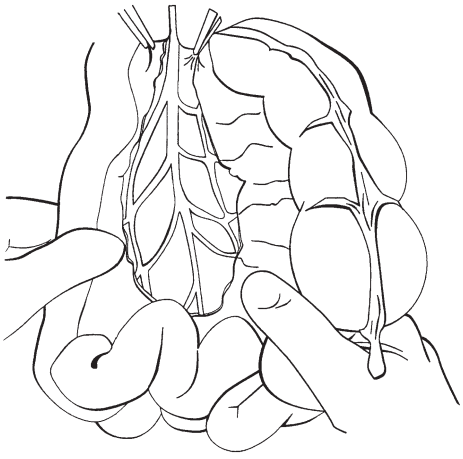

FIGURE 10 The peritoneal layers on the anterior surface of the small bowel mesentery are incised in order to broaden the base of the mesentery. Figure is from the personal collection of M. M. Ziegler.

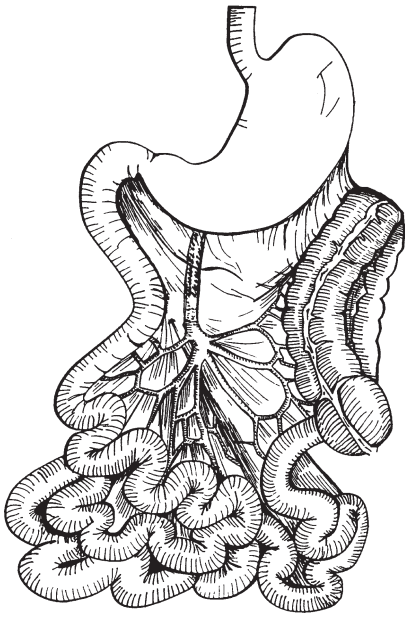

FIGURE 11 The operative findings at the end of a Ladd's procedure. Note that the duodenum is straightened out in the right flank. The cecum is now in the left lower quadrant and an appendectomy has been performed. Figure is from the personal collection of M. M. Ziegler.

In the past 10 years, several groups have shown the safety and efficacy of laparoscopic Ladd's procedures in cases of malrotation without volvulus. The advantage of this technique includes minimal morbidity from trocar sites compared with the generous supraumbilical incision. Return to full feeding can occur as soon as 24 h after surgery compared with several days following open surgery, leading to an overall decrease in hospital stay. There is general agreement that this approach should be limited to cases without volvulus due to the friability and delicate nature of the compromised bowel.

Manometry

FERNANDO AZPIROZ
University Hospital Vall d'Hebron, Autonomous University of Barcelona

achalasia Ineffective esophageal peristalsis and defective relaxation of the lower esophageal sphincter in response to swallowing, due to depletion of inhibitory nerves in the esophageal smooth muscle.

diffuse esophageal spasm Disordered esophageal peristalsis; diagnosed by manometry; frequently associated with chest pain or dysphagia of unknown origin.

Hirschsprung's disease Congenital disorder characterized by severe constipation due to absence of neurones in the myenteric plexus of the distal gut.

hypertensive lower esophageal sphincter Manometric finding of uncertain clinical significance; frequently found in patients with noncardiac chest pain or nonorganic dysphagia without detectable underlying cause.

intestinal pseudo-obstruction Clinical symptoms, either recurrent or chronic, resembling a mechanical obstruction of the gut without demonstrable luminal compromise.

nutcracker esophagus Vigorous peristaltic contractions of the esophageal body; frequently associated with chest pain or other symptoms, such as depression, anxiety, and somatization, without a clear underlying cause and with uncertain clinical significance.

Gut manometry, the measurement of intraluminal pressures in a segment of the gut in order to study motor function. Pressures in the alimentary canal can be measured using an intraluminal tube, either with microsensors mounted over the tube or with a multilumen tube in which each lumen has a distal intraluminal opening and is proximally connected to an external pressure transducer.

ESOPHAGEAL MANOMETRY

Definition and Technique

Esophageal manometry is a well-established and standardized test that measures the motor activity of the esophagus and the sphincters during basal conditions and in response to swallowing. The esophagus is a muscular tube with sphincters on each end. It is separated from the pharynx by an upper sphincter with a basal contraction of about 40–120 mmHg, and is separated from the stomach by a lower sphincter with a basal contraction of about 10–45 mmHg above intragastric pressure. The body of the esophagus is intrathoracic and has negative intraluminal pressure. Pharyngeal contraction during swallowing is associated with a complete relaxation of both the upper and the lower esophageal sphincters, and once the bolus has entered the esophagus, a contraction of the upper sphincter is followed by a peristaltic contraction that migrates distally at a velocity of 2–4 cm/sec. The magnitude of the esophageal contraction increases distally (up to 40–130 mmHg in the lower third). Once the contraction reaches the lower sphincter, it recontracts.

Outcome Measures

Esophageal manometry has several possible outcomes:

1. Achalasia. The manometric diagnosis is based on 100% failed peristalsis (no peristaltic contractions), usually in the form of simultaneous contractions of the esophageal body in response to swallowing. Secondary criteria are incomplete or absent relaxation of the lower sphincter and positive basal pressure in the esophageal body due to retention.

2. Diffuse esophageal spasm. This disorder is defined by normal peristalsis alternating with more than 30% of the swallows with failed peristalsis, usually with simultaneous contractions. No characteristic lesion has been uniformly found in association with this entity.

3. Nutcracker esophagus. This disorder is defined by hypertensive but otherwise normal peristalsis (distal contractions >180 mmHg).

4. Hypertensive lower sphincter. This disorder is defined by increased basal pressure (>45 mmHg) with otherwise normal function.

5. Nonspecific motor disorders. These disorders are represented by a series of manometric findings that seem to occur more frequently in patients with unexplained symptoms, such as dysphagia or noncardiac chest pain, than in healthy subjects; their true clinical significance is not known. These disorders are defined by normal peristalsis plus one or more of the following symptoms: nontransmitted contractions ($>20\%$), prolonged contractions (>6 sec), triple-peak contractions, retrograde contractions, and weak contractions (<35 mmHg).

 Copyright 2004, Elsevier (USA). All rights reserved.

Indications

Suspected achalasia, suspected diffuse esophageal spasm, and symptoms of presumed esophageal origin without detectable abnormalities by conventional radiologic and endoscopic tests; however, the clinical significance of nonspecific motor disorders in this context is not clear. In cases involving systemic diseases, particularly connective tissue diseases, diabetes, and somatic myopathies, manometry may help to establish esophageal involvement by identifying weak peristalsis, weak lower sphincter, and/or nonspecific motor disorders. In patients with gastroesophageal reflux disease, manometry may be indicated before surgery to definitively rule out primary motor disorders and to assess peristaltic function, although the impact of the latter on treatment remains debatable. Because manometry locates the lower esophageal sphincter, it may be used to guide positioning of intraluminal devices, particularly electrodes for pH monitoring. Finally, abnormal esophageal motility may mimic various disorders, such as anorexia nervosa, that may be correctly identified by manometry.

INTESTINAL MANOMETRY

Definition and Technique

Intestinal manometry measures the motor activity of the upper small intestine either with or without simultaneous recording of antral activity. Evaluation of intestinal activity requires long observation periods ($\geq$5 hours) both during fasting and in response to ingestion of a meal. Intubation of the small bowel is usually guided by a steerable catheter or by endoscopy. Normally, during fasting, the upper gut exhibits a cyclical motility pattern of alternating periods of quiescence and activity. The periods of activity develop at variable intervals of about 100 min, initiate in the antrum, and migrate into the intestine at about 5–10 cm/min. After a meal, this cyclical motility pattern is interrupted and converted into a fed pattern, with regular antral activity at three contractions per minute and continuous irregular intestinal activity. The duration of the fed pattern depends on the type and volume of the meal.

Outcome Measures

Intestinal manometry has several possible outcomes:

1. Myopathic pattern. Impaired contractile capability of the intestinal wall produces low-amplitude contractions with otherwise preserved motor patterns. This type of pattern corresponds either to a myopathy (hollow visceral myopathy, myotonic dystrophy, or dermatomyositis) or to an infiltrative process (scleroderma or amyloidosis).

2. Neurophatic pattern. This pattern is characterized by contractions of normal strength but abnormal organization, due to an alteration of the neural mechanisms that control motility. The neuropathy may affect neural pathways at any level between the brain and the gut (brain tumor, autonomic neuropathy, or enteric neuropathy), without distinguishable manometric characteristics. The types of abnormalities are defined as abnormal migration or configuration of the activity periods during fasting (simultaneous appearance, retrograde propagation over 30 cm, or discrete elevation of the baseline of $>$30 mmHg for $>$3 min), bursts of nonpropagated activity (periods $>$2 min with waves $>$20 mmHg at 10–12/min registered in one or more consecutive manometric ports simultaneously), sustained uncoordinated phasic pressure activity ($>$30 min of intense and frequent contractions in one intestinal site uncoordinated with the rest of the gut), and failure to convert to a fed pattern.

3. Obstructive pattern. This is a form of intermittent repetitive activity that develops in the postprandial period, with clusters of waves or prolonged waves repeating rhythmically every 1–3 min. This pattern suggests a partial mechanical obstruction of the gut that may have been overlooked in the previous workup of the patient.

4. Antral hypomotility. Reduced amplitude or frequency of antral waves after a meal is frequent in patients complaining of symptoms without demonstrable cause. The significance of this pattern is doubtful, and hence, the indication for antral recording is debatable.

Indications and Clinical Value

Manometry facilitates management of patients with intestinal pseudo-obstruction by showing either a myopathy, a neuropathy, or an obstructive pattern. In patients with gastroparesis, i.e., gastric retention due to impaired gastric function, it is important to determine whether the intestine is also affected. The same applies to patients with colonic inertia, i.e., severe, intractable constipation due to impaired colonic motility. In patients with functional gastrointestinal disorders, i.e., symptoms such as diarrhea, bloating, or pain without demonstrable cause, intestinal manometry may be indicated if the symptoms are severe, to rule out intestinal neuropathy.

ANORECTAL MANOMETRY

Definition and General Technique

Anorectal manometry evaluates the function of the rectum and anal canal, which is maintenance of continence and controlled evacuation of fecal residues. This function is achieved by a combined action of the rectal reservoir function and regulated anal closure. Evaluation of anorectal function consists of the following battery of tests:

1. Anal sphincters. The anal canal is surrounded by two concentric muscular cylinders. The internal anal sphincter is a smooth muscle that exerts a continuous tonic contraction, thereby maintaining anal closure during basal conditions. The external anal sphincter is a peripheral cylinder of striated muscle that produces additional contraction at will during squeeze. Sphincteric function is evaluated by measuring the pressure at different levels of the anal canal: basal pressures largely reflect the activity of the internal sphincter and voluntary squeeze contractions reflect the activity of the external sphincter.

2. Reflexes. Sphincteric function is controlled by a relatively complex series of neural circuits. The internal sphincter, which can be considered a thickening of the circular muscle layer of the intestinal wall, is innervated by the myenteric plexus, which can be evaluated using the anorectal inhibitory reflex: rectal distension, e.g., by means of a balloon, normally produces a relaxation of the internal anal sphincter and hence a pressure drop in the anal canal. The external sphincter is controlled in part by spinal reflexes that can be evaluated using the cough reflex: an intraabdominal pressure increment, e.g., coughing, normally produces a reflex contraction of the external anal sphincter and hence a pressure increment in the anal canal.

3. Defecatory maneuver. Rectal evacuation, i.e., defecation, is normally produced by an abdominal compression associated with anal relaxation. This maneuver can be evaluated by asking the patient to attempt defecation while simultaneously measuring the pressure in an intrarectal balloon (intraabdominal pressure) and the pressures at different levels in the anal canal.

4. Rectal reservoir function. The rectal wall has a distensibility and a sensitivity that allow the rectum to fill and elicit conscious perception. This function is evaluated by metered rectal distension, using an intrarectal bag or balloon, and by measuring both the compliance (pressure at different distending volumes) and the intensity of conscious perception (for instance, the distending levels that induce first perception, urge to defecate, and discomfort).

Outcome Measures

Isolated dysfunctions may not have clinical relevance, and symptoms may occur only when multiple parameters are affected. The following parameters are usually evaluated:

1. Anal pressures. Decreased resting pressure indicates a weak or disrupted internal anal sphincter. Increased resting pressure may indicate internal anal hypertony, a key pathophysiological factor in anal fissure, or striated muscle spasm, frequently associated to anoperineal pain syndromes. Decreased voluntary squeeze pressure reflects impaired external sphincter contraction.

2. Reflexes. The presence of an anorectal inhibitory reflex rules out Hirschsprung's disease. Impaired cough reflex (anal pressure increment in response to cough smaller than the voluntary squeeze) indicates a defect in the sacropudendal reflex arc.

3. Defecatory maneuver. Impaired relaxation during attempted defecation (incomplete pressure drop) indicates a functional outlet obstruction, which is frequently associated with excessive straining (excessive abdominal compression). A weak abdominal compression, i.e., ineffective straining, may be due to a neuromuscular disease.

4. Rectal evaluation. Increased rectal capacity (megarectum) may be associated with functional outlet obstruction; decreased capacity may be associated with fecal incontinence. Increased rectal sensitivity may be associated with urge and fecal incontinence. Patients with severely reduced sensitivity may be at risk of incontinence due to impaired perception of rectal filling.

Indications

1. Constipation. Manometry can identify a functional outlet obstruction, and these patients may be taught to produce a normal defecatory maneuver. Suspected Hirschsprung's disease is excluded by a normal anorectal inhibitory reflex; if the reflex is repeatedly absent, a deep rectal wall biopsy should be done for histologic evaluation of the status of the enteric nervous system.

2. Anal incontinence. Any type of leakage, soiling, gas, liquid, or solid incontinence should be investigated, particularly in the absence of gross anatomical defects, because these patients may respond to functional treatment.

3. Pelvic floor disorders. Some cases may be related to functional outlet obstruction and perineal stress by excessive straining. In other cases, the disorder affects multiple systems, including the anorectum.

4. Diseases associated with neuromyopathies when anorectal affectation is suspected.

5. Pre- and postanorectal surgery, particularly if anorectal dysfunction is suspected.

6. Anoperineal pain or discomfort syndromes. Manometry may detect a neuromuscular dysfunction or a functional outlet obstruction with defecatory trauma, and these patients may respond to appropriate treatment.

marginal ulcers Also termed stomal or anastomotic ulcers; those peptic ulcers that occur at or near a surgically created gastroduodenostomy or gastrojejunostomy.

Marginal ulcers (also known as stomal or anastomotic ulcers) are peptic ulcers that occur at or near a surgically created gastroduodenostomy or gastrojejunostomy. The original operative procedure may have been performed for the treatment of peptic ulcer disease or benign or malignant gastric, duodenal, or pancreatic diseases. This article discusses the etiology, clinical presentation, diagnostic strategy, and management of patients with marginal ulcers.

INCIDENCE AND TIME TO OCCURRENCE

The incidence of marginal ulcers in patients undergoing vagotomy, resection, and gastroenteric anastomoses for peptic ulcer disease is less than 5%. In these patients, ulcer recurrence occurs most often within the first 3 to 5 postoperative years. Marginal ulcers following gastroenterostomy for diseases other than peptic ulcer disease may occur many years following the original procedure. Marginal ulcers have also been reported in as many as 8% of morbidly obese patients undergoing gastric bypass as an adjunct to weight loss.

ETIOLOGY AND PATHOGENESIS

The most common causes of marginal ulcers are (1) incomplete gastric acid suppression (e.g., incomplete vagotomy or absence or failure of appropriate ulcer prophylaxis with histamine 2 receptor antagonists (H2-RA) or proton pump inhibitors (PPIs) and (2) ulcerogenic medications, particularly aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). Less common causes include hypersecretory states, such as gastrinoma and retained/excluded gastric antrum. In

contrast to the well-known pathogenic role that *Helicobacter pylori* plays in primary ulcer disease, the relationship between *H. pylori* infection and marginal ulcer formation is unclear.

CLINICAL PRESENTATION

The most frequent signs and symptoms of marginal ulceration are abdominal pain or evidence of a complication such as hemorrhage, perforation, or obstruction. Schirmer *et al*. found that 41% of their patients with marginal ulcer presented with hemorrhage, a rate twice that of patients initially presenting with peptic ulcers. Although perforation into the peritoneal cavity is uncommon in patients with marginal ulcers due to inadequate inhibition of gastric acid secretion, recent studies have found that marginal ulcers due to aspirin, and perhaps other NSAIDs, are associated with severe complications including obstruction, bleeding, and even perforation.

DIAGNOSTIC EVALUATION

History and physical examination will identify symptoms and signs of ulcer disease or evidence of complications, (e.g., hematemesis and melena, anemia, vomiting, or weight loss). The history may also provide evidence of aspirin or NSAID use. In the absence of perforation, the diagnosis of marginal ulceration is best made by esophagogastroduodenoscopy, which will document the presence and location of the ulcer and the presence of *H. pylori*. Multiple ulcers and those in atypical locations strongly suggest a hypersecretory syndrome or the use of NSAIDs. Retained food, a gastric bezoar, or a stenotic anastomosis suggests associated impairment of gastric emptying. Endoscopic biopsy of gastric ulcers is of particular importance in detecting cancer in these patients who are at a greater risk than the general population in developing gastric adenocarcinoma. Upper gastrointestinal endoscopy is invaluable in the evaluation and treatment of patients bleeding from a marginal ulcer.

Barium contrast studies of the stomach are of limited value in diagnosing marginal ulcers because of the difficulty in detecting ulcerations in the presence of postoperative deformities of the stomach, duodenum, and small intestine. Contrast radiographs do, however, provide important information in the evaluation of patients with suspected gastric outlet obstruction and in those whose postoperative anatomy is uncertain.

A fasting serum gastrin level should be measured in all patients with marginal ulcers to identify patients with gastrin-mediated hypersecretory syndromes. A normal fasting serum gastrin concentration essentially excludes the possibility of Zollinger-Ellison syndrome, whereas a serum gastrin level greater than 1000 pg/ml, combined with a fasting gastric pH < 2.5, is virtually diagnostic. Patients with lesser degrees of hypergastrinemia require a secretin stimulation test to confirm the diagnosis of gastrinoma.

MEDICAL MANAGEMENT

In the setting in which a patient presents with upper abdominal pain and endoscopy demonstrates a marginal ulcer, appropriate medical therapy consists of a PPI or H2-RA and antibiotics directed at *H. pylori*, if present. The optimal duration of treatment with a PPI or H2-RA is unknown although most evidence supports long-term maintenance PPI or H2-RA therapy. Although no data directly support the eradication of *H. pylori* in patients with postoperative ulcer recurrence, the critical role this infection plays in primary peptic ulcer disease (PUD), the possibility that *H. pylori* promotes NSAID-induced mucosal injury, and the minimal risks associated with *H. pylori* eradication strongly support the use of antibiotic therapy when *H. pylori* is present.

Patients should be carefully counseled regarding the important relationship between NSAID use (including over-the-counter preparations) and ulcer disease, and the necessity of discontinuing these medications. NSAID use, including low-dose aspirin, should be discontinued during the period of ulcer healing, if feasible. Once ulcer healing has been documented endoscopically, non-NSAID analgesic agents should be substituted for the NSAIDs and if these are ineffective, then nonacetylated NSAIDs or a cyclooxygenase 2-specific NSAID should be considered. Consideration should be given for substituting clopidogrel for low-dose aspirin for cardiovascular prophylaxis. If patients are to be continued on low-dose aspirin, they should receive ulcer prophylaxis with misoprostol or a PPI.

SURGICAL MANAGEMENT

The adequacy of prior medical management and the elimination of risk factors for ulcer recurrence (e.g., NSAIDs) are important considerations in determining whether a patient is an appropriate candidate for operative therapy. The choice of a particular operation for a patient with a marginal ulcer should be that with the lowest recurrence risk that the patient is medically able to tolerate and tailored according to the adequacy of a prior vagotomy and drainage procedure, medical comorbidities, presence of complications of the ulcer,

and the extent of the prior resection. Non-acid-reducing procedures, such as local ulcer excision, revision of drainage procedures alone, and closure of perforations, are associated with extremely high failure rates.

The operative approach to patients with marginal ulcer formation after a vagotomy and antrectomy or a distal gastrectomy is partial gastric resection. Recurrent ulcer disease following vagotomy and antrectomy or partial gastrectomy strongly suggests NSAID use or a hypersecretory state. Several recent reports have demonstrated the importance of aspirin abuse in the etiology of such virulent ulcer disease and very high rates of ulcer recurrence following even very aggressive operative intervention. In this setting, further gastric resection may necessitate subtotal or even total gastrectomy, procedures associated with severe postgastrectomy symptoms in as many as 20–40% of patients.

Patients with marginal ulcer and an incomplete vagotomy may benefit from a thoracoscopic truncal vagotomy so long as NSAID use has been eliminated and there is no evidence of gastric stasis or gastric outlet obstruction. This approach avoids a difficult dissection in the upper abdomen and eliminates a likely cause of ulcer recurrence. In those instances of ulcer recurrence accompanied by gastric outlet obstruction, vagotomy and revision of the anastomosis are necessary to relieve the mechanical obstruction and further reduce gastric acid secretion. Also, patients who underwent resection for gastric ulcers appear to have a threefold increase in the risk of gastric adenocarcinoma when followed for more than 25 years following a Billroth II reconstruction. Clearly, an aggressive diagnostic approach including endoscopic biopsy is necessary in patients with gastric ulcers.

The frequency of postoperative ulcer recurrence varies from 8 to 22% depending upon the remedial procedure performed and the persistence of aspirin, and probably NSAID, use. The highest rates of recurrent ulcer formation occur after repeat vagotomy alone, revision of a gastroenterostomy alone, or any other non-acid-reducing operation. Lower rates are associated with re-vagotomy and antrectomy or distal gastrectomy. Patients who continue to take aspirin following the operative management of their marginal ulcer are at particularly high risk of recurrence (80–90%) regardless of the operative procedure performed. The virulence of the ulcer disease is suggested by the high rate of gastric outlet obstruction, perforation, and death in these patients. The mortality rate of operations for recurrent ulcer disease is 2–4%. The presence of complications of ulcer disease necessitating an emergent operation appears to significantly increase the risk of operative mortality. The chronic postoperative complications of both primary and remedial acid-reducing operations include diarrhea, dumping, chronic abdominal pain syndromes, impaired gastric emptying, osteoporosis, and anemia. Most authors report that 60 to 80% of patients who undergo remedial operations for recurrent ulcer disease will have either no or only occasional mild symptoms, whereas 20 to 40% will have severe or incapacitating symptoms including ulcer recurrence. Excluding ulcer recurrence, approximately 10–20% of patients undergoing remedial operative procedures will have chronic symptoms that significantly impact the patients' life.

Mast Cells

ALISON P. WATT AND MADELEINE ENNIS
Queens University of Belfast, United Kingdom

anaphylatoxin A substance (e.g., C5a, C3a) that is capable of directly inducing mast cell mediator release.
anaphylaxis Hypersensitivity reaction triggered by immunological or anaphylatoxin-mediated mast cell mediator release, resulting in vasodilation and smooth muscle contraction. Anaphylactic shock is often fatal.
Fc (fragment crystallizable) Non-antigen-binding fragment of an immunoglobulin molecule.
FcεRi High-affinity receptor for immunoglobulin E. Fc receptors are cell surface receptors that bind the Fc portion of a particular immunoglobulin.
heterogeneity Generally mast cells exhibit significant variation in biochemical, histochemical, and functional aspects of their phenotype with varying tissue location.
histamine Vasoactive amine found in mast cells and basophils. On release, it induces smooth muscle contraction and increased vascular permeability.
immunoglobulin E One of the five major classes of antibodies. Immunoglobulins are globular proteins produced by B cells. They are designed to recognize and bind to specific molecules known as antigens. IgE is associated with allergic reactions.
metachromasia Result obtained when a stain is applied to cells or tissues and gives a color different from that of the stain solution.

Mast cells are mononuclear cells distributed ubiquitously throughout the body, particularly in submucosal tissues that interface with the external environment. These include the gastrointestinal, genitourinary, and respiratory tracts. Mast cells may also be found in close association with blood vessels and peripheral nerves. Mast cells do not represent a homogenous population. Evidence of morphological, histochemical, and functional differences has been observed in different anatomical locations, suggesting that differentiation of mast cells is not complete until they reach their target tissue, where microenvironmental factors are crucial in their development and maturation. Activation of mast cells results in the release of both preformed and newly synthesized mediators, the best known being histamine. Hence, the mast cell is considered, along with the basophil, to be a main effector of acute allergic and inflammatory responses. However, the mast cell is now implicated in a diversity of other biological functions, which include angiogenesis, chronic inflammation, and immunological disorders. Mast cell activity may be modulated by a variety of endogenous and exogenous factors.

HISTORY OF THE MAST CELL

In 1863, Friedrich von Recklinghausen first observed the mast cell. Fifteen years later, a German medical student, Paul Ehrlich, described a cell with cytoplasmic granules, which took up blue aniline dyes in histological sections, but stained a pinkish purple color. Ehrlich called this process metachromasia; he believed that these large cytoplasmic granules represented phagocytosed material and hence named these cells "*Mastzellen*," meaning well-fed cells.

The first important discovery regarding the mast cell granule was in 1937 when Holmgren and Wilander established the presence of heparin in mast cell granules by correlating the heparin concentration in tissues with the number of mast cells present. The mystery of metachromasia was also solved around this period, when it was demonstrated that sulfated glycosaminoglycan heparin changed the color of blue aniline dyes to a reddish purple color.

Richet and Portier first described anaphylaxis in 1902. However, a link between the mast cell and anaphylaxis was not made until 1941, when Jacques and Walters proved that anticoagulation in dogs undergoing anaphylactic reactions was due to the release of heparin. In 1927, the identification of histamine in normal tissues was carried out by Best and co-workers. The first important experiments designed to show an actual release of histamine in association with anaphylactic shock were those of Watanbe, showing differences in the histamine content of guinea pig lung before and after shock. In fact, it was not until 1953 that Riley and West identified mast cells as the major source of tissue histamine after they observed a striking correlation between the histamine content of a tissue and the number of mast cells present.

In the early 1970s, Ishizaka and Ishizaka demonstrated that immunoglobulin E (IgE) induced histamine

 Copyright 2004, Elsevier (USA). All rights reserved.

release from mast cells. Injection of a purified ragweed IgE preparation into normal skin resulted in sensitization of the skin, which disappeared on removal of the IgE antibody. It is now well established that IgE molecules have a high affinity for specific IgE receptors expressed on the mast cell surface and that cross-linkage of these receptors results in mast cell mediator release, thus establishing a central role for mast cells in IgE-mediated hypersensitivity.

ORIGIN, DISTRIBUTION, AND DEVELOPMENT OF MAST CELLS

Origin and Distribution

Mast cells are widely distributed in vertebrates, where they are found within organs, especially in connective tissues and in areas interfacing the external environment, such as the skin, lungs, and gastrointestinal tract. Transplantation studies with beige (C57BL-Bg^J/Bg^J) mice provided the first evidence that mast cells are of hematopoietic origin. Beige mice possess two mutant alleles at the Bg locus and are characterized by the presence of mast cells with giant granules. Bone marrow cells from beige mice injected into normal irradiated (C57BL- +/+) recipients revealed typical mast cells containing giant granules developing in the recipient within 2–3 months of bone marrow transplantation.

Further studies using mast cell-deficient mice provided new insights into the origin and differentiation of mast cells. Mast cell-deficient mice have a double dose of mutant alleles at either the W (W/W^v) or the Sl (Sl/Sl^d) locus. These mice manifest macrocytic anemia, sterility, and lack of hair pigmentation. In addition, they are virtually devoid of mature morphologically identifiable mast cells in all organs and anatomical sites examined.

Transplantation of bone marrow from normal littermates or beige mice into W/W^v mice corrected the mast cell deficiency, suggesting that the defect in mast cell development was in the early progenitor cells of mast cell lineage. However, bone marrow transplantation did not correct mast cell deficiency in Sl/Sl^d mice, reflecting an abnormality in microenvironmental factors that promote mast cell differentiation and maturation in the tissue.

Subsequent studies demonstrated that mast cells originate from multipotential hematopoietic stem cells as demonstrated by the formation of other hematopoietic cells in addition to mast cells from spleen colony-forming units. In sharp contrast to other cells of hematopoietic stem cell lineage, mast cells do not circulate as mature mast cells. Morphologically identifiable mast cell precursors, originating from pluripotential $CD34^+$c-kit^+ CD13 cells in humans, circulate in the blood and lymphatics before invading connective and mucosal tissues. Once in the tissues, these precursors gain their mature morphologic and functional characteristics under the influence of local microenvironmental factors.

Stem Cell Factor and the c-kit Ligand

Stem cell factor (SCF) is a glycosylated protein with a molecular weight of 2–35 kDa; the main sources of SCF *in vivo* are fibroblasts and bone marrow stromal cells. SCF exists in membrane-bound and soluble forms, both of which are biologically active. Molecular analysis of the W locus revealed that it encoded the tyrosine kinase receptor c-kit. SCF exerts its effects by binding to the c-kit receptor. The c-kit receptor consists of an extracellular domain with five immunoglobulin-like repeats and a tyrosine kinase split into two domains by an insert sequence. This structure is well preserved in both rats and humans.

Mast cell deficiency in W/W^v mice is now known as a deficiency of the c-kit receptor, whereas mast cell deficiency in Sl/Sl^d mice is due to an inability to produce functional SCF. The work of Kitamura and colleagues with mast cell-deficient mice clearly demonstrates the critical importance of SCF/c-kit interactions. In addition to promoting the proliferation and development of mast cells, SCF has been implicated in the process of chemotaxis, adhesion, survival, and the synthesis mediators. Thus, SCF is a multifunctional mast cell growth factor.

MAST CELL HETEROGENEITY

Histochemical Characteristics

Mast cells from different tissues exhibit heterogeneity in terms of their morphological, biochemical, and functional properties. Enerbäck reported differences in histochemical and secretory properties between rodent mast cells of the intestinal mucosa and rodent skin mast cells. He discovered that conditions of fixation and histochemical staining could discriminate between mast cell subtypes. The classification of rodent mast cell subtypes is based on the phenotypical differences between connective tissue mast cells (CTMC) of the skin, peritoneal cavity, and other sites in the rats and mucosal mast cells (MMC) observed in the intestinal lamina propria. By analogy to rodent mast cells, variations in fixation properties provided the first documented evidence of the existence of different types of human mast cells. Human intestinal MMC display metachromatic

staining after fixation in Carnoy's solution but not when fixed in neutral buffered formalin, whereas CTMC found in the intestinal submucosa retain metachromatic staining properties regardless of the fixative used. The variation in dye-binding properties observed between the two types of mast cell reflects the different proteoglycans in the two subpopulations. Metachromatic staining occurs as a result of interaction of the cationic dyes with the anionic proteoglycan matrix. The different charges of the proteoglycans account for the diverse staining characteristics of MMC and CTMC. Glycosaminoglycan chondroitin sulfate found in MMC is less sulfated and has a lower charge than the highly sulfated heparin, which is the major proteoglycan in the CTMC. However, subpopulations of mast cells are not confined to particular anatomical regions; consequently, it is inaccurate to designate human mast cells as "mucosal mast cells" or "connective tissue mast cells" on the basis of the cells' sensitivity to formalin.

Biochemical Characteristics

The two principal types of human mast cells are also distinguished by the observation of distinct protease patterns in mast cells in different anatomical locations. Mast cells containing only tryptase are named MC_T; these cells predominate in the alveolar septa of the lung and in the intestinal mucosa. Other human mast cells contain measurable levels of tryptase, chymase, a cathepsin G-like protease, and carboxypeptidase; these cells are designated MC_{TC} for their tryptase and chymase and predominate in the skin and intestinal submucosa. However, all of the tissues mentioned contain representatives of both mast cell subpopulations and therefore cannot be classified as MC_T or MC_{TC} on the basis of tissue locality alone. There have also been isolated reports of mast cells expressing chymase but not tryptase (MC_C).

Heterogeneity in rats may also be distinguished by protease content. Rat CTMC contain the chymotrypsin-like at mast cell protease I (RMCP I) and carboxypeptidase A, whereas rat MMC contain another chymotrypsin-like neutral protease, RMCP II. The tissue localization of human MC_T corresponds most closely to that of rodent MMC, whereas the tissue localization of MC_{TC} corresponds most closely to that of rodent CTMC.

Functional Characteristics

Variation in functional characteristics is also observed between mast cell subpopulations. This is demonstrated by varying sensitivity to drugs and secretagogues. For example, human skin mast cells have been demonstrated to respond to stimulation with the neuropeptide substance P but not to inhibition by the anti-allergy drug disodium cromoglycate. In contrast, mast cells isolated from the lung were insensitive to substance P, yet histamine release was inhibited by disodium cromoglycate.

Similarly, in the rat, there appears to be a correlation between mast cell protease phenotype and histamine release in response to stimulation with compound 48/80 or substance P and between the phenotype and susceptibility to inhibition by disodium cromoglycate. Rat CTMC containing RMCP I are sensitive to compound 48/80 and substance P and also to inhibition by disodium cromoglycate, whereas rat MMC containing RMCP II are insensitive to these compounds.

Origins of Heterogeneity

Factors influencing the development of heterogeneous populations of mast cells have been the subject of extensive investigation. The failure to detect granulated mast cells in the circulation under normal conditions, coupled with the characterization of progenitor cells for both murine and human mast cells, supports the hypothesis that the mast cell does not establish functional and phenotypic maturity until it reaches its resident tissue or microenvironment. Mast cell phenotype is considered to be regulated by microenvironmental factors from a variety of sources. Mast cells are in contact with a number of immune cells, which may synthesize and secrete mediators such as cytokines, chemokines, growth factors, and histamine-releasing agents, all of which may affect the mast cell population. The mast cell itself, through cytokine production, may participate in the regulation of its own numbers and phenotype, particularly during immunological or disease processes.

MAST CELL ACTIVATION

Activation of mast cells may occur via two possible mechanisms: immunological and nonimmunological.

Immunological Activation

The presence of a multivalent allergen stimulates the production of specific IgE antibodies. These antibodies bind with high affinity to FcεRi receptors on the mast cell surface. Following cross-linkage of antigen-bound IgE–FcεRi complex, receptor aggregation occurs and mast cell exocytosis is triggered (Fig. 1).

The FcεRI receptor is a tetrameric member of the antigen receptor family, consisting of one α-chain (45 kDa), one β-chain (33 kDa), and two γ-chain subunits (9 kDa). The α-chain contains one

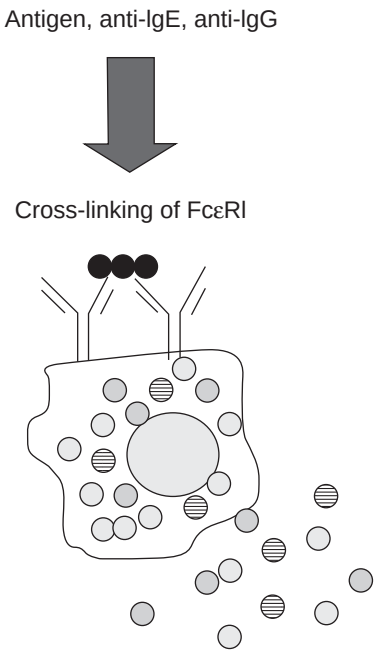

FIGURE 1 Cross-linking of the FcεRI by a specific antigen, IgE or IgG, results in mast cell degranulation.

membrane-spanning region and a single IgE-binding site and does not contribute to the signal transduction properties of the receptor. The β-chain has four membrane-spanning domains, with its amino- and carboxy-termini protruding into the cell cytoplasm, and the γ-chains have one membrane-spanning domain and a long cytoplasmic tail but no extracellular amino-terminal. The γ-chain is thought to belong to the same gene/protein family as the ζ-chain of the T-cell receptor and so the two probably share a common role in signaling.

Nonimmunological Activation

Many other substances and conditions are capable of triggering mast cell secretion. These nonimmunological stimuli can be subdivided into two classes based on whether the mode is cytotoxic or noncytotoxic. Cytotoxic compounds such as the detergent Tween 20 disrupt the plasma membrane, thereby releasing intracellular contents. Noncytotoxic compounds stimulate mediator secretion while the plasma membrane remains intact. Compound 48/80 and the calcium ionophores A23187 and ionomycin are three such known substances. Numerous physiological compounds have been observed to induce mast cell secretion *in vitro*. These include growth factors, cytokines, neuropeptides, and anaphylatoxins. Cold, pressure, stress, and free radicals are also known to initiate mast cell mediator secretion.

MAST CELL MEDIATORS

On activation, mast cells secrete a diverse array of potent biologically active mediators, some of which are stored preformed in the cells' cytoplasmic granules and others of which are synthesized on appropriate cell activation.

Preformed Mediators

Biogenic Amines

Histamine is the single amine known to be stored in human mast cells. Mast cells of other species are known to store additional amines; for example, the rat mast cell stores serotonin. Histamine is formed in the Golgi apparatus of mast cells and basophils during decarboxylation of histidine by the pyridoxal phosphate-dependent enzyme, histidine decarboxylase (Fig. 2). Histamine is then stored by ionic linkage with the carboxyl groups of proteins and proteoglycans of the secretory granules at an acidic pH. During degranulation, histamine dissociates from the proteoglycan–protein complex by cation exchange for extracellular sodium at neutral pH. Rat peritoneal mast cells contain 10–30 pg of histamine per cell, whereas rat mucosal cells contain only 1–3 pg of histamine per cell. In mast cells isolated from human lung, skin, lymphoid tissue, and small intestine, approximately 3–8 pg of histamine per cell has been reported. On release, histamine is rapidly metabolized into methylhistamine, methylimidazole acetic acid, or imidazole acetic acid. For this reason, it is likely that histamine usually influences events at or close to the site of its release. Specific histamine receptors, of which there are four classes, H2, H2, H3, and H4, mediate the wide-ranging biological activities of histamine. One or more of these receptor subtypes are expressed on many different tissues and cell types, including smooth muscle of the respiratory tract, cardiac atrium, uterus, T and B cells, monocytes, neutrophils, glial cells, and nerve cells. H1 receptor signaling differs from H2

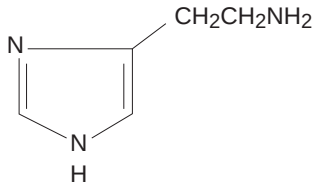

FIGURE 2 Structure of histamine.

signaling; in the H1 pathway, enhanced breakdown of phosphatidylinositol results in the mobilization of intracellular Ca^{2+}, whereas in H2 signaling, the second messenger is cyclic AMP. Although the H1 and H2 receptors were cloned a decade ago, cloning of the H3 receptor did not occur until 1999 and this elucidation quickly led to the discovery of H3 receptor subtypes. Molecular studies have identified $H3_A$, $H3_B$, and $H3_C$ mRNA isoforms in the rat and $H3_L$ and $H3_S$ in the guinea pig. However, similar variants in humans have yet to be identified. A fourth histamine receptor subtype, H4, has recently been cloned and characterized with a gene sequence and imidazole-based pharmacology similar to that of the H3 receptor.

Proteoglycans

Proteoglycans are the major granular constituent of all mast cells and are composed of a central protein core of repeating serine and glycine residues with extended, unbranched carbohydrate side chains of repeating disaccharide subunits constructed of uronic acid and hexosamine moieties. The presence of sulfate groups on each disaccharide gives proteoglycans a high charge, which enables proteoglycans to act as extracellular mediators and as storage matrices for other preformed mediators.

The predominant type of proteoglycan stored in mast cells varies among subpopulations. For example, rat peritoneal and skin mast cells, mouse CTMC, and human cutaneous mast cells all contain heparin, whereas rat intestinal MMC and rat basophilic leukemia cells all contain chondroitin sulfate di-B. The proteoglycans heparin and chondroitin sulfate E are associated with human mast cells. Both stabilize mast cell proteases and alter the biological activity of many enzymes.

Mast cells are thought to be the only source of heparin in the body. Heparin has numerous functions beyond the regulation of mediator storage in the cytoplasmic granule. In addition to being an anticoagulant, heparin can bind certain cytokines, chemokines, and growth factors as well as modulate the proliferation and migration of cells involved in atherosclerosis, wound healing, and tissue remodeling.

Neutral Proteases

Mast cell populations in different species and at varying stages of development may be defined by their granule content of serine proteases. The distinction is most obvious in rodent mast cells but has also been observed in humans and sheep. RMCP I is known to have properties similar to those of α-chymotrypsin, in that it cleaves ester and peptide bonds of carboxy-terminal aromatic amino acids, whereas RMCP II is chemically and antigenically distinct and is localized to mucosal mast cells of the gastrointestinal and respiratory tracts.

The major proteases in human mast cells are tryptase and chymase. Tryptase is the predominant enzyme, composed of a tetramer of 134 kDa, with two subunits of 31−34 kDa and associated with all human mast cells examined. Tryptase is stored bound to heparin and is released as a complex with this proteoglycan. This protease cleaves fibrinogen, activates latent collagenase, hydrolyzes some neuropeptides, and may cause mucus secretion and be mitogenic.

Chymase is stored in the granules of some but not all human mast cells. This monomer of 30 kDa is unaffected by heparin and its function is inhibited by biological inhibitors of serine proteases, such as α1- antichymotrypsin. Biological functions of chymase include conversion of angiotensin I to II, stimulation of mucus secretion, neuropeptide degradation, and conversion of interleukin-1β (IL-1β) to an active form.

Newly Synthesized Mediators

Lipid-Derived Mediators

The most important mast cell-derived lipid mediators are believed to be the cyclooxygenase and lipoxygenase metabolites of arachidonic acid. When mast cell activation occurs, arachidonic acid is mobilized from storage pools by various phospholipases and subsequently converted to prostanoids by cyclooxygenases and to leukotrienes by 5-lipoxygenase. Prostaglandin D_2 (PGD_2) is the major cyclooxygenase product of mast cells, whereas the major lipoxygenase products are the sulfidopeptide leukotrienes (LTs; LTC_4, LTD_4, LTE_4,). Human mast cells also have the capacity to produce LTB_4, but in smaller quantities than either PGD_2 or LTC_4.

PGD_2 is generated following immunological activation of human mast cells and its many functions include inhibition of platelet aggregation, mediation of neutrophil accumulation in human skin, and chemokinesis of human neutrophils. PGD_2 has been detected in supernatants of dispersed and purified human pulmonary mast cells after IgE-mediated activation.

LTB_4, LTC_4, LTD_4, and LTE_4 are all derived from 5-hydroperoxyeicosatetraenoic acid. LTC_4 is formed from LTA_4 by the enzymatic addition of glutathione. Once formed, LTC_4 is released into the extracellular fluid and converted to LTD_4 and LTE_4 by the release of glutamic acid and glycine, respectively. Leukotrienes stimulate prolonged bronchoconstriction with an effect 10−1000 times more potent than that of histamine. They also have the ability to enhance venular permeability, promote bronchial mucus secretion, and induce

the constriction of arterial, arteriolar, and intestinal smooth muscle. LTB_4 is derived from LTA_4 by the enzymatic addition of water and has been demonstrated to possess potent chemotactic activity for neutrophils and eosinophils, to enhance lysosomal enzyme release, and to augment superoxide anion production.

Platelet-activating factor (PAF) has also been detected in some mast cell populations. PAF has been detected following activation of mouse bone marrow-derived mast cells, rabbit basophils, and human mast cells. The synthesis of PAF is closely linked with that of the leukotrienes. The first step of PAF synthesis involves the cleavage of alkylarachidonyl-GPC, and subsequent liberation of lyso-PAF and arachidonic acid. When lyso-PAF is acetylated in the 2-position of the glycerol residue, PAF is formed. Arachidonic acid may be channeled down the 5-lipoxygenase pathway, resulting in leukotriene production. PAF is a potent chemotactic agent for neutrophils and eosinophils, and in addition, it causes eosinophils to adhere to endothelial cells and synthesize LTC_4 and more PAF. PAF causes dose-related aggregation and calcium influx in platelets as well as neutrophil exocytosis, superoxide generation, and chemiluminescence. PAF also induces bronchoconstriction in many species including humans, guinea pig, rhesus monkey, and baboon.

Cytokines

Cytokines are a group of protein or glycoprotein molecules that possess a wide range of bioactivities and have been observed to play roles in cell growth and repair, inflammation, and the immune response. The first evidence that mast cell populations produced cytokines was the observation that cells transformed with Abelson murine leukemia virus constitutively produced granulocyte/macrophage colony-stimulating factor (GM-CSF) and IL-4 mRNA and released GM-CSF and IL-4. It is unclear whether mast cells produce several cytokines simultaneously or whether phenotypes exist with regard to cytokine production. Immunohistochemical studies demonstrate that some mast cells synthesize combinations of cytokines and others appear to produce only one type of cytokine. Immature HMC-1 cells fail to secrete IL-3 and IL-13 and up-regulate IL-4 mRNA only transiently, whereas human cutaneous mast cells fail to secrete IL-3, IL-4, IL-5, and IL-13 after stimulation with anti-IgE, substance P, or compound 48/80.

Rodent and human mast cells secrete a wide range of multifunctional cytokines. Following IgE-mediated stimulation, mast cells produce a broad range of cytokines (Table I), mainly of a T_H2 profile, which include IL-4, IL-5, IL-13, GM-CSF, and tumor necrosis factor α (TNFα), all of which are up-regulated in allergic inflammation. Mast cells are also capable of responding to nonimmunological stimuli by synthesis of pro-inflammatory cytokines. The release of cytokines by the mast cell can influence the recruitment and/or function of additional effector cells, such as vascular endothelial cell, fibroblasts, epithelial cells, and nerves.

Differential Release of Mediators

It is well known that mast cells secrete their mediators by degranulation and compound exocytosis as typically seen in anaphylactic reactions. However, mast cells may, by a more subtle intragranular change known as piecemeal degranulation, selectively release particular mediators. Piecemeal degranulation is characterized by intragranular changes showing different electron densities and crystalline substructures in association with the appearance of small vesicles frequently containing electron-dense material.

TABLE I The Major Mast Cell-Derived Cytokines and Their Primary Biological Function

Cytokine	Function
IL-1	Activates lymphocytes; stimulates macrophages; increases leukocyte/endothelial adhesion; induces acute-phase proteins
IL-3	Mast cell colony-stimulating factor
IL-4	B-cell growth factor; isotype switching of IgE and IgG1; mast cell growth cofactor
IL-5	B-cell growth and differentiation factor; eosinophil differentiation factor
IL-6	B-cell differentiation induces acute-phase proteins
IL-8	Chemotactic for neutrophils and basophils; activates neutrophils
IL-13	B-lymphocyte isotype switching to IgE production
TNFα	Activates macrophages, granulocytes, and cytotoxic cells; increases leukocyte/endothelial cell adhesion; induces acute-phase proteins; stimulates angiogenesis; enhances MHC class I production
TGFβ	Stimulates connective tissue growth and collagen formulation; inhibits most immune functions
GM-CSF	Stimulates proliferation of granulocyte and macrophage precursors

Differential mediator release may be regulated by small differences in the cytoplasmic levels of free calcium ions.

SCF has been demonstrated to induce bone marrow-derived cultured mouse mast cells to release IL-6 accompanied by little or no detectable release of TNFα, leukotriene C_4, histamine, or serotonin. Substance P selectively induces TNFα mRNA expression and secretion from a murine cell line. High concentrations of progesterone trigger the release of serotonin from RPMC, without histamine. Piecemeal degranulation has also been observed in mast cells from patients with interstitial cystitis and irritable bowel syndrome.

MAST CELLS AND THE GASTROINTESTINAL TRACT

Mast cells have been proposed to play a role in the inflammatory response in several gastrointestinal diseases including celiac disease and inflammatory bowel disease. Mucosal mast cells are present in all layers of the gastrointestinal tract, where they are located predominantly in the lamina propria of the mucosal layer and the submucosal layer. Mast cell activation and the subsequent release of mediators induce epithelial ion secretion and enhance permeability of the intestine. This may occur through direct action of mast cell mediators on the epithelial cells or indirectly via cross talk between the mast cells and the nervous system.

Mast cells are frequently found in close proximity to the epithelial surface of the gastrointestinal mucosa, where they are strategically located to ensure early interaction with an invading pathogen. The capacity of the mast cell to release both preformed and newly synthesized mediators and to undergo multiple cycles of release permits a rapid and sustained response to bacterial invasion. Mast cells not only can phagocytose bacteria, they also have the ability to recognize infectious agents through specific receptors present on the mast cell surface. The long life span of mast cells means that it is likely that they will encounter a particular pathogen more than once in their lifetime.

Mast cells also contribute to aspects of the adaptive immune response to pathogens, including the well-known response to parasitic infection. Mast cells are known to accumulate in large numbers in the intestinal mucosa in certain parasitic infections and many of these parasite infections are associated with the development of parasite-specific IgE. *In vivo* studies of rats and mice infected with the intestinal nematodes *Nippostronglylus brasiliensis* or *Trichinella spiralis* demonstrate marked mastocytosis in the intestinal lamina propria. Increased mast cell numbers and elevation of mast cell products at the site of infection may cause direct damage to the invading parasite while also recruiting other effector cells such as eosinophils. For example, rat mast cells have been demonstrated to kill *Schistosoma mansoni* by the secretion of RMCP II.

CONCLUSION

Mast cells are regarded as the main tissue-based effector cells in allergic diseases and it is this aspect of mast cell biology that has driven many investigators in attempts to modify mast cell behavior and thus modify allergic inflammation. Despite their detrimental role in allergic disease, mast cells also have an important protective role in host defense mechanisms against parasites, a process that shares many of the characteristic features of allergic inflammation including IgE production and basophil and eosinophil recruitment. An increased understanding of the multifaceted nature of the mast cell has led to the acceptance of a much broader role for the cell in physiological and pathophysiological processes (Fig. 3). The discovery that mast cells could generate and release cytokines in addition to their preformed and newly synthesized inflammatory mediators indicates that mast cells play an important role in immunoregulation. Mast cells have been implicated in a diversity of biological responses including angiogenesis, wound healing, bone remodeling, rheumatoid arthritis, and inflammatory bowel disease.

Immunological and other disease processes may alter mast cell numbers or phenotype by inducing changes in the microenvironment, which alters the mast cell populations residing in that area. The mast cell itself may serve as an important regulator of its own microenvironment. Mast cell mediators can augment local vascular permeability, allowing them to influence the levels of regulatory factors present in the microenvironment. Furthermore, they are able to recruit other cells that may also modulate the mast cell population. Considering the capacity of the mast cell to influence its own growth, differentiation, and activation state by regulating the local microenvironment, investigation of the modulatory effects of autocrine, paracrine, and neuroendocrine agents on mast cell activity is crucial in gaining a comprehensive understanding of the role of the mast cell in health and disease. The mast cell is a unique and complex cell that participates in a number of diverse biological functions. It is well over 100 years since Friedrich von Recklinghausen first observed the mast cell, yet many aspects of mast cell biology remain to be elucidated.

Mastocytosis, Gastrointestinal Manifestations of

ROBERT T. JENSEN AND DEAN D. METCALFE
National Institutes of Health

histamine A vasoactive amine, vasodilator, and smooth muscle constrictor that is found in high concentrations in mast cells.

mast cell A cell of hematopoietic origin that matures within tissues and functions in both innate and acquired immunity through the release of mediators of inflammation following specific activation.

mastocytosis A term collectively used for a group of rare disorders characterized by an abnormal accumulation of mast cells in one or more organ systems.

Systemic mastocytosis is a disorder characterized by mast cell infiltration of organs other than the skin, especially bone marrow, liver, spleen, lymph nodes, and the gastrointestinal (GI) tract. Gastrointestinal disease in the form of peptic ulcer disease and /or malabsorption is often diagnosed in patients with mastocytosis. Because mastocytosis remains without a cure, the selection of appropriate therapy for GI disease remains a persistent challenge as disease progresses. Involvement of the liver through mast cell infiltration with subsequent fibrosis and venopathy further complicates the picture.

INTRODUCTION

Systemic mastocytosis is a disorder characterized by mast cell infiltration of organs other than the skin, especially bone marrow, liver, spleen, lymph nodes, and the gastrointestinal (GI) tract. Systemic mastocytosis is not a uniform entity and is now divided into clinical variants: cutaneous mastocytosis, indolent systemic mastocytosis (ISM), systemic mastocytosis with associated clonal hematologic non-mast-cell lineage disease (SM-AHNMD), aggressive systemic mastocytosis (ASM), and mast cell leukemia. The involvement of the GI tract varies with the different clinical patterns, with more aggressive forms of disease often having more severe GI disease. The GI involvement is clinically important because it is frequently chronic and can cause significant morbidity.

FREQUENCY OF GI INVOLVEMENT

The overall frequency of symptomatic involvement of the GI tract varies greatly in different series with a range of 14–85% and a mean of 51% (16 series). Most series since 1985 report that 60–80% of patients with mastocytosis have GI symptoms and in the only prospective study of GI manifestations in these patients, 80% had GI symptoms. In this series, GI symptoms were almost as frequent as pruritis (88%) and twice as common as flushing (43%). The frequency of various GI symptoms/signs is summarized from 13 series in Table I. Abdominal pain and diarrhea are the most common symptoms and an enlarged liver and (or) spleen are frequent physical findings, especially in patients with SM-AHNMD or ASM.

GI ABNORMALITIES IN PATIENTS WITH SYSTEMIC MASTOCYTOSIS

Esophageal Abnormalities

Esophageal abnormalities (reflux, motility disorders) are uncommon in these patients, occurring in less than 25%.

Gastric Abnormalities

Between 85 and 100% of patients with mastocytosis have increased production of histamine, which is a potent stimulant of gastric acid secretion. In two studies,

TABLE I Frequency of Different Gastrointestinal Symptoms/Signs in Patients with Systemic Mastocytosis

Clinical feature	Frequency mean (range)
Symptom	
Abdominal pain	51% (12–100)
Diarrhea	43% (14–100)
Nausea /vomiting	28% (0–57)
Gastrointestinal bleeding	11% (0–24)
Peptic ulcer disease	23% (5–44)
Sign	
Steatorrhea /malabsorption	13% (5–24)
Hepatomegaly	48% (12–83)
Splenomegaly	45% (11–86)

Note. Data are from 13 different series (Jensen, 2000).

20–40% of these patients had increased acid secretion and a mean of 23% developed peptic ulcers in various series (Table I). On endoscopic studies, up to 30% of patients have gastric mucosal abnormalities including nodules, ulcers, and urticarial lesions. In one prospective study, almost 60% of the abdominal pain was categorized as dyspeptic due to increased acid production.

Small Intestinal Abnormalities

Malabsorption occurs with a mean frequency of 13% in different series of patients with mastocytosis (Table I); however, in a prospective study 31% had impaired small intestinal (SI) function. In general, the malabsorption is mild. The malabsorption, in addition to fat and carbohydrate absorption, can involve fat-soluble vitamins, vitamin B_{12}, and elements such as calcium /iron. In patients with malabsorption, the SI villi are frequently abnormal (blunted, atrophic) and infiltrated by mast cells. With barium X-ray studies, up to 29–73% of these patients have SI mucosal abnormalities, especially small nodules, edema with thickened folds, and polypoid lesions.

Colon/Rectal Abnormalities

Except for diarrhea (Table I), colonic symptoms are not frequently reported in these patients with mastocytosis. However, on barium X-ray or endoscopic studies, 10–20% had abnormalities including nodules, edema, thickened folds, and polypoid lesions.

Liver Abnormalities

Liver involvement is frequent in these patients with mastocytosis, whether assessed by abnormal liver function studies (16–78%), by detection of hepatomegaly (mean 48%; range 12–83%; Table I), or by clinical evidence of liver malfunction (portal hypertension /ascites: 5–40%). In various studies, hepatomegaly was presentin 0–22% of patients with ISM and in 40% of patients with SM-AHNMD or ASM. Liver biopsies frequently show increased fibrosis (14–100%), cirrhosis (0–15%), mast cell infiltration (34%), inflammatory infiltrates (100%), focal hepatocyte necrosis (59%), and evidence of portal venopathy (12%). The hepatomegaly correlates with the degree of mast cell infiltration. The portal hypertension is primarily due to intrahepatic venous obstruction secondary to fibrosis and possibly to increased blood flow from the splenic vein.

Splenic Abnormalities

Splenomegaly occurs with a mean frequency of 45% in patients with mastocytosis (Table I), varying from 11 to 80% in different series. Mast cell infiltration occurs in 34–100% and is likely one of the main mechanisms causing the splenomegaly.

PATHOGENESIS OF THE PRINCIPAL GI SYMPTOMS

General

Numerous studies show that GI, as well as other symptoms commonly occurring in patients with mastocytosis, can be precipitated in some individuals by drugs (antibiotics, narcotics, aspirin, procaine, anti-inflammatory agents), changes in temperature, stress (trauma, medical procedures), exercise, or ingestion of various foods (chocolate, nuts, red wine, alcohol). Rarely, these agents can cause vascular collapse, hypotension, or syncope.

Pathogenesis of Abdominal Pain

Abdominal pain has been attributed to mast cell infiltration in the GI tract, peptic ulcer disease, a motility disorder, and release of mediators from mast cells resulting in altered bowel function. In a prospective study of the 80% of patients with abdominal pain, in 45% the pain was dyspeptic in nature (relieved by acid suppressants, usually epigastric in location) and in 35% it was nondyspeptic (usually lower GI in location, not relieved by acid suppressants). Most patients (85–100%) with systemic mastocytosis have increased histamine release, which can stimulate acid secretion, and this likely plays an important role in leading to pain in the dyspeptic patient. The nondyspeptic pain has been shown not to be due to increased acid secretion and its mechanism remains unclear, although it is frequently proposed that abnormal motility may be an important factor.

Pathogenesis of Diarrhea

Diarrhea in patients with mastocytosis is frequently an episodic increase in the number of bowel movements per day, which can be accompanied by increased stool weight (>200 g/day) with or without malabsorption. In one prospective study, 50% of the patients with diarrhea had increased stool weight and in most of these patients this was associated with gastric acid hypersecretion, which can cause diarrhea. Other proposed causes of diarrhea in these patients include overproduction of prostaglandin D2, fat malabsorption secondary to mast cell infiltration of the small intestine resulting in generation of hydroxy fatty acids, or altered GI transit due to mediators released by the mast cells.

Pathogenesis of GI Malabsorption

Fat malabsorption is not only uncommon in patients with mastocytosis (5–24%, Table I), it is usually mild (< 20 g/day) (normal: < 7 g/day). The most important mechanism is likely proximal SI dysfunction. Abnormal morphology of villi (blunted, atrophy, mast cell infiltrates) in the proximal SI has been described and in barium X-ray studies, 29–73% of patients with mastocytosis have abnormalities that may contribute to the SI absorptive dysfunction. In various patients it has been proposed that the malabsorption might also be due to gastric acid hypersecretion, inflammatory infiltration in the SI, association with celiac sprue, or disturbed SI motility.

TREATMENT OF GI MANIFESTATIONS OF SYSTEMIC MASTOCYTOSIS

The treatment of GI symptoms (Table I) is dictated by the severity of the abdominal pain, diarrhea, malabsorption, and nausea. The possible contribution of gastric acid hypersecretion can be treated by using proton pump inhibitors or histamine-2 (H2)-receptor antagonists. For nondyspeptic pain, H2-receptor antagonists or a combination of H1- and H2-receptor antagonists are frequently effective. The mast cell membrane-stabilizing drug, disodium cromoglycate, has been used in a number of studies to treat GI manifestations including diarrhea, pain, nausea, and vomiting. In patients with prostaglandin D2 contributing to the diarrhea, it is reported that low doses of aspirin (40 mg/day) or other anti-inflammatory agents may be helpful. In rare patients with severe malabsorption, systemic steroids may be effective. Ascites and/or portal hypertension may be difficult to control with the usual treatment of beta-blocking agents, diuretics, and salt reduction. Portal hypertension was successfully treated in one patient by portacaval shunting. Finally, interferon-α-2b resulted in partial responses in a small number of patients with the malignant forms of mastocytosis.

Meckel's Diverticulum

CYNTHIA D. DOWNARD, SARA LEWICKE, AND MORITZ M. ZIEGLER
Children's Hospital Boston

diverticulum Pouch protruding from a tubular organ.
ectopic Out of place, not in a proper position.
intussusception Infolding of one part of the intestine into another.

Meckel's diverticulum is a 2- to 6-cm out-pocketing of the ileum along the antimesenteric border, usually located 50 to 180 cm proximal to the ileocecal valve. It is the most common congenital aberration of the gastrointestinal tract, occurring in an estimated 2–3% of the population, more commonly in men than women. It is a true diverticulum in that it is composed of tissue from all sections of the ileal wall. Meckel's diverticulum is often described by the "rule of twos"—it may contain of two types of ectopic tissue (gastric and pancreatic), is usually located within 2 feet of the ileocecal junction, occurs in 2% of the population, is close to 2 inches in length, and patients are usually symptomatic before 2 years of age.

INTRODUCTION

History

Meckel's diverticulum was first described in 1598 by Fabricius Hidanus as an "unusual diverticulum" of the small intestine. Littre reported presence of a diverticulum of small bowel present in a hernia in 1742. In 1809, Johann Friedrich Meckel the Younger described the embryological aspects and pathologic nature of an ileal diverticulum, which led to the subsequent adoption of his name for this anomaly.

Embryology

Meckel's diverticulum results from the abnormal persistence of the vitelline (or omphalomesenteric) duct during development. In embryonic life, the vitelline duct is a stalk connecting the midgut of the developing embryo to the yolk sac, and is involved in nutrient transfer and hematopoiesis. Typically, at the end of the sixth week of gestation, the vitelline duct degenerates and the yolk sac detaches from the midgut loop. It is thought that a Meckel's diverticulum develops when the proximal portion of this connection fails to degrade properly. If the entire vitelline duct fails to obliterate, the midgut can remain attached to the umbilicus as a fistula, also called a patent omphalomesenteric duct. Fibrous cords from the diverticulum, with or without cysts, may also remain attached to the umbilicus.

PRESENTATION

General Presentation

Although autopsy series estimate that 2% of the population has a Meckel's diverticulum, less than 20% of people with this anomaly will ever come to clinical attention. A vast majority of Meckel's diverticula are discovered incidentally during laparotomy, during contrast studies for unrelated reasons, or at autopsy.

Symptomatic Presentation

Intestinal Hemorrhage

Intestinal hemorrhage is the most common presentation of symptomatic Meckel's diverticulum in children less than 18 years of age. Ectopic gastric tissue is estimated to be present in 60% of symptomatic Meckel's diverticula. This functional gastric mucosa can produce acid, in turn causing ulceration of the surrounding tissue. Ulcers of this type usually occur at the junction between gastric mucosa within the diverticulum and normal ileal mucosa or opposite the diverticulum on the ileal wall, and can erode into surrounding blood vessels. Interestingly, *Helicobacter pylori*, although often implicated in peptic ulcer disease, is almost never associated with ileal ulceration in Meckel's diverticulum.

Bowel Obstruction

Bowel obstruction is the most common presentation of symptomatic Meckel's diverticulum in the adult population, occurring in over 50% of cases. Intestinal obstruction frequently develops when a fibrous band of a vitelline artery remnant from the Meckel's diverticulum to the

 Copyright 2004, Elsevier (USA). All rights reserved.

umbilicus provides a fixed point for intestinal torsion and closed-loop bowel obstruction. Obstruction may also be due to intussusception with an inverted diverticulum serving as the lead point. This occurs more often in children than in adults. In addition, obstruction may also result due to incarceration of a Littre's hernia, with a Meckel's diverticulum contained within the hernia sac.

Meckel's Diverticulitis

Meckel's diverticulitis occurs in up to one-third of presenting cases, attributable to the irritating effect of peptic acids produced by ectopic gastric mucosa within the diverticulum. Often the symptoms of Meckel's diverticulitis will imitate those of acute appendicitis, highlighting the necessity of examining the ileum for the presence of an irritated Meckel's diverticulum during a negative exploration for presumed appendicitis.

DIAGNOSIS

Meckel's diverticulum is among the most difficult conditions to diagnose preoperatively. Although Meckel's diverticulum is frequently within a differential diagnosis of abdominal pain, only 5–6% of cases are correctly definitively identified preoperatively. Diagnostic tests rely on the unique features of a Meckel's diverticulum, namely, ectopic gastric tissue and ulceration with bleeding, for conclusive identification.

Radionuclide Scanning

The best tool for diagnosing Meckel's diverticulum in children is scintigraphy using [^{99m}Tc]pertechnetate, an isotope taken up by mucus-secreting cells of the gastric mucosa and ectopic gastric tissue within a Meckel's diverticulum. The high incidence of ectopic gastric tissue within symptomatic Meckel's diverticula, particularly in children, makes this scan a useful diagnostic tool. Several agents, such as pentagastrin to increase gastric mucosal absorption, histamine-2 (H2) blockers to decrease excretion of the isotope, and glucagon to decrease peristalsis, can be used to help increase the accuracy and precision of this test.

When intestinal hemorrhage is the presenting symptom of a Meckel's diverticulum, [^{99m}Tc]pertechnetate scintigraphy loses accuracy. Alternatively, erythrocytes can be labeled with a ^{99m}Tc–sulfur colloid to pinpoint a site of hemorrhage in patients losing blood at a rate of at least 0.1 ml/min. If an identified site of bleeding correlates with the terminal ileum, an ulcer associated with a Meckel's diverticulum is the most likely cause. This test is sensitive for identifying bleeding, but is not specific for Meckel's diverticulum.

Angiography

If scintigraphy is not definitive in a patient with continued intestinal bleeding, angiography may be used to identify a site of hemorrhage. When a Meckel's diverticulum is the suspected source, selective superior mesenteric arteriography can be diagnostic. Features highly suspicious for a Meckel's diverticulum are visualization of a vascular blush at the expected site of a diverticulum or persistence of the vitelline artery. False positive results may be obtained on angiography if there is irregular arterial branching from a distal ileocolic artery.

Other Studies

Other radiologic tools, such as ultrasound and computed tomography, have a limited role in the diagnosis of Meckel's diverticulum, but may be employed when other studies are inconclusive. Contrast evaluation may demonstrate a characteristic triangular folding pattern at the site of ileal attachment, a gastric rugal pattern within the diverticulum, or, when the diverticulum is inverted, a polyplike defect within the lumen of the intestine. Air-contrast enema is both diagnostic and therapeutic in cases of intussusception, but it rarely results in a definitive diagnosis of Meckel's diverticulum.

TREATMENT

Symptomatic Diverticula

Symptomatic Meckel's diverticula should be surgically resected. Simple diverticulectomy may suffice when the diverticular opening is small and no ectopic tissue is present. Ileal wedge resection and primary anastomosis are recommended in cases of hemorrhage, ulceration, neoplasia, and chronic inflammation. Long diverticula, with ectopic gastric tissue at the distal end, can be removed by simple transverse resection at the diverticular neck. Shorter diverticula, with gastric tissue on any area, are best removed by wedge resection and end-to-end anastomosis to avoid retention of ectopic gastric mucosa. Simple ligation of the diverticulum and stump invagination are not recommended because the neck of a diverticulum is often too wide to accomplish this effectively.

Asymptomatic Diverticula

Considerable controversy surrounds the treatment of an asymptomatic Meckel's diverticulum because most

Meckel's diverticula are incidentally discovered during laparotomy. It is agreed that the likelihood of a Meckel's diverticulum ever becoming symptomatic is low, but conflicting evidence exists as to whether this usually happens in the earlier decades of life. In addition, varying rates of complication have been reported following incidental diverticulectomy. Prior studies have attempted to offer intraoperative guidelines regarding age of the patient, length of the diverticulum, and presence or absence of ectopic mucosa to determine which asymptomatic diverticula should be resected. In an extensive epidemiologic, population-based project, Cullen and colleagues utilized comprehensive records over a 42-year period from Olmsted County, Minnesota to evaluate incidence and complications arising from Meckel's diverticulum. After assessing all cases of symptomatic and asymptomatic Meckel's diverticulum requiring operation, it was determined that the risk of a Meckel's diverticulum becoming symptomatic does not decrease with age. In addition, the rate of morbidity of incidental removal was sufficiently low (2%) and the rate of early postoperative complication after symptomatic diverticulectomy was adequately high (12%) to warrant a recommendation of routine removal of incidentally discovered Meckel's diverticula. Because this is the most comprehensive review of this subject to date, these suggestions are currently the best supported criteria.

OUTCOME

Full recovery should be expected following diverticulectomy for symptomatic or asymptomatic Meckel's diverticulum. Although up to 12% of patients develop complications such as adhesions, sepsis, and wound infection following symptomatic Meckel's diverticulectomy, these are usually easily treated nonoperatively with antimicrobials and other agents. Mortality, even for symptomatic Meckel's diverticulectomy, is rare.

Megacolon: Neuromuscular Enteric Abnormalities

SAMUEL NURKO
Children's Hospital Boston

Hirschsprung's disease Disease with varying degrees of distal intestinal aganglionosis.
megacolon A condition in which the colon has abnormally large dimensions.

Megacolon in children is a poorly defined entity. Even though functional constipation is the most common etiology, there are some rare neuromuscular enteric abnormalities that present with megacolon. These occur because there are problems with the enteric nervous system, the enteric smooth muscle, or both. This article focuses primarily on the neuromuscular enteric disorders that primarily affect the gastrointestinal tract.

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease is the most common neuroenteric disorder. This article focuses mostly on the clinical aspects of the disease.

Hirschsprung's disease is a congenital problem in which varying degrees of aganglionosis occur in distal segments of the intestinal tract. The length of the aganglionic segment varies. It is limited to the rectum and sigmoid in 75% of cases, involves the whole colon in 8% of cases, and rarely involves the small bowel. The aganglionosis in Hirschsprung's disease results in a lack of intrinsic enteric inhibitory nerves. Intestinal obstruction is produced because there is a lack of nonadrenergic, noncholinergic innervation in the aganglionic segments with a resultant failure to relax during peristalsis. The segment proximal to the obstruction then becomes dilated.

The incidence of Hirschsprung's disease varies from 1 in 5000 to 1 in 10,000 live births. There seems to be a male preponderance with a ratio of 3 : 1 to 5 : 1, particularly in those with short segments. However, the incidence in both sexes seems to be the same in those with long-segment disease.

The mean age at the time of diagnosis has been decreasing over the years. The diagnosis is established in 15% of patients within the first month of life, in 40–50% of patients in the first 3 months, in 60% of patients at the end of the first year of age, and in 85% of patients by 4 years. The diagnosis of Hirschsprung's disease is rarely delayed until adulthood.

The symptoms vary with the age of the patient and the extent of the disease. In the newborn period, bilious emesis, abdominal distension, and failure to pass meconium or abnormal stool frequency are common. Complete intestinal obstruction may occur and perforation of the cecum or the appendix occurs in 3–5% of cases. If the diagnosis is not established in the newborn, the infant may present with mild constipation that may be followed with acute obstruction, frequent episodes of fecal impaction, or the development of acute life-threatening enterocolitis. Enterocolitis develops in 15 to 50% of cases and may be the presenting feature of Hirschsprung's disease in up to 12% of patients. It remains the main cause of death and the mortality rate can reach 20 to 50%.

From infancy until adulthood, mild to severe constipation may be the only symptom, so Hirschsprung's disease must be differentiated from functional constipation. Because clinical features do not allow a complete differentiation between these problems, the diagnosis of Hirschsprung's disease must always be considered in any child, adolescent, or adult with severe intractable constipation.

Diagnosis

Once the diagnosis of Hirschsprung's disease is suspected, confirmation is necessary. The final diagnosis needs to be based on the pathologic demonstration of aganglionosis. Because obtaining biopsies involves risks, other less invasive techniques, such as barium enema and anorectal manometry, can be used to select those patients who require a biopsy.

The barium enema (BE), although not diagnostic can be strongly suggestive and supportive. Single-contrast barium enemas are used and the colon is not prepared. In infants with Hirschsprung's disease, a transition zone from the distal nondilated colon is

 Copyright 2004, Elsevier (USA). All rights reserved.

usually easily detected. The absence of a transition zone, however, does not exclude the diagnosis. BE may be less helpful in the newborn because a visible transition zone is often not present.

Anorectal manometry is a noninvasive technique that allows the detection of the recto-anal inhibitory reflex. In normal individuals, distension of the rectal ampulla causes relaxation of the internal anal sphincter. Intrinsic nerves mediate this effect, which is absent in patients with Hirschsprung's disease. After the newborn period, manometry has been shown to accurately diagnose Hirschsprung's disease in 90 to 100% of the patients, with a specificity of 97% and a sensitivity of 79%. Therefore, in this age group, anorectal manometry is the diagnostic study of choice.

Confirming the absence of ganglion cells in the diseased segment is a necessary step in the diagnosis of Hirschsprung's disease. Rectal suction biopsy, which produces a specimen of mucosa and submucosa, is a commonly employed tool. When ganglion cells are present, the diagnosis of Hirschsprung's disease is clearly excluded. The use of immunohistochemical stains for acetylcholinesterase (AChE) in combination with the hematoxylin and eosin stain can increase the accuracy. There is a marked increase in AChE activity in the lamina propria and muscularis of the patient with Hirschsprung's disease.

For those cases in whom the suction biopsy has produced equivocal results, it may be necessary to obtain a full-thickness biopsy of the rectal wall.

Treatment

The treatment of Hirschsprung's disease is surgical. Initial medical management is important, however, in stabilizing the patient before surgical therapy is undertaken. This includes the correction of fluid and electrolyte imbalances, antibiotic therapy if enterocolitis is present, and rectal decompression with the use of rectal irrigations and rectal tubes until the time of surgery.

The basic principle for the definitive surgical therapy is resection of the aganglionic segment followed by a pull-through of ganglionic bowel down to the anus. The three most common operations performed include the Swenson pull-through (rectosigmoidectomy), the Duhamel pull-through (retrorectal transanal pull-through), and the Soave pull-through (endorectal pull-through). It is difficult to compare the results obtained with the three techniques, because the incidence of complications may be closely related to the skill of the individual surgeon, to the institution, or to the year of the study. Nevertheless, the long-term outcome of these procedures appears to be similar. Independent of the type of surgery, long-term survival is excellent, although death from enterocolitis may occur years after successful surgical reconstruction. Many studies show a higher than anticipated incidence of problems postoperatively, in particular, persistent obstruction, fecal incontinence, or enterocolitis.

TABLE I Common Problems after Hirschsprung's Surgical Repair

Obstructive symptoms and constipation
Anatomic
Anal stenosis, strictures
Functional
Aganglionosis: Residual or new
Neuronal intestinal dysplasia
Dismotility
Internal anal sphincter hypertonicity
Functional fecal retention
Fecal incontinence
Overflow incontinence from constipation
Abnormal sphincteric function
Diarrhea
Bacterial overgrowth syndrome
Enterocolitis
Clostridium difficile
Other pathogens
Growth problems
Diarrhea and malabsorption
Specific nutrient deficiencies

The most common problems encountered after surgical repair are shown in Table I. The treatment will vary depending on the diagnosis and may include laxatives, antibiotics, rectal decompression, surgery, or administration of botulinum toxin to the internal anal sphincter.

OTHER NEUROMUSCULAR DISEASES THAT AFFECT THE INTESTINE

Other disorders that mimic the distal obstruction seen in Hirschsprung's disease are mentioned in Table II. They encompass clinical entities in which there is disruption of the normal control mechanisms of the motor function of the intestine and they include abnormalities of the myenteric plexus or the smooth muscle. Those abnormalities produce ineffective antegrade peristalsis and recurrent symptoms of bowel obstruction.

The clinical presentation will vary depending on the type and extent of the abnormality. It usually includes functional obstruction, delayed intestinal transit, and abdominal pain and there may be associated urinary problems or bacterial overgrowth.

Diseases of the enteric nervous system or the smooth muscle may be familial or sporadic and may be limited to

        - Megacystis–microcolon–hypoperistalsis syndrome
    - Secondary visceral neuropathies

the colon or they may be part of a more generalized disorder that can affect the whole gastrointestinal (GI) tract. In some cases, there may also be extraintestinal involvement or the enteric dysfunction may be a result of abnormal extraintestinal regulation.

Of the primary diseases that affect the smooth muscle, the most common are either hollow visceral myopathy or megacystis microcolon hypoperistalsis syndrome (MMIHS). MMIHS is the most severe form of pseudo-obstruction and affects predominantly female infants. It is characterized by marked dilation of the bladder, a dilated nonperistaltic small bowel, and a malrotated microcolon. Most patients require multiple surgical procedures and are dependent on total parenteral nutrition. The prognosis is poor and most patients die at a very young age from renal insufficiency or sepsis.

Of the primary diseases that affect the enteric nervous system, Hirschsprung's disease is the most common. After Hirschsprung's disease, the most common disorders are those in which there are malformations of intestinal neurons. Among those conditions, neuronal intestinal dysplasia (NID) has been the most controversial. This term has been used to describe qualitative and quantitative abnormalities of the myenteric plexus. These include hyperganglionosis, with the presence of giant ganglia, heterotopic ganglion cells, and abnormal findings using acetylcholinesterase stain. Different types of NID have been recognized and it may be associated with an aganglionic segment. Part of the problem in deciding if NID is a clinically distinct entity stems from the fact that there are no clear and validated criteria for its diagnosis. Recent prospective, controlled studies have tried to validate pathologic criteria for innervation abnormalities like Hirschsprung's disease or NID using rectal biopsies. These investigations demonstrated that even though there is complete agreement in the diagnosis of Hirschsprung's disease, there is great interobserver disagreement and a lack of concordance in making a diagnosis of NID even by a group of experienced pathologists. This lack of agreement probably stems from the lack of information about the normal developmental process that occurs in the myenteric neurons after birth. Further studies of age-dependent normal variation in the morphology of the myenteric plexus are needed.

NID is a pathologic diagnosis and does not seem to represent a distinct clinical problem. When the diagnosis has been made, the clinical symptoms have included intractable constipation and megacolon. Multiple studies have shown, however, that there does not seem to be a correlation between the pathologic findings and the clinical presentation, abnormal functional testing, or outcome. Therefore, caution needs to be exercised in the clinical management of those children who are diagnosed with NID.

Neuromuscular enteric problems can also be secondary to systemic disorders. These include mitochondrial and neurologic diseases, endocrinologic and metabolic abnormalities, connective tissue diseases, neurologic diseases, or after the administration of drugs.

Evaluation and Treatment

The differential diagnosis of megacolon in children includes the problems mentioned in Table II. Most children will have functional constipation and their diagnosis is established clinically after a careful history and physical examination. It is important to exclude anatomic malformations, such as anal stenosis, imperforate

anus, or a mechanical obstruction. The presence of a neuromuscular enteric disorder needs to be excluded in patients with intractable constipation or those with severe obstructive symptoms. Initially, Hirschsprung's disease needs to be excluded as mentioned previously.

If there is no Hirschsprung's disease and there is evidence of a generalized motility disorder, systemic problems need to be excluded. Objective measurements of gastrointestinal transit may be necessary. These include gastric emptying, transit, and motility studies. Antroduodenal manometry may be indicated to evaluate upper GI motility and may help to establish whether the patient's problem is myopathic or neuropathic in nature. If the problem seems to be confined only to the large intestine, a colonic motility test may be necessary. This may reveal evidence of neuropathy or myopathy. A full-thickness biopsy of the rectum may be indicated when there is evidence of a neuroenteric motility disorder of the colon.

In most cases, there is no specific treatment. Nutritional support is important, particularly patients with a generalized problem. Enteral feedings should be tried, but total parenteral nutrition may be necessary. Bacterial overgrowth should be treated. The use of prokinetic agents may be beneficial, as long as there is remaining function of the enteric nerves. Cisapride may be obtained under special programs and octreotide may be used, particularly if there is small bowel dysfunction.

Patients with Hirschsprung's disease need to have surgical resections, and for those patients with normal ganglion cells and a nonrelaxing internal anal sphincter, botulinum toxin or myectomy is indicated. Other surgical therapy should be reserved only for patients with involvement of small and specifically affected segments. The creation of venting ostomies is necessary to relieve pain in those with more severe obstructive symptoms. An ileostomy may be necessary when there is severe colonic dysfunction and a cecostomy may be indicated for the administration of colonic lavage. For patients with severe small bowel dismotility, an intestinal transplant may be the only option for long-term survival.

Ménétrier's Disease

J. Steven Burdick*, Stephen H. Settle†, and Robert J. Coffey†
*University of Texas Southwestern Medical Center, Dallas, and †Vanderbilt University

antral sparing Pattern of gastropathy in which the proximal stomach (fundus and body) is primarily involved and the distal stomach (antrum and pylorus) is relatively or totally free of disease ("spared").

epidermal growth factor Peptide that is tropic for the growth of epithelial cells in the gastrointestinal mucosa and elsewhere.

gastropathy Disorder of the stomach that may or may not be associated with mucosal inflammation (gastritis).

Ménétrier's disease Form of gastropathy characterized by hyperplasia of the lining epithelium and hypertrophy of the mucosa, with or without inflammation (gastritis).

Ménétrier's disease (hypoproteinemic hypertrophic gastropathy) is gastropathy characterized by decreased acid production (hypochlorhydria), excessive mucin production, hyperproliferation of the gastric folds, and hypoproteinemia associated with selective loss of serum proteins across the gastric mucosa into the gastric lumen. The disease linkage with Ménétrier dates to 1888 with the description of enlarged gastric folds, "polyadenomes en nappe rugae," that resembled cerebral convolutions. The disease is rare, acquired, and a premalignant disorder. Gastric cancer has been reported at diagnosis and during followup of patients with hypertrophic gastropathy. No specific therapy is predictive of response to symptoms. The disease has been linked with ligands of the epidermal growth factor receptor, thus antagonism of this receptor as a therapeutic modality is being investigated.

ETIOLOGY

The cause of Ménétrier's disease is unknown. *Helicobacter pylori* and cytomegalovirus infection have been associated with a reversible hypertrophic gastropathy. Cytomegalovirus infection is noted predominantly in pediatric presentations but also has been reported in immunocompetent adults. Eradication of *H. pylori* has correlated with resolution of hypertrophic gastropathy and clinical expression in some patients. The hypothesis that up-regulation of transforming growth factor-α is a feature of this disease is supported by studies of transgenic mice and human data. Increased expression of transforming growth factor-α in the stomach can recapitulate the phenotype of Ménétrier's disease, including reduced acid production, excessive mucin production, and hyperproliferation of mucosa. Transforming growth factor-α is one of seven mammalian ligands of the epidermal growth factor (EGF) receptor. Thus, increased expression of any of these ligands may contribute to the disease. Blockade of EGF receptor in a patient with Ménétrier's disease results in decreased clinical and biochemical expression of the disease. There is an accompanying decrease in the proliferation of the mucosa and emergence of parietal cells after EGF blockade. The collective data from transgenic mice, humans, and response to EGF blockade are supportive of a role of enhanced epidermal growth factor receptor signaling in the pathogenesis of Ménétrier's disease.

PATHOLOGY

Ménétrier's disease is a form of hypertrophic gastropathy characterized by foveolar hyperplasia and glandular atrophy. The findings of mucosal inflammation and glandular atrophy are quite variable. The lymphocytic inflammatory response and the foveolar hyperplasia have been used to separate the gastropathy into two groups, hypertrophic lymphocytic gastritis and massive foveolar hyperplasia. Hypertrophic lymphocytic gastritis is associated with severe inflammation with numerous intraepithelial lymphocytes and mild foveolar hyperplasia, whereas massive foveolar hyperplasia has greater foveolar hyperplasia, thicker mucosa, and greater mucosal edema. Hypertrophic lymphocytic gastropathy is considered a spectrum of lymphocytic gastritis by several researchers.

CLINICAL

Patients with Ménétrier's disease frequently present with complaints of epigastric pain, fatigue, weight loss, edema, and vomiting. Severe presentations of Ménétrier's disease include hypoalbuminemia and iron deficiency anemia. Giant rugae are the hallmark of the disease. Normal folds are around 5 mm in width and are parallel to the long axis of the stomach. The folds in Ménétrier's are thick, tortuous, and convoluted. The

 Copyright 2004, Elsevier (USA). All rights reserved.

enlarged folds are particularly noted in the fundus and body of the stomach (Fig. 1). However, the entire stomach can be involved in approximately 50% of cases and duodenal involvement may occur in 3%. Excessive mucus production and hyposecretion of acid occur. The selective loss of proteins across the gastric mucosa may lead to hypoalbuminemia. Thick gastric fold changes are not specific to Ménétrier's disease and it is necessary to consider other diseases, including Zollinger–Ellison syndrome, *H. pylori* infection, gastritis, cytomegalovirus infection, gastritis, lymphoma, eosinophilic gastritis, sarcoid, syphilis, histoplasmosis, and infiltrative diseases, including neoplasms and amyloid. Large-forcep biopsies and snare biopsies may aid the pathologic evaluation. Endoscopic ultrasound changes include 5-mm thickenings of the second hypoechoic layer and cystic changes.

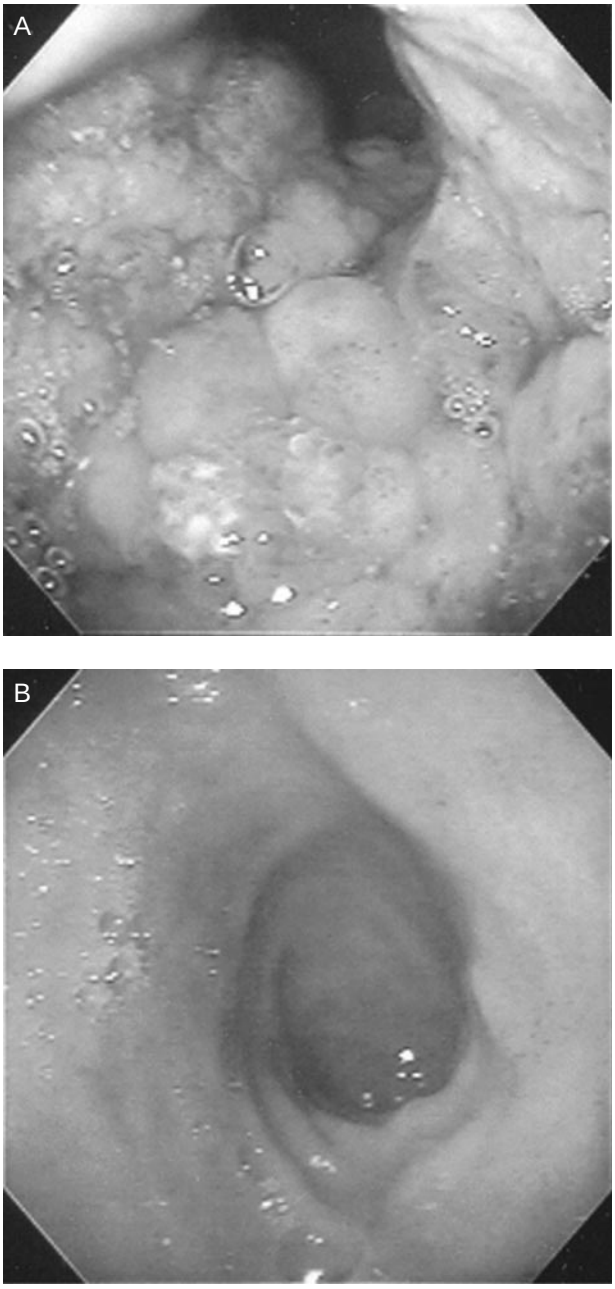

FIGURE 1 Gastroscopic appearance of Ménétrier's disease. (A) Note the enlarged folds, with excessive mucus production, in the gastric body and fundus. In the same patient, the distal stomach (B) appears fairly normal ("antral sparing").

Partial regression of abnormalities may occur but spontaneous resolution is rare. In a review of 40 patients, 55% improved with or without medical therapy at a mean followup of 7.6 years. No randomized trials are available to compare treatments. However, retrospective reviews and reports of various therapies are available. This experience indicates that no single agent uniformly leads to a clinical response. Anticholinergic therapy, the somatostatin analogue octreotide, histamine-2 (H2) receptor antagonists, and proton pump inhibitors have been used. Surgery is an option for severe disease and is required in around 10% of cases. Currently, an investigative protocol using an epidermal growth factor receptor antagonist is available for patients with severe disease. Multiple case series studies report the concomitant diagnosis of gastric cancer and Ménétrier's disease a initial presentation. Additionally, on followup, gastric cancer developed in over 7% of cases. The risk of developing gastric cancer suggests a need for continued endoscopic surveillance.

Microflora, Overview

E. T. T. L. TJWA* AND L. A. DIELEMAN†

**University Medical Centre St. Radboud, Nijmegen, The Netherlands, *University of North Carolina at Chapel Hill, and †University of Alberta, Canada*

commensalism State of colonization that results in either no damage or clinically inapparent damage to the host, though it can elicit an immune response.

germ free Gnotobiotic (Greek for "known flora") state in which all microflora are absent.

probiotics Living bacteria that colonize a host in amounts sufficient to alter the normal host microflora, resulting in a beneficial health effect for the host.

The normal intestinal microflora, which are mostly bacterial, consist of the resident populations of microbial species that inhabit the digestive tract of their host. Because "normal" is often undefinable, "indigenous" microflora, or biota, is a better term. The colonizing microbes are diverse: bacteria are in the majority, but fungi and protozoa are also present. Understanding the complex interplay between the indigenous biota, their associated metabolisms, and the host digestive tract forms the basis of understanding the microbial role in disease, but also in maintaining health. There are more than 400–500 bacterial species in the human colon of a single healthy individual, amounting to about 10^{12} viable bacteria per gram of colonic content. Considering this, the intestinal microflora can be viewed as a potential metabolic organ.

INTRODUCTION

Environmental and microbial factors contribute to the pathogenesis of many intestinal diseases. The role that indigenous microflora play in the health of their hosts has been point of controversy since Pasteur hypothesized a necessary but sometimes detrimental role, and Metchnikoff argued a more beneficial one. Most of the published work on (development of) the human gastrointestinal flora has been restricted to analysis of the fecal flora using conventional methods such as cultures. However, culture results from fecal microflora reflect only 50–80% of the total microscopic bacterial count. Studies using novel tools to identify greater numbers of microflora by molecular methods are emerging and have the potential to provide new insights on how microflora influence their host in health and disease.

IDENTIFICATION TECHNIQUES

Most of our knowledge of the microflora of the human digestive tract is derived from studies using traditional techniques of culture and microscopy. Most of the studies of intestinal microflora use fecal cultures, assuming that fecal microflora and large bowel microflora are equivalent. Microflora of the upper digestive tract have been studied through a sampling method, described by Gorbach, using a flexible plastic tube to aspirate samples. It is unlikely that all of the important organisms that are present in the intestinal crypts or gastric mucosa are present in such collected samples. The interpretation of microflora data is further complicated considering sampling, storage, and culture methods. Sampling in the highly inaccessible digestive tract is complex, and most samples are gathered in nonphysiologic situations, such as during surgery or postmortem. Ideally, the bulk of microflora should be stored in absolutely anaerobic conditions, which cannot typically be met in a standard setting. Only 10–20% of intestinal bacteria can be cultured, meaning that 80–90% of the microorganisms are uncultivatable. Novel techniques to identify microflora, without requiring culture, have therefore been established. One of these improved species identification techniques involves detection of bacterial 16S ribosomal RNA. This small ribosomal subunit contains the hypervariable V regions, which define the signature of phylogenetic groups and species of bacteria. Identification of genera, species, and even strains of the microflora of the digestive tract using detection methods for 16S ribosomal bacterial RNA sequences will substantially increase our knowledge of the composition of the intestinal microflora. In addition, molecular techniques such as denaturation or temperature gradient–pulsed gel electrophoresis (D/TGGE), fluorescence *in situ* hybridization (FISH), flow cytometry, and genetic fingerprinting with DNA microarrays have been used as novel microflora identification methods.

MICROFLORA OF THE DIGESTIVE TRACT

Microbial commensalism occurs within a few days of birth, with development of a succession of organisms as local microenvironments change. Commensalism begins perorally, as demonstrated in infants with congenital small bowel obstruction, in which a fecal-type flora is present proximal of the site of obstruction, whereas the distal bowel remains sterile. The first bacteria that colonize the human gut are derived from the aerobic and anaerobic flora of the birth canal; in neonates, *Escherichia coli*, *Clostridium* spp., *Streptococcus* spp., *Lactobacillus* spp., *Bacteroides* spp., and *Bifidobacterium* spp. predominate. After 4–6 days, the microflora of vaginally delivered, formula-fed, full-term newborns consist of mostly anaerobes, mainly *Bacteroides fragilis*, whereas the fecal microflora of breast-fed newborns consist of significantly more bifidobacteria. In contrast, the digestive tract of newborns delivered by cesarean section contains only 60% anaerobes (of which only 9% is *B. fragilis*). These results indicate the effects of delivery route and dietary constituents (breast milk or formula), but other early exogenous factors, such as eruption of teeth, gestational age, hospitalization, geographic variations, and sanitary conditions, can also determine the composition of the intestinal microflora. A few weeks after, birth, numerous colonizing organisms are present, maintaining an orderly and stable presence in the niches of the stomach, small intestine, and large intestine.

The stomach is often considered to be "sterile," defined as $<10^3$ colony-forming units (CFUs)/ml of gastric aspirate. The most important factor controlling the gastric flora is acidity. The bactericidal nature of gastric secretions is affected by alterations in pH. In health, when stomach pH is less than 2, gastric microflora consist of predominantly gram-positive aerobic bacteria, including streptococci, staphylococci, lactobacilli, and various fungi. Oral anaerobes such as *Peptostreptococcus, Fusobacterium*, and *Bacteroides* species are present in very low numbers. Hypochlorhydria and gastric surgery can increase the number of bacteria found in the stomach, which can include oral microflora as well as fecal-type bacteria. Since *Helicobacter pylori* was identified, it has become clear that many gastric microbes are *Helicobacter* species or closely related microaerophilic spiral organisms. *Helicobacter pylori* is considered a pathogen and is associated with peptic ulcers. In contrast to the pathogenic role of *H. pylori*, some non-*pylori* species are indigenous to the human stomach and could even have a beneficial role.

The small intestine serves as a transition zone between the relatively "sterile" upper digestive tract and the densely populated lower digestive tract. The key factor regulating commensalism in the small intestine is peristalsis. The composition of microflora of the proximal small intestine is similar to that of the stomach, although a higher concentration of the various microorganisms can be detected (10^5 CFUs/ml of jejunal aspirate). Anaerobic and coliform bacteria are present in relatively low concentrations.

TABLE I Dominant Genera of the Human intestinal Microflora (Most Common Species)

Genus	Species
Bacteroides	*thetaiotamicron, fragilis, vulgatus, ovatus*
Fusobacterium	*mortiferum, necrophorum*
Eubacterium	*aerofaciens, lentum, contortum*
Bifidobacterium	*infantis, adolescentus, longum*
Lactobacillus	*acidophilus, fermentum, plantarum*
Clostridium	*perfringens, bifermentans, ramosum*
Peptostreptococcus	*productus*
Enterococcus	*faecium, faecalis*

The microflora composition of the distal small intestine resembles that of the large intestine. In the colon, the microbial concentration is approximately 10^{12} CFUs/ml, whereas in the distal small bowel this is 10^7 to 10^8 CFUs/ml. The large intestine of individuals consuming a Western diet contains mostly obligate anaerobic bacterial species (Table I). These include gram-negative rods such as *Bacteroides* (predominantly), *Fusobacterium, E. coli, Enterobacter*, and *Klebsiella*, as well as gram-positive bacteria such as *Eubacterium*, but bifidobacteria, lactobacilli, clostridia, and gram-positive cocci such as *Peptostreptococcus, Enterococcus, Streptococcus*, and *Staphylococcus* are also found. Several bacterial species have been associated with pathogenic properties (*B. fragilis, Enterococcus faecium, Clostridium difficile, E. coli* O157:H7) as well with nonpathogenic characteristics (*Lactobacillus fermentum*).

ESTABLISHING A STABLE MICROFLORA

Each individual has a unique composition of indigenous microflora; within this population, there is both competition and cooperation. The microfloral makeup is shaped by various events exclusively connected to the specific host and its environment. Once established, many of the biota persist for years if not for the life of the host. However, there can be a marked variation in the complexity and stability of microflora between hosts. The stability of the microflora is remarkable considering the complexity of the ecologic environment of the digestive tract and the perpetual introduction of

microorganisms. This persevering microbial stability is the result of regulation of microflora and host interactions, even after multiple environmental insults.

The ability to colonize the intestinal tract correlates with the capacity to adhere to mucosal surfaces. Adherence capacity is not only bacterial species specific but is also dependent on host intestinal epithelial cell factors. Bacterial adherence is mediated by binding of microbial adhesins or lectins to complementary host epithelial cell receptors. These receptors consist of a variety of glycolipids, glycoproteins, and carbohydrate chain structures. However, not all microorganisms are capable of colonizing, because host defense mechanisms have evolved in order to block adherence of various species. Microbe-specific factors (production of specific secretory immunoglobulins, such as IgA; epithelial receptor analogues) as well as local environmental host factors (e.g., motility, the availability of essential nutrients, redox potential, and enteric secretions such as gastric acid and unconjugated bile) are means of controlling commensalism, maintaining the status quo, and preventing bacterial overgrowth. Interactions between the various microbes also form an important regulating factor. Resident flora may interact to promote or prevent the growth of other species and of themselves. Production of bacteriocin or short-chain fatty acids results in direct prevention of adherence and of growth of gram-positive bacteria such as the streptococci. Stimulation of the phagocytic system and other immunologic clearance systems has also been demonstrated to be a host resident flora defense mechanism against potential pathogens.

Environmental factors can alter the composition of the intestinal microflora. Chronic use of alcohol can induce a higher prevalence of gram-negative microorganisms in the upper digestive tract. Stress is also known to influence the gastrointestinal microflora, and *Lactobacillus* populations are among the species that are affected. Reports demonstrating a marked influence of diet on the gastrointestinal flora contradict studies comparing standardized institutional diets to random diets, which fail to demonstrate a significant effect of diet on the stable resident microflora.

Selective decontamination of (parts of) the digestive tract has been used in neutropenic patients and in many clinical situations to prevent postoperative wound infection. Although selective bowel decontamination can prevent opportunistic infections and bacterial translocation, the resident flora can shift toward a relative overgrowth of certain species, notoriously *C. difficile* and *Candida albicans*, resulting in disease. This suggests that some species of the indigenous flora can protect against bacterial and fungal pathogens. Antimicrobial agents can have a long-lasting effect on the normal gastrointestinal flora; amoxicillin treatment for only 7 days results in predominant antibiotic-resistant strains for up to 6 months.

BENEFICIAL MICROFLORA

Probiotic components of the intestinal bacterial flora are beneficial for the host. Probiotics include bacteria such as lactobacilli, bifidobacteria, and nonpathogenic *E. coli*. Lactobacilli play an important role in the maintenance of colonization resistance and in prevention of overgrowth of enteric pathogens. Lactobacilli species, albeit not predominant, are present throughout the gastrointestinal tract of healthy humans. Among the *Lactobacillus* species able to colonize the digestive tract are *Lactobacillus plantarum*, *Lactobacillus acidophilus*, *Lactobacillus fermentum*, and *Lactobacillus casei* strain GG. Probiotics can reduce fecal bacterial β-glucuronidase, a marker of intestinal bacterial metabolism, and produce antimicrobial substances that inhibit growth of anaerobic bacteria *in vitro*. Lactobacilli confer many other nutritional and protective benefits, ranging from fiber fermentation, removal of toxins, and enhancement of intestinal IgA secretion and macrophage responses. Probiotics are also capable of preventing adherence of pathogenic bacteria to intestinal epithelial cells. Several human clinical trials have shown the efficacy of several species of probiotics in viral- and bacterial-induced infectious colitis as well as in antibiotic-associated diarrhea. Rectal administration of native murine *Lactobacillus* spp. prevented colitis in interleukin (IL-10)-deficient mice and a similar effect was shown by oral prebiotic lactulose, which stimulated the growth of endogenous *Lactobacillus* species. Continuous oral administration of *Lactobacillus plantarum* 299v to germ-free IL-10-deficient mice colonized with specific pathogen-free (SPF) flora could attenuate established colitis, whereas oral administration of *Lactobacillus rhamnosus* GG prevented relapse of colitis in SPF HLA-B27 transgenic rats after antibiotic treatment. A probiotic preparation including four species of *Lactobacillus*, three species of *Bifidobacterium*, and *Streptococcus salivarius* (VSL#3) maintained remission of refractory pouchitis in patients after transient antibiotic therapy. This probiotic cocktail (VSL#3) was also beneficial in the treatment of colitis in IL-10-deficient mice.

INTRODUCTION

The interdigestive pattern of gastrointestinal motility begins from 2 to 3 hours after a meal and after digestion and absorption of the nutrients in the meal have taken place. The contractile behavior in the interdigestive state is detected either by placement of pressure sensors into the lumen or by attachment of electrodes to the gastrointestinal surface. At a single recording site, the migrating motor complex (MMC) pattern consists of three periods. The first is a silent period, called

Copyright 2004, Elsevier (USA). All rights reserved.

Phase I, which has no contractile activity; the second period, Phase II, follows, consisting of irregularly occurring contractions. Phase II is followed by Phase III, which consists of regularly occurring contractions, and then Phase I begins again at the end of Phase III, to repeat the cycle. Multiple sensors positioned on the stomach and continuing at equally spaced intervals along the small intestine reveal that activity representing Phase II and Phase III starts in the stomach and propagates slowly down the intestine. The migratory nature of the contractions is the basis for describing the interdigestive pattern as the MMC.

Migrating Motor Complex Activity Front

The MMC, at any given time, occupies a limited length of intestine termed the "activity front." As such, the activity front has an upper boundary, where it begins, and a lower boundary, where it ends (Fig. 1). The activity front slowly advances (migrates) along the intestine at a rate that progressively slows as it approaches the ileum. Peristaltic propulsion of luminal contents in the anal direction occurs repeatedly within the activity front. Each successive peristaltic wave starts at the upper boundary of the activity front, propagates over the length of the activity front, and stops at the lower boundary. Successive peristaltic waves start a short distance further along the intestine than the previous one and propagate a short distance beyond the lower boundary where the last one stopped. This causes the activity front to migrate slowly down the intestine, sweeping the lumen clean as it progresses.

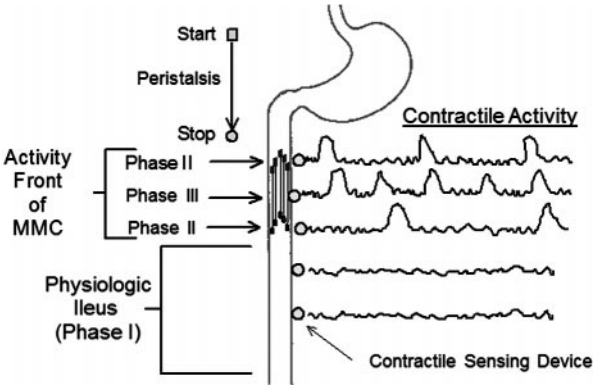

FIGURE 1 The activity front of the migrating motor complex consists of repetitive cycles of peristaltic propulsion as it slowly advances down the intestine. Peristaltic propulsion of luminal contents in the aboral direction occurs between the orad and aborad boundaries of the activity front. Successive waves of peristaltic propulsion start on average slightly further along in the aborad direction and propagate on average slightly beyond the boundary where the previous one stopped. This is responsible for the impression that the activity front migrates slowly in the aborad direction. Contractile activity described as Phase II or Phase III occurs because of irregularity of the orad boundary where each consecutive peristaltic wave starts and irregularity of the arrival of the contractile wave at the aborad boundary. As the leading and trailing edges of the activity front pass a contractile sensor, only the peristaltic waves that pass the sensor are recorded, and this gives the appearance of irregular contractions (i.e., Phase II). When the central region of the activity front passes a sensor, every recurrent peristaltic wave is recorded, giving the appearance of regular contractions at higher frequency (i.e., Phase III). Physiologic ileus is in effect in the regions of intestine outside the activity front (i.e., Phase I).

In humans, the time between cycles is longer during the day than at night. The activity front travels at 3–6 cm per minute in the duodenum and progressively slows to 1–2 cm per minute in the ileum. The speed of travel of the activity front is much slower that of the electrical slow waves, action potentials, and peristaltic contractions that make up the activity front. Slow waves with associated action potentials and contractions within the activity front travel 10 times faster than the activity front.

Phase III of the MMC reflects the propulsive contractions within the activity front as it slowly progresses along the intestine. Phase III lasts for 8–15 minutes as the activity front passes by a single recording site (Fig. 1). The shortest duration of Phase III is in the duodenum, with a progressive increase in duration occurring as the complex migrates toward the ileum. Each slow wave, with action potentials and associated contractions, reflects a single propulsive event occurring within the activity front. Phases I and II each occupy about half of the rest of the cycle as recorded at a single site. The irregular electrical and contractile activity of Phase II reflects the activity at the leading and trailing edges of the activity front as it moves along the intestine. At the leading edge, the irregularity reflects failure of some of the peristaltic waves within the front to propagate as far as others. At the trailing edge, irregular activity indicates failure of some slow-wave cycles to initiate the propulsive contractions as the end of the front passes the point on the bowel where the electrode or device for detecting contractions is placed.

A MEAL STOPS THE MIGRATING MOTOR COMPLEX

The MMC continues until it is terminated by the ingestion of food. Ingestion of a meal with sufficient caloric content halts the MMC. Termination requires contact of the meal with the upper digestive tract, because intravenous feeding does not end the fasting pattern. The

short time required for postprandial termination of the MMC suggests a neural or hormonal mechanism. Two hormones, gastrin and cholecystokinin, which are released on ingestion of a meal, terminate the MMC when injected intravenously. Nevertheless, this effect occurs only in the stomach and upper small intestine, not in the ileum.

The MMC is one of the motor programs in the program library of the enteric nervous system and requires that the enteric nervous system be fully functional. The MMC continues in the small intestine after interruption of all inputs from the central nervous system, but stops when it reaches a region of the intestine where the enteric nervous system has been interrupted experimentally. In experimental animal models, MMCs occur in autotransplanted stomachs that have no connections with the central nervous system. Presumably, command signals to the enteric neural circuits are necessary for initiation of the interdigestive pattern; however, whether the commands are neural or hormonal or both is unknown. Although levels of the hormone motilin increase in the blood at the onset of the interdigestive state, it is unclear whether motilin is a hormonal command to the enteric nervous system, to call up the MMC from its program library, or is released secondary to start up of the MMC program.

FUNCTIONAL SIGNIFICANCE

The adaptive significance of the MMC appears to be a mechanism for clearing indigestible debris, mucus secretions, and sloughed mucosal epithelial cells from the stomach and intestine during the fasting state. Large indigestible particles are emptied from the stomach only during the interdigestive state. Contraction of the gallbladder and delivery of bile into the duodenum occur as the activity front approaches the site where the bile duct enters the duodenum. Once in the duodenum, the activity front carries the bile downward to the ileum, where it is absorbed and transported to the liver to be secreted and again stored in the gallbladder. Contraction of the gallbladder and emptying of bile into the intestine are components of the neural program for the MMC and may be a mechanism that prevents bile from becoming overly concentrated in the gallbladder during the interdigestive state, when the digestive functions of bile are not required. Because gallstones form when bile becomes overly concentrated, the MMC may ensure movement of bile in the enterohepatic circulation during the interdigestive state and thereby protect against lithogenesis.

Bacterial overgrowth in the small intestine is associated with absence of the MMC in human patients. This suggests that the "housekeeper" function of the MMC may play a role in preventing the overgrowth of microorganisms that might occur in the small intestine if the contents were allowed to stagnate in the lumen.

Minimally Invasive Surgery

THOMAS E. CLANCY AND DAVID C. BROOKS
Brigham and Women's Hospital and Harvard University

fundoplication Fixation of the gastric fundus, usually around the distal esophagus, for the purpose of treating gastroesophageal reflux disease.
laparoscopic surgery The use of laparoscopy to perform diagnostic and therapeutic procedures in the abdominal cavity.
laparoscopy Visual inspection of the abdominal cavity via an endoscope or telescope, most often utilizing video monitoring via attachment of a camera to the endoscope.
pneumoperitoneum The presence of air in the peritoneal cavity; the condition is created to provide a working space in the abdomen.

With the introduction of minimally invasive surgery in the late 1980s, a revolutionary change has taken place in the way in which surgical problems are approached and the way in which operations are performed. Laparoscopic cholecystectomy was first performed in 1987 and subsequently was rapidly adopted by general surgeons as the standard of care of routine cholecystectomy. The ability to perform surgery with minimal trauma and the possibility for reduced postoperative pain, shorter hospitalization, and less disability led to the rapid development of a wide variety of laparoscopic applications for intra-abdominal operations. Minimally invasive approaches are now commonplace for the treatment of common bile duct stones, gastroesophageal reflux disease, preoperative staging of many intra-abdominal malignancies, splenectomy, and appendectomy in addition to cholecystectomy. The current article, although not comprehensive, will focus primarily on minimally invasive surgery for gastrointestinal disorders.

BACKGROUND

The majority of laparoscopic surgery utilizes carbon dioxide (CO_2) gas insufflation into the peritoneal cavity to a pressure of 10 to 15 mm Hg. The pneumoperitoneum allows for a working space within the abdomen. Carbon dioxide has the advantage of being noncombustible as well as rapidly eliminated via systemic absorption and excretion through the lungs. Pneumoperitoneum is established by either a closed or an open technique. With the closed method, CO_2 is insufflated via a Veress needle placed into the abdominal cavity and the initial trochar and sheath are placed blindly. In the open technique, a small incision is made and a sheath without the trochar (Hasson cannula) is inserted under direct vision. The laparoscope is inserted through this sheath and accessory sheaths of 5 or 10 mm in diameter are inserted under direct vision to allow access for laparoscopic instruments. The use of a video camera attached to the eyepiece of the laparoscope allows magnification as well as the ability for multiple viewers to see the operative field.

Many studies have demonstrated that laparoscopic surgery has a reduced effect on postoperative cardiac performance and perioperative pulmonary function. Stress responses, as measured by cortisol and catecholamine levels, are decreased compared to open surgery. Cellular immune function is preserved to a greater degree following laparoscopic procedures. Clinically, these benefits translate into decreased postoperative pain and ileus, more rapid return to full activity, shorter hospitalization, and often decreased costs.

Despite the advantages of minimally invasive procedures compared to standard "open" surgical approaches, several disadvantages exist. The two-dimensional video image limits perspective, there is somewhat limited freedom of movement of instruments, there is little tactile feedback when manipulating tissues, and potential adverse effects of carbon dioxide pneumoperitoneum have been described, including hypercarbia, acidosis, and arrhythmia. Clinically, complications with CO_2 pneumoperitoneum are quite rare. When minimally invasive procedures were introduced, several conditions were considered absolute contraindications to laparoscopic surgery, including pregnancy, bowel obstruction, obesity, cirrhosis, coagulopathy, and acute cholecystitis. With improvements in technique and increased experience, these are now considered only relative contraindications or are not considered contraindications at all (Table I).

Prior surgery was originally considered a contraindication due to the risk of bowel injury from trochar insertion with multiple adhesions. However, the formation and extent of adhesions are unpredictable

 Copyright 2004, Elsevier (USA). All rights reserved.

TABLE I Contraindications to Laparoscopic Surgery

Absolute	Relative
Unable to tolerate general anesthesia	Severe obstructive lung disease
Uncorrected coagulopathy	Prior abdominal surgery; adhesions
Generalized peritonitis	Morbid obesity
Other condition requiring laparotomy	Pregnancy
	Cirrhosis/portal hypertension
	Possible malignancy (other than staging procedures)

and laparoscopic adhesiolysis can be performed. Obese patients may present difficulties with trochar insertion and cannula displacement; however, with the use of longer trochars and slightly higher insufflation pressures, few patients with morbid obesity need be denied laparoscopy. With pregnancy, concerns about the effects of CO_2 pneumoperitoneum on the mother and fetus include increased intra-abdominal pressure on venous return, cardiac output, and uterine blood flow, with possible maternal and fetal acidosis. Risks include teratogenesis and miscarriage in the first trimester and preterm labor in the third trimester, with decreased risks of all complications in the second trimester. There have been multiple reports of safe laparoscopic procedures in all trimesters and pregnancy is therefore considered only a relative contraindication.

LAPAROSCOPIC CHOLECYSTECTOMY

First performed in the late 1980s, laparoscopic cholecystectomy was rapidly adopted as the method of choice for treating symptomatic cholelithiasis and some cholecystitis. The procedure was first popularized in the community setting and soon thereafter in academia. By 1993, it was estimated that greater than 85% of all cholecystectomies in the United States were performed laparoscopically. Now just over 10 years later, laparoscopic cholecystectomy is one of the most commonly performed general surgery operations.

The indications for laparoscopic cholecystectomy are the same as for open cholecystectomy and primarily include symptomatic cholelithiasis (biliary colic), cholecystitis, gallstone pancreatitis, and symptomatic biliary dyskinesia. Less than 20% of people with asymptomatic gallstones develop symptoms over many years, so generally cholecystectomy is not performed in these cases due to potential risks of surgery. With typical biliary colic, the only preoperative evaluation necessary is an ultrasound to document the presence and number of gallstones, gallbladder wall thickness, pericholecystic fluid, sludge, and the diameter of the common bile duct. A technetium-99-iminodiacetic acid scan may be useful in confirmation of acute cholecystitis. Biliary dyskinesia can be shown using cholecystokinin-stimulated gallbladder emptying of radionuclide. Endoscopic retrograde cholangiopancreatography (ERCP) is indicated for patients with gallstone pancreatitis without improvement or for those with abnormal liver function tests suggesting common bile duct (CBD) stones.

General anesthesia is utilized in all cases. The camera is inserted through a 10 mm periumbilical trochar; additional "working" trochar sites usually include two 5 mm subcostal trochars and a 10 mm epigastric trochar. A reverse trendelenberg position is used to increase visualization. The gallbladder is retracted superiorly over the liver and toward the diaphragm with a grasping instrument placed through the lateral subcostal port, and the neck of the gallbladder is retracted anteriorly and laterally using another grasping instrument placed in the medial subcostal trochar. Using blunt and sharp dissection with instruments placed through the 10 mm epigastric port, adhesions are dissected off the gallbladder, the cystic duct and artery are identified, clipped, and divided, and the gallbladder is dissected from the liver with electrocautery. The gallbladder is removed through the umbilical port after the laparoscope is moved to the epigastric cannula.

Cholangiography is usually performed selectively based on either history or anatomy. History of jaundice, pancreatitis, ultrasound evidence of choledocholithiasis, elevations of bilirubin, alkaline phosphatase, amylase, or lipase, and presence of a large cystic duct and small gallstones all have been considered indications. Before the cystic duct is clipped and divided, it may be incised anteriorly with introduction of a small catheter. Evaluation of the cholangiogram includes the size of the common bile duct, filling defects, location of the junction between cystic duct and CBD, free flow of contrast into the duodenum, and anatomy of the proximal biliary tree.

Conversion to open cholecystectomy occurs in 1.8 to 8.5% of cases and is usually greater earlier in a surgeon's career. Reasons for conversion include suspected bile duct or blood vessel injury, unclear anatomy, failure to progress in dissection, or unexpected pathology. Acute cholecystitis, if approached surgically more than 48 to 72 h after presentation, can provide unique challenges. The gallbladder is inflamed, thick-walled, and tensely distended with thickened and edematous surrounding tissue. Initiation of laparoscopic

cholecystectomy during this subacute phase will likely result in an increased chance of conversion to open cholecystectomy. With regards to other complications, most series report major complications in the 0.7 to 4.0% range, with bile duct injuries under 0.5–0.7%. Although low, this still exceeds the rate of bile duct injuries seen with open cholecystectomy. Mortality is extremely rare.

LAPAROSCOPIC CHOLEDOCHOLITHOTOMY

Choledocholithiasis is present in approximately 10% of patients who present with cholelithiasis. Definitive treatment of these patients includes clearance of the entire biliary ductal system. With the increased use of laparoscopic cholecystectomy, many surgeons have turned to methods such as ERCP. However, laparoscopic methods may be used for the management of CBD stones, including balloon catheter manipulation and choledochoscopy.

If CBD stones are suspected preoperatively, one option is to attempt ductal treatment preoperatively with ERCP and stone extraction with or without sphincterotomy. This is successful in clearing the duct in over 90% of cases, but is associated with slight morbidity (5–19%). Similarly, laparoscopic common bile duct exploration is successful in clearing the duct in over 90% of cases. Small CBD stones detected on intraoperative cholangiogram can usually be flushed out with a catheter threaded into the CBD after administration of IV glucagon, which relaxes the sphincter. If unsuccessful, a 4-French Fogarty balloon catheter may be used to retrieve stones and debris under fluoroscopic monitoring; similarly, a stone retrieval basket may be inserted into the cystic duct and followed with fluoroscopic guidance. If stones are large and the ducts are large (5–12 mm), extraction may be performed using a choledochoscope and stone basket or flexible electrohydraulic lithotriptor. Dilation of the cystic duct may be required to allow insertion of a 10-French choledochoscope. If stones are large or the cystic duct cannot be used to gain access to the CBD, the anterior wall of the CBD may be incised directly to allow insertion of a larger choledochoscope. The choledochotomy is traditionally closed over a T-tube, although primary closure of the choledochotomy is widely reported. Failure of the above techniques may require either postoperative ERCP and papillotomy or laparotomy and transduodenal sphincteroplasty. Generally, sphincterotomy is difficult to perform via the laparoscopic antegrade approach and is performed with the endoscopic retrograde approach.

LAPAROSCOPIC ANTIREFLUX SURGERY

Laparoscopic esophageal surgery is second only to biliary surgery in frequency of minimally invasive procedures in general surgery practice. Most common of these procedures on the esophagus is laparoscopic fundoplication for gastroesophageal reflux disease (GERD). Mechanisms thought to be important for the establishment of reflux control with fundoplication include (1) reconstruction of anatomical relations at the gastroesophageal junction, i.e., diaphragmatic crura, and (2) fixation of an adequate length of lower esophageal sphincter in the abdomen. Fundoplication is indicated for severe GERD, including patients with esophagitis, stricture, Barrett's esophagus, and patients dependent on proton pump inhibitors for symptomatic control. The most common indication is GERD in patients who have residual symptoms on maximal medical therapy or who are unwilling to accept lifelong medical therapy. Of note, fundoplication does not cause regression of Barrett's metaplasia and does not protect against malignant transformation and patients with Barrett's esophagus must therefore undergo long-term endoscopic surveillance for the presence of dysplasia. Whereas intestinal metaplasia and perhaps low-grade dysplasia are indications for an antireflux procedure, higher-grade dysplasia may be an indication for preemptive resection of the esophagus.

All patients under consideration for antireflux surgery should undergo a detailed diagnostic evaluation to corroborate the diagnosis and rule out other pathology. Upper endoscopy allows examination and/or biopsy of the esophagus, gastroesophageal junction (GEJ), stomach, and duodenum. Barrett's esophagus, as well as strictures or rings, may be identified. Distance to the GEJ is measured to rule out esophageal shortening. Twenty-four-hour pH monitoring, the definitive test for reflux, should be performed if the diagnosis is in question. A pH drop below 4 for more than 4% of a 24 h period is considered abnormal. Esophageal manometry must be performed to detect unsuspected functional motility disorders such as achalasia or scleroderma that would cause difficulty in propulsion of food into the stomach after a fundoplication. Barium swallow (esophagography) may demonstrate hiatal hernia, stricture, and esophageal shortening, but generally endoscopy is used for this anatomic information. Barium swallow is therefore not routinely utilized. Gastric emptying studies are employed selectively in patients with gastric symptoms, diabetes, peptic ulcer diseases, or history of bezoar. Delayed gastric emptying may require concurrent pyloroplasty or pyloromyotomy and may in fact indicate diffuse intestinal motility dysfunction.

One of the most commonly performed antireflux procedures is the Nissen fundoplication, which involves a 360° wrap of the fundus around the GEJ. The intra-abdominal esophagus and distal mediastinal esophagus are dissected and the short gastric vessels are divided. The right and left diaphragmatic crura are approximated with interrupted sutures and the fundus of the stomach is wrapped behind the esophagus, usually with a bougie in the esophagus. A fundoplication is created with interrupted sutures including two sides of the fundus and the esophagus. The Toupet fundoplication, similar in initial dissection but utilizing a 270° wrap, is indicated in patients with GERD but with poor esophageal motility. Such patients may otherwise experience postoperative dysphagia with a full 360° wrap. In patients with esophageal shortening (approximately 5% of patients presenting for surgery), a standard fundoplication may "slip" or herniate postoperatively. Such patients may be candidates for a Collis-Nissen technique to elongate the esophagus. This procedure uses stapling to create a tube of stomach as a continuation of the distal esophagus that easily lies beneath the diaphragm and may be followed by a standard fundoplication.

Multiple studies have shown that laparoscopic fundoplication can relieve typical reflux symptoms of regurgitation and dysphagia in more than 90% of patients at up to 3 years follow-up. Dysphagia is common postoperatively but commonly resolves by 3 months. Rare complications include gastric and esophageal perforation (0.5–0.8%), conversion to open technique (2–3%), pneumothorax or pneumomediastinum, and rarely bleeding.

OTHER APPLICATIONS—MINIMALLY INVASIVE ESOPHAGEAL SURGERY

Paraesophageal hernias, involving herniation of the gastric fundus into the thorax with or without cephalad displacement of the GEJ, may be associated with significant complications. Although the presence of an asymptomatic paraesophageal hernia is not universally recognized as an indication for surgery, given the risks of obstruction, perforation, and emergency surgery, most surgeons recommend elective repair. Laparoscopic repair of paraesophageal hernias is well described. However, volvulus of the stomach is associated with difficulty in identification of anatomy and the laparoscopic approach can be significantly more difficult than standard laparoscopic fundoplication. Surgery requires reduction of the hernia and removal of the entire peritoneal sac, followed by closure of the diaphragm. Given a high association with reflux and likely disruption of the normal antireflux mechanism during surgery, a fundoplication is performed after reduction of the hernia to maintain the GEJ in an intra-abdominal position. Complication rates are slightly higher than those for standard fundoplication.

Treatment of achalasia by eliminating the functional gastroesophageal obstruction includes pharmacologic methods, endoscopic injection of botulinum toxin, pneumatic dilation, and surgical cardiomyotomy. Surgery has been associated with some of the more durable symptomatic relief reported. Minimally invasive Heller myotomy can be performed through abdominal or thoracic approaches. Through the abdominal approach, the distal esophagus is mobilized and a myotomy is created with electrocautery for a distance of 4–6 cm. Taking care to preserve the anterior vagus nerve, the myotomy is carried 1 cm onto the anterior stomach. To minimize postoperative reflux after dissection of the hiatus, myotomy is followed by fundoplication, usually the Toupet procedure. Reported results are excellent, with approximately 90% of patients reporting good or excellent relief of dysphagia.

MINIMALLY INVASIVE GASTRIC SURGERY

Unlike many other commonly accepted laparoscopic applications, minimally invasive gastric surgery is largely in its infancy. Although applications exist for laparoscopic management of peptic ulcer disease, most minimally invasive gastric surgery consists of resection for benign and malignant masses. Critical to these procedures is the need to follow strict oncologic principles for resection of malignancy.

Rarely will optimal medical therapy for intractable peptic ulcer disease fail, leading to surgical intervention. Highly selective vagotomy (HSV) is associated with recurrence rates under 15% with a very low rate of complications. In the presence of a prepyloric ulcer (type II or III gastric ulcer), however, recurrence rates of greater than 30% are reported. Similarly, HSV is difficult with inflammation on the lesser curve of the stomach often present in type I gastric ulcers. Unlike duodenal ulcers, gastric ulcers may be managed best with either distal gastrectomy or truncal vagotomy with drainage procedure. Laparoscopic truncal vagotomy with gastrojejunostomy has been described but is not considered a standard of practice.

Laparoscopic gastric wedge resections may be performed for benign lesions such as leiomyomas. However, laparoscopic resection of gastric carcinoma

remains experimental. Although the role of staging laparoscopy in gastric carcinoma is well recognized (see below), pertinent questions include the sufficiency of lymphadenectomy with laparoscopy and the seeding of trochar sites with tumor cells.

MINIMALLY INVASIVE SURGERY FOR MORBID OBESITY

Severe obesity, defined as twice the ideal body weight or a body mass index (BMI) of more than 40 kg/m^2, is a source of serious health problems for millions people in the United States. However, conservative treatment is notoriously unsuccessful, with failure of more than 95% of treatment attempts. A number of surgical procedures have been developed to produce weight loss; two performed commonly today by laparotomy include the vertical banded gastroplasty (VBG) and the Roux-en-Y gastric bypass (RYGB). Due to the complexity of performing these procedures laparoscopically in morbidly obese patients, the minimally invasive variants of bariatric operations were slow to emerge but as experience has been gained they are more frequently performed. It is thought, however, that the well-documented benefits of laparoscopic surgery in nonobese patients may be more significant in the obese patient with associated higher risk for cardiopulmonary, infectious, and wound-related morbidity.

The VBG is primarily a gastric restrictive operation. Stapling techniques are utilized to create a narrow gastric pouch, thereby restricting enteral intake. In small series, patients undergoing laparoscopic VBG lost roughly 50% of excess weight at 2-year follow-up, results comparable to those with traditional VBG. A newer procedure, adjustable gastric banding, has been performed in some centers with encouraging results. The surgical approach is similar to the VBG but an inflatable band is placed around the 15 to 30 ml gastric pouch; band restriction is adjustable by manipulating a subcutaneous port on the abdominal wall. Weight loss is generally comparable to that obtained by VBG. Complications may be more common, with approximately one-third of patients requiring repeat surgery within 3 years, often for band erosion. The RYGB, which combines gastric restriction with intentional malabsorption, is now the most commonly performed bariatric operation in the United States. Long-term weight loss is reported to be far more durable than with the VBG, with 50–60% of excess body weight commonly reported at 5- to 15-year follow-up. The laparoscopic approach mimics the open procedure, which creates a 15 to 30 ml gastric pouch with an anastamosis to a 75 to 100 cm retrocolic, retrogastric Roux-en-Y limb of jejunum. Short (1- to 4-year) follow-up of patients after laparoscopic RYGB suggests weight loss similar to that obtained with the open technique, with 65–80% of extra weight lost. Complications are reported to be slightly higher with laparoscopic bariatric surgery, particularly leaks at the gastrojejunal anastamosis. Given the demonstrated benefits of gastric bypass for weight loss and the potential advantages of the minimally invasive approach, the incidence of laparoscopic RYGB will likely continue to increase.

MINIMALLY INVASIVE SURGERY FOR STAGING OF MALIGNANCY

Precise staging information is paramount in the management of patients with malignancy, for both prognostic and therapeutic considerations. Preoperative imaging modalities, including computerized tomography (CT), magnetic resonance imaging, ultrasound, and endoscopic procedures, although valuable, can often understage and lead to unnecessary surgery. The use of laparoscopy, particularly in combination with laparoscopic ultrasound, has been shown to improve the accuracy of staging, particularly in the recognition of metastases. Although surgery provides the only chance of cure with localized disease, it has no effect on outcome in most patients with metastatic disease. Identification of those patients with metastatic diseases through minimally invasive means has the potential to decrease nontherapeutic laparotomies and thus morbidity. Although laparoscopy is sometimes performed immediately prior to laparotomy to rule out unresectable disease or peritoneal metastases, staging laparoscopy should ideally be performed as a separate procedure to allow assessment of cytology or biopsy specimens.

Many different staging algorithms exist at different institutions and the role of laparoscopy is not universally agreed upon. However, studies have demonstrated excellent sensitivity of laparoscopy for detection of hepatic metastases and peritoneal dissemination. Evaluation generally consists of a systemic evaluation of the abdomen, inspection of the peritoneum and liver, and fluid sampling for cytology. The lesser omentum may be divided to inspect the celiac axis for lymphadenopathy, particularly in cases of esophageal, gastric, or pancreatic cancer. With pancreatic cancer, the pancreas may be inspected from a supragastric approach through the lesser omentum, from an infragastric approach through the gastrocolic ligament, or from an infracolic approach to the left of the middle colic

vessels. Laparoscopic staging of Hodgkin's lymphoma is reported in some centers, including sampling of portal, celiac, and splenic lymph nodes as well as liver biopsy and splenectomy. Non-Hodgkin's lymphomas are generally not staged laparoscopically.

Laparoscopic staging for colon cancer has not been as widely accepted as the above modalities. The minimally invasive approach prohibits the standard palpation of the liver and porta hepatis of conventional colon surgery and preoperative CT may detect only 70–80% of liver metastasis. Intraoperative ultrasound has been used by some clinicians to assess the liver for metastasis with good results. Preoperative laparoscopy to assess for metastasis from colorectal cancer does not have the same benefit as it does for other cancers since most patients will require resection even without liver or other distant metastases.

One potentially problematic issue with the use of minimally invasive surgery in cancer patients is implantation of tumor cells in the laparoscopic trochar sites (port site metastasis). Such metastases have been described with numerous types of tumors, including biliary, pancreatic, colonic, and gynecologic tumors. The risk of spread, however, is small and is not a contraindication to staging laparoscopy.

Of note, laparoscopic approaches to gastrointestinal malignancy—particularly colorectal cancer—have not been definitively proven to provide equivalent oncologic benefit to standard approaches. Minimally invasive surgery for cure of GI cancers should be performed primarily in the setting of prospective clinical trials.

MINIMALLY INVASIVE SURGERY FOR CROHN'S DISEASE

Complications requiring surgical intervention are common in patients with Crohn's disease, including strictures and obstruction, fistulas, bleeding, and intractability. Most of these, when requiring operation, have led to conservative enteric resection. Minimally invasive approaches to this disease are attractive in that Crohn's primarily affects young patients who often require multiple procedures. Some centers have recently described laparoscopic approaches to treating Crohn's disease with good outcomes. The minimally invasive approach can be quite technically challenging in Crohn's disease, however, given the presence of inflamed friable bowel and thickened mesentery with tendency for abscess and fistula formation. Chronic inflammation can obscure normal anatomical planes and may increase the risk of injury to other anatomic structures. The range of minimally invasive procedures for Crohn's disease includes the following: diagnostic laparoscopy, lysis of adhesions, fecal diversion for perineal sepsis or complex fistulas, closure of stomas, segmental bowel resection, and strictureplasty. Contraindications to laparoscopy for the above situations include the presence of dense adhesions (a "frozen abdomen"), critical illness or free perforation, peritonitis, and multiple complex fistulas.

LAPAROSCOPIC APPENDECTOMY

The issue of whether laparoscopic appendectomy provides benefit compared to standard open appendectomy remains to be shown. However, laparoscopic appendectomy may be particularly useful in several conditions. Reproductive-age women often have possible pelvic/gynecologic processes in the differential diagnosis, with a high rate of negative diagnostic laparotomy. Diagnostic laparoscopy may be performed with full view of intra-abdominal structures, followed by appendectomy if indicated. With no appendicitis on exploration, the appendix is often removed to avoid future confusion in care, unless significant regional pathology exists, such as severe pelvic inflammatory disease that could put the staple line at risk. Laparoscopic appendectomy is also particularly useful in obese patients who would otherwise require a larger incision. The laparoscopic approach is generally contraindicated in pregnancy or in patients with cardiorespiratory insufficiency. Patients with significant involvement of the cecum or base of the appendix may be at risk for stump leak in the case of laparoscopic appendectomy and an open procedure should be performed instead.

Whereas some authors have shown laparoscopic appendectomy to be a superior approach to appendicitis, other authors have reported the opposite result. In most cases, compared to open appendectomy, the lengths of hospital stay are similar or shorter, with similar or earlier return to normal activities and less postoperative pain. In addition, there is a clear advantage in cases of diagnostic uncertainty. Most authors, however, feel that there are not sufficiently clear data to consider it the gold standard for appendicitis.

SUMMARY

Minimally invasive surgery has dramatically altered the surgical approach to a host of intra-abdominal and gastrointestinal conditions and has provided, in most cases, comparable short- and long-term outcomes with minimal morbidity. This has led to increased patient

acceptance and satisfaction. Additionally, increased surgeon experience and technical advances have made performance of these procedures easier and safer.

stomach had been totally denervated, leaving it under the sole control of circulating hormonal substances. Eventually, motilin was identified and the structure of motilin was deduced using an extract of porcine small intestine with a side fraction material prepared for the purification of cholecystokinin in the laboratory of Professor Victor Mutt at Karolinska Institute. The active peptide was purified by successive chromatographies (gel permeation and ion exchange), using the dog stomach *in vivo* as a bioassay for its recognition. Brown called the substance motilin because of its obvious action on gastrointestinal motility. Biochemical purification through successive chromatographies (gel permeation, ion exchange, and high-performance liquid chromatography) and using a radioimmunoassay (RIA) to recognize the immunoreactive material subsequently allowed the identification of dog motilin. Since 1980, molecular biology techniques have characterized motilin from numerous species, including humans, rabbits, chickens, horses, monkeys, and guinea pigs. Two points characterize the biochemistry of motilin, species heterogeneity and the marked structural heterogeneity of rodent motilin. Human motilin is identical to the originally purified peptide found in pigs, but the structure is much different in other species. This structural heterogeneity has led to difficulties in recognition of the molecule by RIA and may also be responsible for specific patterns of bioactivities. Rodent motilin has never been sequenced. The logical explanation is that the structural heterogeneity is so marked in rodents that tools (antisera or probes) developed from known motilin structure in other species cannot recognize rodent motilin. The practical consequence is that the most common and useful laboratory animals cannot be used in the field of motilin research.

STRUCTURE–ACTIVITY AND RECEPTOR

Using a goal-directed approach with a motilin probe for motilin receptor recognition, all attempts have failed to sequence the intestinal motilin receptor. In 1999, researchers in the Merck laboratories followed a different strategy by first cloning and sequencing a large variety of G-protein-coupled receptors, and then looking at the nature of ligands for these receptors. Starting from an orphan receptor found in the thyroid with close structural similarity to the receptor for the growth hormone secretagogue (GHS), mass screening of more than 500 peptide and nonpeptide molecules was performed to obtain positive results for motilin. Much of our knowledge on the motilin receptor has been derived up to now from structure–activity studies of peptide analogues and binding of radioactive ligands on various tissue membranes prepared *in vitro*.

Nuclear magnetic resonance shows that the motilin molecule (Fig. 1) is shaped like a golf club or shepherd's crook. The N-terminal portion is responsible for receptor binding and *in vitro* bioactivity. Peptide fragments containing the first 12 amino acids of the molecule have demonstrated full binding capacity *in vitro*, whereas removal of the first amino acid is enough to abolish motilin activity. Amino acids 4 and 7 also seem to play a major role in this N-terminal sequence. Interestingly, the C-terminal structure, not required for *in vitro* bioactivity, is essential for *in vivo* bioactivity. The N-terminal fragments of 15 amino acids, fully active *in vitro*, are inactive *in vivo*, whereas longer fragments with 19, 20, or 21 amino acids can mimic the motor activity of the 22-amino-acid peptide. In the field of peptide pharmacology, the apparent importance of the α-helix-shaped C-terminal structure in protecting the whole molecule, probably against circulating degrading enzymes is an interesting concept.

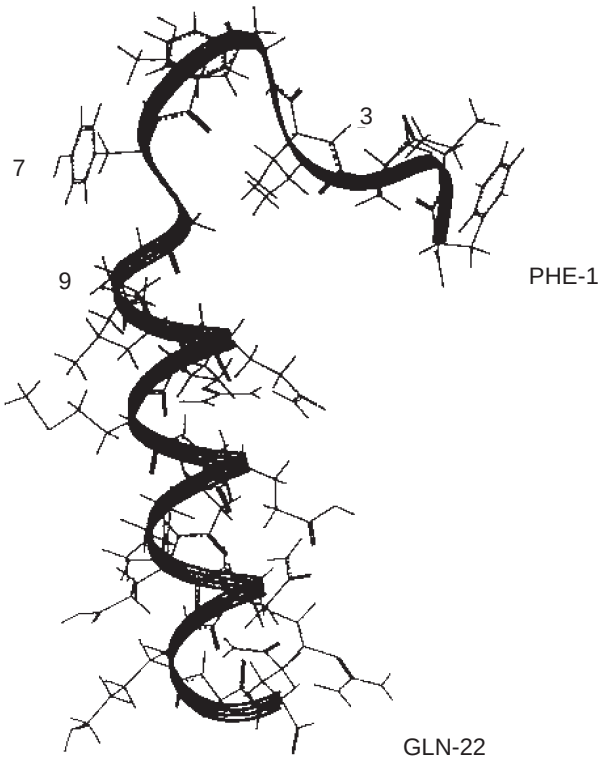

FIGURE 1 Structure of the 22-amino-acid motilin peptide revealed by nuclear magnetic resonance. The N-terminal curved sequence binds to the receptor whereas the α-helix C-terminal structure protects the molecule for *in vivo* bioactivity.

Receptors have been studied in membrane solutions prepared from various species (mostly humans or rabbits) and from neural or muscle elements of the intestinal wall. The binding of motilin analogues is different in membranes prepared from human or rabbit antrum, suggesting that motilin receptor structure is, as for motilin,, different among species. Solutions enriched in muscle or in neural elements of the intestinal wall have allowed the identification of specific and distinct responses to various motilin synthetic analogues, indicating the existence of structurally heterogeneous motilin receptor subtypes specific to muscle or neural elements (M and N receptor subtypes).

PHARMACOLOGICAL ACTION

As its name implies, motilin acts on digestive motility. Figure 2 shows the expected effect in humans after the administration of motilin or motilin receptor agonists. Stimulation of antroduodenal motility remains the dominant action of the peptide.

Initial *in vitro* studies with intestinal tissues from rabbits and humans have revealed that motilin can stimulate smooth muscle contraction by a direct effect on muscle cells; the peptide action was seen despite the addition of all neural blockers, including tetrodotoxin. Experiments with isolated muscle cells have confirmed the presence of motilin receptors on muscle cell membranes. However, *in vivo* studies in dog and human tissues clearly indicate that the motor action of motilin is mediated by muscarinic transmitters. As discussed previously, binding experiments support the existence of motilin receptor subtypes (M and N) that are functionally and structurally different. Currently, the most interesting hypothesis proposes that the interdigestive motor action of motilin (induction of Phase III contraction) is elicited at low doses through an action via neural cholinergic receptors, whereas postprandial stimulation of antral motility is evoked at higher doses via muscle receptors.

PHYSIOLOGICAL ROLE

The characteristic action of motilin is the induction of Phase III contractions of the migrating motor complex (MMC). The MMC is the basic organization of motor activity of the gut during the fasting interdigestive period. It lasts 80 to 120 min and comprises three successive phases: in Phase I, no significant contraction is seen for 20 to 60 min; in Phase II, intermittent and irregular contractions start to occur during 20 to 60 min before Phase III, when strong peristaltic contractions, lasting 3 to 10 min, start from the stomach and lower esophagus, migrating distally to the duodenum, jejunum, and ileum until reaching the colon. This Phase III peristaltic wave has been proposed to clean bacteria or nutrients from the gastrointestinal tract; accumulated microflora during the digestive period could have deleterious effects on the gut (bacterial overgrowth, etc.). Feeding interrupts the intermittent cyclical fasting motility and

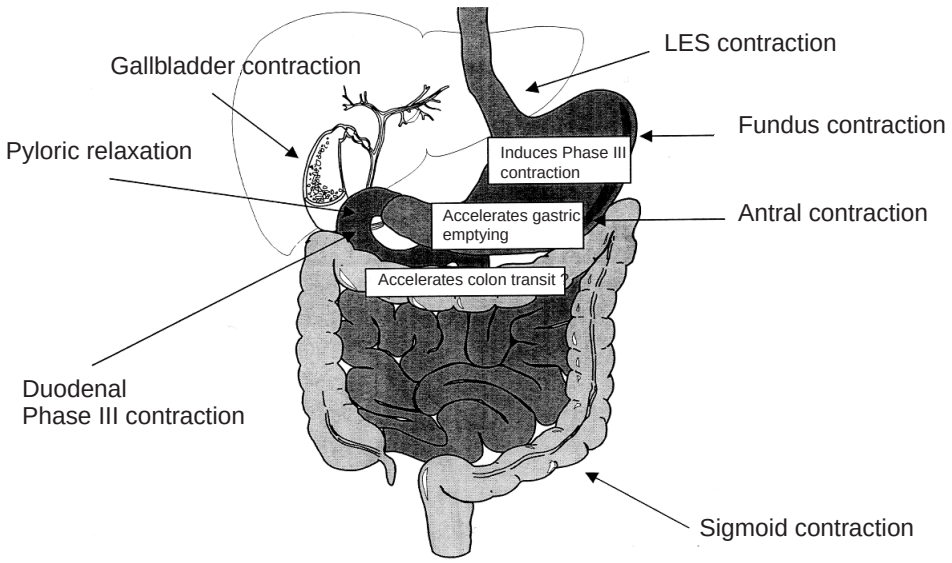

FIGURE 2 Activation of motilin receptors. Biological effects in the human gastrointestinal tract in response to injection of motilin or a motilin receptor agonist such as erythromycin. LES, Lower esophageal sphincter.

induces a more constant motor activity of moderate amplitude to allow the optimal absorption of ingested nutrients; accelerated transit during Phase III would impair nutrient absorption.

Regulatory peptides can exert their influence via different pathways: endocrine (hormonal), neurocrine, paracrine, or autocrine. Motilin is in the unique position, as a gastrointestinal (GI) regulatory peptide, of being an interdigestive hormone. This has been well established in the dog, for which all four of the criteria of Morton Grossman establishing the endocrine contributions of peptides have been fulfilled: (1) regulation of the cyclical pattern of the MMC is under the control of circulating factors, as shown in various experiments in which the MMC persisted in animals when the stomach had been completely denervated; (2) perfect correlation exists between circulating peak levels of motilin and the initiation of Phase III contractions from the stomach or proximal duodenum; (3) there is induction of Phase III contractions of the MMC by small doses of exogenous motilin, reproducing physiological plasma variations; and (4) inhibition of circulating motilin occurs following the administration of specific motilin antisera, which blocks Phase III contractions from the upper gut. Although the situation cannot be explored under such perfect experimental conditions in humans, most evidence suggests that circulating motilin also plays a key role in the regulation of Phase III initiated from the human antrum.

RELEASE MECHANISMS

Most gastrointestinal hormones are released after a meal to allow or facilitate the digestion and absorption of nutrients. Motilin is a unique hormone. It is released periodically during the interdigestive fasting period, and its cyclical release is abolished after a meal, as shown schematically in Fig. 3. Therefore, a "biological clock" somewhere in the organism periodically signals motilin cells to release the peptide into the circulation. *In vitro* preparations of intestinal mucosal cells enriched in motilin cells show that muscarinic receptors are present on the motilin cell membrane and that protein kinase C activators are the most potent second messengers eliciting motilin release. In the *ex vivo* perfused canine intestine, bombesin has been identified as a direct stimulant of motilin release, whereas the effect of opiates is mediated by acetylcholine. Phenylephrine and somatostatin appear to act on M cell membrane receptors to block release of the peptide. In humans, meal ingestion is followed by a very early and brief increase in plasma motilin before the interdigestive release cycle is interrupted. This early release can be mimicked by central stimulation with modified sham feeding and by distension of the fundus with an air-filled balloon. The contribution of this postprandial motilin release (not present in the dog) in the process of nutrient digestion remains to be characterized.

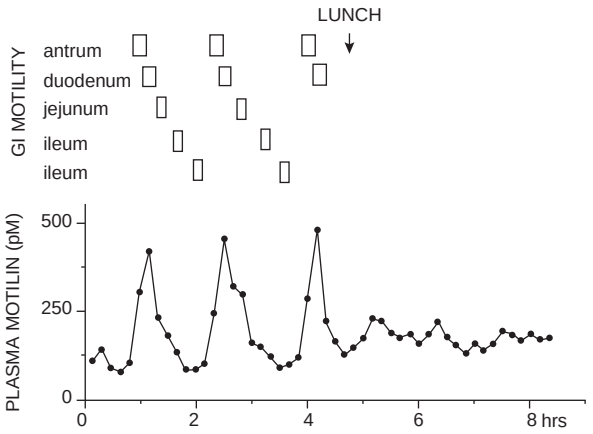

FIGURE 3 Schematic representation of canine plasma motilin variations. During the fasting interdigestive period, motilin is released cyclically every 80–120 min (lower panel) to induce Phase III contraction of the migrating motor complex from the stomach to the ileum (indicated by boxes in the upper panel). After eating, motilin cyclical peak increases are abolished for 2–8 hours (depending on the content and nature of the meal) while the fed pattern motility profile is taking place.

CONTRIBUTION TO CLINICAL MEDICINE

Some GI hormones, such as gastrin or vasoactive intestinal polypeptide (VIP), are important to clinicians because of the disease symptoms they can generate. Up to now, there has been no clinical phenotype attributed to motilin hypersecretion. High levels of circulating motilin have been documented in some patients with pancreatic tumors and Zollinger–Ellison syndrome, as well as in subjects with carcinoid tumors of the gut. Although it is tempting to speculate on the role of motilin in the diarrhea found in these patients, its contribution to the biological alterations remains unknown.

Because motilin hypersecretion could be expected to generate GI hypermotricity and hypersecretion with probable diarrhea, it is logical to expect that hypomotilinemia will induce GI hypomotility. Some investigators have indeed found low levels of plasma motilin in patients with idiopathic intestinal pseudo-obstruction and idiopathic or postoperative gastroparesis. Up to now, however, plasma motilin measurement has not proved useful for inclusion in the workup diagnosis of any clinical situations.

On the other hand, motilin has been recently of major interest to medical clinicians because of the capacity of motilin receptor agonists to act as powerful stimulants of GI motor activity in patients with hypokinetic disorders. Zen Itoh in Japan was the first to observe that erythromycin could mimic the motor effect of motilin when injected in dogs. It was soon established that erythromycin was in fact acting on motilin receptors, and Janssens *et al*. in Leuven made the capital observation that erythromycin was the most potent gastrokinetic ever tested to stimulate gastric emptying in diabetic patients with gastroparesis. Since then, intravenous or periorbital erythromycin has been used by many clinicians for the treatment of patients with gastroparesis or intestinal pseudo-obstruction. Motilides, i.e., motilin receptor agonist substances derived from the erythromycin macrolide and with improved gastrokinetic activity but devoid of antibiotic properties, have been developed by many pharmaceutical companies. At least three motilides have been tested in humans, but, for various reasons (rapid tachyphylaxis, no significant clinical benefit, or potential side effects), clinical trials with these newly derived molecules have failed to substantiate the impressive pharmacological potential seen with intravenous erythromycin. Whether the gastrokinetic capacity of motilin receptor agonists will be amenable to commercial development and clinical exploitation remains to be seen.

CENTRAL NERVOUS SYSTEM AND THE PEPTIDE FAMILY

Most GI peptides are found in the brain and/or act as neuropeptides, but the situation remains unclear for motilin. Motilin mRNA has been identified in brain tissues, but RIA determination of motilin content has provided ambiguous results. Motilin administration in brain tissue induces activities (suggesting that there are motilin receptors in the brain) that are quite unexpected, including appetite stimulation, growth hormone (GH) release, and anxiety suppression. Yet no valid data support the role of motilin as a neuropeptide.

Most peptides are members of a "peptide family" that includes structurally related compounds; gastrin/cholecystokinin and secretin/VIP are typical examples. A recent discovered peptide in the gastric mucosa shows 25% similarity to motilin. It has been called motilin related peptide (MTL-RP) by some, but the name "ghrelin," because of its effect on GH release, is more commonly used. Interestingly, ghrelin administration induces central actions that are similar to those described for motilin (such as GH release or appetite stimulation). Peripherally, ghrelin mimics motilin and appears to be the most potent gastrokinetic agent we have ever tested in the rodent. Future studies should tell us more about the importance of this new family of peptides.

Mucosa-Associated Lymphoid Tissue (MALT)

HYUN SIL KIM
University of California, San Diego

M cell Specialized type of epithelial microfold cell that is found in the epithelium overlying organized lymphoid follicles, the Peyer's patches. Endocytosis and transport of intestinal microbial organisms and large molecules from the lumen into the underlying lymphoid tissues are the main functions of M cells.

mucosa-associated lymphoid tissue Organized immune system found in mucosal sites. Gut-associated lymphoid tissue is a component of MALT; these are inductive sites where luminal antigens are processed.

Peyer's patch Lymphoid nodule located underneath M cells in the lamina propria; the sites of antigen recognition and processing, which induce activation of resident B and T cells.

The gastrointestinal tract represents a unique immunologic compartment that is actively involved in managing responses to luminal food antigens and protecting the host from infectious agents and environmental toxins. Given these exposures, one method the intestine has devised to defend itself from such antigenic challenges is by creating a physical barrier in the form of an epithelial single-cell layer that lines the mucosa from the esophagus to rectum. A mucosa-associated lymphoid tissue comprises the immune system that responds to disruption of the mucosal barrier.

INTRODUCTION

For intestinal luminal antigens, such as food particles and/or intestinal bacteria, to elicit a local and/or systemic immune response, an antigen must either cross an intact epithelium or secrete noxious mediators that disrupt the tight protective gastrointestinal barrier, allowing for entry into the lamina propria and interaction with immune-responsive cells. Many infectious diseases of the gastrointestinal tract involve the disruption of this protective epithelial barrier by bacteria or viruses and the invasion of these foreign pathogens into the host. Therefore, in addition to the physical barrier, the intestine has also devised an elaborate system of mucosal immunity to limit injury and regulate immune responses from potentially deleterious agents.

INNATE/ACQUIRED IMMUNE RESPONSES

The immune system is composed of innate (or natural) and adaptive (or acquired) immunity. The innate immune system consists of (a) cells, including monocytes, neutrophils, and intestinal epithelial cells (IECs); (b) toll-like receptors, which are cell surface and intracellular proteins that recognize bacterial components such as lipopolysaccharide (LPS), lipid/carbohydrate components of the bacterial wall, and bacterial DNA; and (c) soluble proteins, such as cytokines and complement products that can be released rapidly to initiate host immune response. The cells, receptors, and soluble mediators of the innate immune system provide immediate recognition of a general class of foreign antigens. In contrast, acquired immunity is mediated primarily by B and T lymphocytes. Such adaptive immunity develops over a longer period of time and provides recognition of specific antigens. The two types of immunity are closely dependent on each other for activation. In addition, the innate immune system play a key role in the selection of particular types of B and T cells needed to participate in an acquired immune response.

PEYER'S PATCHES AND M CELLS

As seen in Fig. 1, the gastrointestinal (GI) tract contains immune-responsive cells that reside both within the epithelial and subepithelial layers and that are important regulators of the mucosal immune system. These cellular elements function in direct phagocytosis/cytolysis of foreign intruders, in antibody and cytokine production, and in recruitment of additional immune-reactive cells to areas of infection and/or injury. The gut-associated lymphoid tissue (GALT) contains a loosely affiliated group of immune cells in the lamina propria and an organized component (Peyer's patches). Found predominantly in the small intestine, Peyer's patches are lymphoid nodules that are composed of a central B cell zone and a parafollicular T cell zone. Over the dome of Peyer's patches, a specialized epithelium containing microvillus fold cells (M cells)

 Copyright 2004, Elsevier (USA). All rights reserved.

functions in the transport of antigens from the lumen to the Peyer's patches. Macrophages and dendritic cells exist in close proximity to M cells within Peyer's patches. Known infectious agents that adhere to and are transported by M cells include human immunodeficiency virus, reovirus, poliovirus, *Vibrio cholerae*, mycobacteria, *Salmonella*, and *Shigella*. Within Peyer's patches antigen-specific B cells and T cells are activated. Some of these activated lymphocytes migrate from the lamina propria via lymphatics to mesenteric lymph nodes and eventually enter the systemic circulation, and may return to the lamina propria and other mucosal tissues. As such, the organized lymphoid tissue functions as an inductive or afferent site and the loosely affiliated cells in the lamina propria function as an efferent or effector site.

INTESTINAL EPITHELIAL CELLS

In addition to their function in nutrient absorption, IECs serve an important immune regulatory function in the GI tract. As a component of the innate immune system within the gut, IECs constitutively produce factors such as tumor growth factor-β (TGF-β), complement proteins (C3, C4, and factor B), and leukotrienes, all of which are involved in providing immune protection and controlling the recruitment and activation state of local T cells. TGF-β secreted by the IECs, for example, may regulate expression of an adhesive molecule on IECs that functions in intestinal intraepithelial lymphocyte (iIEL) and IEC interactions (see later). In addition, as shown in various *in vitro* models of bacterial infections, IECs produce a variety of chemokines and proinflammatory cytokines, including interleukin-8 (IL-8), granulocyte–macrophage colony-stimulating factor (GM-CSF), and IL-6. Similarly, pathogenic bacteria such as *Shigella dysenteriae*, *Yersinia enterocolitica*, enteroinvasive *Escherichia coli*, and *Salmonella dublin* induce IL-8, monocyte chemotactic protein, and tumor necrosis factor α (TNFα). IL-8 is a potent chemoattractant for neutrophils. Thus, the constitutive and induced expression of a specific set of cytokines by IECs demonstrates that IECs serve a vital role in initiating and amplifying the mucosal inflammatory response as an important aspect of gastrointestinal innate immunity. The paracrine and autocrine signals provided by IECs alert the local mucosal immune system to respond appropriately in an infectious process and initiate the processes of T cell activation and recruitment. Furthermore, IECs have been shown to process and present soluble antigens to activate mucosal T cells. Extracellular antigens that are internalized by IECs appear to enter an endolysosomal route and are presented on the IEC surface. Therefore, IECs have been shown to act as an important regulator of mucosal immune responses by responding to and secreting cytokines and potentially participating indirectly (through M cells) and directly in antigen presentation.

MUCOSAL B LYMPHOCYTES

Another crucial component of the mucosal immune system is B cells, which are abundantly present within the lamina propria. These lymphocytes mainly produce IgA, the principal immunoglobulin found in mucosal secretions. IgA in secretions recognizes antigens in the gut lumen while they are external and thus prevents pathogens from entering the host systemically. Therefore, the immune exclusion function of IgA represents one of the first lines of defense against many microbial organisms. In infections with noninvasive pathogens, as seen in *V. cholerae* and enterotoxigenic *E. coli*, secretory IgA is an important host defense mechanism along with other aspects of cell-mediated immunity. As seen in Fig. 1, B cells and plasma cells are located in the loose corrective tissue of the lamina propria. The basolateral surfaces of the epithelial cells lining the GI tract express a receptor, the polymeric Ig receptor, that functions in the transport of IgA and IgM. The dimeric IgA secreted by B cells and plasma cells in the lamina propria binds to the polymeric Ig receptor (pIgR) on the basolateral surface of IEC, after which it is internalized and transported through a vesicular pathway to the apical surface of the IEC facing the lumen. Prior to its release, the pIgR is cleaved at the transmembrane domain, and the extracellular portion of the receptor and IgA is released into the lumen as secretory IgA (sIgA). This form of IgA is resistant to proteolytic degradation by normal intestinal proteases, allowing it to bind to any pathogenic microorganisms and their associated toxins that are present in the lumen, thus preventing their attachment and/or absorption. The immune function of sIgA is not limited to binding luminal antigens; IgA can also neutralize infectious agents present within epithelial cells. It is thought that during the transport of IgA across epithelial cells, IgA can recognize and neutralize specific antigens within infected epithelial cells. In addition, IgA produced locally within the lamina propria has been shown to bind antigens that have gained access across the epithelial lining into the lamina propria. IgA can form immune complexes with these antigens and extrude viral pathogens back onto the lumen via the pIgR, thus containing infection locally and limiting local and/or systemic infection.

MUCOSAL T LYMPHOCYTES

The interactions between IECs and T cells must be tightly regulated in order to coordinate appropriate mucosal responses in normal and disease states. The careful balance between the two immunologic states is determined, in part, by specific IEC/T cell interactions that trigger differential expression of various cell surface molecules and secretion of cytokines. Depending on the recognition of a specific antigen in the context of major histocompatibility complex (MHC) or MHC-like molecules, T cells undergo activation either to maintain the normal hemostasis of the gut mucosa or to initiate inflammatory processes, as occurs in infections and idiopathic inflammatory diseases of the bowel.

Two types of T cells are observed throughout the GI tract: (1) intraepithelial T lymphocytes (iTEL) that are found between epithelial cells adjacent to the basolateral surfaces of IECs and (2) lamina propria T lymphocytes (LPLs) (see Fig. 1). The activation of T cells occurs when a T cell receptor (TCR) expressed on the surface of the T cell recognizes a specific antigen presented by an MHC molecule expressed on the surface of an antigen-presenting cell (APC) such as an IEC, macrophage, dendritic cell, or B cell. Along with the TCR, T cells also express a coreceptor, either the CD8 or CD4 molecule, on the cell surface. The processed antigen is usually a small peptide derived from a larger polypeptide, such as a viral or bacterial protein that entered the APC. Virtually all cells express MHC class I molecules on their surface; however, the expression of MHC class II molecules is primarily restricted to professional APCs, namely, B cells and mononuclear phagocytes, and nonprofessional APCs exposed to cytokines such as interferon γ (IFNγ). An antigen presented by an APC in the context of an MHC class I molecule and in the context of an MHC class II molecule activates CD8+ T cells and CD4+ T cells, respectively. CD8+ T cells are commonly referred to as cytolytic T cells because they can directly lyse and kill infected APCs expressing peptides derived from intracellular pathogens or tumors. CD4+ T cells are commonly known as helper T cells, which are activated by peptides derived from

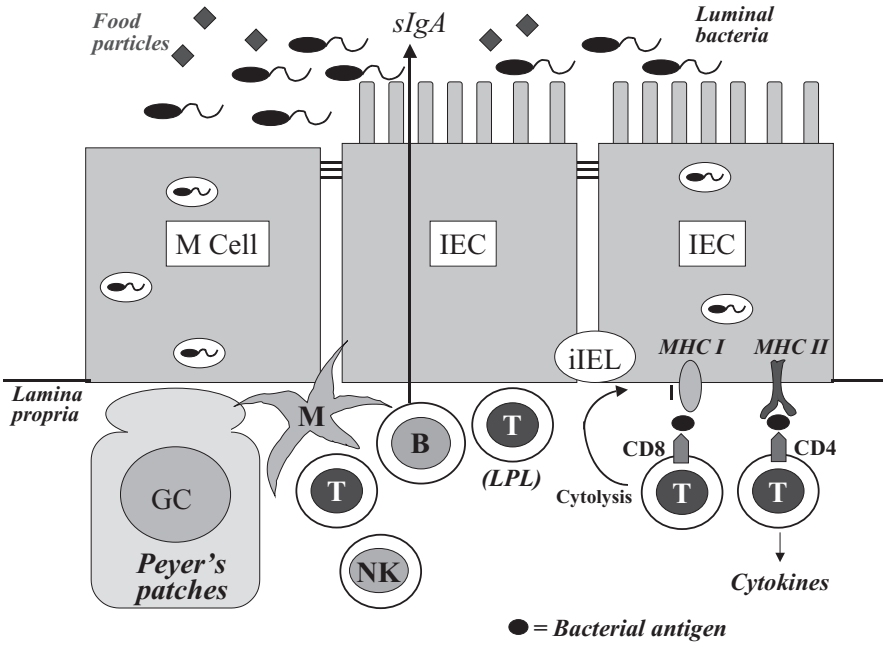

FIGURE 1 Mucosa-associated lymphoid tissue is an organized lymphoid tissue found in the intestine; it consists of M cells and intestinal epithelial cells (IECs) that transport and process luminal antigens (food particles and microbial organisms). The follicle-associated M cells are located above Peyer's patches, and B cells are found within germinal center (GC). The antigen-activated T cells—intraepithelial lymphocytes (IELs) and lamina propria T lymphocytes (LPLs)—are an important source of cytokines such as interferon γ (IFN-γ), interleukin-4 (IL-4), and tumor necrosis factor α (TNF-α) which are potent inflammatory cytokines that able to regulate local immune responses. A macrophage (M), a natural killer (NK) cell, and B and T lymphocytes are depicted. MHC, Major histocompatibility complex.

extracellular pathogens; on activation helper T cells release many important cytokines, such as IL-2, IL-4, IL-10, TGF-β, and interferon γ, which recruit other T cells, activate B cells to produce antibodies, and enhance the phagocytic function of macrophages and natural killer (NK) cells.

iIELs are located immediately adjacent to the basolateral surface of IECs in a unique compartment separated by a basement membrane from other immune cells found within the lamina propria. The proximity of the iIEL to the IEC suggests that iIELs may play a vital role in immunoregulation and immunosurveillance within the epithelium. Human iIELs are predominantly T cells and display a limited number of sets of TCRs on their cell surface, despite direct exposure of these cells to numerous antigens contained in the gut lumen. A majority of these cells are CD8+ memory T cells, which suggests that iIELs have already been activated to respond to a limited set of specific antigens in the context of an MHC class I or MHC class I-like molecule.

Lamina propria lymphocytes are most likely thymically derived lymphocytes that have previously responded to luminal gut antigens. These gut antigen-activated lymphocytes enter the systemic circulation after initial antigen encounter within the Peyer's patches and return to the lamina propria by a characteristic homing mechanism. The majority of LPLs are memory T cells. Similar to iIELs, many LPLs show a limited range of TCR expression on their surface. Some studies show overlap in TCR usage for iIELs and LPLs, suggesting that lymphocytes may be mobile between the epithelium and lamina propria compartments. Several features of LPLs indicate that they are a special subset of lymphocytes that have distinct modes of activation and function. First, LPLs exhibit an increased basal level of activation by expressing the IL-2 receptor, which is not seen in unactivated peripheral blood or splenic lymphocytes. LPLs also express other cell surface molecules that are markers of lymphocyte activation. Second, LPLs respond to antigens primarily with cytokine production, which may be responsible for the high levels of IgA production characteristic of this compartment. Finally, LPLs undergo programmed cell death, also known as apoptosis. Apoptosis may serve an important regulatory mechanism in which LPLs undergo cell death to limit inflammation and clonal expansion of antigen-activated LPLs, which may otherwise harm the host by initiating and/or perpetuating deleterious inflammatory processes.

SUMMARY

The gastrointestinal tract represents an important immunologic compartment in which active immune recognition and activation take place. The mucosa-activated lymphoid tissue is an organized immune system at mucosal sites and in the intestinal tract; it is composed of a variety of cell types, including M cells, dendritic cells, and macrophages and effector cells, represented by T cells, B cells, and NK cells. Challenged by luminal antigens such as food particles and microbial organisms, the MALT serves a vital role in protecting the host from foreign organisms and in the recognition of self from non-self antigens via activities of resident immune-responsive cells located within the intestine.

Mucosal Biopsies

HARVEY GOLDMAN
Beth Israel Deaconess Medical Center and Harvard Medical School

Barrett's esophagus Condition of chronic esophagitis, characterized by a change (metaplasia) of the normal squamous epithelium to a glandular mucosa.

collagenous colitis Condition of chronic colitis, characterized by thickening of the collagen layer beneath the surface epithelium. Typically seen in middle-aged and older women with watery diarrhea.

dysplasia Lesion of the epithelium (squamous or glandular), characterized by irregular and atypical proliferation and cytologic abnormalities. When seen in a patient with a chronic inflammatory disorder (Barrett's esophagus, chronic gastritis, ulcerative colitis, and Crohn's disease), the finding of dysplasia serves as a marker that the patient has or is especially apt to develop adenocarcinoma.

lymphocytic colitis Condition of chronic colitis, characterized by watery diarrhea, no gross radiographic or endoscopic abnormality, and biopsies showing prominent increase of lymphocytes within the surface and upper crypt epithelium.

metaplasia Change from the normal histology to a different mature differentiation. The finding of metaplasia serves as a marker that the patient has a chronic inflammatory lesion. Examples in the alimentary tract include the glandular metaplasia in Barrett's esophagus, intestinal metaplasia in chronic gastritis, gastric mucous cell metaplasia in chronic duodenitis, pyloric gland metaplasia in Crohn's enteritis, and Paneth cell metaplasia in ulcerative colitis.

mucosa-associated lymphoid tissue lymphoma Malignant lymphoma of the marginal-type B lymphocytes within the alimentary tract. This is most commonly seen in the stomach as a complication of chronic *Helicobacter pylori* gastritis.

pouchitis Inflammatory condition, either acute or chronic, involving the ileal pouch following a colectomy and ileal pouch–anal anastomosis.

pseudomembranous colitis Inflammatory condition, characterized by the presence of prominent inflammatory membranes on the colonic mucosal surface. Typically present in patients with *Clostridium difficile* colitis, but can be seen as well in cases of ischemic disease and other infections of the colon.

With the widespread use of flexible endoscopes, there has been a large and steady increase in the procurement of and dependence on mucosal biopsies of the gut. Lesions are being detected and evaluated at early stages, in some instances before they are grossly evident. Furthermore, with serial examinations, the spectrum of stages and the evolution of many disorders are being appreciated. Endoscopic biopsies are used not only to determine a specific diagnosis but also to assess the extent and severity of a lesion, to monitor the course, and to detect complications. It is imperative that relevant clinical information and particular reason for the examination be provided to ensure an appropriate and intelligent analysis of the biopsy, and the questions posed should be specifically answered in the pathologic report.

GENERAL FEATURES

This article concentrates on biopsy uses and interpretation in selected inflammatory disorders of the gut, with brief mention of the utility of mucosal biopsies in tumor detection. The jejunum, which is not ordinarily visualized by endoscopy, is not included.

Technical Aspects

Mucosal biopsies of the gut include those obtained directly at endoscopy and those obtained by aspiration to secure submucosal tissue. Orientation of the biopsy specimen is essential for analysis of the jejunal mucosa and is optimal when the endoscopist places the specimen luminal side upward on filter paper or other substrate that can be embedded and cut. For other biopsies, sufficient orientation is ordinarily achieved by obtaining multiple sections. Buffered formalin is an adequate fixative for most studies, provided that tissue and cellular shrinkage are considered. When finer nuclear detail is desired, as in the identification of lymphomas and other cellular tumors, a mercury- or picric acid-containing solution such as Bouin's or Hollande's is preferable. Because many mucosal lesions are tiny, two to three levels of any biopsy, with at least four sections at each level, are recommended. Ordinary hematoxylin and eosin (H&E) stain is usually sufficient, using special procedures when indicated. Cytologic smears are an important adjunct for identification

of tumor cells and organisms (viral inclusions, fungi, protozoa, and ova).

Effects of Preparation, Endoscopy, and Biopsy Procedures

Preparation, endoscopy, and biopsy procedures may cause variable degrees of trauma to the tissue, resulting in distortion and tears, flattening or denudation of surface epithelium, edema, congestion, and hemorrhage. These effects must be discounted before considering abnormalities. For evidence of injury, it is best to look for sure signs of epithelial damage coupled with the presence of neutrophils, eosinophils, or increased mononuclear inflammatory cells in the epithelial layer.

ESOPHAGUS

Normal Esophageal Mucosa

The esophagus is covered by a layer of nonkeratinizing, stratified squamous epithelium. The basal zone of proliferative cells is ordinarily only a few cells thick but may extend to up to 15% of the epithelial thickness; the papillae of the lamina propria reach up to 50% of the epithelial thickness. Squamous epithelium contains small number of mononuclear inflammatory cells (lymphocytes, Langerhans cells) but no neutrophils and only rare eosinophils. Endoscopic biopsies typically contain little or no lamina propria, resulting usually in less than optimal orientation of the epithelium. Aspiration-type biopsies contain substantial amounts of lamina propria and typically extend into the muscularis mucosae, which is normally very thick in the esophagus. The submucosa is usually not sampled.

Reflux Esophagitis

Features of milder acute (or active) lesions include basal zone hyperplasia exceeding 20–25% of total epithelial thickness, the presence of intraepithelial eosinophils or neutrophils, and elongation of papillae with dilated venules beyond 75% of the epithelial layer. Accurate estimates of basal zone hyperplasia and papillae length require well-oriented biopsies that are usually of the aspiration type, whereas intraepithelial granulocytes can be readily appreciated in the smaller endoscopic biopsies. More marked lesions show necrosis with ulceration and granulation tissue. Chronic lesions reveal the presence of glandular metaplasia (Barrett's esophagus), consisting of any admixture of gastric cardiac and intestinal mucous cell epithelia (Fig. 1). This must be differentiated from normal gastric fundic mucosa, which indicates a hiatal hernia; and from carditis, which is often due to *Helicobacter pylori*.

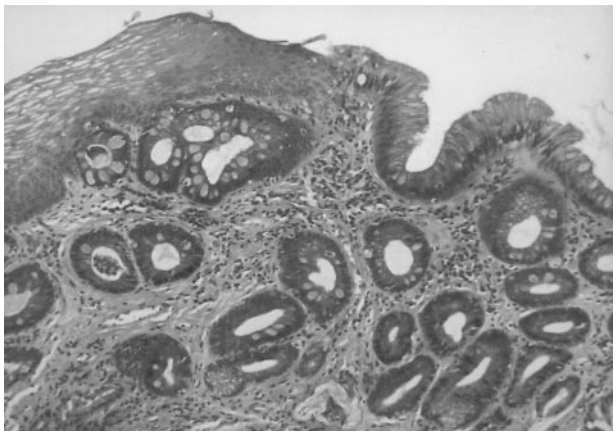

FIGURE 1 Esophageal mucosal biopsy, showing Barrett's esophagus. There is a small portion of normal epithelium in the upper left section, consisting of nonkeratinizing stratified squamous epithelium. The rest of the mucosa consists of glandular tissue, including gastric-type cells that are narrow and have mucus in the luminal end, and distended mucus-filled goblet-type cells of the intestinal type.

Other Forms of Esophagitis

Esophagitis may manifest in other forms:

1. Infections. Biopsy is used principally to demonstrate viral inclusions of herpes simplex in the epithelium, cytomegalovirus in ulcers, and fungi such as *Candida*. The lesions are often focal and may spare the distal esophagus, the typical site of reflux disease.
2. Radiation. Biopsy is done mainly to exclude tumor or opportunistic infections. Features of radiation at the mucosal level are relatively nonspecific; atypical mesenchymal cells and vascular ectasia may be seen.
3. Drug effects. Most cases are due to localized entrapment and pressure injury from a pill, resulting in a focal ulcer with nonspecific acute inflammation.
4. Neuromuscular disorders. Most common are systemic sclerosis and late effects of esophageal atresia. Injury is due to impaired motility (and acid clearance) and/or lower sphincter incompetence, which promote development of peptic esophagitis. Biopsy may also assist in surveillance for late tumors in cases of achalasia.
5. Immune disorders. Allergic (eosinophilic) gastroenteritis is more common in children, and the esophagus may also be involved. The features are similar to reflux injury, with a tendency to show large

aggregates of eosinophils; functional tests are needed to separate.

6. Rare disorders. Include pemphigus and other skin conditions, Crohn's disease, sarcoidosis, and Behçet's disease.

Tumors of the Esophagus

Squamous cell papilloma is a rare, small, wart-like lesion, and biopsy reveals a papillary hyperplasia of the squamous layer without dysplasia. Biopsy and cytology are used to detect and monitor lesions of squamous cell dysplasia and carcinoma. Adenocarcinomas arise from the gastric cardia, Barrett's metaplasia, heterotopic stomach, or esophageal glands. Cases developing in Barrett's mucosa are usually associated with glandular dysplasia, and this dysplasia should be sought as the precursor lesion. Adenocarcinomas located in the distal esophagus, esophagogastric junction, and gastric cardia have a common histology. Other tumors include lymphomas, endocrine and mesenchymal lesions, rare primary melanoma, and metastatic tumors.

STOMACH

Normal Gastric Mucosa

The antral mucosa has relatively long pits (foveolae) and prominent fibromuscular stroma in its lamina propria. Chronic inflammatory cells are commonly present in the lamina propria of the antrum and cardia, and this increases with age. The body and fundus have short pits, few inflammatory cells, and are composed mainly of compact glands containing parietal and chief cells. Also present are a variety of endocrine cells that are mainly located at the gland bases; the cells have central nuclei and clear cytoplasm and are best visualized with silver-binding stain (Grimelius) or specific immunocytochemical stains (chromogranin, synaptophysin, gastrin, or somatostatin).

Chemical and Drug Gastritis

Common causes are reflux of bile salts, ethanol, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDS). The major histologic effects are edema and congestion, elongation and regeneration of the pits, with minimal or no inflammation; hemorrhage and erosion occur in severe cases (Fig. 2).

Chronic Gastritis

General features of chronic gastritis include an increase of mononuclear inflammatory cells with lymphoid nodules in the lamina propria, atrophy of specialized glands, hyperplasia of gastric pits, and the appearance of intestinal and pyloric metaplasia. Active disease shows neutrophils in the pits and lamina propria, with ulcers in severe cases.

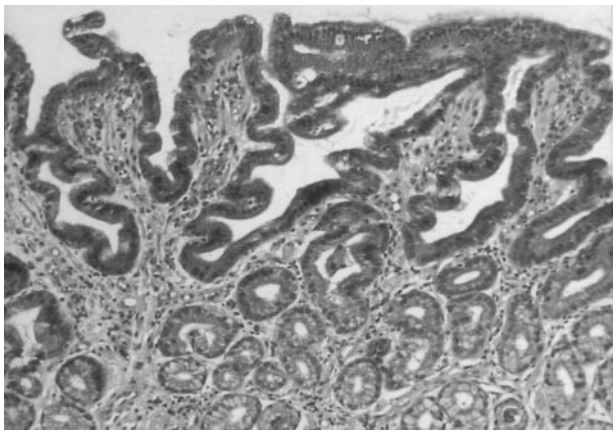

FIGURE 2 Gastric antral mucosal biopsy, showing the typical features of chemical- or drug- induced gastritis. The surface is at the top. In the bottom portion are seen the normal gastric antral mucous cells, which are distended with mucin. In the upper portion, there is marked regeneration of the gastric pits characterized by tortuous and elongated glands that contain cells with enlarged nuclei that occupy a large portion of the cell. There is also some edema and congestion of the lamina propria but minimal cellular inflammation.

Chronic antral gastritis occurs due to exogenous agents, and about two-thirds to three-quarters of cases of active chronic gastritis are associated with the presence of *H. pylori* on surface and in gastric foveolae. The lesion starts in the antrum but often progresses to involve the corpus/fundus and cardia. The organisms can be seen with H&E and are accented by Giemsa and silver (Warthin–Starry or Dieterle) stains. The bacteria may also be found wherever there are gastric surface mucous cells, including the duodenal mucosa at sites of gastric mucous cell metaplasia, Barrett's esophagus, and in heterotopic stomach.

Chronic fundic gastritis is an immunologic disorder with dominant effect in the corpus and fundus; it may progress to atrophic gastritis and primary pernicious anemia. The severe "atrophic" form shows complete loss of specialized fundic–corpus cells and prominent metaplasia of pyloric and intestinal glands. Biopsy is of limited use in overall diagnosis because of the potential of sampling error; biopsy is mainly done to exclude other diseases or as surveillance procedure to detect dysplasia and early carcinoma. The low acid may also lead to enhanced G cell stimulation in the antrum, resulting in proliferation of the enterochromaffin-like (ECL) cells in the body.

Biopsy helps to detect the several complications of chronic gastritis, including xanthoma, hyperplastic polyp, glandular dysplasia, adenocarcinoma, and endocrine cell hyperplasia/neoplasia.

Other Forms of Gastritis

There are several other causes and forms of gastritis:

1. Other infections. Biopsy can identify opportunistic agents, including cytomegalovirus, mycobacteria, and fungi.
2. Ischemic lesions. These are seen in stress and shock. Noted are hemorrhages, erosions, and ulcers, simulating changes seen in severe chemical gastritis.
3. Granulomatous gastritis. This is most marked in the antrum, and cases grossly mimic carcinoma. Causes include Crohn's disease, tuberculosis and other infections, foreign bodies, isolated (most common), and sarcoidosis.
4. Eosinophilic (allergic) gastroenteritis. Glandular necrosis and regeneration with many eosinophils are seen, most marked in the antrum. Associated lesions may be in the esophagus, small bowel, and/or colon. In cases with enteritis, gastric antral biopsy helps to separate an allergic disorder and other causes such as celiac disease or viral enteritis.

Chronic Peptic Ulcer

Diagnosis must distinguish between epithelial alterations due to degeneration or regeneration and true dysplasia; conservatism is the rule. The ulcers due to aspirin and other antiinflammatory drugs are suggested by noting normal mucosa at the edge (present in about one-half of cases). There is invariably inflammation in the chronic peptic ulcer cases. *Helicobacter pylori* are present in the inflamed antral mucosa in the large majority of cases of chronic peptic ulcers, both of the stomach and the duodenum.

Mucosal Hypertrophy and Hyperplasia of the Stomach

Biopsy can help to demonstrate the pure hyperplasia of the gastric pits in Menetrier's disease, and the increase of parietal cells in the Zollinger–Ellison syndrome. Other causes of rugal hypertrophy include normal variation, some inflammatory conditions, and tumors.

Gastric Polyps

Biopsy distinguishes the more common hyperplastic (inflammatory, regenerative) and cystic fundic gland polyps from the true neoplastic (adenomatous, villous) types. Rarer forms are juvenile, Peutz–Jegher, and inflammatory fibroid polyps. The major object of biopsy is to determine whether the polyp is an adenoma. If it is an adenoma, the polyp must be completely excised because of the strong chance of having or developing carcinoma. If the polyp is nonneoplastic, the particular type (and name) may depend on full clinical and distributional data.

Malignant Tumors of the Stomach

Adenocarcinomas, lymphomas, and other tumors must be differentiated. For optimal detection of adenocarcinomas, multiple biopsies are obtained from the edges and central ulceration of the lesion. The peripheral samples identify most tumors with gland formation, whereas the central biopsies are better to show lesions that are infiltrative under the mucosa, such as the signet ring cell form of adenocarcinoma and mural tumors. Biopsies are also useful in the detection of glandular dysplasia or early carcinoma in patients with promoting conditions, such as chronic gastritis or polyposis.

Patients with long-standing *H. pylori* gastritis may develop a malignant lymphoma involving the marginal B cells, commonly called mucosa-associated lymphoid tissue (MALT) lymphoma. Biopsy shows proliferation of immature lymphoid cells with invasion into the pit epithelium, termed lymphoepithelial lesion. Because the early lesions may be subtle and difficult to distinguish from simple chronic gastritis, other tests using fresh samples may be needed, including immunostains, flow cytometry, and polymerase chain reaction to determine monoclonality. Other gastric tumors include endocrine, mesenchymal, and metastatic lesions.

DUODENUM

Normal Duodenal Mucosa

Endoscopic biopsies are obtained to assess duodenitis and unusual ulcers, to screen for malabsorptive disorders, and to detect tumors of the duodenum and adjacent structures. In contrast to the jejunum, the mucosa of the proximal duodenum frequently reveals variation in villous height and more chronic inflammation, possibly reflecting constant physiologic damage from acid.

Duodenitis

In peptic duodenitis, there is variable villous shortening, epithelial cell degeneration, and active inflammation, in the form of increased intraepithelial lymphocytes or neutrophils. Chronic duodenitis causes

gastric mucous cell metaplasia and Brunner gland hyperplasia.

In infections, biopsy is done mainly to look for *Giardia* or for opportunistic infections in immunosuppressed patients. Common examples are viral inclusions of herpes and cytomegalovirus (CMV), *Mycobacterium avium* in acid-fast stains, fungi, cryptosporidia, and microsporidia in gram stains. Other causes of duodenitis include stress hemorrhages and ulcers, drug effects, radiation, and Crohn's disease.

Malabsorptive Disorders

Endoscopic biopsy of the duodenum is used to screen for a diffuse enteritis such as celiac disease. If biopsy is normal, it effectively excludes celiac disease, which would always involve the duodenum. Conversely, if biopsy reveals enteritis, it is not specific, because identical changes could be due to peptic injury. Features of celiac disease include shortening of villi, degeneration of surface absorptive cells, increased intraepithelial lymphocytes, crypt hyperplasia with more mitoses, and increased mononuclear inflammatory cells and eosinophils in the lamina propria. Biopsy may also help to detect focal lesions of Whipple's disease or lymphangiectasia, and a variety of other immunologic disorders.

Tumors of the Duodenum

Benign nodules include heterotopic stomach, Brunner gland hyperplasia, and lymphoid aggregates. Neoplasms may be detected in the duodendal mucosa and ampulla, showing the full range of adenoma, adenocarcinoma, lymphoma, and endocrine tumors.

ILEUM

Normal Ileal Mucosa

Compared to the jejunum, there is a greater number of goblet mucous cells in the villi and larger quantities of lymphoid tissue in the ileum. Furthermore, biopsies of ileum proximal to an anastomosis or stoma often reveal a variable degree of atrophy, characterized by villous shortening and crypt hyperplasia. For a diagnosis of active ileitis, it is necessary to see definite destruction of the surface or crypt epithelium, usually associated with neutrophils.

Ileitis

Biopsy is done in patients who have had ileocolic anastomosis, ileal pouch, or ileostomy and present with ileal dysfunction or suspected inflammation. The presence of pyloric gland metaplasia is especially helpful in detecting chronic ileitis.

Mechanical, vascular, or septic complications of a nonspecific nature may occur. Prestomal ileitis is characterized by nonspecific inflammation and ulceration, typically associated with a dilated intestinal segment. Pouch ileitis, or acute pouchitis, occurs in about 20–25% of cases and usually responds to antimicrobial drugs. Chronic changes of severe atrophy are noted in a small percentage of patients, and such patients have an increased risk for dysplasia and carcinoma in the pouch mucosa. Recurrent Crohn's disease is suspected by stenosis or sinuses away from anastomosis or stoma. There is a need to see both ulceration and granuloma in biopsy, because either alone may not signify specific or active disease.

Tumors of the Ileum

Exceptionally, lesions of the terminal ileum may be biopsied through an intact ileocecal valve. Endoscopy and biopsy are also used for the detection of dysplasia, adenomas, and carcinomas in an ileostomy segment and in pouches, in patients who have had colectomy for adenomatous polyposis or ulcerative colitis.

COLON AND RECTUM

Normal Colonic/Rectal Mucosa

Biopsies are employed for the diagnosis, extent, and severity, and complications of the various inflammatory disorders; and also for the detection and typing of abnormal mucosal growths—polyps, primary and metastatic cancers, dysplasia in chronic colitis, multiple and diffuse polyposis syndromes, and tumor-like conditions.

The crypts are generally arranged in a parallel fashion, are composed predominantly of goblet mucous cells, may show minor branching at the base, and extend from the surface to abut on the muscularis mucosae. The surface epithelial cells between the crypts are more variable and include nonmucous forms. There is a considerable variation in the quantity and types of chronic inflammatory cells (including lymphocytes, plasma cells, eosinophils, and macrophages) in the lamina propria, and also present are numerous lymphoid nodules covered by an attenuated epithelium of M cells. Because of this great variation, it is best not to make a diagnosis of inflammatory disease unless there is the presence of neutrophils and particularly the appearance of damage or repair of the epithelial cells. Paneth cells are normally present in the right portion of the colon. The lower part of the rectum may show shortened crypts and increased inflammation, simulating chronic inactive colitis.

Infections

The lesions are often focal in the early stage but then proceed to a more diffuse colitis, and granulomas may be present in some cases. For most viral and bacterial infections, specific cultures are required. Biopsy may be used to identify some specific agents—particularly in opportunistic infections affecting immunocompromised patients and others at high risk—including viral inclusions of herpes (more in anal squamous cells) and cytomegalovirus (in glandular epithelium and mesenchymal cells), fungi, protozoa, and helminthic ova.

Antibiotic-Associated Pseudomembranous Colitis

Early lesion is distinctive, showing discrete foci of dilated crypts and overlying marked mucus and neutrophils, in the shape of a mushroom. Later lesions are less specific, revealing more necrosis, inflammation, and hemorrhage and resembling ischemic disease or other acute colitis. Specific diagnosis requires identification of *Clostridium difficile* toxin.

Ischemic Disease

Early lesion of hemorrhage and crypt dropout with minimal acute inflammation are characteristic. Later lesions show ulceration and marked acute inflammation ("ischemic colitis") and mimic other causes of active colitis, especially infections due to *C. difficile* and enterohemorrhagic *E. coli*.

Ulcerative Colitis and Crohn's Disease

There are multiple reasons for the performance of endoscopy and biopsy in patients with idiopathic inflammatory bowel disease:

1. To detect or exclude, in selected cases, other specific causes of colitis or proctitis that have a distinctive histology (e.g., early ischemic disease, pseudomembranous colitis, protozoan infection).

2. To confirm, exclude, or document a case of suspected colitis or proctitis—subsequent biopsy may be able to distinguish between chronic disease in remission (by noting some alteration of crypts) and complete recovery of a reversible acute colitis (which would appear completely normal). But, this distinction may be confounded by the treatment, leading to a normal-appearing biopsy in patients with chronic inactive colitis.

3. To distinguish acute self-limited colitis (mostly, infectious) and chronic colitis (usually ulcerative colitis or Crohn's disease)—major features of chronic colitis include crypt irregularity in the form of complex branching, crypt atrophy, villiform surface, Paneth cell metaplasia, and the presence of lymphocytes and plasma cells in the base between the crypts and the muscularis mucosae (Fig. 3). Acute colitis is suggested by the presence of normal crypt architecture and a relatively superficial damage of the epithelium, with appearance of only neutrophils, but this is not absolute, because some cases of chronic colitis may initially show such features.

4. To assist in the diagnostic distinction between ulcerative colitis and Crohn's disease—accurate diagnosis of the particular type requires consideration of the gross features and distribution of the disease, as assessed by X ray and endoscopy as well as the mucosal biopsies. The patterns available on the superficial mucosal biopsy are limited. A normal biopsy as evidence of a spared rectum or other skip area, a focal colitis or proctitis, or the presence of granulomas would support or indicate CD. A diffuse colitis or proctitis would be compatible with either form, and in such cases the diagnosis would depend on other data.

5. To determine disease extent and severity—whatever the type, biopsies may be used to monitor the course and estimate activity in cases of apparent remission.

6. To distinguish polypoid dysplasia versus adenoma—sporadic adenoma- and colitis-associated dysplasia cannot be distinguished by histology. There is a tendency to favor adenoma in older patients, in those with disease of shorter duration, and the finding in an

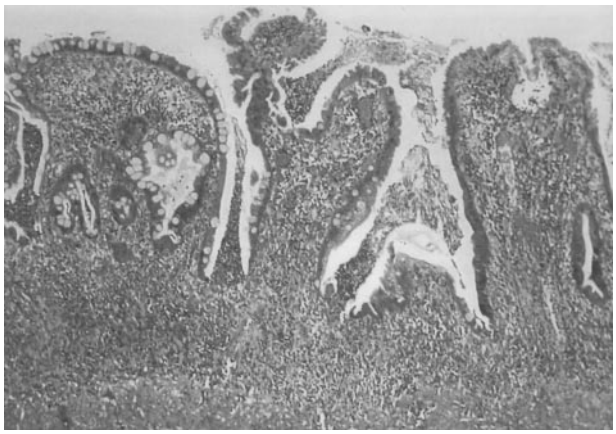

FIGURE 3 Colonic mucosal biopsy, showing chronic active colitis in a patient with ulcerative colitis. The luminal surface is at the top. There is diffuse irregularity of the crypts and marked infiltrate of mononuclear inflammatory cells and eosinophils in the base of the mucosa separating the crypts from the muscularis mucosae (at the bottom). Also seen is active disease in the form of crypt abscesses.

area without surrounding colitis, particularly if the lesion has a stalk. Conversely, dysplasia seems more likely in younger patients, in those with more extensive disease of longer duration, and in lesions that are sessile and present within an area of the colitis.

7. To detect dysplasia and carcinoma—biopsy is done of grossly evident mass or stenotic lesion and also in colonoscopic surveillance to detect dysplasia. Biopsies should be taken from any villous growth, from other atypical-appearing polyps, and from flat areas that seem the least inflamed. They must distinguish histologically between effects of degeneration and regeneration and true dysplastic epithelium. This may be difficult in an area of great inflammation, and experience is essential.

The following biopsy classification for dysplasia has been suggested:

a. Negative for dysplasia—includes normal mucosa and effects of inactive (or quiescent) colitis and active colitis.

b. Indefinite for dysplasia—specify particular technical or interpretative reason, such as excessive acute inflammation or appearance of unusual growth pattern. These are further rated as probably negative, unknown, or probably positive, because this assists in decisions about early rebiopsy.

c. Positive for dysplasia (Fig. 4)—rate by worse area as low-grade dysplasia or high-grade dysplasia. Low grade is roughly equivalent to mild dysplasia and shows architectural abnormalities that are not greater than those seen in chronic colitis but, in addition, palisading of nuclei that occupy up to half the cell height, not related to inflammation. High grade encompasses all abnormalities from moderate to severe to carcinoma *in situ*. Extension of atypical cells to the surface helps to distinguish dysplasia from effects of regeneration alone.

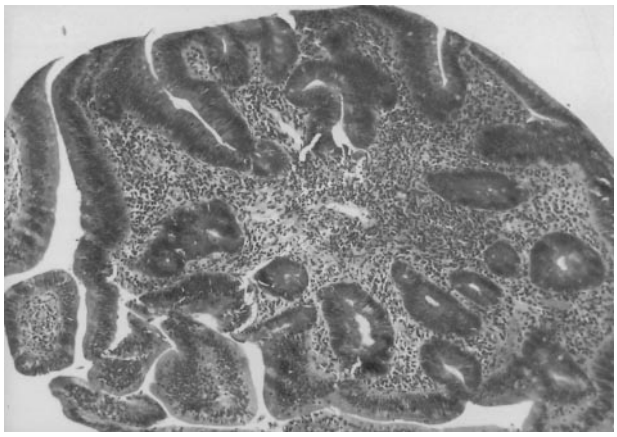

FIGURE 4 Colonic mucosal biopsy in a patient with chronic ulcerative colitis, revealing high-grade glandular dysplasia. The cells contain large and palisading nuclei that occupy more than half the height of the cell and show variable hyperchromatism. The altered cells extend to the surface at the top. Contrast with the nondysplastic epithelium seen in Fig. 3.

Other Inflammatory Disorders of the Colon and Rectum

Motor and mechanical conditions may require biopsy. Biopsy is used to look for ganglia in the submucosa and for associated colitis in cases of Hirschsprung's disease; and to evaluate cases of diverticular disease, diversion-related colitis, and obstructive colitis. Vascular disorders, i.e., ectasias and malformations, can be visualized by endoscopy and then cauterized. In vasculitis, the lesions tend to involve larger submucosal vessels and are missed by ordinary endoscopic biopsy, which usually contains only the mucosa; for these cases, deeper aspiration-type biopsy can be taken from the rectum.

Immunologic diseases can be assessed using biopsies. Allergic disease is either due to a single allergen (milk or soy protein) or is part of a generalized reaction (eosinophilic or allergic gastroenteritis). Patients with the form limited to the large intestine (allergic proctitis or colitis) are very young (average age, 2 months) and usually present with rectal bleeding alone or in combination with diarrhea. Biopsy reveals focal areas of crypt destruction with numerous eosinophils; the lesion may be very tiny, and multiple sections are recommended. There is often a more diffuse increase of eosinophils in the lamina propria and the musculus mucosae. An increase of apoptosis in the crypt epithelia is sought in cases of graft-versus-host disease.

Collagenous colitis occurs mostly in middle-age women, presenting with chronic watery diarrhea. Radiographic and gross endoscopic examinations are normal. The only constant abnormality is thickening (usually, greater than 10 μm) of the collagen layer beneath the surface epithelium. The lesion may be focal in early and in healing stages, and the rectum may be uninvolved. An increase in lymphocytes within the surface epithelial layer is often present. The collagen lesion is nonspecific; similar thickenings are noted uncommonly in other types of colitis, particularly due to radiation, and in hyperplastic polyps. In lymphocytic colitis, there are similar clinical features, but with a wider age range, and the disease also occurs in men. There is the presence of focal cryptitis and increased lymphocytes in the surface epithelial layer and lamina propria but no collagen thickening.

Biopsy may be useful in miscellaneous conditions that occur in many other disorders that can affect the large intestine, including radiation injury and foreign body reactions to barium and oil; chemical and drug effects from strong enema solutions, cathartics, NSAIDS, heavy metals, and chemotherapeutic agents; metabolic and infiltrative lesions seen in uremia, amyloidosis, and storage diseases; and tumorlike lesions such as endometriosis and pneumatosis.

Polyps of the Colon and Rectum

Polyps may be inflammatory, lymphoid, juvenile (retention), other hamartomatous, hyperplastic, and neoplastic (adenomatous or tubular, villous, mixed). If a polyp is neoplastic, look for the presence and extent of carcinoma—true *in situ* (limited to gland, without trespass of basement membrane), intramucosal (invasion into lamina propria but not through the muscularis mucosae), and submucosal. If there is submucosal invasion, it is important to separate those polyps with stalks from sessile lesions. It is also necessary to distinguish between invasion and effects of inflammation leading to "misplacement" of the benign epithelium into the stalk region. The misplaced tissue contains normal lamina propria, whereas carcinoma has an abnormal fibrovascular stroma.

Polypectomy is sufficient treatment for lesions that are adenomas or contain a carcinoma that is just *in situ* or intramucosal, whereas additional intestinal resection is usually recommended for sessile tumors that show invasion of carcinoma into the submucosa. Polypectomy may also be adequate for pedunculated adenomas with a moderately or well-differentiated carcinoma extending into the stalk but not at or within 1 mm of the resection margin (identified by cautery effect). If the carcinoma is at or very near the stalk margin, is poorly differentiated, or there is definite lymphatic invasion, colonic resection is ordinarily performed.

Malignant Tumors of the Colon and Rectum

Biopsy is done of polyps, masses, and ulcerated and stenotic lesions to detect primary carcinoma, mainly adenocarcinoma, carcinoid tumors, lymphomas, and other mural lesions tumors, and recurrent and metastatic tumors. The biopsy may also be helpful in the evaluation of the differentiation and degree of invasion of the tumor, the assessment of drug and radiation effects, the identification of opportunistic infections, and in surveillance for coexisting and future tumors.

Multiple Endocrine Neoplasia (MEN)

JEFFREY C. BUEHLER AND GORDON C. HUNT
University of California, San Diego

catecholamines Group of physiologic substances, mainly epinephrine, norepinephrine, and dopamine; act as neurotransmitters in the functioning of the sympathetic nervous system.

gastrinoma Neuroendocrine tumor found mainly in the wall of the duodenum and in the pancreas; secretes excessive amounts of the growth hormone, gastrin.

insulinoma Insulin-producing tumor of the pancreatic beta cells in the islets of Langerhans.

kindred Family relationship by birth, or sometimes by marriage.

medullary thyroid carcinoma Malignant tumor of the thyroid gland; the most common tumor found in multiple endocrine neoplasia types 2A and 2B.

pancreatic islet cells Small groups of cells found throughout the pancreas; subdivided into alpha, beta, and delta islet cell types, which produce glucagon, insulin, and somatostatin, respectively.

prolactinoma Pituitary adenoma that secretes excessive amounts of prolactin, which may lead to the clinical symptoms of galactorrhea or amenorrhea.

VIPoma Endocrine tumor that produces vasoactive intestinal peptide, which belongs to the secretin family of hormones. The resulting syndrome causes a watery diarrhea–hypokalemia–achlorhydria syndrome.

The multiple endocrine neoplasia (MEN) syndromes are rare causes of hormone excess. The MEN syndromes involve hyperplasia, adenomas, and carcinomas of several different endocrine glands. MEN disorders are usually clustered in families and are inherited in an autosomal dominant pattern. Traditionally, MEN syndromes are diagnosed after patients present with clinical signs and symptoms related to elevated hormone levels, and evaluation reveals multiple endocrine abnormalities. Alternatively, MEN syndromes may be discovered when a single endocrine disorder is identified, but a family history of MEN leads to further evaluation and discovery of multiple endocrine abnormalities. With the recent advent of DNA testing for these disorders, people with a genetic predisposition for MEN are being diagnosed in an asymptomatic state.

MEN 1

MEN 1 is characterized by a predisposition to tumors of the parathyroid glands, the pancreatic islet cells, and the anterior pituitary gland. Parathyroid hormone (PTH) excess is the most common abnormality, occurring in excess of 90% of cases of MEN 1, with hypercalcemia being a frequent clinical presentation. Patients usually present in their second to fourth decade of life and are affected almost universally before age 50. Patients with excess PTH (and resultant hypercalcemia) may present with generalized symptoms of weakness and confusion or with gastrointestinal (GI) symptoms of constipation, nausea, or abdominal pain. More commonly, they present with kidney stones from excess calcium filtration into the urine. Elevated calcium levels may also be detected during routine lab testing.

Pancreatic islet cell tumors occur in 40–80% of MEN 1 patients. The tumors can often be asymptomatic and elusive to the physician despite a robust workup. Gastrinomas are the most common symptomatic islet cell tumors, producing excess gastrin and causing recalcitrant peptic ulcer disease. Symptomatic insulinomas occur less frequently. These tumors may present with hypoglycemic symptoms that can result clinically in an altered mental status and that can uncommonly manifest as seizures. Other less common islet tumors include vasoactive intestinal peptide tumors (VIPomas), glucagonomas, and nonfunctioning tumors.

Anterior pituitary tumors are present in a majority of patients with MEN 1 but are clinically apparent in only 15–20%. Presenting symptoms occur from tumor mass effect or from the hormone that is being produced in excess. Prolactinomas are most frequent, but adrenocorticotropic hormone (ACTH)-producing and growth hormone-producing tumors are also seen. Nonfunctional pituitary tumors also occur and frequently present with visual changes due to mass effect.

MEN 2

MEN 2 is subdivided into two types, MEN 2A and MEN 2B. Both disorders are autosomal dominant. MEN 2A is defined by a predisposition to medullary thyroid carcinoma, pheochromocytoma, and parathyroid hyperplasia. Medullary thyroid carcinoma is the most frequent manifestation, occurring in over 90% of cases.

 Copyright 2004, Elsevier (USA). All rights reserved.

The thyroid carcinoma of MEN 2A usually presents in the third and fourth decades of life, most often as a thyroid nodule or cervical adenopathy. Pheochromocytoma with excess catecholamine production (most often epinephrine) is present in about half of MEN 2 cases. Clinical presentation varies, and patients may develop anxiety, excess sweating, headache, and heart palpitations. Hypertension, often paroxysmal, is common and patients will occasionally present in hypertensive crisis. Pheochromocytomas rarely present before the medullary thyroid disease. The last component of MEN 2A is parathyroid excess, which is seen about 25% of the time.

Patients with MEN 2B, like those with MEN 2A, also have a predisposition to medullary thyroid carcinoma and pheochromocytoma, but do not have parathyroid abnormalities. Several other abnormalities are associated with the MEN 2B syndrome, including Hirschsprung's disease, mucosal neuromas, and a marfanoid habitus.

GENETIC TESTING

The MEN 1 gene was discovered in 1997 and mutations in the gene have been present in a majority of MEN 1 kindreds that have been tested. Testing for the MEN 1 gene defect is not yet standard, because there is no proved clinical benefit in determining a presymptomatic diagnosis.

Unlike MEN 1, for which early diagnosis through genetic testing confers an uncertain mortality benefit, the newly developed genetic test for the receptor tyrosine (RET) proto-oncogene defect as seen in MEN 2 patients is of profound benefit. The medullary thyroid carcinoma that is almost universally present in MEN 2 cases is curable with early surgery. Earlier diagnosis through genetic testing for the RET oncogene has helped identify patients needing prophylactic thyroidectomy. Genetic testing has also reduced the number of false positive tests that were generated by older biochemical stimulation testing. Earlier diagnosis is especially crucial in MEN 2B cases, in which the medullary thyroid carcinoma is aggressive, often presenting earlier in life.

GASTROINTESTINAL AND PANCREATIC ISLET CELL TUMORS

Pancreatic endocrine tumors, although often present in cases of MEN 1, are rarely seen in cases of MEN 2. The hyperparathyroidism of MEN 1 almost universally precedes the appearance of pancreatic endocrine tumors. The parathyroid and pituitary endocrinopathies of MEN 1 patients are often effectively managed with surgery and hormone replacement. Unlike pituitary and parathyroid surgery, in which involved organs are removed completely (pituitary) or almost completely (parathyroid), pancreatic tumors are usually enucleated, leaving the remaining pancreas behind. The remaining pancreatic tissue still has malignant potential and screening for recurrent tumor development is problematic and a subject of continued research.

Pancreatic endocrine tumors classically present in the fourth or fifth decade with symptoms of hormone excess. Approximately one-third of MEN 1 patients become symptomatic. More often these tumors are asymptomatic. Because asymptomatic tumors may go undetected, the true prevalence of pancreatic endocrine tumors is difficult to determine. Advanced biochemical testing and anatomical/pathological studies reveal these tumors in up to 80% of MEN 1 cases. Despite being asymptomatic, these pancreatic islet and gastrointestinal tumors may be malignant. In contrast, some symptomatic tumors can be difficult to find despite extensive imaging and evaluation.

Zollinger–Ellison (Gastrinoma) Syndrome

Approximately 60% of patients with MEN 1 have symptoms from excess gastrin or have asymptomatic elevations in serum gastrin. Conversely, about 25% of Zollinger–Ellison (ZE) cases are subsequently diagnosed with MEN 1. The number of peptic ulcers due to gastrin excess is estimated at 0.1% or less, but with improved medical therapy for peptic ulcer disease, ZE ulcer symptoms may be controlled and formal testing for a hypergastrinemic state not performed. This potential for misdiagnosing gastrinomas would result in a misrepresentation of the true prevalence.

Gastrinomas present most commonly after age 20 years as symptoms related to gastroesophageal reflux disease, abdominal pain, and peptic ulcers. The ulcer disease in MEN 1 gastrinomas is more severe than in common peptic ulcers. Gastrinoma-induced ulcers are more often multiple, frequently resistant to treatment, recurrent, and can be atypically located as distal as the jejunum. Diarrhea is also a common presenting symptom and can help distinguish gastrinoma-induced ulcers from other common ulcers. The diarrhea is believed to be the result of excess gastric acid production. Two mechanisms explain this diarrhea. First, excess acid output overwhelms the resorptive capacity of the small bowel and colon, causing a secretory diarrhea. Second, excess acid in the stomach lowers the pH in the duodenum, compromising pancreatic enzyme digestion of lipids, and steatorrhea results. As one would expect with a secretory diarrhea, fasting does not affect the diarrhea. Nasogastric suctioning may, however, alleviate the diarrhea.

TABLE I Causes of Hypergastrinemia

Pharmacologically (drug) induced
Helicobacter pylori infection
Hypochlorhydria/achlorhydria +/− pernicious anemia (i.e., gastric atrophy, chronic atrophic gastritis, gastric carcinoma)
Retained gastric antrum
Incomplete vagotomy
G cell hyperplasia
Renal insufficiency
Massive small bowel resection
Gastric outlet obstruction
Others (rheumatoid arthritis, vitiligo, diabetes, pheochromocytoma, gastroparesis)

A variety of tests are available for diagnosing gastrinomas. Secretin stimulation tests and fasting serum gastrin levels with pH testing of the stomach have been used. Blood samples for determination of fasting serum gastrin levels are drawn while documenting gastric acid hypersecretion through pH analysis of the stomach. Gastrin levels in excess of 1000 pg/ml are very specific for gastrinomas. Less profound levels of gastrin elevation are seen in other disorders, including pernicious anemia, atrophic gastritis, small bowel resection, gastric outlet obstruction, and renal insufficiency. Antisecretory therapy (i.e., proton pump inhibitor therapy) also causes hypergastrinemia by reducing stomach acid and causing gastrin levels to rise through the feedback inhibition loop. Common etiologies of hypergastrinemia are outlined in Table I.

In cases of mild elevation of gastrin, the secretin stimulation test is helpful. Secretin paradoxically causes a release of gastrin from gastrinoma cells, whereas gastrin release is inhibited in normal gastric G cells. This test, however, has been difficult to perform because of a nationwide shortage of secretin. Differentiating sporadic ZE cases from those associated with MEN 1 is important, because their management is different. For example, MEN 1-related hyperparathyroidism can exacerbate gastric acid secretion through hypercalcemia. Treatment of the hypercalcemia can improve gastrin-related symptoms (ulcer pain, diarrhea, reflux). The surgical approach and results are also different in MEN 1 gastrinomas in which tumors are often multiple, small, and often located outside of the pancreas, most commonly in the wall of the duodenum. Malignancy, defined by the presence of metastatic disease (rather than by histology), is present about 60% of the time in MEN 1-related cases, but hepatic metastases are more frequently seen in sporadic gastrinoma cases. Largely due to the aforementioned differences between sporadic ZE gastrinomas and MEN 1 gastrinomas, surgical attempts to cure MEN 1 patients have been less successful. However, some surgeons advocate surgical intervention in patients with MEN 1 only when tumors exceed 2.5 cm in size. In contrast to surgical therapy, medical therapy for gastrinomas is very effective. Proton pump inhibitor (PPI) medications, which reduce gastric acid output and control symptoms, are the mainstay of therapy.

Insulinoma

Insulinomas are the next most common functional pancreatic endocrine tumor, occurring in approximately 20% of MEN 1 patients (Fig. 1). The average age of presentation in most series is between 40 and 50 years of age, with 60% of the insulinomas occurring in females. Most insulinomas present with hypoglycemic (neuroglycopenic) symptoms, including confusion, lightheadedness, blurry vision, behavioral changes, drowsiness, and, rarely, seizure. Hypoglycemic symptoms often occur during periods of increased demand (exercise) or decreased supply (fasting). Sweating, tremor, and palpitations from catecholamine excess occur less often. Because of the general nature of these symptoms, there is often a delay in diagnosis on the order of years, and not infrequently, patients are misdiagnosed with neurologic or psychiatric disorders. Taking a careful history may reveal a pattern of frequent meals to suppress symptoms; consequently, obesity is present in approximately 40% of patients at diagnosis. The diagnosis of insulinoma is made by documenting hypoglycemia in the setting of elevated blood insulin

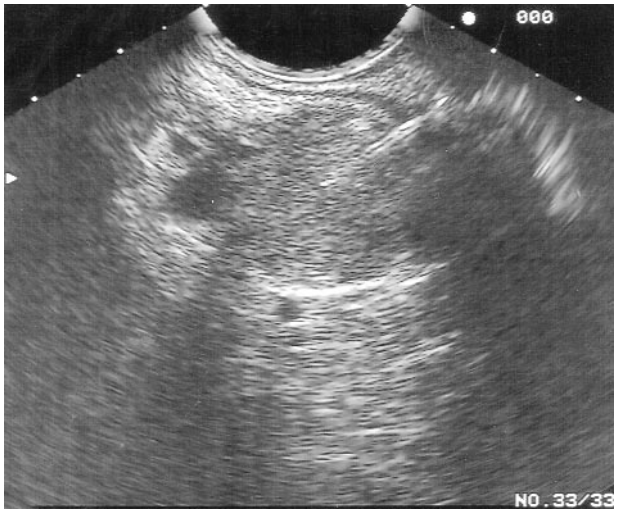

FIGURE 1 EUS image (7.5-MHz linear array echoendoscope) of a 1.7-cm hypoechoic insulinoma as seen in the tail of the pancreas. Fine needle aspiration needle is seen entering the tumor from the 1 o'clock position. This 55-year-old male patient presented with episodes of hypoglycemia and was ultimately diagnosed as having MEN 1 syndrome.

levels with classic hypoglycemic symptoms that reverse with the administration of glucose. A 72-hour fast with serial blood tests for insulin and glucose is the most reliable test to make the diagnosis. Serum samples should also be obtained for C peptide levels and for proinsulin, which will help differentiate from other causes of inappropriately elevated insulin levels.

Unlike gastrinomas, which are frequently found outside of the pancreas, insulinomas are almost invariably present within the pancreas. Insulinomas are characteristically small, measuring less than 1 cm almost half of the time. The insulinomas found in MEN 1 patients are more often multiple and are often accompanied by other types of islet cell tumors. Malignancy is found in a minority of cases, approximately 10%. Recurrence of insulinomas at 10 years occurs approximately 20% of the time in the setting of MEN 1, and 5% of the time in sporadic cases. Therapy is largely surgical, with tumor resection showing the best results. Medical therapy is used in patients who are poor surgical candidates, for whom surgery fails to eradicate the hypoglycemia, or who have metastatic disease. The somatostatin analogue octreotide controls hypoglycemia in roughly 40% of cases.

Other Pancreatic Endocrine Tumors

Other endocrine tumors seen in MEN 1 include pancreatic polypeptide tumors (PPomas), VIPomas, glucagonomas, and growth hormone-releasing factor tumors (GRFomas), the latter three occurring in less than 5% of MEN 1 cases. Pancreatic polypeptide (PP)-secreting PPomas are probably the most common tumors of the endocrine pancreas, but because they are nonfunctional tumors, their true prevalence is difficult to determine. PP is elevated in many of the other functional pancreatic endocrine tumors and thus is not diagnostic of PPoma. Without clinical warning signs, these tumors may appear late in the course of disease, with signs of local enlargement (back pain) or metastatic disease (hepatomegaly). The rare endocrine vasoactive intestinal peptide-secreting VIPomas result in VIP syndrome, characterized by a severe, watery, secretory diarrhea with hypokalemia and hypochlorhydria. Most VIPomas are sporadic, with less than 1% occurring as part of the MEN 1 syndrome. Glucagonomas are rare glucagon-secreting tumors that cause a syndrome of glucose intolerance, weight loss, and anemia. Migratory necrolytic erythema, a rash specific to glucagonomas, develops in the majority of cases. The rash begins with erythema that then blisters and heals with scarring and hyperpigmentation. Growth hormone-releasing factor secreting GRFomas cause acromegaly. These rare tumors are associated with MEN 1 in about one-third of cases.

TUMOR LOCALIZATION

Once clinical symptoms and/or biochemical testing identify a pancreatic endocrine tumor, imaging is necessary in order to determine the location of the primary tumor and whether metastatic disease is present. Traditional imaging with ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) is often used initially because these tests are widely available and noninvasive (Fig. 2). Unfortunately, the sensitivity of the tests is directly dependent on tumor size and many of the pancreatic endocrine tumors, specifically insulinomas, are small (<1 cm) and therefore difficult to detect. The sensitivity of these tests for recognizing primary pancreatic tumors is generally below 50%. The sensitivities for detecting liver metastases are significantly better but usually not above 80%. Imaging is further compromised by the variable location of tumors. For example, gastrinomas, which frequently occur in the duodenal wall, would be missed on imaging studies dedicated to viewing the pancreas.

Two other modalities for localizing endocrine tumors are being used with increasing frequency, endoscopic ultrasound (EUS) (Fig. 3) and somatostatin

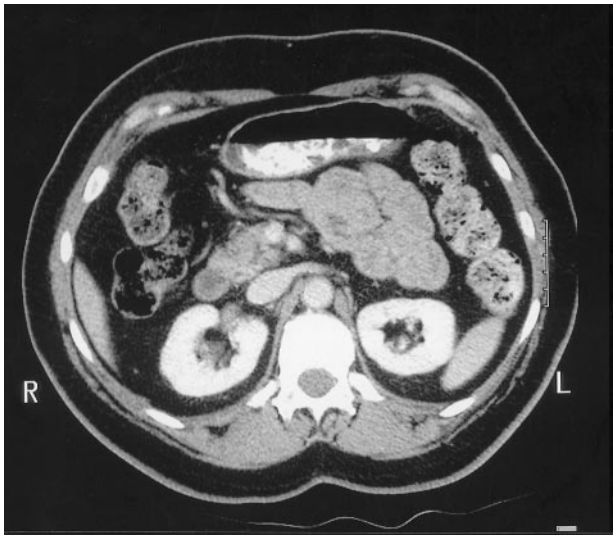

FIGURE 2 Computed tomography scan image of a nonfunctioning (asymptomatic) neuroendocrine tumor in the tail of the pancreas. The tomography scan was ordered to follow up an abnormal ultrasound of the liver, which was performed due to mildly elevated liver function tests. A pancreatic tumor is seen just above the left kidney and below the stomach. No hepatic metastases were present.

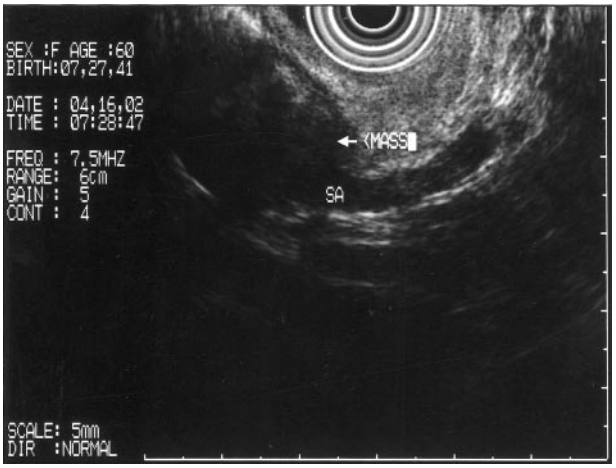

FIGURE 3 Endoscopic ultrasound image (7.5-MHz radial echoendoscope) of a nonfunctioning (asymptomatic) neuroendocrine tumor in the tail of the pancreas, as seen in Fig. 2. The mass is invading the splenic artery (SA) on this image, and also was invading the splenic vein.

receptor scintigraphy (SRS). The proximity of the EUS probe to the pancreas allows for detection of small structures, even those less than 5 mm. The reported sensitivity of EUS for pancreatic tumors is in excess of 80%. EUS is also able to evaluate extrapancreatic tumors in the duodenal wall and local lymph nodes with a sensitivity of over 50%. EUS requires specialized endoscopists and on occasion is unable to visualize the pancreatic tail adequately. Further advances in EUS are being made with the introduction of ultrathin probes, which actually cannulate the main inner duct of the pancreas. Because of their proximity to the pancreas, ultrathin probes provide detailed imaging and accurate detection of pancreatic endocrine tumors.

SRS is based on the high concentration of somatostatin receptors found in most pancreatic endocrine tumors. In SRS, a radiolabeled somatostatin analogue is injected into the patient's bloodstream and binds to tumors with somatostatin receptors. Subsequent imaging reveals the location of these tumors. The primary advantage of SRS is the ability to scan the entire body, including the pancreas, liver, surrounding lymph nodes, and duodenum. Although SRS detects PPomas, gastrinomas, VIPomas, and glucagonomas from 77 to 100% of the time, it is less successful in detecting insulinomas, with an approximate sensitivity of only 50%.

All of these techniques are not widely available, thus the ideal imaging technique is institution dependent. Newer innovations are continuously being refined and developed. The type of tumor dictates which imaging studies are most useful. Broadly speaking, the evaluation of insulinomas starts with one of the three traditional modalities, and if no tumor is found, EUS is often used as the next step. Gastrinomas and other endocrine tumors are well detected by SRS imaging; because of its superior detection rate for both primary and metastatic disease, SRS is often used in addition to traditional imaging. When further localization is needed, more invasive techniques of portal venous sampling and angiography are conducted.

Once a diagnosis is made and the location of the tumor is determined accurately, therapy is possible. Surgical resection is the primary treatment of nonmetastatic disease, and in metastatic disease, surgical debulking may play a role. MEN 1-associated pancreatic tumors, often being multiple and small, are more difficult to cure compared to sporadic cases. In the setting of metastatic disease, different chemotherapy regimens have been tried with variable success. Liver transplantation is increasingly being used in patients with metastatic neuroendocrine tumors.

Münchausen's and Münchausen by Proxy Syndromes

HILARY K. KLEIN
St. Louis University, Missouri

Münchausen by proxy syndrome Illness intentionally produced in a child by a parent who wants to be seen as concerned and caring.
Münchausen's syndrome Self-inflicted illness in a conscious attempt to gain attention.

Münchausen's syndrome (MS) is a psychiatric disorder in which patients self-inflict symptoms of illness in a conscious attempt to gain attention. Münchausen by proxy syndrome is a type of child abuse in which serious illness is intentionally produced in a child by a parent who wants to be seen as caring and concerned.

MÜNCHAUSEN'S SYNDROME

Münchausen's syndrome (MS) is a chronic psychiatric disorder in which patients consciously simulate or self-inflict symptoms of illness in repeated attempts to gain hospital admission. These patients seem to be motivated by the desire to play the sick role and to be the center of attention.

Clinical Features

Clinical features include the following: pathological lying with presentation of the history in a dramatic, vague, and inconsistent manner; evidence of prior treatment at various hospitals; multiple scars; medical sophistication; disruptive behavior while hospitalized; symptoms that shift from one organ system to another; tolerance for painful and invasive procedures; frequent demands for analgesic medications without signs of withdrawal when they are discontinued; and absence of visitors.

Symptoms of gastrointestinal cases include chronic diarrhea, abdominal pain, nausea and vomiting, ingestion of a foreign body, and patient-reported intestinal obstruction or inflammatory bowel disease.

Diagnosis

The diagnosis of MS is usually made by exclusion after diagnostic procedures have failed to elucidate a physiologic derangement. All means of noninvasive testing should be used to confirm a diagnosis of MS. For example, in cases of chronic diarrhea, stool testing for phenolphthalein, sulfate, magnesium, or anthracene derivatives can identify laxative use. Finally, psychiatric consultation should be sought.

Evidence gathering should be limited to situations in which significant morbidity or mortality is imminent. When imminent danger is not clear, legal and ethical consultation should be sought prior to initiating any action that violates the patient's rights to privacy and confidentiality. Obtaining the patient's consent for videotape surveillance has been successfully used in some cases because it provides these patients with the attention that may be a primary motivating factor in MS. None of these actions should be undertaken without first discussing the situation with legal personnel.

Treatment

Managing the patient with MS is difficult, with many patients continuing to deny their complicity in their illness and fleeing the hospital to avoid further confrontation. The primary goal of treatment is to prevent secondary complications from unnecessary tests and procedures. Staff that feels angry may make premature confrontations, resulting in discharge of the patient against medical advice. If confrontation of the patient is advisable, a psychiatrist can help to plan a conference where the disparities between the patient's presentation and findings are discussed with the patient. Confrontation, however, is not a cure. An offer for referral for psychiatric treatment can be made but these offers may be rebuffed. Co-morbid psychiatric disorders should be diagnosed and treated. Finally, the medical chart should be flagged in order to communicate the

 Copyright 2004, Elsevier (USA). All rights reserved.

necessity for definitive diagnostic testing prior to any invasive treatment.

MÜNCHAUSEN BY PROXY SYNDROME

Münchausen by proxy syndrome (MBPS) is a chronic form of child abuse in which the parent, usually the mother, produces serious illness in her child. She is usually motivated by a desire to be publicly recognized for her apparent devotion to the child. In approximately 25% of cases, the abusing parent also has a history of overt MS.

Clinical Features

Clinical features include the following: dramatic presentation of the history by a parent who claims to have saved the child's life; occurrence of illness events when the parent is present and absence of episodes of illness when the parent is separated from the child; and the absence of any independent observer who could corroborate the onset of the illness symptoms.

Diagnosis

Covert surreptitious videotaping in order to catch the parent in the act of abusing the child may frequently reveal a parent who ignores the child for long periods of time when no one else is present. It may also provide direct legal evidence of criminal behavior since the child may be unable to reveal the abuse. The necessity to protect a child from harm is a legal and ethical principle that takes precedence over the principle of confidentiality. A mortality rate of 9% and incalculable physical and psychological morbidity make intervention critical.

Treatment

The safety and protection of the child are the primary concerns. Other siblings may need protection as they have as much as a 25% risk that they are also being victimized. In addition, children who are victimized in this way have an increased risk of developing MS as adults. Suspicions must be reported to the appropriate child protective services agency immediately so that a formal investigation can proceed as quickly as possible.

Mycobacterial Infection

HYUN SIL KIM
University of California, San Diego

***Mycobacterium avium* complex** A member of the *Mycobacterium* family, it causes diffuse systemic infection in immunocompromised patients and can lead to cachexia, fever, and weight loss.

Mycobacterium tuberculosis An acid-fast intracellular bacterium that causes tuberculosis. The primary site of infection is the lung but infection can involve the gastrointestinal tract and can spread throughout the body, where it is termed miliary tuberculosis.

Mycobacterial infection of the gastrointestinal tract is relatively uncommon in the United States, although the number of reported cases has increased since the late 1980s due to the epidemic of acquired immunodeficiency syndrome (AIDS). *Mycobacterium tuberculosis* is the most common mycobacterial infection and accounts for the majority of mortality associated with mycobacterial infection. *Mycobacterium avium* complex is an opportunistic infection since it affects mostly immunocompromised patients, such as those who have AIDS, those on immunosuppressive medications, the severely ill, and the elderly.

INTRODUCTION

Mycobacterium is an acid-fast intracellular bacterium found throughout the world. In the United States, 90% of mycobacterial infections are caused by *Mycobacterium tuberculosis* (Mtb) and $<5\%$ are due to *Mycobacterium avium* complex (MAC). The influx of new immigrants from indigent areas with a high prevalence of Mtb and the epidemic of acquired immunodeficiency syndrome (AIDS) have presented a major challenge to patients and health care professionals in recent years, and the resurgence of Mtb and MAC infection in the United States has generated a renewed focus on the epidemiology and various treatment options for patients infected with mycobacterial organisms.

MYCOBACTERIUM TUBERCULOSIS

Historically, tuberculosis infection has been a major culprit of a significant mortality worldwide and over one-third of the world's population is currently infected with Mtb. Prior to the AIDS epidemic, Mtb infections were predominantly seen in immunocompromised patients and those who live in endemic areas, such as Southeast Asia, Africa, and Latin America. The disease is transmitted from person to person through respiratory aerosolization. In rare cases, tuberculosis infection of the gastrointestinal tract can occur when unpasteurized milk from *Mycobacterium bovis*-infected cattle is consumed.

Mtb infection of the intestine is relatively uncommon and it is usually seen in the setting of miliary tuberculosis. Gastrointestinal involvement by Mtb is thought to occur either by swallowing Mtb-infected respiratory secretions or by ingesting the organism directly. The most common sites of involvement are the terminal ileum, cecum, and appendix. Patients may present with abdominal pain, diarrhea, fever, weight loss, anorexia, and, in patients with severe pulmonary Mtb infection, cough and night sweats. Mtb lesions of the intestine initially may show mucosal ulcerations with necrosis or inflammation, but such complications as perforation, hemorrhage, fistula formation, and obstruction due to severe fibrosis can be seen in chronic infection. Often, enlargement of mesenteric lymph nodes accompanies intestinal infection and the lymph nodes can become caseous and granulomatous. It is thought that similar to pulmonary lesions, the pathogenesis of intestinal Mtb is mediated by lamina propria macrophages that ingest Mtb, which then release various pro-inflammatory cytokines and induce the host mucosal immune response, leading to caseating necrosis and inflammatory changes with granuloma formation, the pathologic hallmark of tuberculosis infection.

Diagnosis of Mtb infection is made by culture, histology, and most recently, polymerase chain reaction amplification techniques using tissue biopsies and stool specimens with Mtb organism-specific sequences. Histologic examination may reveal acid-fast bacilli with large foamy macrophages and granulomas. The treatment of Mtb requires multidrug regimens due to the high incidence of antibiotic resistance but is effective in most cases. A standard initial therapy includes isoniazid,

 Copyright 2004, Elsevier (USA). All rights reserved.

rifampin, and pyrazinamide, and other anti-mycobacterial agents, such as ethambutol and streptomycin, can be added according to the culture and susceptibility results. Occasionally, due to strictures and obstruction, surgical resection may be indicated.

MYCOBACTERIUM AVIUM COMPLEX

Although MAC infection is usually subclinical and self-limited in healthy individuals, it is a common gastrointestinal bacterial infection in AIDS patients whose CD4 counts are $<50-100/mm^3$ and in patients who receive immunosuppressive treatment. MAC can be found in many environmental sources, including water, soil, and dust. The pathogenesis of MAC infection is similar to that of Mtb, which involves the phagocytosis of the MAC organism by macrophages, leading to intense inflammatory responses resulting in observed clinical characteristics of diffuse systemic lymphadenopathy, organomegaly, and thickening of the intestine. In addition, MAC infection of the liver and biliary tree is common in AIDS patients. Infected patients typically present with persistent fever, diarrhea, abdominal pain, weight loss, and progressive wasting. MAC infiltration of the small intestine can lead to malabsorption and a severe wasting syndrome. Major intestinal bleeding and colitis with ulceration can be found in some patients with MAC infection. Diagnosis can be made by blood or bone marrow cultures or histology (e.g., intestinal or liver biopsy), which may demonstrate acid-fast organisms within enlarged macrophages.

The current recommendation for patients infected with human immunodeficiency virus and patients with AIDS whose CD4 counts fall below $50/mm^3$ is a prophylactic treatment against MAC infection with azithromycin, clarithromycin, or rifabutin. For those patients with documented MAC infection, treatment regimens include clarithromycin, ethambutol, rifabutin, ciprofloxacin, ofloxacin, or amikacin. Despite multidrug treatment, however, the response is slow, the eradication of MAC remains difficult, and many patients have a recurrence of symptoms from persistent MAC infection.

SUMMARY

Mycobacterium is the cause of significant mortality and morbidity throughout the world, and since the AIDS epidemic, two major mycobacterial organisms, *M. tuberculosis* and *M. avium* complex, have emerged as important agents that infect the intestine and cause diarrhea, inflammation, bleeding, and malabsorption. Careful workups that include necessary microbial studies to identify the organism are essential for the proper treatment and follow-up of patients.

Nausea

ROBERT M. STERN
The Pennsylvania State University

area postrema An area of the medulla where toxins can be detected and vomiting is initiated.
gastric tachyarrhythmia Abnormal dysrhythmic gastric activity that occurs at a frequency of 4–9 cycles per minute and that is often accompanied by reports of nausea.
optokinetic drum A device with alternating black and white vertical stripes that is rotated around a subject to provoke motion sickness.
vasopressin An antidiuretic hormone that is secreted by the posterior pituitary and that increases in the blood when subjects report nausea.
vection The illusion that a stationary subject is rotating caused by the rotation of the surround.

Nausea is a difficult-to-describe sick or queasy sensation usually attributed to the abdominal area. Nausea is similar to pain and fatigue in that it is an unpleasant sensation, but it may be crucial for survival. Very little is known, however, about the complex pathophysiology or biopsychosocial mechanisms of nausea.

INTRODUCTION

Nausea is often assumed to be the conscious awareness of unusual activity in the chemoreceptor trigger zone, the so-called vomiting center in the medulla of the brainstem, but despite numerous references to a vomiting center in the literature, the existence of such an anatomically well-localized structure remains controversial, as does its relationship, if any, to nausea. The subjective nature of nausea, as opposed to vomiting, with its easily observable and quantifiable characteristics, may partly account for the paucity of research and knowledge about nausea.

Nausea, in addition to being a sensation, is a complex control mechanism with multiple detectors that inhibits food intake in certain situations, such as when the available food is perceived as being disgusting, when the available food has been previously associated with nausea (conditioned taste aversion), or when one's stomach is not functioning normally.

Nausea is frequently followed by vomiting and sometimes the symptoms of nausea abate following vomiting. This sequence of events has led some to assume that nausea and vomiting are on a continuum. However, there are situations in which nausea is present to varying degrees, but the individual does not vomit, such as in some individuals receiving chemotherapy for cancer, and other situations in which individuals vomit without any sensations of nausea, such as astronauts in space. Furthermore, there are drugs, such as ondansetron, that act as anti-emetics, effectively reducing vomiting following chemotherapy, but that do little to relieve nausea. The relationship of nausea to emesis is obviously not simple or clear.

THE ROLE OF NAUSEA IN THE SURVIVAL OF THE ORGANISM

It is generally thought that in cases in which a toxin has been ingested, the biological basis for emesis is to remove the toxin, whereas the role of nausea is to create a conditioned aversion to that substance so that it will be avoided in the future. Such life-saving aversion might not develop in the absence of nausea, since uncomplicated vomiting may not be particularly noxious; e.g., a person might drink 10 beers, vomit, and drink 10 more beers.

Several investigators have discussed the role of nausea in each of four levels of toxin defense: (1) nausea and avoidance evoked by smell and taste; (2) detection of ingested toxins by gastric receptors followed by a central reflex that evokes nausea and vomiting; (3) detection of circulating toxins by chemoreceptors in the area postrema followed by a central reflex that evokes nausea and vomiting; and (4) detection of disturbances in normal sensory input and/or motor control. Disturbance of this system is often suggested to be the cause of the nausea and vomiting that are seen as symptoms of motion sickness.

As indicated above, nausea is a control mechanism and, as such, inhibits ingestion either when there may be something wrong with food being approached or eaten or when there may be something wrong with one's stomach; i.e., it is not functioning normally because of abnormal local activity or because of unusual signals

 Copyright 2004, Elsevier (USA). All rights reserved.

from the central nervous system. The survival value of avoiding foods that have made one nauseated in the past, conditioned taste avoidance, is obvious. Several authors have pointed out that the most potent internal event for producing taste aversion is nausea.

THE THRESHOLD FOR NAUSEA

There are large individual differences in the threshold for the complex control mechanism that is labeled "nausea" that depend on the interaction of inherent and situational factors and the threshold may change from moment to moment. What follows is a brief description of some of the factors that have been studied, but the list is not exhaustive nor are the factors included here thought to be independent.

Inherent Factors

1. Age: Younger people tend to report more nausea than older individuals.
2. Gender: Women report more nausea than men.
3. Race: Asian American people report more nausea than European Americans or African Americans.

Situational Factors

There is great overlap among the following situational factors and, indeed, what one investigator refers to as, for example, "anticipation," another may label "expectation."

1. Anxiety: Reports of nausea are common in patients with various anxiety disorders, such as generalized anxiety disorder, and it has been found that high anxiety contributes to greater side effects, including more nausea and vomiting associated with chemotherapy.

2. Expectation: Several studies have found that expectations about nausea prior to one's first chemotherapy treatment can lower that individual's nausea threshold.

3. Anticipation: Anticipatory nausea prior to chemotherapy is thought to be a learned response; it is seldom reported by patients who have not experienced nausea during previous treatments. Data tend to support a classical conditioning model with the chemotherapy nurse or the sight or smell of the clinic acting as the conditioned stimulus, the chemotherapy drugs acting as the unconditioned stimulus, and nausea and vomiting being the unconditioned response.

4. Adaptation: Adaptation occurs in most individuals exposed to provocative motion who are reexposed to the nauseogenic stimulus within 48 h.

5. Pregnancy: Nausea and vomiting during the first trimester of pregnancy are normal and common, but little is known about the cause, treatment, or role of nausea during the first trimester of pregnancy.

THE SUBJECTIVE EXPERIENCE OF NAUSEA

Nausea is a subjective experience and, as such, its occurrence and characteristics are best described by individuals experiencing the feeling. Health care professionals and caregivers tend to underestimate significantly the frequency, duration, and severity of nausea experienced by patients. A variety of self-report questionnaires have been developed to describe the experience of nausea. Visual analogue scales have been used frequently to describe its occurrence and severity. Morrow developed a questionnaire to assess the nausea and vomiting of cancer patients receiving chemotherapy based on the frequency, severity, and duration of nausea and vomiting.

In a recent study designed to explore the possibility that the experience of nausea may be very different in different situations and for different individuals, descriptors were obtained for the sensation of nausea from a large group of subjects voluntarily undergoing vection-induced motion sickness inside of a rotating optokinetic drum. The descriptors were factor-analyzed and Muth *et al*. developed a nausea profile. The results indicated that there are three dimensions of nausea that can be compared across subjects or patients in a variety of situations. Using this new questionnaire, a total nausea score is calculated, and a nausea profile is determined for each subject or patient that is composed of a score on each of three dimensions: bodily distress, gastrointestinal distress, and emotional distress.

PHYSIOLOGICAL CHANGES THAT ACCOMPANY THE DEVELOPMENT OF NAUSEA

Subjects who experience nausea when exposed to a rotating optokinetic drum show an increase in sympathetic nervous system activity and a decrease in parasympathetic nervous system activity, followed by a change in gastric myoelectrical activity from a regular 3 cycles per minute (cpm), the normal gastric frequency of humans, to dysrhythmic 4–9 cpm activity, or gastric tachyarrhythmia. The disruption in normal gastric myoelectrical activity is usually followed by reports of nausea and an increase in vasopressin levels in the blood.

Similar changes in gastric activity have been found in patients reporting nausea following chemotherapy, suggesting a similar role for the autonomic nervous system in the expression of nausea in that context.

Several studies have demonstrated that nausea is accompanied by abnormal dysrhythmic electrical activity in the stomach and little or no normal muscular activity. In short, the stomach is functionally shut down and may not be able to empty. If one were to eat while one's stomach was in this state, the food would remain in the stomach longer than usual, possibly leading to a feeling of fullness, epigastric discomfort, and more severe nausea.

Vasopressin, an antidiuretic hormone, is released by the posterior pituitary and increases in the blood of individuals who report nausea after injection of apomorphine, after cancer chemotherapy agents, and after the stimulation of sitting in a rotating chair. It is not clear in these situations whether plasma vasopressin increases immediately before or immediately after the experience of nausea, although several authors have stated that nausea causes an increase in vasopressin release. However, in those few experiments in which several vasopressin measurements were made over time rather than just one prestimulus and one poststimulus measurement, reports of nausea did not usually precede increases in vasopressin levels but rather the two phenomena covaried. In a more recent study by Xu *et al.*, gastric dysrhythmias preceded the onset of nausea and vasopressin release. Vasopressin levels in the blood of symptomatic subjects increased along with reports of nausea and decreased as nausea subsided. In contrast, levels of stress hormones, such as epinephrine, increased with reports of nausea, but did not decrease until long after nausea subsided. Asymptomatic subjects developed neither gastric dysrhythmias nor increased vasopressin release during exposure to drum rotation.

To summarize, the physiological measures that correlate highly with the development of nausea are increased sympathetic nervous system activity, decreased parasympathetic nervous system activity, increased gastric tachyarrhythmia, and increased plasma vasopressin levels.

preterm newborn Human born before 37 weeks of gestation.
term newborn Human born with or after 37 weeks of gestation.

Necrotizing enterocolitis is a disease of focal or diffuse ulceration and necrosis of the gastrointestinal tract, primarily the distal small bowel and colon, occurring in the newborn period.

EPIDEMIOLOGY

Necrotizing enterocolitis (NEC) is an almost exclusively newborn disease. The incidence is 1 to 3 in 1000 live births and the prevalence is 1 to 5% of all infants in neonatal intensive care unit, especially premature infants. There is no seasonal, geographic, or gender disparity. The age at onset of NEC is inversely related to birth weight and gestational age. Immature infants, particularly low-birth-weight (LBW) babies, are at prolonged risk as they can develop NEC as late as 10 weeks of age. Infants weighing less than 1000 g are particularly vulnerable. Advances in neonatal intensive care have improved survival of premature infants beyond the first days of life. This situation has been accompanied by a further increase in NEC-associated infant mortality, from 11.5 deaths per 100,000 live births in the presurfactant era to 12.3 in the postsurfactant era. Nevertheless, 10 to 35% of affected neonates are full-term infants with different risk factors than those found in premature infants (Table I).

PATHOLOGIC FINDINGS

The distal ileum and ascending colon are the areas mainly affected, although lesions have been noted throughout both organs. The earliest pathologic lesions are superficial mucosal ulceration and submucosal edema and hemorrhage with little infiltration of acute inflammatory cells, evidence against a primary infectious process. The mucosal process progresses to coagulative transmural necrosis, leading to perforation and, in some cases, intramural gas in the submucosa and subserosa. If there is no progression to complete transmural disease and perforation, healing occurs by epithelialization and fibroblast proliferation, and granulation tissue is laid down, sometimes leading to stenosis.

Changes in the neural elements within the intestinal wall have also been described in NEC. The pathological features resemble those of acquired hypoganglionosis and may result in dysfunctional intestinal motility.

PATHOGENIC MECHANISMS

NEC has a multifactorial pathogenesis with no evidence that there is one universal cause, although host prematurity is clearly the most important predisposing factor. Enteral feeding, ischemia, and infectious agents may contribute to the process (Fig. 1).

Enteral Feeding

Milk feeding is a nearly universal observation among patients with NEC. Oral alimentation may provide a substrate for bacteria, and during digestion and absorption, increased oxygen demand increases the risk of intestinal tissue hypoxia. Hyperosmolar feedings can directly damage the intestinal mucosa and may alter intestinal perfusion. Maldigestion of nutrients may be a contributory factor, particularly lactose maldigestion in the very premature infant because of a relative deficiency of the lactase enzyme. The lipid component of

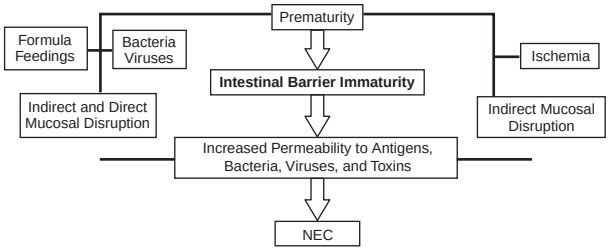

FIGURE 1 A proposed pathogenic framework for necrotizing enterocolitis.

formula may increase mucosal permeability, also predisposing to NEC. On the other hand, minimal enteral intake early after birth may facilitate gastrointestinal maturation and has not been shown to cause an increase in the incidence of NEC.

Artificial formula feeding compared with the feeding of human milk seems to predispose to NEC. Maternal milk remains an optimal source of nutrition, although for certain infants supplementation of feeding with special formulas is necessary. Breast milk contains elements that participate in classic host defense, such as immunoglobulin A (IgA), lymphocytes, and macrophages, which secrete anti-inflammatory substances, such as platelet activating factor-acetyl hydroxylase (PAF-AH). Other nonspecific host defense factors in human milk include complement, lysozyme, lactoferrin, and antioxidant compounds.

Ischemia

The pathologic findings in NEC are consistent with ischemic events, but case-control studies have identified few risk factors that might cause ischemia in the premature infant. However, the fact that NEC most commonly occurs in the distal ileum and proximal colon, which make up the watershed area of the superior and inferior mesenteric arteries, suggests that derangement of the circulatory system is involved. The occurrence of NEC in full-term infants and the predisposing risk factors (see Table I) also indicate that ischemia is an important etiologic factor in these infants.

In animals, the intestinal circulation in neonates has a decreased vascular resistance, an increased blood flow, and increased oxygen delivery when compared with older animals.

The vascular endothelium can help regulate vascular tone by producing vasoactive agents such as nitric oxide (NO) and PAF. PAF antagonists attenuate hypoxic ischemia and increased levels of PAF have been demonstrated in human preterm infants who have been fed. Other inflammatory mediators that may be involved in ischemia in NEC are tumor necrosis factor α, endothelin-1, and cachectin, a potent vasoconstrictor peptide. Lumenal nutrients, especially lipids, seem to intensify tissue injury from ischemia. Cocaine compromises the uterine blood flow and fetal oxygenation. In LBW or premature infants, the risk is two to three times higher in babies who have *in utero* exposure to cocaine than in controls.

Bacteria

The histopathology of the disease suggests that bacterial proliferation and invasion result from the already compromised intestinal mucosal barrier. The role of milk leukocytes in the protection against experimental NEC as well as the efficacy of feedings of an IgA–IgG supplement to premature infants in preventing NEC supports the implication of bacteria in the pathogenesis of NEC. No specific pathogen has been implicated but colonization with potential pathogens is thought to be a prerequisite to develop NEC.

Host Factors

Prematurity seems to be the most important factor in all of the epidemiologic studies of NEC. Up to 90% of the infants with NEC are of LBW and the disease is more frequent and more severe in those infants with the earliest postconceptual age.

Intestinal host defense components mature through the prenatal and perinatal period. Basal acid output, protease levels, IgA concentration in saliva, stool, and serum, and the number of intestinal T lymphocytes, and levels of other components, are low at birth. Intestinal motility is slower in the prenatal and perinatal period, potentially contributing to the overgrowth of bacteria.

The regulation of the immune response mediators also develops postnatally. In the human newborn, PAF-AH activity is decreased and PAF synthesis pathways are increased. This imbalance places the newborn at special risk of an increased PAF response before adequate immune stimuli are developed. The expression of defensins and epidermal growth factor receptor ("lumenal surveillance" peptides available to stimulate repair with a key role in intestinal maturation) is decreased in the preterm infant, as well.

CLINICAL FEATURES

The clinical course of NEC may vary from a slow, indolent process to a fulminant one. The classic triad of symptoms includes abdominal distension, bilious vomiting, and blood in the stools. Few patients have such a classic sequence of symptoms, but instead show less

specific signs indicative of generalized sepsis. Signs vary in the time of their appearance according to the severity of the disease process. The diagnosis is confirmed radiologically on the basis of pneumatosis intestinalis or air in the porta hepatis. Intestinal distension with multiple dilated loops of small bowel is most commonly seen, with separation of the loops suggesting mural edema. Pneumoperitoneum and intra-abdominal fluid are ominous signs, indicating the need for immediate surgical intervention. Levels of IL-6 in umbilical cord blood and reducing substances, α1-anti-trypsin, endotoxin, and short-chain fatty acids in the stool may be early signs of the disease. Portal vein ultrasonography is useful especially when the abdominal radiograph gives normal or nonspecific results. Although these tests may be helpful, they have not replaced the clinical presentation and plain abdominal radiograph in the diagnostic evaluation. A set of diagnostic criteria have been designed as a helpful tool in effecting some uniformity in therapeutic decision-making (Table II). Signs of clinical decompensation accompany the advancing course of NEC. Bowel necrosis generally accompanies this clinical deterioration.

TREATMENT

The management of the infant with NEC is largely supportive. As soon as the diagnosis is suspected, certain measures are undertaken to prevent the progression of the disease. All oral feedings are withheld and a nasogastric tube is placed either to gravity or very gentle suction. Intravenous access is ensured to provide fluids, electrolytes, and nutrition while enteral feedings are withheld. The duration of restriction of oral intake depends on the confirmation of the diagnosis of NEC, which is dictated by the radiographs and the clinical status. The reinstitution of feedings generally is done in a slow and cautious manner, using an elemental formulation to allow for optimal absorption of all nutrients and to avoid further potential injury to the intestinal mucosa.

Cultures of blood, stool, urine, and cerebrospinal fluid are obtained and broad-spectrum parenteral antibiotics are given. It is important to know the prevailing flora of the infants in the neonatal intensive care unit (NICU) and the current NEC bacteriology as NEC cases cluster, as does the predominant organism. Fluid and electrolyte monitoring is essential because large third-space losses may occur with edema and severe metabolic acidosis. Perfusion and blood pressure must be maintained. An abdominal radiograph is obtained to look for the pathognomonic signs of NEC and is repeated periodically to assess the progression of the disease as well as to determine the existence of pneumoperitoneum, indicating perforation.

Different experimental therapies have been studied, mostly in animal models, to prevent the onset of the disease or to diminish its severity. L-Arginine, to increase the NO production, vitamin E, to function as an antioxidant agent, and recombinant PAF-AH have been proposed as preventive or therapeutic agents. None of these has gained universal acceptance.

The indications for surgery include pneumoperitoneum and cellulitis of the anterior abdominal wall, suggesting peritonitis and gangrenous bowel. The classic operative approach consists of resection

TABLE II Staging Criteria for the Management of Necrotizing Enterocolitis

Stage I (Suspect)
- a. Any one or more historical factors producing perinatal stress
- b. Systemic manifestations: temperature instability, lethargy, apnea, bradycardia
- c. Gastrointestinal manifestations: poor feeding, increasing pregavage residuals, emesis (may be bilious or test positive for occult blood)
- d. Abdominal radiographs show distension with mild ileus

State II (Definite)
- a. Any one or more historical factors
- b. Above-mentioned signs and symptoms plus persistent occult or gross gastrointestinal bleeding; marked abdominal distension
- c. Abdominal radiographs show significant intestinal distension with ileus, small bowel separation (edema in bowel wall or peritoneal fluid), unchanging or persistent "rigid" bowel loops, pneumatosis intestinalis, portal vein gas

Stage III (Advanced)
- a. Any one or more historical factors
- b. Above-mentioned signs and symptoms plus deterioration of vital signs, evidence of septic shock or marked gastrointestinal hemorrhage
- c. Abdominal radiographs may show pneumoperitoneum in addition to others listed under IIC

Reprinted from Bell, M. I., *et al.* (1987). Neonatal necrotizing enterocolitis: Therapeutic decisions based upon clinical staging. *Ann. Surg.* **187**, 1, with permission.

of the grossly gangrenous bowel and proximal enterostomy. A conservative approach to surgery when a significant amount of the small bowel is affected involves a proximal enterostomy without resection and a return to the operating room usually within 1 week to assess the damage to the intestine. This approach diminishes the incidence of short gut syndrome. In clinically deteriorated patients and in extremely premature infants, short-duration procedures have been explored. In premature infants with intestinal perforation, drainage alone may allow acute improvement with subsequent laparotomy for definitive treatment.

PROGNOSIS

The decrease in the mortality rate over the years (from 78 to 20%) is most likely due to earlier diagnosis combined with intensive medical and surgical therapy. Mortality is directly related to the presence of bacteremia and low birth weight as well as lower gestational age. Morbidity related to long-term complications is seen in 10 to 30% of affected children.

Strictures of the intestines, particularly in the colon, are the most common sequelae of NEC, occurring in 10 to 36% of survivors. Some of these spontaneously resolve, whereas others require more aggressive treatment, such as surgery.

The short gut syndrome is seen in a small number of the surgically treated infants and survival after extensive resection can occur. If more than 70% of the intestine is removed, serious nutritional-consequences prevail. Preservation of the terminal ileum and of the ileocecal valve is an important survival factor.

Overall, the prognosis for infants surviving the acute stage of NEC is good. Patients discharged from their primary hospitalization have a greater than 80–95% chance of long-term survival with a good quality of life in 75% of patients.

PREVENTION

Since there is no specific treatment for the disease, research has been directed at prevention of the disease. NEC might be ameliorated if the factors important in its pathogenesis, such as bowel ischemia, bacterial proliferation, and the effects of oral feeding or gut immaturity, were eliminated or decreased.

Feeding

A very slow regimen for increases in feeding with maternal milk is optimal. Alternatively, a formula containing low-osmolar protein hydrolysate, easily digested glucose polymers, and MCT oil seems to be most prudent for initiating artificial-formula feedings in sick, LBW infants. Omega-3 fatty acids and egg phospholipid-containing diets have been used. These lipids seem to have an anti-inflammatory effect and a significant decrease in the incidence of stage III NEC in premature infants born prior to 32 weeks of gestation.

Bacterial Proliferation

The use of prophylactic antibiotics in treating bacterial proliferation has been shown to be ineffective in preventing NEC. Supplementing formula with an IgA–IgG preparation in LBW babies (in whom mucosal sIgA is suboptimal) was shown in some studies to prevent the development of NEC although further studies have failed to prove the advantage of oral IgG as a preventive measure.

Host Maturation

Since immaturity is the most significant predisposing factor, strategies directed toward making the immature intestinal barrier more potent have been investigated. The effectiveness of host defense enhancement has been demonstrated for breast milk macrophages in the rodent model of NEC. Corticosteroids, other hormones, and growth factors stimulate the maturation of the intestinal barrier. Furthermore, in the suckling rat, these agents accentuate the sequence of glycoconjugate development on the intestinal surface necessary for bacterial attachment and colonization to occur, stimulate the metabolism, and inhibit the synthesis of PAF. Corticosteroids have also been shown to be effective in preventing the occurrence of NEC in some studies in humans.

autoinfection Replication of a nematode parasite within the primary host.
larva Immature form of a nematode that requires molting to develop to adult stage.
molting Process of developmental transformation toward the adult worm stage.

In terms of global health and disease, nematodes (roundworms) stand out as a most important class of human parasite. Billions of people worldwide are infected with one or more species of nematode. The adult stage of many parasitic nematodes commonly resides in the intestine, although some are localized to the bloodstream, lymphatics, or somatic tissues. Those nematode parasites that reside in the intestinal tract cause a variety of gastrointestinal symptoms, including pain, vomiting, and diarrhea, in addition to physiologic, neurologic, immunologic, and systemic symptoms.

GASTROINTESTINAL NEMATODES

Ascaris lumbricoides

Ascaris lumbricoides is the largest intestinal nematode that infects humans; adult worms reach up to 30 cm in length. Ascariasis has a worldwide distribution, with more than 1 billion people infected in both rural and urban environments. Infection occurs when eggs shed in the feces of the host are ingested. The eggs embryonate, hatch, and release first-stage larvae in the small intestine. These larvae penetrate the mucosa, enter the venous circulation, and are carried to the lungs, where they access the alveolar space. The larvae then migrate up the trachea and are swallowed, ultimately returning to the small intestine. During this migration the worms undergo a series of developmental molts and eventually become adults. Light to moderate infections with *Ascaris* may be asymptomatic, whereas heavy infections may cause fatal obstruction of the intestine. Additionally, adult worms may aberrantly migrate from the intestinal lumen to the appendix, liver, or pancreas. In these cases, infection with even a single worm may cause severe complications.

Ascaris infection is routinely diagnosed by identifying eggs in the feces under light microscopy. The eggs are ovoid in shape and range from 45 to 70 μm long by 30 to 50 μm wide (Fig. 1). The recommended treatments for ascariasis include albendazole (400 mg orally, single dose), mebendazole (100 mg/day orally for 3 days), or pyrantel pamoate (11 mg/kg/day for 3 days), each of which is highly effective at eradicating the infection. The initiation of therapy may trigger active movement of the adult worms, leading to obstruction or extraintestinal migration. Strategies for prevention of initial infection include sanitary disposal of solid human waste to avoid contamination of food sources with eggs, as well as targeted chemotherapy directed at high-risk populations.

Hookworms: *Necator americanus* and *Ancylostoma* spp.

Infections with the human hookworms, *Necator americanus* and *Ancylostoma duodenale*, are a leading cause of iron-deficiency anemia in the developing world. Although eventually eradicated due to the efforts of the Rockefeller Sanitary Commission, hookworm was a major public health problem in the southeastern United States during the first half of the twentieth century. Presently, hookworms remain endemic throughout much of Central and South America, Africa, and Asia.

Infection with hookworm occurs when a mammalian host contacts free-living infective (filariform) larvae. These larvae quickly penetrate the host skin and travel via the venous bloodstream to the lungs, where they exit blood vessels and enter the airway. The larvae then migrate up the trachea, are swallowed to gain access to the small intestine and molt to the adult stage. There the adult hookworms attach to the small intestine and lacerate mucosal vessels using cutting plates or teeth in their buccal capsule. Adult hookworms mate and release eggs in the feces of the infected host.

The pathogenesis of hookworm anemia is a direct result of intestinal blood loss that occurs during adult worm attachment to the mammalian small intestine. Each adult hookworm may feed on up to 0.2 ml of blood per day, with some infected individuals harboring hundreds to thousands of parasites. Iron-deficiency anemia and protein malnutrition are the primary clinical illnesses associated with hookworm infection. In children, especially those with concomitant dietary iron deficiency, the chronic effects of hookworm may ultimately lead to growth and cognitive delays. In Australia, human infection with the dog hookworm, *Ancylostoma caninum*, has been implicated as a cause of eosinophilic enteritis, often associated with the presence of a single adult blood-feeding worm.

The diagnosis of hookworm infection is made by identifying eggs in the feces by light microscopy (Fig. 1). Laboratory evaluation may reveal iron-deficiency anemia, hypoalbuminemia, and mild eosinophilia. Recommended treatments for hookworm include albendazole (400 mg orally, single dose), mebendazole (100 mg/day orally for 3 days), or pyrantel pamoate (11 mg/kg/day for 3 days). Prevention of infection can be accomplished by taking preventive measures to limit exposure to the

infective larvae. Proper waste disposal, including avoidance of the use of human feces as fertilizer (night soil), is the primary method employed to remove infective larvae from the environment.

Trichuris trichiura (Whipworm)

Trichuris trichiura, or whipworm, occurs in most parts of the world where other soil-transmitted helminths, e.g., *Ascaris* and hookworm, are found. Infection occurs when ingested eggs hatch in the intestine and develop into adults when they reach the large intestine. Although most individuals with light infection are asymptomatic, heavily infected individuals may experience a severe inflammatory colitis associated with significant hemorrhage (*Trichuris* dysentery). Chronic infection in children has been associated with rectal prolapse, as well as growth delay and cognitive deficits. The diagnosis of *T. trichiura* infection requires identification of the characteristic oval, operculated eggs in the feces (Fig. 1). The recommended treatments for whipworm include albendazole (400 mg orally, single dose) or mebendazole (100 mg/day orally for 3 days), although *Trichuris* is resistant to pyrantel pamoate. Prevention of infection is accomplished by the sanitary disposal of contaminated feces.

Enterobius vermicularis (Pinworm)

Human infection by the parasitic nematode *Enterobius vermicularis*, or pinworm, is the most common nematode infection in developed countries. Pinworm infections are often found in preschool-aged children, particularly those who are not toilet trained. Adult female worms, which may grow to 1 cm in length, reside in the large intestine. At night, the females migrate out of the body and release eggs on the perianal skin. The eggs become infective within several hours, and the life cycle is completed when the eggs are ingested and hatch, to release the larval form of the worm in the host small intestine. The pinworm larvae undergo several molts, eventually developing into adults when they reach the colon. Pinworm eggs are light and may be dispersed in fomites, potentially spreading the infection in institutions and daycare centers because of contamination of environmental surfaces.

The clinical sequelae of pinworm infection are generally mild, and include pruritus ani and superficial cellulitis of the perianal skin. However, aberrant migration of adults has also been recognized to cause urinary tract infection and salpingitis in girls, as well as appendicitis. Local colonic inflammation may also give rise to abscess formation characterized by a profound eosinophilic infiltrate. An association between pinworm and infection with the protozoan parasite *Dientamoeba fragilis* has also been reported. The diagnosis can be made using the "Scotch tape test," in which adhesive tape that has been applied to the perianal skin is examined under a microscope for the presence of eggs. The eggs are ovoid and measure 50–60 μm long by 20–30 μm wide (Fig. 1). The recommended treatment for *E. vermicularis* infection is albendazole (400 mg orally) in a single dose, or mebendazole (100 mg orally) or pyrantel pamoate (11 mg/kg orally), in one dose, with a second dose 14 days later to treat the recently developed adult worms.

Strongyloidiasis

Strongyloidiasis is the disease caused by the nematode parasites *Strongyloides stercoralis* and *Strongyloides fuelleborni*. *Strongyloides stercoralis* is endemic throughout the tropics and subtropics, including parts of the southeastern United States. In contrast, *S. fuelleborni* is found primarily in the South Pacific, particularly in Papua New Guinea, as well as in parts of Africa. Infection occurs when free-living larvae penetrate the host skin and travel to the lungs via the venous circulation. In the lungs, the larvae enter the airways and migrate up the trachea and are swallowed. In the small intestine, the worms develop to the adult stage and embed within the intestinal epithelium. Eggs are shed by adult female worms into the gut and develop into larvae to be released in the feces. The life cycle of *Strongyloides* is unique in two respects. First, unlike nearly all other parasitic nematodes, the worm can complete a free-living life cycle outside the host, with larvae developing in the soil to mature adults. Second, larvae may develop to the infectious filariform stage during transit in the gut, ultimately penetrating the colonic mucosa or perianal skin to complete their life cycle within a single host. This process, termed autoinfection, may have severe consequences in certain hosts, particularly those who are receiving glucocorticoids for the treatment of malignant or autoimmune diseases. In addition, autoinfection explains how certain individuals remain infected with *S. stercoralis* for decades after leaving endemic areas.

Most patients with chronic strongyloidiasis are asymptomatic, although diarrhea and nonspecific abdominal pain may occur. Penetration of the skin by infectious larvae may be associated with a pruritic and erythematous rash, referred to as larva currens (racing larva), which, in cases of autoinfection, may be localized to the perineum and buttocks. Children with *S. fuelleborni* infection may present with a constellation of findings known as "swollen belly syndrome," characterized by severe abdominal distension, malnutrition,

and lethargy. Disseminated strongyloidiasis occurs in immunocompromised hosts, often following treatment with cytotoxic chemotherapy or glucocorticoids. In this setting, increased numbers of larvae undergo the autoinfective cycle, leading to amplification of the infection and overwhelming larval migration. Such patients may develop a hemorrhagic pneumonitis from massive larval transit through the lungs, or a secondary meningitis caused by bacteria carried with larvae that penetrate the central nervous system.

Laboratory test results generally reveal mild to moderate eosinophilia along with increased levels of circulating immunoglobulin E (IgE). Serologic assays are available to detect serum antibodies to *S. stercoralis*, although cross-reactivity with other parasitic nematode infections can occur. The definitive diagnosis of *Strongyloides* infection is accomplished by identification of the first-stage (rhabditiform) larvae in the feces of the host. Because egg production is low, it may be necessary to employ stool-concentrating techniques or to test multiple samples in order to confirm the diagnosis. Disseminated strongyloidiasis should be suspected in patients receiving glucocorticoid therapy who present with bacterial meningitis caused by enteric pathogens. Larvae may also be detected in sputum or lung biopsy specimens. Interestingly, most patients with disseminated infection do not have peripheral eosinophilia. The recommended treatment for chronic strongyloidiasis is ivermectin (200 μg/kg/day for 2 days). An alternative therapy is thiabendazole (50 mg/kg twice daily for 3 days), although this agent is associated with more significant side effects. Treatment of disseminated disease with ivermectin (200 μg/kg/day) should be continued for atleast 1 week. Because the mortality from disseminated strongyloidiasis is high (at least 50%), screening of individuals from endemic areas prior to initiation of immunosuppressive therapy is essential, because even those who are asymptomatically infected should be treated.

Trichinella

Infection with *Trichinella spiralis* occurs throughout most of the world, perhaps due to its lack of an environmental life cycle stage. Infection occurs after ingestion of raw or undercooked meat containing encysted *T. spiralis* larvae. The encysted larvae are released, migrate to the small intestine, penetrate the columnar epithelium, and develop into adult worms. Adult females release motile larvae that enter the host circulatory system and migrate to somatic tissues, including striated muscle. The larvae remain within a specialized cell termed a nurse cell, where they await consumption by a new host.

Acute symptoms associated with ingestion of contaminated meat include nausea, vomiting, diarrhea, and fever. A second phase of illness, characterized by the migration of larvae to somatic tissues, is characterized by edema of the face and eyelids, muscle pain, fever, and conjunctivitis. Both myocarditis and respiratory symptoms may also occur secondary to the host inflammatory response directed at larvae invading the heart and diaphragm, respectively. The diagnosis of *Trichinella* infection requires a high index of suspicion. Eosinophilia is a nearly universal laboratory finding, and levels may reach 50% or greater of the total leukocyte count. A definitive diagnosis is made by identifying encysted larvae in a muscle biopsy. Serologic testing is available through specialty laboratories and the United States Centers for Disease Control and Prevention. A history of raw or undercooked meat consumption, especially pork or horsemeat, is suggestive of the diagnosis.

The role of antihelminthic therapy in the management of trichinellosis is controversial, because the activity of most available agents against tissue-encysted larvae is variable. Both mebendazole (200 mg twice a day for 10 days) and thiabendazole (25 mg/kg twice a day for 10 days) have been reported to improve symptoms of trichinellosis in adults compared to placebo, although thiabendazole was associated with significant side effects. Albendazole (400 mg twice a day) is also recommended. Oral prednisone may be helpful in relieving inflammatory symptoms associated with *Trichinella* infection.

biliary atresia Progressive fibro inflammatory process resulting in obliteration of the extra hepatic biliary duct in infants.
cholestasis Condition in which bile excretion is blocked.
***FIC1* gene** Familial intrahepatic cholestasis gene involved in inherited disorders of neonatal cholestasis.
progressive familial intrahepatic cholestasis Inherited disorders of neonatal cholestasis.

Neonatal cholestasis is defined as an impairment of bile flow in the first 3 months of life. It is generally associated with a measured conjugated (direct-acting) bilirubin fraction of greater than 2 mg/dl or more than 20% of the total bilirubin. Prolonged conjugated hyperbilirubinemia in the newborn period is never physiologic and always requires an expeditious evaluation. The incidence of neonatal cholestasis is estimated to be about 1 in 2500 live births. There are multiple causes of cholestasis in the first 3 months of life, of which the majority fall into a few discrete yet overlapping categories. The importance of prompt recognition and definitive diagnosis of neonatal cholestasis cannot be overemphasized. Many causes of cholestasis, such as sepsis, endocrinopathies, galactosemia, fructosemia, tryosinemia, inborn errors of bile acid synthesis, biliary atresia, and choledochal cyst, are either reversible or treatable.

INTRODUCTION

Although the list of disorders causing neonatal cholestasis seems exhaustive (Table I), idiopathic neonatal hepatitis and biliary atresia account for over 60% of all cases. The overlap of these entities has been well recognized, and in 1974, Benjamin Landing, a pediatric pathologist, proposed that biliary atresia, neonatal hepatitis, and choledochal cyst represent a spectrum of disease, resulting from a unifying process. He observed that histologically all three disorders share common findings that include syncytial giant cell transformation of hepatocytes, extramedullary hematopoiesis, lobular disarray, and cellular and canalicular cholestasis with variable degrees of portal and lobular inflammation. He proposed that a viral infection primarily affecting either the hepatocyte or cholangiocyte was responsible for these entities and coined the term "infantile obstructive cholangiopathies."

In general, disorders of extrahepatic obstruction present in an asymptomatic, thriving infant who has clinical jaundice. Often the infant is seen in the clinic because neighbors, family, or friends comment on the infant's yellow skin color. Further investigation will reveal an otherwise healthy infant with light or acholic stools, dark urine, and the presence of hepatomegaly without splenomegaly. Initial laboratory analysis will reveal a moderate direct hyperbilirubinemia, elevated canalicular enzymes (alkaline phosphatase and γ-glutamyl transferase), and normal to mild elevation of amino-transferases. Early in the disease process, growth velocity is normal and hepatic synthetic function, clotting factors, and albumin are preserved.

Infants with cholestasis as a result of an infectious origin usually have a male predominance and failure to thrive or growth failure. An infectious risk may or may not be identified. These infants usually have a marked elevation of serum aminotransferases, variable elevation of canalicular enzymes, and a modest coagulopathy that is commonly a result of mild disseminated intravascular coagulation (DIC). Skin lesions or intracranial calcifications may be pathognomonic.

Infants suffering from a metabolic defect often have mild growth failure and present with a sepsislike picture manifested as hepatic synthetic dysfunction. Metabolic disease may present with ascites and a coagulopathy out of proportion to elevated aminotransferase or canalicular enzymes. These infants have the most varied presentation in terms of age at onset, associated symptoms, and rate of progression to hepatic failure. The clinical course depends on the underlying metabolic disorder.

EXTRAHEPATIC NEONATAL CHOLESTASIS

Biliary atresia is the most common cause of obstructive cholestasis in infants younger than 3 months of age. This disorder occurs in 1 in 8000–15,000 live births and is

TABLE I Classification of Cholestatic Disorders[a]

Classification	Example
I. Bile duct obstruction	
Extrahepatic disorders	Biliary atresia, choledochal cysts, spontaneous perforation of common bile duct, Caroli's disease, bile duct stenosis, cholelithiasis, tumors/masses (intrinsic and extrinsic)
Intrahepatic disorders	Alagille's syndrome, nonsyndromic paucity of intrahepatic ducts, neonatal sclerosing cholangitis, congenital hepatic fibrosis, inspissated bile/mucous plug
II. Neonatal Hepatitis	
Viral	Cytomegalovirus, herpes (simplex, zoster, human type 6), rubella, reovirus type 3, adenovirus, enteroviruses, parvovirus B19, hepatitis B, human immunodeficiency virus, bacterial and parasitic, bacterial sepsis, listeriosis, tuberculosis, toxoplasmosis, malaria
Idiopathic	
III. Cholestatic syndromes	
Progressive familial intrahepatic cholestatis caused by transport defects	Type 1 (Byler's disease, defect in FIC1, a P-type ATPase), type 2 (defect in BSEP, canalicular bile acid pump), type 3 (defect in MDR-3, a canalicular phospholipid transporter)
Hereditary cholestasis with lymphedema (Aagenaes syndrome)	
Cholestasis in North American Indians	
Nielsen syndrome (Greenland Eskimos)	
Benign recurrent cholestasis (defect in same gene as PFIC type 1)	
IV. Metabolic disorders	
α1-Antitrypsin deficiency	
Cystic fibrosis	
Neonatal iron storage disease	
Endocrinopathies	Hypopituitarism (septooptic dysplasia), hypothyroidism
Amino acid disorders	Tyrosinemia, hypermethionemia, mevalonate kinase deficiency
Lipid disorders	Niemann–Pick disease, Gaucher's disease, Wolman's disease, cholesterol ester storage disease
Urea cycle disorders	Arginase deficiency
Carbohydrate disorders	Galactosemia, fructosemia, glycogen storage disease type IV
Mitochondrial disorders (respiratory chain)	
Peroxisomal disorders	Zellweger syndrome, infantile Refsum's disease, other enzymopathies
Bile acid synthetic defects	3β-Hydroxy-Δ^5-C_{27}-steroid dehydrogenase isomerase, Δ^4-3-oxosteroid 5β-reductase, oxysterol 7α-hyroxylase
V. Toxic	
Drugs, parenteral nutrition, aluminum	
VI. Miscellaneous Associations	Shock/hypoperfusion, histiocytosis X, neonatal lupus erythematosus, Indian childhood cirrhosis, autosomal trisomies, graft-versus-host disease, erythrophagocytic lymphohistiocytosis, extracorporeal membrane-oxygenation, venoocclusive disease, Donahue syndrome (leprechaunism), arthrogryposis, cholestatic pigmentary-disease, renal dysfunction syndrome, erythro-blastosis fetalis

[a] Modified with permission from Suchy F. (2001), Approach to the infant with Cholestasis. *In* "Liver Disease in Children" (Suchy, Sokol and Balistreri, eds.). Copyright Lippincott, Williams & Wilkins, 2001.

slightly more common in females and infants of Asian or African American descent. Formerly called extrahepatic biliary atresia, it is now clear that this disorder results from a progressive inflammatory sclerosing fibroobliterative process involving both the intra- and extrahepatic ducts in the majority of infants. The result is biliary ductular luminal obliteration and the development of biliary cirrhosis. If untreated, biliary atresia is uniformly fatal by 2 years of age. Death results from end-stage liver disease, portal hypertension, and variceal

bleeding. Biliary atresia is the leading indication for liver transplantation in children, accounting for 50% of all pediatric liver transplants.

Biliary atresia is a clinicopathologic entity and as proposed by Landing may represent a spectrum of disorders. There has been no familial clustering, and reports of discordance in monozygotic twins do not support a classic genetic basis for the disease. There appear to be two distinct phenotypes, an embryonic or fetal type and a perinatal type. Although the clinical consequences of the embryonic or fetal type of biliary atresia are similar to the classic or perinatal form, the etiologies may be very different.

Etiology of Biliary Atresia

The embryonic or fetal type accounts for approximately 20% of all cases and is associated with other congenital anomalies (e.g., polysplenia syndrome). Associated congenital anomalies include malrotation of abdominal viscera, interrupted inferior vena cava, midline liver, preduodenal portal vein, polysplenia, situs inversus, and congenital heart anomalies. Early-onset cholestasis and acholic stools characterize this form of biliary atresia, which may be caused by a defect in morphogenesis of the biliary tree. It is proposed that the constellation of anomalies is caused by abnormalities of laterality. A disorder similar to biliary atresia—polysplenia syndrome exists in the *inv* mouse. This transgenic mouse has a recessive deletion of the inversion (*inv*) gene that results in situs inversus and obstructive jaundice. Studies suggest that abnormalities in the human orthologue of the inversion gene might be involved in the fetal form of biliary atresia. However, no mutations in the *INV* human gene have been found in human patients with biliary atresia.

The perinatal form of biliary atresia is far more common and accounts for almost 80% of all cases. It is believed to occur at or following birth with progressive postnatal destruction of a normally formed biliary tree. Clinically, the infant presents with later-onset jaundice following a jaundice-free period. The jaundice-free period may be obscured by breast-feeding jaundice. Although the pathogenesis of this form of biliary atresia is not understood, several factors have been proposed and are undergoing investigation. Most data suggest that there is an infectious, probably viral, insult with a secondary immunologic pathogenesis that is specific to the neonate less than 3 months of age. The most promising viral etiologies currently under investigation include reovirus type 3, and rotavirus group C.

Observations of the similarity of weanling mice with hepatic histologic lesions due to infection with reovirus type 3 and infants with biliary atresia raised interest in reovirus as a candidate pathogen for biliary atresia. Two large series of patients with neonatal cholestasis detected serologic evidence of reovirus infection in 60% of infants with biliary atresia or neonatal cholestasis, versus 12% of controls or patients with other cholestatic disorders. Reovirus antigen and viral particles have been found in the bile duct of an infant rhesus monkey that spontaneously developed a disorder similar to biliary atresia. Reovirus antigen and viral-like particles have also been identified in bile duct remnants resected from infants with biliary atresia. Although other investigators have not shown an association, this may reflect the age of the patient when studied, tissue preparation, and viral isolation techniques. Utilizing a reverse transcriptase and polymerase chain reaction (RT-PCR) assay specific for Reovirus RNA, virus was detected in over 50% of patients with perinatal biliary atresia (11/20), in none of the fetal type of biliary atresia (0/3), and in 80% (7/9) of infants with a choledochal cyst. Reovirus virus was detected in only 8–15% of autopsy controls or infants less than 1 year of age with other liver disease.

Rotavirus C, another virus of the Reoviridae family, has recently attracted interest as a candidate pathogen for biliary atresia. Studies in which rotavirus was administered orally or by intraperitoneal injection to newborn mice resulted in an intrahepatic lesion strikingly similar to human biliary atresia. Further studies have shown that this model mimics human biliary atresia, resulting in extrahepatic biliary atresia and intrahepatic cholangitis with bile duct proliferation. Studies using interferon α (IFNα), an antiviral that disrupts viral replication, prior to rotavirus infection aborted this disease progression. There was no protective effect if the antiviral was given after infection. Investigation of patients with biliary atresia for evidence of rotavirus has been inconclusive and probably reflects intrinsic problems with study design and patient selection. The similarities between the infant mouse models of reovirus and rotavirus infection and the association of at least one study demonstrating a 50% frequency of each virus in patients with biliary atresia warrant further investigation. Additionally, human papillomavirus has recently been proposed as another candidate virus associated with neonatal cholestasis.

The multihit hypothesis of the etiology of perinatal biliary atresia is gaining popularity. This hypothesis proposes that there is a genetic/immune predisposition, which requires a viral infection at the appropriate time, resulting in the exposure of neoantigens on biliary epithelium, simulating an inflammatory process. The importance of biliary atresia as a significant disorder of

infancy that is the primary indication for pediatric liver transplantation has resulted in the National Institutes of Health (NIH)-supported Biliary Atresia Clinical Research Consortium. This consortium of nine large pediatric liver centers will embark on an effort to define the etiology and to improve current treatment outcomes.

Despite these recent advances, the etiology of biliary atresia remains elusive. Prognosis is dependent on an accurate and timely diagnosis and subsequent surgical intervention to restore bile flow.

Diagnosis of Biliary Atresia

In the diagnosis of biliary atresia, patient history should be compatible with an obstructive presentation. Infants are usually healthy appearing, thriving, with clinical jaundice, hepatomegaly, and rarely splenomegaly. Stools are consistently acholic. Many first-time parents may not recognize the stools as unusual, thus direct examination of the stool is often beneficial. There is no single laboratory or radiology test to diagnosis biliary atresia definitively. Abdominal ultrasound often will note the absence of the gallbladder, but the presence of a gallbladder on ultrasound does not rule out biliary atresia. Importantly, obstructive cholestasis in the neonatal liver results in ductular neoproliferation and not ductular dilation as in the adult. Radionucleotide imaging has been used to determine biliary obstruction. Early in the disease, patients with biliary atresia will have good uptake of radiolabel from the circulating pool, but no excretion into the bowel after 24 hours. Many other disorders, however, will mimic this pattern, and this test will not eliminate the need for histologic analysis. Novel approaches to define the biliary tree include endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiogram (MRC). These tests currently remain investigational. Evaluation of hepatic tissue reveals periportal inflammation, bile ductular proliferation, bile plugs, and occasional giant cell transformation, with relative preservation of hepatic lobular architecture. Intraoperative cholangiogram and laparotomy demonstrating nonpatency of the biliary tree confirm the diagnosis.

Prognosis and Management of Biliary Atresia

The treatment of choice is a hepatoportoenterostomy with a Roux-en-Y enteroanastomosis (Kasai procedure). This procedure involves the excision of the obliterated extrahepatic ducts and apposition of the resected surface of the porta hepatis to the bowel mucosa. Through the years, many variations of the Kasai procedure have been proposed. Despite these modifications, the outcome remains dependent on the experience of the center where the surgical correction is performed and the age of the infant at the time of the procedure. Of infants who are less than 2 months of age at the time of surgical intervention, 80% will reestablish bile flow. Successful establishment of bile flow decreases to less than 20% if the infant is older than 90 days at the time of surgery. Complications following the Kasai procedure include recurrent cholangitis, pruritus, growth failure, hypersplenism, and portal hypertension with variceal bleeding. Medical treatment options are summarized in Table II. Despite successful establishment of bile flow, up to 80% of children with biliary atresia will ultimately require liver transplantation to obtain long-term survival.

INTRAHEPATIC NEONATAL CHOLESTASIS

Paucity of Intralobular Biliary Ducts

Syndromic Paucity of Interlobular Bile Ducts—Alagille's Syndrome

Alagille's syndrome (AGS) was first described in 1969 in a group of children with idiopathic bile duct paucity and a constellation of anomalies. This disorder has been termed arteriohepatic dysplasia, intrahepatic biliary hypoplasia, Watson–Alagille syndrome, and syndromic paucity of interlobular bile ducts. It was recognized that many family members would display similar characteristics and that the disorder was inherited as an autosomal dominant with variable expressivity. Associated findings include cardiac, musculoskeletal, ocular, facial, renal, pancreatic, and neurodevelopmental abnormalities. The prevalence has been reported to be about 1 per 100,000 live births, although this probably underestimates the true frequency, because some affected patients have subclinical expression.

Etiology of AGS In 1997, mutations in the *JAG1* (*Jagged 1*) gene were shown to be associated with AGS. *JAG1* is located on chromosome 20p and is a cell surface protein that functions as a ligand of the Notch receptor. This pathway is a part of an evolutionarily conserved signaling pathway for cell fate. The Notch pathway has been primarily studied in the fruit fly, *Drosophila melanogaster*. Notch and *JAG1* derived their names from the phenotypic observation of a notched or jagged wing found in heterozygote mutations in these flies. Homozygote mutations are uniformly fatal. The finding that mutations in *JAG1* cause AGS indicates that Notch signaling is important in the development of the involved organ systems, i.e., the liver, heart, skeleton,

TABLE II Treatment of Complications of Chronic Cholestatic Liver Disease[a]

Indication	Treatment	Dose	Toxicity/comments
Intrahepatic cholestasis	Phenobarbital	3–10 mg/kg/day	Drowsiness, irritability, interference with vitamin D metabolism
	Cholestyramine/colestipol hydrochloride	250–500 mg/kg/day	Constipation, acidosis, binding of drugs, increased steatorrhea
	Ursodeoxycholic acid	15–20 mg/kg/day	Transient increase in pruritus
Pruritus	Phenobarbital or cholestyramine/colestipol (or both)	15–20 mg/kg/day	—
	Antihistamines		
	Diphenhydramine	5–10 mg/kg/day	Drowsiness
	Hydrochloride hydroxyzine	2–5 mg/kg/day	Drowsiness
	Ultraviolet B light	Exposure as needed	Skin burn
	Carbamazepine	20–40 mg/kg/day	Hepatotoxicity, marrow suppression, fluid retention
	Rifampin	10 mg/kg/day	Hepatotoxicity, marrow suppression
	Ursodeoxycholic acid	15–20 mg/kg/day	Transient increase in pruritus
Steatorrhea	Formula containing medium-chain triglycerides (e.g., Pregestimil)	120–150 calories/kg/day for infants	Expensive
	Oil supplement containing medium-chain triglycerides	1–2 ml/kg/day	Diarrhea, aspiration
Malabsorption of fat-soluble vitamins	Vitamin A	10,000–25,000 units/day	Hepatitis, pseudotumor cerebri, bone lesions
	Vitamin D	800–5000 units/day	Hypercalcemia, hypercalciuria
	25-Hydroxycholecalciferol (vitamin D)	3–5 mcg/kg/day	Hypercalcemia, hypercalciuria
	1,25-Dihydroxycholecalciferol (vitamin D)	0.05–0.2 mcg/kg/day	Hypercalcemia, hypercalciuria
	Vitamin E (oral)	25–200 IU/kg/day	Potentiation of vitamin K deficiency
	Vitamin E (oral, TPGS)[b]	15–25 IU/kg/day	Potentiation of vitamin K deficiency
	Vitamin E (intramuscular)	1–2 mg/kg/day	Muscle calcifications
	Vitamin K (oral)	2.5 mg twice per week to 5 mg/day	—
	Vitamin K (intramuscular)	2–5 mg every 4 weeks	—
Malabsorption of other nutrients	Multiple vitamins	Up to twice the standard dose	
	Calcium	25–100 mg/kg/day	Hypercalcemia, hypercalciuria
	Phosphorus	25–50 mg/kg/day	Gastrointestinal intolerance
	Zinc	1 mg/kg/day	Interference with copper and iron absorption

[a] Modified with permission of The McGraw-Hill companies from Sokol and Narkewicz (2003) in "Current Pediatric Diagnosis" (Hay, Hayward *et al*. eds.), 16th Ed.
[b] D-α-Tocopheryl polyethylene glycol-1000 succinate.

eye, face, and kidney. The timing and specificity of the Notch receptor–ligand interactions are incompletely understood at this time. Over 230 AGS probands have been studied molecularly and *JAG1* mutations have been demonstrated in approximately 70%. Mutations are distributed over the entire coding region of the *JAG1* gene and 50–70% of mutations occur *de novo*.

Diagnosis of AGS Other than the identification of a mutation in *JAG1*, there is no specific test to identify patients with AGS. The diagnosis is based on recognition of associated anomalies and hepatic histology with a paucity of intralobular bile ducts (<0.5 bile ducts per portal tract). Both sexes are equally affected and infants usually demonstrate mild growth failure. Patients with AGS present with mild to severe cholestasis although serum alkaline phosphatase, γ-glutamyl transferase (GGT), and cholesterol are markedly elevated, especially early in life. Serum bile acids are always elevated. Aminotransferases are mildly increased, but clotting factors and other liver proteins are usually normal.

A characteristic facies is often described at an early stage, although it becomes more obvious with age. During childhood, the forehead, ears and nasal bridge are prominent, eyes are deep set and widely spaced, and the chin is small, slightly pointed and projected forward. Cardiac murmurs are present in 95% of patients and cardiac anomalies range from the more common peripheral and valvular pulmonary stenosis to complex lesions such as tetralogy of Fallot. Butterfly vertebrae (incomplete fusion of the vertebral body or anterior arch) occur in up to 50% of affected individuals. Ocular anomalies are varied; however, the most common is posterior embryotoxon, which is identified on ophthalmic evaluation in up to 90% of patients. Posterior embryotoxon is a prominent Schwalbe's ring or line at the point where corneal endothelium and uveal trabecular meshwork join. Renal anomalies occur in about 50% of patients and include solitary, bifid, ectopic, or horseshoe kidney; renal tubular acidosis; or interstitial nephropathy.

AGS must be differentiated from other causes of cholestasis, and most importantly from biliary atresia. Abdominal ultrasound will exclude choledochal cyst. Radionuclide imaging may be abnormal but is not specific; up to 60% of AGS patients will not show excretion of label into the bowel. Liver histology is the most useful preoperative study for the discrimination of AGS from biliary atresia. Unfortunately, in very young infants, bile ducts may be present, confounding the diagnosis. Intraoperative cholangiogram may reveal an anatomically normal but very narrow extrahepatic biliary tree. The diagnosis is made with appropriate hepatic pathology and at least two of the above-mentioned extrahepatic organ system anomalies, or by finding a *JAG1* mutation.

Prognosis and management of AGS Treatment is aimed at medical management of chronic cholestasis (Table II). Growth retardation with normal to increased levels of growth hormone is common. Pruritus is the most severe of any chronic liver disease. Although rarely present before 3–5 months of age, it is observed in most children by the third year of life, even in those who are anicteric. Xanthomas are common in patients with a serum cholesterol >500 mg/dl and cholesterol may reach levels up to 2000 mg/dl. Total serum bile salt elevation up to 100 times the upper limit of normal is the most dramatic laboratory abnormality.

Approximately 30–40% of patients develop complications and progress to cirrhosis, portal hypertension, or synthetic liver failure. Liver transplantation is eventually necessary in 20–50% of patients who have hepatic symptoms in infancy. Indications for transplantation include synthetic failure, complications of portal hypertension, bone fractures, intractable pruritus, disfiguring xanthomata, and growth failure. Posttransplant survival is approximately 90% in patients without significant cardiac or renal anomalies.

Nonsyndromic Paucity of Interlobular Biliary Ducts

Nonsyndromic bile duct paucity is the term used to describe all instances of paucity except those occurring in AGS. This term includes cases either with or without an associated "primary" disease. The overall prognosis for nonsyndromic paucity is poor, with over 70% of cases progressing to cirrhosis. The prognosis is associated with the prognosis of the primary disease, which can include trisomy 21, hypopituitarism, cystic fibrosis, α1-antitrypsin deficiency, cytomegalovirus infection, congenital rubella, chromosomal abnormalities, graft-versus-host disease, primary sclerosing cholangitis (idiopathic), Zellweger syndrome, and some cases of progressive familial intrahepatic cholestasis or inborn errors of bile acid synthesis. Nonsyndromic paucity without an identifiable primary disorder may be a result of a yet unknown metabolic defect.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) manifests as inherited disorders that present as cholestasis in the neonatal period up to the first year of life. There are several distinct phenotypes. The pattern of affected children within families is suggestive of autosomal recessive inheritance. Recent molecular and genetic studies have allowed the identification of

genes responsible for three types of PFIC. Additionally, recognition of abnormal bile acid patterns has allowed for identification of several disorders of bile synthesis.

PFIC Type 1 (Byler's Disease)

Progressive familial cholestasis type 1 was first described in the Amish, as descendants of Jacob Byler. This disorder consists of at least three clinical entities previously considered to be unrelated: PFIC-1, benign recurrent intrahepatic cholestasis (BRIC), and Greenland familial cholestasis (GFC). Patients usually present with severe pruritus, diarrhea, jaundice, and low or normal GGT and cholesterol levels, and may develop sensorineural hearing loss. In both PFIC-1 and GFC, the disease is progressive and leads to cirrhosis and death from liver failure in the first decade of life.

Etiology of PFIC-1 A locus for PFIC-1 has been mapped to 18q21−q22 in the original Byler pedigree. Genetic studies have revealed locus heterogeneity in the *ATP8B1* (*FIC1*) gene locus. The gene product is a P-type ATPase that may be involved in transport of aminophospholipids. The gene is expressed on the canalicular membrane in the liver, small intestine, pancreas, and other organs. The exact function is not known, but it is postulated that mutations in *FIC1* indirectly disturb biliary secretion of bile acids.

Diagnosis and management of PFIC-1 Diagnosis is based on the exclusion of other cholestatic disorders, especially biliary atresia. There is no specific diagnostic test, but patients will have varying degrees of cholestasis and normal or low serum GGT and cholesterol levels. Serum aminotransferases may be variably elevated and clotting factors are normal. Genetic tests may reveal mutations of *FIC1*. Liver histology reveals fibrosis, canalicular cholestasis, and absence of ductular proliferation. Electron microscopy reveals characteristic coarsely granular bile within the canaliculus.

No specific treatment is available for PFIC-1. Medical management is aimed at the treatment of chronic cholestasis (Table II). Ursodeoxycholic acid and partial external biliary diversion may present alternative options to liver transplantation. Liver tests normalize in 40% of patients treated with ursodeoxycholic acid. Partial external biliary diversion can provide effective relief from pruritus, improve growth, and appears to stabilize or even reverse liver fibrosis.

PFIC Type 2

Progressive familial intrahepatic cholestasis type 2 is clinically indistinguishable from PFIC type 1 except that diarrhea may be less common. Patients are unrelated to the original Byler family and have previously been considered to have "Byler syndrome." Patients present with cholestasis, pruritus, and low or normal GGT and cholesterol levels. Serum bile acids are elevated and biliary bile acids are low.

Etiology of PFIC-2 Genetic studies of patients with phenotypic findings suggestive of PFIC-1 but unrelated to the Byler kindred have revealed mutations in the *ABCB11* locus, which has been mapped to 2q24. The gene product is the ATP-dependent bile salt export pump (BSEP), which is localized to the canalicular membrane. Multiple mutations have been identified. It is proposed that impaired bile secretion causes accumulation of intracellular bile acids and ongoing hepatocellular damage.

Diagnosis, prognosis, and management of PFIC-2 Diagnosis is the same as for PFIC-1 with the exception of liver histology. Liver histology reveals fibrosis, canalicular cholestasis, and absence of biliary ductular proliferation as in PFIC-1, but there is an increase in lobular disarray, fibrosis, inflammation, and presence of giant cell transformation. Electron micrographs reveal amorphous bile in the biliary canaliculus.

Patients with PFIC-2 have a more rapid progression to cirrhosis compared to patients with PFIC-1 and usually suffer end-stage liver disease in the first few years of life. Medical management is similar and, because most patients ultimately undergo liver transplantation, early treatment with ursodeoxycholic acid and/or partial external biliary diversion should be considered.

PFIC Type 3

Progressive familial intrahepatic cholestasis type-3 can be distinguished from the other forms of PFIC by a high serum GGT level. In general, patients with PFIC-3 usually present somewhat later in childhood, with only 30% of cases presenting during the first year of life. Gastrointestinal bleeding due to portal hypertension is often the presenting symptom in older children.

Insight into the etiology of PFIC-3 has resulted from the identification of a similar nonsuppurative cholangitis in mice with a homozygous mutation of the *mdr*2 gene. The mouse *mdr*2 and the human multidrug resistance 3 gene, (*MDR*-3) are P-glycoproteins that function as phospholipid translocators involved in biliary phosphatidylcholine secretion. The gene product is predominantly expressed in the canalicular membrane of hepatocytes. It is proposed that the liver pathology is a result of the toxic effects of bile acids on bile duct epithelia in the absence of biliary phospholipids.

Diagnosis, prognosis, and management of PFIC-3 Patients present with mild and variable pruritus,

moderately elevated serum bile acids, and normal biliary bile acids. Cholesterol is normal but GGT is markedly elevated, distinguishing type 3 from types 1 and 2. Serum lipoprotein X is absent. Liver histology of PFIC-3 also differs from PFIC types 1 and 2. There is a prominence of portal tract inflammatory infiltrate and profound bile ductular proliferation. Care must be given to distinguish PFIC-3 from biliary atresia when the patient is a neonate.

Patients with PFIC-3 ultimately progress to end-stage liver disease, portal hypertension, and variceal hemorrhage. Due to the progressive nature of the disorder, children often require rescue liver transplantation. Partial biliary diversion has not been uniformly helpful. There is a varied response to treatment with ursodeoxycholic acid and up to 45% of patients will have some improvement in liver tests. Responders may represent a partial or missense mutation, and have some residual phospholipid transport.

Idiopathic Neonatal Hepatitis

Neonatal hepatitis is defined as a clinicopathologic disorder in the absence of an identifiable etiology and is among the most common causes of neonatal cholestasis. Previously, neonatal hepatitis accounted for up to 50% of all cases. Over time, the relative percentage of cases has decreased to 25–30% due to recognition of specific disorders mimicking neonatal hepatitis. Two distinct patterns have been identified, familial and sporadic. The sporadic form occurs more frequently and has a better prognosis; over 80% of infants will recover or have residual nonprogressive liver disease. Familial neonatal hepatitis has a poorer prognosis, with up to 80% of patients developing end-stage liver disease. Most investigators believe that the familial form represents variants of PFIC and other undiscovered genetic disorders. Other diseases that originally were classified as idiopathic neonatal hepatitis include identified infections, α1-antitrypsin deficiency, Alagille's syndrome, Niemann–Pick type C, PFIC, bile acid synthesis defects, and other inherited metabolic defects.

Diagnosis, Treatment, and Management of Neonatal Hepatitis

Neonatal hepatitis has a higher prevalence in males and there is often an associated history of intrauterine growth retardation, prematurity, poor feeding, emesis, growth failure, and partially or intermittently acholic stools. The liver may be enlarged or small but is often firm, and splenomegaly may be present. Laboratory studies are varied; however, serum aminotransferases are usually markedly elevated. Alkaline phosphatase and GGT levels are variable. The prothrombin time may be abnormal due to vitamin K deficiency. Abdominal ultrasound may reveal a heterogeneous hyperechoic liver with a normal gallbladder. Radionuclide studies often are nonexcreting and do not reliably distinguish neonatal hepatitis from biliary atresia. Liver histology reveals marked lobular disarray, hepatocellular ballooning, focal hepatic necrosis, multinuclear giant cell transformation, hepatocellular cholestasis, and extramedullary hematopoiesis. Varying degrees of fibrosis may be present. Portal tracts may be expanded with an inflammatory infiltrate but there is an absence of bile ductular proliferation. Intraoperative cholangiogram will reveal an intact extra- and intrahepatic biliary tree, although it may appear hypoplastic.

There is no specific treatment for neonatal hepatitis. As with other neonatal cholestatic disorders, the treatment is aimed at prevention and ultimately treatment of complications of cholestasis (Table II). Prognosis for sporadic neonatal hepatitis is generally good, with most infants having either a complete or partial recovery without progression to end-stage liver disease.

Metabolic or Genetic Disorders Associated with Neonatal Cholestasis

Metabolic disorders present with a wide variety of clinical manifestations depending on the nature of underlying defect. Table III provides a summary of these disorders, their metabolic defect, characteristic hepatic pathology, and definitive diagnostic test.

Disorders of Bile Acid Synthesis

In 1984, infants with suspected neonatal cholestasis were screened for defects in bile acid synthesis using the then-novel technique of fast-atom bombardment ionization mass spectrometry (FAB-MS). The presumption was that infants with idiopathic neonatal cholestasis had an unrecognized infection or genetic defect as the primary cause of their disorder. Using this approach, six defects in bile acid synthesis have been identified to date and account for 2–3% of cholestatic disorders of infancy and childhood. In neonates, the presentation is similar to PFIC. Laboratory tests are variable, but all infants have atypical urinary bile acids identified by FAB-MS.

3β-Hydroxy-C_{27}-steroid dehydrogenase/isomerase deficiency This defect was first identified in a Saudi Arabian patient who was the third of five children to be affected with a progressive familial cholestasis. All of the children were products of a consanguineous marriage and the older two affected siblings had died. All had elevated levels of aminotransferases and a normal

TABLE III Metabolic and Genetic Causes of Neonatal Cholestasis[a]

Disease	Inborn error	Hepatic pathology[b]	Diagnostic studies
Galactosemia	Galactose-1-phosphate uridylyltransferase deficiency	Cholestasis, steatosis, necrosis, pseudoacini, fibrosis	Galactose-1-phosphate uridylyltransferase assay of red blood cells
Fructose intolerance	Fructose-1-phosphate aldolase deficiency	Steatosis, necrosis, pseudoacini, fibrosis	Liver fructose-1-phosphate aldolase assay or leukocyte DNA analysis
Tyrosinemia	Fumarylacetoacetase deficiency	Necrosis, steatosis, pseudoacini, portal fibrosis	Urinary succinylacetone, fumarylacetoacetase assay of red blood cells
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator gene mutations	Cholestasis, neoductular proliferation, excess bile duct mucus, portal fibrosis	Sweat test and leukocyte DNA analysis
Hypopituitarism	Deficient production of pituitary hormones	Cholestasis, giant cells	Thyroxine, thyroid-stimulating hormone, cortisol levels
α1-Antitrypsin deficiency	α1-Antitrypsin gene mutations (PiZZ phenotype)	Giant cells, cholestasis, steatosis, neoductular proliferation, fibrosis, PAS-diastase-resistant cytoplasmic granules	Serum α1-antitrypsin phenotype
Gaucher's disease	β-Glucosidase deficiency	Cholestasis, cytoplasmic inclusions in Kupffer cells (foam cells)	β-Glucosidase assay in leukocytes
Niemann–Pick disease	Lysosomal sphingomyelinase deficiency	Cholestasis, cytoplasmic inclusions in Kupffer cells	Sphingomyelinase assay of leukocytes or liver or fibroblasts (type C); leukocyte DNA analysis
Glycogen storage disease type IV	Branching enzyme deficiency	Fibrosis, cirrhosis, PAS-diastase-resistant cytoplasmic inclusions	Branching enzyme analysis of leukocytes or liver
Neonatal iron storage disease	Unknown	Giant cells, portal fibrosis, hemosiderosis, cirrhosis	Histology, iron stains, buccal mucosa biopsy
Peroxisomal disorders (e.g., Zellweger syndrome)	Deficient peroxisomal enzymes or assembly	Cholestasis, necrosis, fibrosis, cirrhosis, hemosiderosis	Plasma very-long-chain fatty acids, qualitative bile acids, plasmalogen, pipecolic acid, liver electron microscopy
Abnormalities in bile acid metabolism	Several enzyme deficiencies defined	Cholestasis, necrosis, giant cells	Urine, serum, duodenal fluid analyzed for bile acids by fast-atom bombardment mass spectroscopy
PFIC types 1 and 2	*FIC1* and BSEP gene mutations	Cholestasis, necrosis, giant cells, fibrosis, (pericentral)	Histology, family history, normal cholesterol, low or normal γ-glutamyltranspeptidase, DNA analysis
PFIC type 3	MDR-3 gene mutations	Cholestasis, bile duct proliferation, portal fibrosis	Bile phospholipid level, DNA analysis
Alagille's syndrome (syndromic paucity of interlobular bile ducts)	*Jagged* 1 gene mutations	Cholestasis, paucity of interlobular bile ducts, increased copper levels	Three or more clinical features, liver histology, DNA analysis

GGT level. Total serum bile acid levels were normal, despite the degree of cholestasis. The defect identified was in the second step in primary bile acid synthesis, disrupting the conversion of 7α-hydroxycholesterol to 7α-hydroxy-4-cholesten-3-one. FAB-MS of urine identified a qualitative absence of normal glyco- and tauro-conjugates of primary bile acids. Treatment with oral cholic acid, 250 mg/day, normalized biochemical parameters and reversed liver disease in all cases.

Δ^4-3-Oxosteroid 5β-reductase deficiency The defect was first identified in monochorionic twin boys whose older brother had died of neonatal hepatitis. Unlike 3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase deficiency, serum GGT was elevated. In this condition, serum bile acids may be elevated, depending on the assay methodology. FAB-MS identified that over 90% of urine bile acids were atypical. If treatment with cholic and ursodeoxycholic acid is initiated prior to the onset of significant liver injury, resolution of jaundice and normalization of biochemical parameters can be achieved. The dose of oral bile acids is based on monitoring urine Δ^4-3-oxo bile acids.

Oxysterol 7α-hydroxylase deficiency Described in only one 10-week-old male infant, this disorder is manifested by progressive cholestasis, cirrhosis, and liver synthetic failure. This infant had hepatosplenomegaly, elevated serum aminotransferases, and a low GGT level. FAB-MS of urine revealed an absence of primary bile acids and an abundance of monohydroxy bile acids. Treatment with ursodeoxycholic acid led to deterioration of liver tests, and cholic acid therapy proved ineffective.

α1-Antitrypsin Deficiency

α1-Antitrypsin (A1AT) deficiency was first described in 1969 as a distinct entity causing neonatal cholestasis. A1AT deficiency accounts for up to 10% of all cases of neonatal cholestasis. There are three major alleles, M, S, and Z. A1AT deficiency is an autosomal recessive disorder associated with an 85–90% reduction of serum A1AT levels. Homozygous ZZ is relatively common, affecting about 1 in 2000 live births. Significant liver disease occurs in up to 20% of affected individuals. Compound heterozygotes (SZ) are at similar risk for liver disease. The gene product is a serine protease inhibitor that is active against proteases released from activated neutrophils. The gene defect reduces the stability of the monomeric form, causing polymerization, misfolding, and retention of the gene product in the endoplasmic reticulum. The mechanism of how the abnormally retained product causes liver disease has yet to be elucidated. Homozygous ZZ adults suffer from emphysema, most likely as a result of decreased circulating levels of the protease inhibitor, and pulmonary damage by neutrophil elastase.

Affected infants presenting with neonatal cholestasis often have mild growth failure. Serum aminotransferase, alkaline phosphatase, and GGT levels are often elevated. About 10% of affected infants will have hepatosplenomegaly, ascites, and liver synthetic dysfunction. This disorder must be distinguished from biliary atresia. There is a report of A1AT deficiency and biliary atresia occurring in a single patient. Liver ultrasound is usually normal. Often patients exhibiting ZZ or SZ phenotypes have no radionuclide biliary excretion. Serum A1AT level will be markedly reduced; serum A1AT level in conjunction with a Pi phenotype should be measured. Liver biopsy will reveal characteristic periodic acid–Schiff (PAS)-positive diastase-resistant globules in the periportal hepatocytes. There is no specific treatment for this disorder. Liver transplantation is curative for end-stage liver disease and prevents the development or worsening of lung disease.

Hereditary Tyrosinemia Type 1

Tyrosinemia was first described in 1932. Almost all infants died of liver disease or hepatocellular carcinoma in infancy or early childhood. In 1977, the defect was identified as a deficiency of fumaryl acetoacetate hydrolase, which is the last enzyme in the tyrosine degradation pathway. The result is an accumulation of succinylacetone, which can be measured in urine. Tyrosinemia is inherited as an autosomal recessive trait. Overall, this is a relatively rare disorder with a frequency of 1 in 100,000 live births. It is most common in French Canadians, particularly the Lac St.-Jean area of northern Quebec, where the incidence is 1 in 1846 live births.

Infants usually present in the first 2 months of life with cirrhosis or decreased hepatic synthetic function manifested as a coagulopathy and ascites for which the cause is not evident. The diagnosis is made by identification of succinylacetone in the urine. Previously, all infants underwent urgent liver transplantation until the discovery of 2(-2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) as a therapeutic agent. NTBC is an herbicide that inhibits the second enzyme in the tyrosine degradation pathway. The initial dose is 1 mg/kg/day, and blood tyrosine levels are monitored. In a recently published study of over 300 patients worldwide, over 95% responded to treatment without apparent side effects. Concern remains regarding the development of hepatocellular carcinoma despite effective treatment. In addition to NTBC, patients

continue a phenylalanine- and tyrosine-restricted diet and are monitored for blood tyrosine and α-fetoprotein levels.

SUMMARY

Cholestatic disorders can be classified into several large categories. These include intra- and extrahepatic biliary obstruction, metabolic disorders, congenital or acquired infections, and infiltrative disease. Despite the wide variety of causes, the clinical presentation of the different types of neonatal cholestasis is similar, reflecting the response of a physiologically immature liver to a variety of insults. There are, however, some unique clinical clues to allow for a directed and cost-effective approach to diagnosis and treatment of neonatal cholestasis. Further research will undoubtedly identify other genetic defects causing neonatal cholestasis.

Neonatal Hemochromatosis

KAREN F. MURRAY AND KRIS V. KOWDLEY
University of Washington, Seattle

β2-microglobulin A 12 kDa nonpolymorphic immunoglobulin-like polypeptide that is homologous to the C_3 domain of IgG and is one subunit of the major histocompatibility class I antigens.
hereditary hemochromatosis A common autosomal recessive disorder of excessive intestinal absorption of iron, resulting in iron deposits on the liver and other organs, affecting adults.
oligohydramnios Insufficient amniotic fluid.
polyhydramnios Excessive amniotic fluid.
Sjögren's syndrome An immunological disorder causing mucosal and conjunctival dryness from progressive destruction of exocrine glands and associated with other autoimmune phenomena.

Hereditary hemochromatosis is a common autosomal recessive disorder, resulting in excessive iron deposition in the liver as well as in extrahepatic sites. Symptoms related to hepatic insufficiency, cardiac dysfunction, or endocrinological abnormalities usually present between 40 and 60 years of age. Involvement in adults under the age of 30 years is uncommon and involvement in children has only rarely been reported. Neonatal hemochromatosis (NH), also known as neonatal iron storage disease, is a phenotypically similar disorder; however, its extremely early onset of liver failure makes it notably unique. Originally described in 1957, there have now been over 100 cases reported. Liver failure in the first 30 days of life is uncommon, with neonates representing less than 2% of children listed for liver transplantation, but of these few patients, NH may be one of the most common causes of liver failure. Despite a lack of clear etiology and pathogenesis and the possibility that it is not a primary disease state, the syndrome of NH is now well recognized and universally found to have an aggressive course and carry a poor prognosis. This article discusses the most common clinical presentation as well as less common clinical associations. Genetic inheritance and theories that pertain to abnormal iron metabolism versus NH as the final pathway of multiple possible *in utero* insults are also reviewed. Methods of diagnosis, liver histology, treatment, and prognosis are discussed.

CLINICAL PRESENTATION

When not stillborn, infants with neonatal hemochromatosis (NH) are frequently premature or are small for gestational age. The pregnancy may be complicated by intrauterine growth retardation, oligohydramnios, placental edema, or sometimes polyhydramnios. Illness is usually evident within hours of birth, although there have been individuals diagnosed at a few weeks of age. Patients have features of liver failure with hypoalbuminemia, hypoglycemia, coagulopathy, low fibrinogen, and, frequently, thrombocytopenia and anemia. If not present at birth, ascites develops shortly thereafter, as does hyperbilirubinemia. Transaminase levels are characteristically low.

Clearly the onset of the liver disease is *in utero* with end-stage liver disease already established even in the prematurely born infant. Hepatocellular synthetic insufficiency can explain the coagulopathy, low fibrinogen, and hypoalbuminemia. The hypoalbuminemia in turn contributes to a low intravascular oncotic pressure, edema, contracted blood volume, oliguria, and resultant oligohydramnios. The edema and ascites may be due to anemia, heart failure, or portal hypertension. The characteristically low transaminases and hypoglycemia, which is secondary to poor glycogen stores, are evidence of overall hepatocellular loss. The frequently seen anemia is probably multifactorial, caused by severely limited hepatic erythropoiesis, acquired defects in erythrocyte membranes due to liver disease, and hypotransferrinemia and low erythropoietin levels due to hepatocellular synthetic insufficiency.

OTHER CLINICAL ASSOCIATIONS

The NH phenotype, with respect to clinical presentation, laboratory abnormalities, liver histology, and parenchymal iron deposition, has also been seen in children ultimately diagnosed with Δ^4-3-oxosteroid 5β-reductase deficiency, a defect in bile acid synthesis. Clayton points out, however, that this enzyme is labile and hence its activity may be substantially reduced with hepatocyte damage. Consequently, Δ^4-3-oxosteroid 5β-reductase deficiency may or may not be a primary diagnosis in a subset of NH patients.

A report of an infant with NH born to a mother with Sjögren's syndrome and high levels of anti-Ro/SS-A and

 Copyright 2004, Elsevier (USA). All rights reserved.

anti-La/SS-B antibodies raises the possibility of an autoimmune pathophysiology to this condition.

Most patients with NH do not have other significant congenital abnormalities; however, patients with two separate syndromes have been described with some frequency. Four children, two pairs of siblings, have been reported with trichomalacia, diarrhea, facial dysmorphology, and some degree of congenital heart disease; Verloes *et al*. coined the name "tricho-hepato-enteric syndrome" to describe the condition. Additionally, four patients have been described with NH and renal tubular dysgenesis, also an autosomal recessive condition. These findings support the concept that NH is the result of an *in utero* insult to the fetus.

GENETICS

There have been family analyses to determine whether there is a genetic basis for NH and whether there is a genetic link to hereditary hemochromatosis. Transmission of the disorder has been described as autosomal recessive, codominant, and autosomal dominant with variable penetrance. There are now multiple reports of recurrence of NH in siblings and half-siblings. In most analyses of family occurrences, an autosomal recessive pattern of inheritance has emerged. Another observation, however, cannot be ignored. Several women have had infants with NH fathered by different men, yet no man has fathered children with NH with different women. This suggests possible mitochondrial inheritance, an acquired and persistent maternal factor, or gonadal mosaicism for a dominant mutation lethal in spermatogenesis but not in oogenesis.

A genetic relationship with hereditary hemochromatosis is an attractive idea since the distribution of parenchymal iron and the liver histology in the two conditions are similar. The HFE (hereditary hemochromatosis) gene is mutated in the majority of patients with hereditary hemochromatosis. This gene is located on the short arm of chromosome 6 and there is an association with the human leukocyte antigen (HLA)-A3 alloantigen. The HFE gene mutation has been found in parents of children with NH and parents and affected children may share the HLA-A3 alloantigen. Other studies have disputed this link and association, however. Furthermore, infants with the HFE gene mutation do not necessarily have NH.

IRON METABOLISM AND THE PHYSIOLOGIC BASIS OF DISEASE

The bulk of the body's iron is found as essential iron, specifically heme compounds: enzymes with iron–sulfur complexes. The largest store of essential iron is erythron in red blood cells, the next largest fraction is found in myoglobin in muscle, and, the third largest fraction is present in mitochondrial enzymes. These iron fractions are essential for bodily functioning. Iron in these forms is relatively stable, limited by the life span of the cells in which it is contained.

Tissue iron is stored primarily in ferritin. Ferritin is a polypeptide sphere that encloses iron atoms and it is found in cellular cytoplasm and lysosomal membranes. Glycosylated, iron-free ferritin is secreted into the serum from all ferritin-producing cells and therefore reflects tissue iron stores. Ferritin secretion into serum increases, however, under conditions of inflammation, particularly when the inflammation involves ferritin-rich tissues. In lysosomes, the ferritin molecules aggregate and the degraded polypeptides and iron coalesce into hemosiderin, which can be seen with Prussian blue staining under light microscopy.

Transferrin, the main molecule that mediates the transfer of iron between tissues, is a single polypeptide with two iron-binding sites. Occupation of none (apoferric), one (monoferric), or both (diferric) of the iron-binding sites determines the degree of iron saturation. Transfer of the iron to tissues occurs by the interaction of the transferrin–iron complex with specific membrane receptors and subsequent internalization of the transferrin–iron complex. Fibroblasts from patients with NH synthesize ferritin and transferrin receptors and iron regulates the cellular expression of ferritin and transferrin receptors to the same degree as do fibroblasts from individuals without NH. Furthermore, the intracellular processes by which iron is metabolized are unaffected in NH fibroblasts. It is now known that the transferrin receptor interacts with both HFE protein and β2-microglobulin (β2M). Proper interaction of these molecules allows for regulated internalization and subsequent cycling back to the cell surface of the transferrin–iron–HFE protein–β2M complex, therefore maintaining correct tissue-iron concentrations. In hereditary hemochromatosis, mutation of the HFE gene results in an abnormal HFE protein that does not associate with β2M and after internalization is not transported back to the cell surface. HFE protein is expressed in the crypt cells of the small intestine. It is believed that in individuals with homozygosity for specific HFE gene mutations (C282Y and H63D), the mutant HFE is trapped extracellularly, hence impeding the transport of iron via the transferrin–transferrin receptor interaction. Parkkila *et al*. found that the transferrin receptor and HFE protein–β2M complex are also located in the apical plasma membrane of the syncytotrophoblast cells of the fetal placenta, thus

playing a role in iron transport across the placenta. Placental iron levels, in turn, may regulate the expression of transferrin receptors on the syncytotrophoblast apical plasma membrane and therefore maintain steady iron uptake into the placenta.

Non-transferrin-bound iron (NTBI) ligands may also play a role in hemochromatosis. In hereditary hemochromatosis, a chelator-inaccessible fraction of NTBI has been observed. The identity of this presumably high-affinity ligand has not yet been elucidated. In the case of hemochromatosis, it is possible that this NTBI-ligand fraction is extruded from the cytoplasm of damaged cells. Cytoferrin (host-associated iron transfer factor), an iron-binding compound of lower molecular weight than transferrin, is found mainly in the cellular cytoplasm but also in low concentrations in serum. Cytoferrin concentrations are known to increase with liver disease or in the setting of iron loading. Knisely *et al*. compared the serum concentration of cytoferrin among adult nonselected women, parturient women, normal infants (cord serum), and an infant with NH. The difference between parturient and nonparturient women was not significant. Cord sera from normal neonates, however, had a cytoferrin concentration twice that of the women and sera from the NH infant had a concentration 270 times that of the women. The transplacental gradient of cytoferrin suggests that this compound may be involved in maternofetal transport of iron. The dramatic increase in cytoferrin in the NH neonate may simply be secondary to the liver disease, but its possible role in this disorder warrants further investigation.

DIAGNOSIS

Diagnosis is generally made after other causes of neonatal liver failure are excluded (Table I) and confirmatory tests have been performed. Serum concentrations of ferritin are elevated in patients with NH; thus, an elevated ferritin will help to confirm the diagnosis. However, body-iron stores are normally high in infancy; furthermore, elevated ferritin is nonspecific and may simply represent total body overload, nonspecific liver disease, or inflammation. When measured, the iron-binding capacity (transferrin) is low, reflecting the impaired synthetic ability of the liver. The percentage iron saturation, however, has been reported to markedly exceed the normally high saturation seen in the cord blood of newborns without liver disease (80%), with saturations of 95 to 100% being common.

Siderosis of the liver is normal in the third trimester but can be distinguished from NH hepatic siderosis by the extrahepatic siderosis with reticuloendothelial sparing. Specifically, although the iron deposition in NH is most notable in the liver, it is also present in the heart, pancreas, exocrine and endocrine organs, intestines, and gastric and salivary glands. The siderosis explicitly spares the reticuloendothelial elements, however, as it does in hereditary hemochromatosis. Siderosis of extrahepatic sites including the salivary glands makes it possible to verify the diagnosis histologically without the need for a liver biopsy. Knisely *et al*. showed that siderosis of acinar epithelial cells was found in the minor salivary glands of all patients proven to have NH and in none of 30 patients without liver disease. Salivary gland siderosis was also seen in patients with tyrosinemia, parvovirus B19, rubella, α-thalassemia, and renal–hepatic–pancreatic cystic dysplasia of Ivemark, but these could generally be distinguished on other clinical and laboratory grounds.

Due to the paramagnetic influence of ferric ions (Fe^{3+}) on the image signal during magnetic resonance imaging (MRI), this radiological tool can be useful in the diagnostic evaluation of an infant with possible NH. The signal alterations caused by the ferric ions cause shortening of the T1 and, more impressively, the T2 relaxation times. Any tissue containing iron will therefore have low signal intensity. In NH with T2-weighted images, the signal intensity of the liver and pancreas will be lower than that of the normal-intensity spleen. Furthermore, the more rapid imaging possible with T2 gradient-recalled echo can be used for morphologic and functional assessment of myocardial siderosis. In situations where a fetus is at risk of having NH, MRI can also be used to evaluate the infant during the third trimester of pregnancy. In this case, fetal liver intensity can be compared to other fetal tissues and to the mother's liver.

LIVER HISTOLOGY

Nodular cirrhosis with severe cholestasis is typically found at the time of biopsy or autopsy. It is not unusual to see regenerating nodules separated by wide bands of bland fibrosis containing proliferating bile ducts and multinucleated giant cells. Central vein sclerosis with thickened venular walls and lumens either stenosed or occluded by fibrous tissue is also common. The siderosis is always, by definition, significant. Within tubular hepatocytes, hemosiderin occupies the apical cytoplasm adjacent to the bile canaliculi. In hepatic giant cells, the iron and bile are more diffusely distributed. Extramedullary erythropoiesis, usually obviously apparent in the neonate, is found only in the sinusoids of liver nodules in NH and probably contributes to the anemia in these patients. Although less common, hepatocellular carcinoma has been reported in cases of NH at the time

TABLE I Differential Diagnosis in Neonatal Liver Failure

Disease category	Disease	Diagnostic tests
Metabolic	Galactosemia	Urine reducing substances
		Red blood cell galactose-1-phosphate uridyl transferase
	Tyrosinemia	Plasma quantitative amino acids
		Urine succinylacetone
		α-Fetoprotein
	Neonatal hemochromatosis	Salivary gland or liver biopsy
		Hypersaturation of transferrin with decreased absolute transferrin concentrations
		Appropriate pattern of hepatic and extrahepatic siderosis on MRI
	Δ^4-3-Oxosteroid 5β-reductase deficiency	Urinary bile acid analysis by fast-atom-bombardment mass spectroscopy
	Hereditary fructose intolerance	Liver aldolase activity
		Allele-specific oligonucleotide analysis of peripheral genomic DNA
Storage diseases	α_1-Antitrypsin deficiency	Quantitative serum α1-antitrypsin level
		Protease inhibitor typing
	Zellweger syndrome	Plasma very long plasma fatty acids
	Niemann–Pick disease type C	Skin biopsy for fibroblast culture
		Studies of cholesterol esterification and accumulation
	Glycogen storage disease type IV	Skin biopsy for branching enzyme assay in cultured fibroblasts
		Liver biopsy
Infectious	Parvovirus B19	IgM
		Blood PCR
	Echovirus 9	Culture from pharynx or blood
		PCR
	Coxsackie virus	Culture from urine or blood
		PCR
	Adenovirus	IgM
		Culture from urine or blood
	Cytomegalovirus	Buffy coat antigen
		IgM
	Herpes simplex virus	Culture from nasopharynx or rectal swab
		Buffy coat PCR
	Hepatitis A virus	IgM
	Hepatitis B virus	HBsAg
		PCR
	Hepatitis C virus	PCR
	Rubella	IgM
		Culture from urine or nasopharynx
	Syphilis	VDRL or RPR
	Toxoplasmosis	DS-IgM EIA or ISAGA
	Human herpes virus 6	Blood PCR
Other	Hemophagocytic lymphohistiocytosis	Hemophagocytic histiocytosis in liver and bone marrow
	Mitochondrial cytopathy	Lactic acidosis
		Muscle or liver biopsy for analysis of respiratory chain enzyme function
	Neonatal lupus erythematosus	Maternal anti-Ro/SS-A and anti-La/SS-B antibodies
	Hepatic neuroblastoma	Ultrasound or computed tomography
		Biopsy of mass
	Budd–Chiari syndrome	Doppler ultrasound

Note. DS-IgM EIA, Double-sandwich IgM enzyme immunoassay; HBsAg, Hepatitis B surface antigen; IgM, Immunoglobulin M; ISAGA, IgM Immunosorbent agglutination assay; PCR, Polymerase chain reaction; RPR, Rapid plasma reagin; VRDL, Venereal disease research laboratory.

TABLE II Disorders of the Neonate with High Iron Deposition in the Liver and Other Organs with Reticuloendothelial Organ Sparing

Diagnosis	Hepatic iron content
Neonatal hemochromatosis	+++
Δ^4-3-Oxosteroid 5β-reductase deficiency	+++
Echovirus 9	+++
Cytomegalovirus	+++
Neonatal lupus	+++
Herpes simplex virus	++
Tyrosinemia	++
Mitochondrial cytopathy	++
Zellweger syndrome	+
Rubella	+
Parvovirus B19	+
Congenital hepatic fibrosis	+

of transplantation or autopsy, reinforcing the prenatal onset of this condition.

Whereas the average liver weight is lower in NH patients than in normal individuals (reflecting loss of hepatic parenchyma) even when adjustments are made for gestational age and body size, the mean hepatic iron concentration is higher in NH than in comparable controls. Knisely found that the hepatic iron concentration in patients with NH ranged from 240 to 38,200 μg/g of dry weight, whereas that of a healthy neonate was 250 μg/g of dry weight. It must be noted, however, that despite the clearly elevated liver iron in most cases, the range overlaps with normal perinatal hepatic iron concentrations in some subjects. Furthermore, there are conditions other than NH in which the iron content is elevated in the liver and other nonreticuloendothelial organs (Table II). This elevated iron content in other organs is particularly likely with cirrhosis and may indicate a shunt siderosis similar to that frequently seen in adult liver disease.

TREATMENT AND PROGNOSIS

NH is nearly universally fatal and experience with treatment is limited because many patients die before diagnosis. Deferoxamine therapy is not efficacious and it has been suggested that its use may potentiate bacterial growth. Additionally, despite early preliminary reports to the contrary, deferoxamine combined with an antioxidant cocktail has not been proven to be universally successful.

Although experience is very limited, liver transplantation has been successful in treating NH. In one study of 14 infants with NH who were treated with an antioxidant cocktail, 5 patients survived to transplantation and 3 were alive 1 year after transplantation. In most cases, the iron overload resolves slowly after transplantation. In 1 patient, however, iron accumulated in the allograft as early as 7 days posttransplant and the patient died of cardiac arrhythmia 2 months posttransplant. The iron accumulation in the allograft liver was thought to be secondary to redistribution of the preexisting body iron and the authors speculated that deferoxamine and antioxidant therapy may be beneficial after transplant.

SUMMARY

NH is a dramatic condition that, though rare, may be one of the most common causes of liver failure in the newborn. Its cause is not clear and there is even controversy over whether it is a unique disease state. It is known, however, that NH can recur in families and has shown inheritance patterns and it may or may not be related to hereditary hemochromatosis. Furthermore, although medical treatments have not been successful, liver transplantation provides some hope for the families and individuals affected. Ongoing research into its cause and pathogenesis will eventually uncover some of the mysteries related to this disease state.

choreoathetosis Abnormal movements of the body of combined choreic and athetoid pattern.

gene promoter A noncoding DNA sequence of a gene at which RNA polymerase and transcription factors bind and regulate transcription.

heme The oxygen-carrying portion of hemoglobin.

hemolysis Destruction of red blood cells with concomitant release of hemoglobin.

hyperbilirubinemia A condition in which an abnormally large amount of bilirubin circulates in the blood, resulting in serum total bilirubin concentrations greater than the 95th percentile for hour of life.

kernicterus A severe neurologic condition associated with yellow staining and degenerative lesions of the basal ganglia of the brain of severely jaundiced term newborns or moderately hyperbilirubinemic premature neonates.

Jaundice is a common condition of the newborn and refers to a yellow discoloration of the skin and sclerae, the result of bilirubin deposition in these visible tissues. Hyperbilirubinemia occurs when the serum total bilirubin concentration exceeds the 95th percentile for the neonate's age in hours. Kernicterus, a permanent neurological condition associated with severe hyperbilirubinemia, occurs when bilirubin becomes deposited in the basal ganglia of the brain.

indicating a serum total bilirubin (STB) concentration of 5–6 mg/dl, appearing in approximately 60% of otherwise healthy, term newborns during the first days of life. In most cases, the STB concentrations do not exceed the normal range, the upper limit for which is currently defined as the 95th percentile for hour of life. This point corresponds to STB concentrations of 15.0 to 17.0 mg/dl, with a maximum STB level noted on the third to fourth day of life. An individual neonate's peak may be affected by prematurity, being breast-fed, and East Asian parentage. Not every jaundiced newborn is necessarily hyperbilirubinemic; only in a fraction of cases do the STB concentrations exceed the 95th percentile and enter the dangerous range.

Rarely, dangerously high bilirubin levels may be reached and bilirubin encephalopathy, or permanent, irreversible brain damage called kernicterus, may ensue. Prior to the 1990s, kernicterus was seldom encountered, as STB concentrations were for the most part prevented from exceeding 20.0 mg/dl. This concept was derived from the outcome of rhesus factor (Rh) isoimmunized neonates, who rarely developed kernicterus provided STB values were kept below this concentration. However, there is evidence of a recent resurgence of kernicterus not only in North America, where over 125 cases have been recorded in an informal kernicterus registry, but in other countries as well. A more liberal attitude toward neonatal hyperbilirubinemia, the (subsequently disproved) belief that kernicterus will not occur in the absence of hemolysis, and a growing trend to mandatory early discharge prior to STB concentrations peaking, have all contributed to this tragedy. In most cases, with the possible exception of severe, sudden hemolysis due to glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, kernicterus should be a preventable condition provided management guidelines of the American Academy of Pediatrics (AAP) are adhered to. Unfortunately, this was not always the case.

In the majority of cases of neonatal jaundice, the serum bilirubin is of the unconjugated, or indirect-reacting, type. As conjugated, or direct-reacting, bilirubin does not cross the blood–brain barrier and therefore does not cause bilirubin encephalopathy, in the remainder of this discussion only indirect hyperbilirubinemia will be addressed.

BILIRUBIN FORMATION AND ELIMINATION

More than 80% of the bilirubin produced in the human body derives from heme catabolism, liberated from senescent red cells. Heme is degraded by the enzyme heme oxygenase to biliverdin and subsequently to bilirubin (see Fig. 1). For each molecule of bilirubin produced by this mechanism, equimolar quantities of carbon monoxide (CO) are produced. The latter binds to hemoglobin to form carboxyhemoglobin, in which form it is transported to the lungs and exhaled. Bilirubin itself enters the bloodstream and binds to albumin, on which it is transported. As long as this unconjugated bilirubin remains bound to albumin, it will be prevented from entering the basal ganglia. To begin its excretion process, bilirubin enters the hepatocyte, where it is rendered water-soluble by conjugation with glucuronic acid, a process catalyzed by the enzyme UDP-glucuronosyltransferase 1A1 (UGT). The resulting conjugated bilirubin fractions are excreted via the bile into the bowel, where much is converted to nonreabsorbable products and excreted in the stool. However, in the postnatal period, especially in breast-fed neonates, the glucuronide molecules can be cleaved off by the mucosal and bacterial enzyme β-glucuronidase. The resulting unconjugated bilirubin can now be reabsorbed, reentering the bilirubin pool. This mechanism is known as the enterohepatic circulation of bilirubin.

PHYSIOLOGICAL JAUNDICE

Jaundice occurs when the rate of bilirubin production exceeds the body's ability to eliminate it. *In utero*, the placenta is responsible for removal of bilirubin, and, except for instances of severe intrauterine hemolysis, the fetus does not usually become jaundiced. However, within a few days of delivery, STB concentrations may increase rapidly from approximately 1.5 mg/dl in umbilical cord blood to an average of 5–6 mg/dl. Mild imbalance between the bilirubin production and elimination processes should not result in dangerously high STB concentrations. Physiological jaundice peaks at approximately 3 to 4 days and diminishes toward the end of the first week of life.

Conditions resulting in physiological jaundice include those increasing bilirubin production, those diminishing conjugation or excretion, increased enterohepatic circulation, or a combination of all mechanisms. Increased heme production may be the result of high hemoglobin concentrations at the time of delivery, shortened neonatal RBC life span, bruising, or cephalhematoma. Maturation of UGT enzyme activity is a function of progressing gestational age and prematurity is therefore a major cause of diminished bilirubin conjugation. Diminished activity of UGT may also result from hypoxia, hypothermia, and hypothyroidism. The

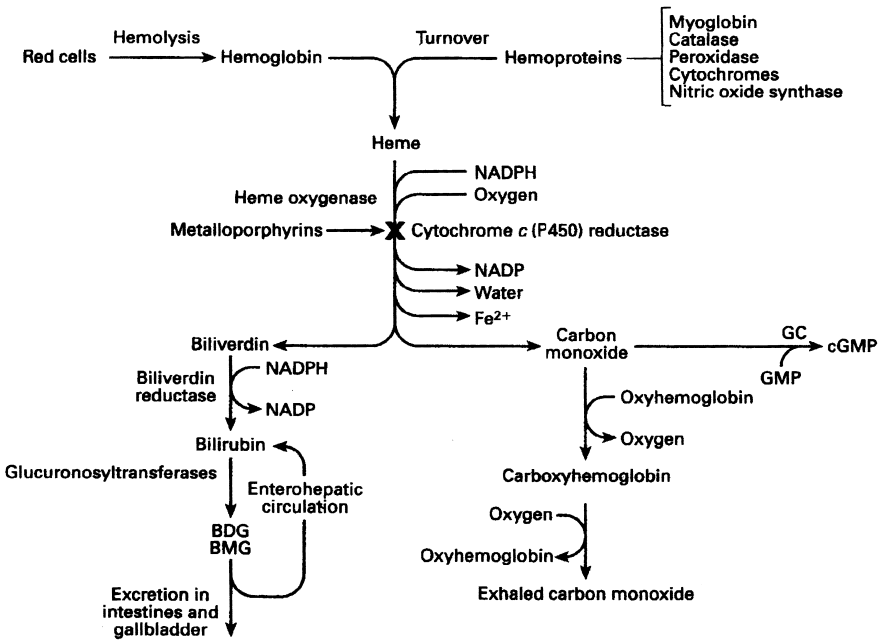

FIGURE 1 Metabolic pathway of the degradation of heme and the formation and excretion of bilirubin. BDG, bilirubin diglucuronide; BMG, bilirubin monoglucuronide. Reprinted from Dennery, P. A., Seidman, D. S., and Stevenson, D. K. (2001). Drug therapy: Neonatal hyperbilirubinemia. *N. Engl. J. Med.* **344**, 581–590, with permission. Copyright 2001, Massachusetts Medical Society. enterohepatic bilirubin circulation has been shown to increase under fasting conditions and may result in augmented bilirubin reabsorption in poorly feeding nursing infants.

Beneficial Properties of Bilirubin

Despite its potential for encephalopathy, bilirubin may have beneficial, physiologic properties. *In vitro* studies have demonstrated antioxidative properties associated with bilirubin and it is possible that *in vivo* some degree of bilirubinemia may help prevent reactive oxygen species-mediated diseases.

PATHOLOGICAL JAUNDICE

As in physiological jaundice, conditions resulting in pathological hyperbilirubinemia can be divided into those causing increased bilirubin production, on the one hand, and those causing diminished bilirubin conjugation or elimination, on the other.

Increased Bilirubin Production

Increased production of bilirubin, or hemolysis, may be due to immune causes, such as blood group incompatibilities. Rh isoimmunization was, in the past, a frequent cause of hyperbilirubinemia and kernicterus. However, prophylaxis of this condition by antenatal and immediate postnatal administration of Rhogam (anti-D antibody) have made this condition rare. In the remainder of cases, severity of disease has been ameliorated by vigilant antenatal surveillance and intrauterine blood transfusion where indicated. Undoubtedly, the most common blood group incompatibility currently causing immune hemolysis is ABO blood group heterospecificity, in which situation the mother has blood group O and her anti-A or anti-B antibodies cross the placenta and hemolyze the fetal A or B red blood cells (RBCs). Isoimmunization may also be the result of other antibodies, such as anti-E and anti-C. A positive direct Coomb's test, indicating maternal antibody deposited on the neonate's RBCs, will frequently be found, but is a poor predictor of hemolysis and hyperbilirubinemia.

Nonimmune causes of hemolysis include G-6-PD deficiency, a common enzyme deficiency occurring in some Mediterranean, Asian, and African populations. Severe hemolysis, often the result of an identifiable chemical trigger, may occur. Structural abnormalities of the RBC membrane (hereditary spherocytosis, elliptocytosis), propensity to increased

hemolysis in certain racial groups (e.g., Asian), pyruvate kinase deficiency, and extravasated blood (cephalhematoma, bruising) are other causes of nonimmune, increased hemolysis.

Diminished Bilirubin Elimination

Of the conditions resulting in diminished bilirubin conjugation, Crigler-Najjar syndrome is the most severe (also known as Arias type 1). This is a rare condition in which coding area mutations of the *UGT1A1* gene result in an abnormally structured UGT enzyme. The type 1 variant frequently leads to kernicterus early in neonatal life. Type 2 is less severe and typically responds to phenobarbital therapy, an inducer of UGT activity. Gilbert's syndrome is a genetic condition associated in Western populations with additional TA sequences in the promoter region of the *UGT1A1* gene. Jaundice in this condition may be the result of diminished bilirubin conjugation due to decreased UGT enzyme expression and also of increased heme catabolism combined with decreased bilirubin uptake into the hepatocyte. Gilbert's syndrome may combine with factors increasing bilirubin production to potentiate severe hyperbilirubinemia. A gene interaction has been proposed between Gilbert's syndrome and G-6-PD deficiency; neither Gilbert's syndrome nor G-6-PD deficiency, individually, results in an increase in the incidence of STB concentration >15.0 mg/dl over that of baseline. However, when the two conditions coexist, the incidence of hyperbilirubinemia increases significantly. Gilbert's syndrome also potentiates hyperbilirubinemia in hereditary spherocytosis and ABO blood group incompatibility and is associated with prolonged jaundice. In Asian populations, Gilbert's syndrome may be caused by a *UGT* gene-coding area mutation, Gly71Arg, which is also associated with hyperbilirubinemia.

Miscellaneous Causes

Sepsis, macrosomia associated with maternal diabetes, hypothyroidism, and being breast-fed are other conditions known to increase the severity of neonatal hyperbilirubinemia.

JAUNDICE IN BREAST-FED NEONATES

Some degree of jaundice is very common in breast-fed neonates. Not only do they have higher STB concentrations than formula-fed counterparts, but a higher incidence of hyperbilirubinemia as well. Almost all neonates readmitted to the hospital for hyperbilirubinemia are breast-fed. The jaundice may be due to unsuccessful breast-feeding, associated with chronic dehydration and failure to gain weight, which can be attributed to decreased milk or caloric intake. This condition usually becomes manifest in the first week of life and is frequently associated with weight loss >7% of birth weight, few wet diapers, and a small number of stools daily. The problem can be resolved by frequent nursing, including at night, and counseling regarding breast-feeding techniques. This condition has been distinguished from true breast milk jaundice, which develops gradually toward the second week of life. The cause is unclear, but exaggeration of the enterohepatic bilirubin circulation or the presence of β-glucuronidase or other substances in the milk may be associated. Increased hemolysis has not been demonstrated in these neonates. The diagnosis is one of exclusion, by ruling out other causes of indirect hyperbilirubinemia in a breast-fed infant. Usually the jaundice resolves, but STB concentrations may occasionally reach dangerous levels and kernicterus has been reported in breast-fed neonates with no additional cause of their hyperbilirubinemia. Temporary cessation of breast-feeding or a short period of phototherapy is usually effective in preventing further increases in STB.

ASSESSMENT OF JAUNDICE AND PREDICTION OF HYPERBILIRUBINEMIA

Age-Specific Serum Total Bilirubin Concentrations

It is important to assess the degree of jaundice according to an infant's age in hours. A study of the nomogram in Fig. 2 will reveal that there is a rapid increase in STB concentrations over the first few days of life. Thus, a neonate with a STB concentration of 12.0 mg/dl at age 72 h will be below the 40th percentile for hour of life, whereas a similar infant with the same STB concentration at 36 h will be above the 95th percentile. This concept is of extreme importance because of the current trend toward early discharge; babies sent home at age 48 h or less will frequently not yet have developed visible jaundice and bilirubin concentrations can be expected to increase during the next few days. In a study of universal predischarge bilirubin screening, babies whose STB concentrations were >95th percentile for hour of life at 18 to 72 h had a 40% risk of developing subsequent hyperbilirubinemia, whereas, in contrast, those whose concentrations were <40th percentile had zero risk. This method of

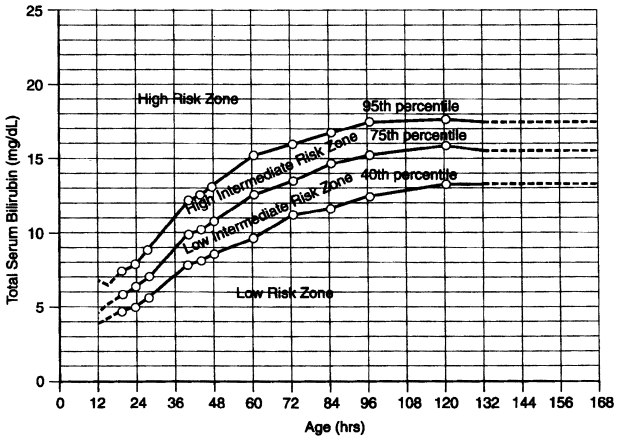

FIGURE 2 Nomogram for hour-specific serum total bilirubin values and the risk category for hyperbilirubinemia, in term and near-term neonates. Reprinted from Bhutani, V. K., Johnson, L., and Sivieri, E. M. (1999). Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. Reproduced with permission from *Pediatrics* vol. **103**, 6–14, Fig. 2. Copyright 1999, American Academy of Pediatrics.

prediction is not infallible but does serve to indicate which neonates can be sent home with a wide margin of safety.

Assessment of Hemolysis

The AAP has recommended determining whether hemolysis, a risk factor for kernicterus, is present when evaluating a jaundiced neonate. Commonly used indices, such as falling hemoglobin or hematocrit count, reticulocytosis, or haptoglobin, are unreliable indicators of hemolysis in newborns. Assessment of the endogenous rate of CO production affords an accurate index of the rate of bilirubin production (Fig. 1). Commercially available, noninvasive devices are currently available for determining the end-tidal CO (ETCO) concentration in the neonates' exhaled breath. ETCO concentrations >95th percentile accurately detect increased hemolysis but, because the rates of bilirubin elimination vary, are not predictive of the development of hyperbilirubinemia.

KERNICTERUS

Kernicterus occurs when free bilirubin (unbound to serum albumin) crosses the blood–brain barrier and is deposited in the basal ganglia of the brain. Bilirubin may also enter the brain after the blood–brain barrier has been damaged by conditions such as asphyxia or hyperosmolarity. Pathological findings of kernicterus include staining and necrosis of the basal ganglia, hippocampus, and subthalamic brain nuclei. It is thought that bilirubin-induced damage is the result of interference with oxygen utilization by the cerebral tissue, possibly by causing damage to the cell membrane.

Current thinking suggests that it is unlikely that kernicterus will develop in an otherwise healthy, term infant, with no evidence of hemolysis, if STB concentrations do not exceed 25 mg/dl. This level of bilirubin may not be safe, however, in actively hemolyzing neonates or in prematures. Hypoalbuminemia, conditions such as acidosis, sepsis, and hypothermia, or drugs including sulfisoxazole and benzyl alcohol may affect the ratio of free bilirubin : albumin bound bilirubin and facilitate the entry of free bilirubin into the brain.

Clinically, bilirubin encephalopathy is characterized by acute and chronic phases. Classically, the first stage of kernicterus is characterized by poor sucking and hypotonia in an obviously severely jaundiced neonate. A typical high-pitched cry, seizures, and stupor ensue. Several days later (second stage), hypertonia of the extensor muscles, especially arching of the back, opisthotonus, retrocollis, and fever develop. The third stage, following the first week, is characterized by hypotonia, diminishing yet persisting stupor, and poor sucking and swallowing movements. Survivors of the acute stage demonstrate hypotonia and delayed motor skills in the first year, followed by extrapyramidal abnormalities including movement disorders, choreoathetosis, and involuntary muscle spasms. Upward gaze, diminished cognitive function, and high-frequency sensorineural hearing loss frequently occur. Some children may be more mildly affected by bilirubin encephalopathy and display moderate neuromuscular incoordination, varying degrees of hearing loss, and learning problems, which become apparent only on entering school.

TREATMENT OF HYPERBILIRUBINEMIA

The primary reason for treating hyperbilirubinemia is to prevent bilirubin encephalopathy. The mainstay of therapy is phototherapy, with exchange transfusion held in reserve for the few cases nowadays that do not respond to phototherapy. Additional therapeutic modalities include the use of intravenous immune

globulin (IVIG), drug induction of UGT, and synthetic metalloporphyrins for the inhibition of bilirubin production.

The AAP has formulated guidelines, currently in the process of revision, for the management of jaundice in healthy, term neonates. It should be realized that these guidelines have not been based on controlled, therapeutic trials, but rather on experience and clinical practice. Treatment is instituted at lower levels of STB in situations in which hyperbilirubinemia is evident on the first day of life and in septic, otherwise ill or premature infants. Newborns with evidence of hemolysis should be treated with great vigilance and STB concentrations should not be allowed to exceed 20 mg/dl in these cases. Neonates with very high STB levels (>25 mg/dl, or >20 mg/dl in the presence of hemolysis) who do not respond to a trial of approximately 4 h of intensive phototherapy or whose STB levels continue to rise despite treatment should have exchange transfusion performed or a trial of IVIG therapy where indicated (see below).

Phototherapy

Phototherapy has been in clinical use for over 30 years. It is safe and effective and has been instrumental in preventing kernicterus and avoiding the need for exchange transfusion in neonates worldwide. Phototherapy should be instituted in order to prevent STB concentrations from reaching levels that are associated with neurotoxic damage.

Bilirubin is one of the few body substances that absorb light energy, especially in the blue range of 450 nm. Light causes isomerization of the bilirubin molecule, forming lumirubin, and this water-soluble substance can be more readily excreted via the liver than regular bilirubin. Photooxidation of bilirubin accounts for a small fraction of the bilirubin eliminated via phototherapy.

The rate of lumirubin production, and therefore the effectiveness of phototherapy, is dependent on the total intensity of irradiance delivered. The light energy can be increased by replacing white light bulbs with blue when using fluorescents and decreasing the distance from the bulbs to the infant or increasing the body surface area exposed to light. The intensity of light irradiance can be measured at the bedside in units of microwatts per square centimeter per nanometer and phototherapy units should be regularly assessed, as light output of the bulbs within the given spectrum may weaken with time. Fluorescent bulbs are frequently used, but halogen lamps or fiberoptic blankets or mattresses are also available. Phototherapy is generally regarded as safe to use, although the eyes must be well covered prophylactically.

Exchange Transfusion

Exchange transfusion definitively corrects hyperbilirubinemia by physically removing bilirubin, as well as antibodies when present, from the body. The procedure is usually performed via an umbilical catheter. Aliquots of blood are removed from the infants and replaced by donor RBCs mixed with plasma. One double volume exchange transfusion is usually effective, but sometimes additional exchange procedures are necessary depending on the degree of postexchange STB rebound.

Complications of the procedure include apnea, bradycardia, cardiorespiratory arrest, necrotizing enterocolitis, and a small risk of death. Exchange transfusion also carries the risk of complications associated with blood transfusion. Prior to embarking on an exchange transfusion, the risks should clearly be weighed against the benefits.

Pharmacologic Therapy

Phenobarbital

Phenobarbital, administered either to the pregnant mother or to the already delivered baby, is instrumental in inducing UGT enzyme activity and also in enhancing bilirubin excretion. However, it may take several days for it to be effective and may itself have neurotoxic properties.

Heme Oxygenase Inhibitors

Heme oxygenase is the enzyme responsible for converting heme to biliverdin, from which bilirubin is subsequently formed. Some metalloporphyrins have been shown to be powerful inhibitors of heme oxygenase, thereby preventing the formation of bilirubin from heme. Although not yet approved for routine clinical use, studies in Argentina and Greece have demonstrated the efficacy of tin-protoporphyrin in preventing hyperbilirubinemia. Toxicity appears to be minimal, in the form of transient erythema.

Intravenous Immune Globulin

IVIG has been shown to reduce the need for exchange transfusion in Rh isoimmunization and also to decrease the degree of hemolysis in Coombs' positive ABO blood group heterospecificity. It is thought that IVIG acts by blocking the Fc receptor in the reticuloendothelial system, thereby inhibiting hemolysis.

CONCLUSIONS

Neonatal jaundice is extremely common and in most cases resolves with no ill effects. However, the resurgence of kernicterus is a frightening reminder of the tragic and devastating potential danger of hyperbilirubinemia. All newborn babies should be closely monitored for icterus. If a serum or transcutaneous bilirubin test is performed, the risk of hyperbilirubinemia should be assessed by plotting the result on the hour-by-hour nomogram. Parents must be interviewed about hyperbilirubinemia in previous siblings or even in themselves as infants. They should be closely questioned about their family's geographic area of origin in order to exclude the possibility of G-6-PD deficiency. The AAP has recommended that all neonates discharged at 48 h or less should be examined 2 to 3 days later for the development of jaundice. Vigilant management of all neonates and careful explanations to parents are necessary if future cases of kernicterus are to be prevented.

Neonatal Intestinal Obstruction

AMIR KAVIANI, DARIO FAUZA, AND MORITZ M. ZIEGLER
Children's Hospital Boston and Harvard Medical School

atresia Absence or closure of a natural passage or channel of the body.
meconium Dark greenish mass of desquamated cells, mucus, and bile that accumulates in the fetal bowel and is typically discharged shortly after birth.
polyhydramnios Excessive accumulation of amniotic fluid.

Intestinal obstruction is the most common surgical emergency of the newborn. The incidence of neonatal intestinal obstruction is approximately 1 in every 500–1000 live births. Approximately 50% of these cases are associated with intestinal atresia or stenosis.

ETIOLOGY

Intestinal obstruction in the neonate may be caused by the comprehensive list of conditions depicted in Table I. Practically, neonatal intestinal obstruction is most commonly due to intestinal atresia, malrotation with or without volvulus, meconium ileus, and Hirschsprung's disease. Table II lists a practical age-related etiology for the most commonly encountered cases of generic pediatric intestinal obstruction.

CLINICAL PRESENTATION AND DIAGNOSIS

In most cases, intestinal obstruction in the newborn becomes apparent shortly after birth. In some cases, proximal obstructing lesions may result in proximal bowel dilatation and hyperperistalsis, demonstrated by prenatal ultrasonography. Polyhydramnios may be present when a "high" intestinal obstruction is present. The classic "double-bubble" sign associated with duodenal atresia can also be identified by prenatal ultrasonography.

Findings suggesting intestinal obstruction in the neonate include (1) maternal polyhydramnios, (2) excessive gastric aspiration at birth accompanied by the inability to tolerate initial feeds, (3) abdominal distension, (4) bilious emesis, and (5) obstipation. The presence and severity of each of these findings depend largely on the level of obstruction along the gastrointestinal tract.

Maternal Polyhydraminos

Amniotic fluid is normally swallowed by the growing fetus and is absorbed by the fetal gastrointestinal tract. The fetal kidneys excrete the fluid back into the amniotic sac, it crosses into the maternal circulation through the placenta, and is ultimately excreted by the mother's kidneys. Proximal gastrointestinal obstruction in the fetus results in interruption of this normal process and leads to accumulation of excess amniotic fluid. Distal intestinal obstruction usually does not result in excessive amniotic fluid accumulation, because most of the absorption takes place in the proximal small bowel.

Excessive Gastric Aspiration

Passage of a nasogastric tube or orogastric tube is commonly performed in the neonatal care unit in premature infants or in infants with a history of maternal polyhydramnios. Intestinal obstruction should be suspected if the initial aspirate is large (50–100 ml), or bilious in nature.

TABLE I Causes of Neonatal Intestinal Obstruction

Common
Malrotation (duodenal obstruction, volvulus, internal hernia)
Duodenal atresia, stenosis, annular pancreas
Jejunal atresia or stenosis
Ileal atresia or stenosis
Simple meconium ileus
Meconium ileus with perforation
Hirschsprung's disease
Hypertrophic pyloric stenosis
Uncommon
Pyloric atresia or web
Tumors
Intussusception
Segmental intestinal dilatation
Small left colon syndrome
Milk bolus obstruction
Colonic atresia
Functional intestinal obstruction
Intestinal pseudo-obstruction

TABLE II Age-Based Classification of the Most Common Etiologies of Intestinal Obstruction in the Pediatric Population

Age	Etiology
Newborn	Atresia
	Malrotation ± volvulus
	Meconium ileus
	Hirschsprung's disease
2 Months to 2 years	Incarcerated inguinal hernia
	Intussusception
Over 2 years	Adhesions

Bilious Emesis

Although preterm infants may display bilious emesis as a result of a poorly developed pyloric sphincter, bilious emesis in a term infant is distinctly abnormal. In cases of intestinal obstruction, vomiting begins usually shortly after birth in a proximal, complete lesion but may be delayed several hours in more distal or incomplete obstruction. Bilious emesis in the newborn remains a particularly urgent finding that may herald the diagnosis of malrotation with volvulus.

Failure to Pass Meconium

A normal newborn typically passes copious amounts of thick, dark green meconium within the first 8–24 hours after birth. Failure to do so may be normal, but it may also suggest obstruction. Passage of meconium does not, by itself, exclude the possibility of obstruction. Preterm infants may have delayed passage of meconium, and this must be taken into consideration when evaluating the premature infant for a bowel obstruction.

Intestinal patterning and peristalsis that is visible through the abdominal wall are suggestive of obstruction, and distended loops of small bowel may be palpated through the abdominal wall as tubular masses. Hypotonia and lethargy develop late in the obstructed infant and are usually a result of sepsis. Ecchymosis and discoloration of the abdominal wall may suggest free perforation or frank intestinal ischemic infarction.

DIAGNOSIS

The diagnosis of neonatal intestinal obstruction is based on clinical findings supplemented with radiographs. Flat, upright, and decubitus abdominal radiographs are helpful in elucidating the diagnosis. Air swallowed by the newborn shortly after birth normally reaches the proximal small intestine in 30 minutes and it passes to the level of the colon by 3–4 hours. In a complete bowel obstruction, the air pattern stops abruptly just proximal to the site of obstruction. Multiple dilated small bowel loops with the characteristic "step-ladder" pattern may be seen on an upright radiograph in cases of distal obstruction. Peritoneal or scrotal calcifications may signify intrauterine perforation with meconium peritonitis.

Contrast barium enema radiographs are useful when attempting to delineate the cause of a distal intestinal obstruction; for example, in cases of meconium ileus, meconium plug syndrome, distal bowel atresia, and Hirschsprung's disease, specific findings may be present. Upper gastrointestinal (GI) contrast studies are most useful in cases in which abnormal bowel rotation is suspected.

PATHOPHYSIOLOGY

Proximal bowel obstruction in the neonate leads to a loss of fluid that has high concentrations of hydrogen, potassium, and chloride ions, leading to a hypochloremic, hypokalemic metabolic alkalosis. More distal obstruction leads to significant intravascular volume depletion due to the osmotic fluid shifts resulting from the fluid sequestered in the intestinal lumen. When pronounced, this may lead to oliguria and shock. Ultimately, severe dehydration may lead to poor end organ perfusion, and when coupled with bowel distension, perforation, and necrosis, metabolic acidosis may result. Significant abdominal distension may also impair diaphragmatic excursion and lead to respiratory acidosis.

TREATMENT

When neonatal intestinal obstruction is suspected, the early management includes gastric decompression with a nasogastric tube to prevent vomiting and aspiration. Resuscitation with appropriate fluids and electrolytes should begin immediately. Surgical intervention, when indicated, should be undertaken immediately once adequate resuscitation has been achieved.

Neonatal Tracheoesophageal Anomalies

AMIR KAVIANI, DARIO FAUZA, AND MORITZ M. ZIEGLER
Children's Hospital Boston and Harvard Medical School

atresia Absence or closure of a natural passage or channel of the body.

fistula Abnormal passage or communication, usually between two internal organs or leading from an internal organ to the surface of the body.

VACTERL Acronym for abnormalities of vertebrae, anus, cardiovascular tree, trachea, esophagus, renal system, and limb buds; condition associated with administration of sex steroids during early pregnancy.

Tracheoesophageal malformations in the neonate refer to a spectrum of developmental anomalies in which an abnormal anatomic arrangement exists between the esophagus and the tracheobronchial tree.

INTRODUCTION AND HISTORICAL BACKGROUND

The first description of esophageal atresia (EA) dates back to 1670 in *A Narrative of a Monstrous Birth in Plymouth*, in which William Durston described a blind-ending esophageal pouch in one infant of a set of conjoined twins. Thomas Gibson, in 1697, was the first author to describe EA with the typical tracheoesophageal fistula (TEF), in *The Anatomy of the Human Body Epitomized*. Numerous case reports appeared in the literature in the eighteenth and nineteenth centuries regarding these conditions, meticulously detailing some of the associated anomalies, including spina bifida, horseshoe kidney, and imperforate anus.

The first successful report of primary repair of EA with TEF was described by Cameron Haight in 1941. After Haight's initial success, numerous other reports appeared in the literature, detailing successful operative repair and various surgical approaches to these conditions.

EPIDEMIOLOGY

The incidence of congenital tracheoesophageal malformations in the United States is approximately 1 in every 4500 live births. In some regions of the world (i.e., Finland), the incidence may be as high as 1 in every 2400 births. There is a slight male preponderance for EA, with a male : female ratio of 1.2 : 1. There is a reported increased incidence of EA and TEF in first pregnancies and a slight correlation with increasing maternal age.

Although most cases of EA and TEF are sporadic, familial patterns of inheritance have been reported. Parents with one affected child have a 1–2% chance of a tracheoesophageal malformation affecting subsequent offspring. If more than one offspring is affected, the risk is 20%. The rate of twinning among infants with EA and TEF is higher than that of the general population (6 vs. 1%), as is the incidence of chromosomal anomalies. The most common chromosomal anomalies include trisomies 13 and 18, and the well-described VACTERL (involving abnormalities of the vertebrae, anus, cardiovascular tree, trachea, esophagus, renal system, and limb buds) association. Environmental teratogens associated with these conditions include prolonged exposure to contraceptive pills and exposure to estrogen and progesterone during pregnancy. In addition, a higher incidence has been described in infants of diabetic mothers and in those with intrauterine exposure to thalidomide.

ANATOMY AND EMBRYOLOGY

Normal development of the esophagus and trachea remains poorly understood, and therefore the pathogenesis of EA and TEF is uncertain. Nevertheless, numerous theories have been put forth, mostly based on the original work of Wilhelm His, who described the invagination of the lateral longitudinal ridges as they give rise to the dorsal digestive tract and the ventral respiratory system. Most theories on the origin of EA and TEF conclude that an aberrant migration of the longitudinal ridges accounts for the spectrum of anomalies seen in EA and TEF.

Based on their studies of human embryos, O'Rahilly and Muller have proposed an alternate theory for the pathogenesis of EA and TEF. Their hypothesis suggests that the lung bud separates from the digestive tract by day 28 of gestation, descending caudally into the ventral mesenchyme of the foregut. Rather than proposing that the failure of regression of a normal connection between the two structures accounts for TEF, they suggest that a fistula is created by an abnormal epithelial-lined communication between the two originally separate tubes. They postulate that this event likely occurs on day 33 of gestation, when the esophagus and the tracheal bifurcation are in very close proximity.

Candidate genes responsible for EA and TEF have been proposed in chromosomal segments believed to be responsible for limb and foregut patterning. These genes may be responsible for normal migration and cell–matrix interactions during normal organ development.

CLASSIFICATION

Numerous classification systems exist for describing the spectrum of anomalies encountered in EA and TEF. In 1944, Ladd introduced a numeric form of classification that consisted of specific anomalies. Gross altered this numeric system in 1953, and introduced an alphabetical system that is commonly referenced today. Type A lesions are isolated esophageal atresia without a tracheoesophageal fistula and are frequently associated with a "long gap" between the proximal and distal esophageal segments. Type B lesions are esophageal atresias in association with a proximal tracheoesophageal fistula and are very rare, accounting for less than 1% of lesions. Type C lesions constitute the most common anomaly, and include a blind-ending proximal esophageal pouch with a distal tracheoesophageal fistula. In type D anomalies, there are two tracheoesophageal fistulas, one each from the proximal and distal esophageal segments. In type E anomalies, a tracheoesophageal fistula is present without an atresia (H-type fistula). Type F anomalies consist of congenital esophageal stenosis and are exceedingly rare.

ASSOCIATED ANOMALIES

Numerous congenital anomalies are associated with EA and TEF (Table I). Some reports have suggested that between 50–70% of infants with EA have other associated anomalies. These anomalies are most common in cases of EA without TEF, and least common in cases of H-type TEF. The most common anomalies involve the

TABLE I Anomalies Associated with Tracheoesophageal Fistula and Esophageal Atresia

Anomaly	Defect	Incidence (%)
Cardiovascular	Ventricular septal defect, tetrology of Fallot, atrial septal defect, patent ductus arteriosus, coarctation of aorta	49
Genitourinary	Hypospadias, cryptorchdism, renal agenesis, renal hypoplasia, cystic renal diseases, hydronephrosis, vesicoureteral reflux, ureteric duplication, urachal anomalies, cloaca or bladder exstrophy, posterior urethral valves	24
Gastrointestinal	Anorectal atresia, duodenal atresia, ileal atresia, malrotation, annular pancreas, pyloric stenosis	24
Neurologic	Hydrocephalus, neural tube defects, holoprosencephaly, microcephaly	23
Skeletal	Vertebral anomalies, radial limb deformities	13
VACTERL	Vertebral, anal, cardiovascular tree, tracheal, esophageal, renal, limb bud defects	25
CHARGE	Coloboma, heart, atresia (choanal), retardation, genital and ear defects	3
Choanal atresia	—	5.2
Facial cleft	—	7.2
Abdominal wall defect	—	4.3
Diaphragmatic hernia	—	2.9
Tracheobronchial	—	50

cardiovascular system (49%), followed by the genitourinary (24%), gastrointestinal (24%), and skeletal (13%) systems. Associated gastrointestinal anomalies include anorectal atresia, duodenal atresia, ileal atresia, malrotation, pyloric stenosis, and annular pancreas. Genitourinary defects include hypospadias, undescended testes, renal agenesis, cystic renal disease, hydronephrosis, and vesicoureteral reflux. Complex cardiac anomalies account for most of the deaths associated with EA. The most common single cardiac anomaly is ventricular septal defect, followed by tetrology of Fallot, patent ductus arteriosus, and atrial septal defects.

Quan and Smith proposed a broad spectrum of associated malformations in newborns. They described the acronym VATER (vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia, and renal defects.) The affected individuals had no family history of any given disorder, no chromosomal abnormalities, and no known exposure to a teratogen *in utero*. Later, the acronym was expanded to VACTERL, incorporating the frequently seen cardiac and limb anomalies. Infants with esophageal atresia who have features of VACTERL have a high mortality and poor overall prognosis.

CLINICAL PRESENTATION

Infants with EA and TEF typically become symptomatic in the first few hours of life. The most common symptom shortly after birth is the presence of excessive salivation resulting from pooling of secretions in the proximal blind-ending esophageal pouch and oropharynx. Feeding often results in regurgitation, choking, and cyanosis. Atelectasis, tachypnea, and respiratory distress occur as a result of reflux of gastric contents through the TEF into the airway, or aspiration of saliva or formula from the proximal blind pouch. Inspired air passing through the TEF into the stomach further distends the stomach and elevates the diaphragm, leading to more respiratory compromise. These symptoms may be less apparent in children with tracheoesophageal fistula without esophageal atresia (H-type fistula), for which the clinical presentation may be delayed until indolent or recurrent pulmonary symptoms require further evaluation.

DIAGNOSIS

The prenatal diagnosis of EA is suggested by the finding of a small or absent gastric bubble in conjunction with maternal polyhydramnios. Although suggestive, this finding occurs in only 42% of cases of EA and has a positive predictive value of 56%. *In utero* ultrasonographic visualization of the blind upper esophageal pouch has been reported, but this relies on advanced ultrasonographic skills and is an inconsistent finding.

Pooling of secretions in the posterior oropharynx may be one of the earliest findings, and typically the first feeding is followed by regurgitation and coughing. Cyanosis with or without feeding may be present, and passage of a gastric decompression tube will be impossible. Resistance is typically encountered when the tube is passed to about 11−12 cm. A plain chest radiograph typically demonstrates the nasogastric tube coiling in the proximal esophageal pouch. The abdominal portion of the X ray may reveal bowel gas or even a "double-bubble" sign if an associated obstruction is present. The distance between the distal most margin of the coiled tube and the carina is used to estimate the gap between the blind-ending proximal esophageal pouch and the distal esophageal segment. A distance of less than two vertebral bodies is associated with a higher likelihood of being able to effect a primary repair. If diagnostic uncertainty exists, a small volume of water-soluble contrast (1−2 ml) can be carefully injected through the catheter under radiographic guidance to outline the blind-ending pouch. A proximal coiled tube associated with a gasless abdomen suggests that the correct diagnosis is an isolated esophageal atresia without a TEF. Once the diagnosis is confirmed, a thorough search for other recognizable congenital defects should begin.

TREATMENT

Initial treatment of infants with tracheoesophageal malformations is aimed at prevention of aspiration and resultant pulmonary soiling. A suction catheter is placed in the proximal esophageal pouch to continuously aspirate saliva and limit aspiration. The infant is positioned in an upright position to minimize gastroesophageal reflux and prevent aspiration through the TEF. Broad-spectrum antibiotics and a histamine-2 (H2) blocker are empirically started. Routine endotracheal intubation is avoided if at all possible, because ventilated air entering through the tracheoesophageal fistula can cause worsening respiratory distress resulting from abdominal distension, and in a worst-case scenario, gastric perforation may occur.

The surgical approach depends on the specific anomaly present. For type C lesions, division of the fistula and the primary anastomosis of the esophagus is the procedure of choice. The usual approach is a right-sided posterolateral extrapleural thoracotomy through the 4th interspace, unless preoperative evaluation reveals a right-sided aortic arch. Recently, minimally

TABLE II Spitz Classification and Survival

Group	Description	Total representation (%)	Survival (%)
I	Birth weight >1500 g without major congenital cardiac defect	79	97
II	Birth weight <1500 g or major congenital cardiac defect	19	59
III	Birth weight <1500 g and major congenital cardiac defect	2	22

invasive thoracoscopic techniques have been applied to this operation. In cases of isolated tracheoesophageal fistulas (E type), a cervical approach is usually possible, and the fistula is divided through a right-sided incision. In cases of "long-gap" esophageal atresia, other modalities of delayed or staged therapy may be necessary, including colonic interposition and gastric pull-up in order to reestablish a conduit.

OUTCOMES

Overall survival of neonates with tracheoesophageal malformations in modern series is approximately 90%. The original Waterston classification incorporated risk factors associated with EA and TEF and was based on birth weight, presence of pneumonia, and other congenital anomalies. These factors predicted those infants with a poor risk for survival and they helped guide operative treatment and neonatal critical care. Infants in the "good" risk category (A) were typically treated with immediate operative repair, "moderate-risk" infants (B) were managed with delayed repair, and "high-risk" infants (C) were treated by staged repair. Given the numerous advances in neonatal intensive care, more options have become available for the infant with multiple congenital anomalies, leading to development of newer classification schemes. In 1992, Spitz and colleagues published their results of a large review demonstrating that birth weight and presence of major cardiac disease remained important predictors of survival (Table II).

Complications after repair of tracheoesophageal anomalies include anastomotic leak (14–20%), recurrent tracheoesophageal fistula (3–14%), esophageal stricture (20–40%), gastroesophageal reflux (40–70%), and tracheomalacia and/or obstruction (10–20%). Esophageal dysmotility in the esophageal segment below the anastomosis is common and is part of the original lesion, not secondary to surgical transection of the esophagus.

functional gastrointestinal disorders Associated with symptoms that are present in the absence of any observable organic or physical abnormalities; symptoms include abdominal pain, bloating, early satiety, and urgency of defecation.

Neurogastroenterology is the name given to a relatively new scientific and clinical subspecialty that developed in the last quarter of the twentieth century. Neurogastroenterological research is a logical progression of the neurologically oriented research in basic medical sciences and of the advances in the understanding of functional gastrointestinal disorders in clinical gastroenterology.

NEUROGASTROENTEROLOGY DEFINED

In clinical medicine, neurogastroenterology subspecializes further the subspecialty of gastroenterology. Neurogastroenterology encompasses the investigative sciences dealing with functions, malfunctions, and malformations in the brain and spinal cord and the sympathetic, parasympathetic, and enteric divisions of the autonomic innervation of the digestive tract. Somatomotor systems are included insofar as pharyngeal phases of swallowing and pelvic floor involvement in defecation and continence are concerned. Basic physiology of smooth muscles, as it relates to enteric neural control of motor movements, is a part of neurogastroenterology. Psychologic and psychiatric relations to gastrointestinal disorders are significant components of the neurogastroenterologic domain, especially in relation to projections of discomfort and pain to the digestive tract.

Neurogastroenterology as the descriptor for a specialized sector of gastroenterology has emerged from the parallel fertilization of research in the basic medical sciences and of diagnosis and treatment of functional gastrointestinal disorders in clinical medicine. Basic neurogastroenterologic research integrates physiology, biochemistry, neurobiology, anatomy/histology, endocrinology, microbiology, immunology, and pharmacology into a unified subspecialty focused on the innervation of the digestive system. Clinical gastroenterology applies the emergent knowledge in the diagnosis and treatment of functional gastrointestinal disorders, examples of which are irritable bowel syndrome, functional dyspepsia, and brain–gut relations in physical and emotional stress.

Neurotensin

ARTHUR SHULKES
University of Melbourne

autocrine action Activity elicited from a nonneuronal cell in response to factors released by that same cell.
enterogastrone Hormonal substance released in response to the presence of intestinal fats; causes physiological inhibition of gastric acid secretion.
neurocrine action Activity elicited from a neuron in response to factors released by an adjacent cell or neurone.
neuromodulator Substance that can alter the release or effect of a neurotransmitter.
paracrine action Activity elicited from a nonneuronal cell in response to factors released by an adjacent cell.

Neurotensin is a 13-amino-acid peptide originally isolated from the hypothalamus; similar peptides have been subsequently found in other parts of the brain, the pituitary, and the intestine. The gut, predominantly the ileum, contains more than 90% of immunoreactive neurotensin. Although circulating neurotensin concentration is increased by a meal, the mechanisms of action are predominantly neurocrine, paracrine, and neuromodulator rather than endocrine. The most important functions in the gut are vasodilation, stimulation of the exocrine pancreas, growth of normal and cancerous tissues, and slowing of gastrointestinal transit.

CHEMISTRY, ISOLATION, AND DISTRIBUTION

During the isolation of substance P from bovine hypothalami, Leeman and colleagues in 1973 isolated a 13-amino-acid peptide; because of the vasodilatory and cyanotic effects of the peptide, it was named neurotensin. Neurotensin (NT) was subsequently shown to have a widespread distribution in the central nervous system, pituitary, and intestine. Furthermore, neurotensin and neurotensin-related peptides are represented across the phylogenetic tree (Table I). The C terminus, which is the bioactive core, is conserved, whereas the N-terminal peptide, NT(1–8), may be an inactive but stable degradation product generated following cleavage at the dibasic Arg^8–Arg^8 residues. Some of the early literature is contradictory and confusing, often because the specificity of the antisera is not stated and the extraction technique could generate artifacts or degradation products. The ileum contains the highest concentration of neurotensin, with lesser amounts in the jejunum and duodenum. Neurotensin is present in specific endocrine cells, the N cells, and in nerves, predominantly in the myenteric plexus. Overall, the intestine contains more than 90% of neurotensin. Most of the remaining NT is in the brain, particularly the hypothalamus and pituitary.

GENE AND PRECURSOR STRUCTURE

The complementary deoxyribonucleic acid (cDNA) for neurotensin was first obtained in 1987 using cultured canine ileal mucosal cells, which would have been

enriched for both neurotensin peptide and mRNA. Neurotensin is synthesized within a 170-amino-acid precursor that also encodes the related peptide neuromedin N (Fig. 1). These two peptides are located near the C terminus and are separated by basic residue pairs. The rat neurotensin/neuromedin N gene was isolated by screening a genomic library with the canine cDNA. The rat gene has 10.2 kb and is divided into four exons, with exon 4 containing the coding region for both neurotensin and neuromedin N. Two species of mRNA have been identified (1.0 and 1.5 kb); the differences reside in the lengths of the 3′ untranslated tail. A similar pattern is seen in the human gene. The 1.0-kb form predominates in the intestine and pituitary, with equivalent amounts of the 1.0- and 1.5-kb forms in the brain and in tumors. The nucleotide and amino acid sequences are highly conserved (>80%) between humans, dogs, cows, and rats. Not all the precursor molecules are processed and proneurotensin and proneuromedin are found in the gastrointestinal tract and in tumor cell lines. In the gut, proneurotensin accounts for 2–5% of neurotensin immunoreactivity, but proneuromedin N is the major form of gut neuromedin. Proneurotensin is an order of magnitude less potent than neurotensin, but because of increased stability may contribute to the actions of neurotensin. The prohormone convertases, PC1 and PC, have the major roles in the processing of gut proneurotensin.

SECRETION

Ingestion of fat is the most potent stimulant of gastrointestinal neurotensin release; glucose and amino acids cause insignificant increases. The majority of neurotensin is rapidly metabolized into biologically inactive but stable N-terminal fragments, predominantly neurotensin(1–8), with the bioactive C-terminal fragment neurotensin(9–13) being very rapidly metabolized. Thus, the increase in circulating bioactive neurotensin following a meal is quite modest and less than that required for a biological effect, such as inhibition of acid secretion or gastric emptying. Nevertheless, neurotensin may function in concert with other regulatory peptides, such as cholecystokinin, to influence gastrointestinal functions. Infusion of fat into the jejunum but not the ileum of humans and dogs increases NT release. However, ileal resection abolishes the increase in NT. Together, these data suggest that neurotensin is released from the ileum via a local humoral or neural stimulus emanating from the proximal intestine. Two facts—that the initial release of neurotensin following a meal occurs within 10 minutes, which is before chyme would reach the ileum, and that it is abolished by atropine—support this reflex hypothesis. Neurally mediated release appears to involve a nonvagal cholinergic mechanism, because truncal vagotomy does not abolish the postprandial increase and stimulants of vagal tone, such as sham feeding and insulin hypoglycemia, have no effect on neurotensin. Cholinergic independent mechanisms may also be involved, because bombesin-stimulated release of neurotensin is not atropine sensitive.

RECEPTORS

Neurotensin binding sites were first demonstrated in rat brain synaptic terminals and subsequently detected in jejunum and ileum, especially in the submucosal and myenteric plexuses. Three receptor subtypes that recognize the C-terminal, biologically active part of neurotensin have been cloned and characterized. Neurotensin receptor type 1 (NTR1) and NTR2 are both G protein-coupled receptors, whereas NTR3 is identical to the previously cloned human gp95/sortilin receptor.

Neurotensin Receptor Type 1

The cDNA clone for NTR1 was obtained from a rat brain cDNA library using an electrophysiological assay in *Xenopus* oocytes as the end point. The cDNA encodes a 424-amino-acid protein (similar in size to that reported earlier by chemical isolation) that, as suggested by pharmacological studies, is a member of the G protein-coupled receptor family. The human receptor has been cloned from the colonic adenocarcinoma

cell line HT29. The receptor has a high affinity (0.2 n*M*), is insensitive to levocabastine, and is expressed in the intestine and brain. Studies with NTR1 knockout mice have demonstrated a major role for this receptor in mediating central temperature control and gastric and colonic motility. Signal transduction mechanisms are through coupling with phospholipase C and subsequent increases in intracellular Ca and inositol 1,4,5-trisphosphate. Mitogen-activated protein kinases are also activated by neurotensin. Both pathways are inhibited by nonpeptide neurotensin receptor antagonists such as SR 48692 and SR 142948. Based largely on studies with these antagonists, NTR1 is the probable mediator of the growth effects of NT on pancreas, and gastrointestinal tract and on pancreatic and colorectal cancer cell lines, although NTR3 may also play a contributory role (see later). NTR1 mRNA has been detected in many colorectal and pancreatic carcinoma cell lines. However. receptor autoradiography of resected colorectal tumors was positive for NTR1 in only one of 25 tumors.

Neurotensin Receptor Type 2

NTR2 is a low-affinity (5−7 n*M*) receptor that shares about 60% homology with NTR1 and is sensitive to levocabastine. Although it has the characteristics of a G protein-coupled receptor, the transduction mechanisms have not been completely characterized and appear to be system and species specific. Furthermore, neurotensin antagonists have paradoxical agonist functions in some species. The receptor is expressed mostly in the brain but in a distribution pattern different to NTR1, so there is rarely coexpression. The NTR2 receptor appears to mediate neurotensin-induced analgesia. No specific gastrointestinal role has been demonstrated for NTR2 and no NTR2 binding sites could be detected in the human colon and no NTR2 mRNA in human pancreatic and colon cancer cell lines.

Neurotensin Receptor Type 3

A third neurotensin binding site was isolated by affinity cross-linking of brain extracts; following cloning, the site was shown to have 100% homology with the previously cloned human gp95/sortilin receptor. This protein has a large luminal domain, a single-transmembrane domain, and a short cytoplasmic tail. The majority of NTR3 is located in intracellular vesicles, but some is also found on the cell membrane. NTR3 mRNA and intracellular binding sites are detected in pancreatic and colonic cancer cell lines. NTR3 mediates NT-stimulated cell growth in cancer cell lines either alone or as a heterodimer with NTR1.

BIOLOGICAL EFFECTS

Neurotensin has a variety of biological effects; more than 30 different *in vitro* and *in vivo* effects have been documented. Peripheral effects include vasodilation, cyanosis, increased histamine release, stimulation of the endocrine and exocrine pancreas, effects on gastrointestinal tract smooth muscle activity and motility, stimulation of intestinal secretion, and inhibition of blood flow to adipose tissue. Neurotensin promotes the growth of the gastrointestinal tract as well as gut- and pancreatic-derived cancer cell lines. Centrally, neurotensin has hypothermic and antinociceptive effects and modulates brain dopamine systems, luteinizing hormone, and prolactin release. Only the gastrointestinal effects will be considered further.

Neurotensin secretion is stimulated by fat and is thought to be the mediator of many of the effects influenced by fat ingestion. These include inhibition of gastrointestinal transit and gastric acid secretion and stimulation of pancreatic secretion and intestinal blood flow. However, infusion studies mimicking the postprandial release of neurotensin indicate that the amount secreted is insufficient to mediate these actions. Neurotensin is therefore thought to function by interacting with other hormones, such as cholecystokinin, secretin, and the cholinergic and noncholinergic components of the enteric nervous system. Finally, neurotensin functions as a locally acting paracrine agent, and its location in specific enteric neurones indicates a role as a neurotransmitter.

Gastrointestinal Secretions

Neurotensin administered either intracerebroventricularly or peripherally inhibits gastric acid secretion. The peripheral effect is dependent on an intact vagus. The concentration of neurotensin required to inhibit gastric acid secretion is higher than that achieved following a high-fat meal and it is likely that neurotensin acts in concert with other meal-stimulated enterogastrones, such as secretin.

A similar interaction is observed with exocrine pancreatic secretion. Neurotensin alone increases exocrine pancreatic secretions whereas the combination of neurotensin with secretin potentiates pancreatic protein output and the combination of neurotensin with cholecystokinin potentiates pancreatic bicarbonate secretion. Cholinergic pathways also contribute to the pancreatic stimulatory effect of neurotensin. Early studies reporting that neurotensin stimulated insulin secretion used pharmacological doses. Neurotensin is now not thought to have a role in regulating the

endocrine pancreas. Intestinal secretion is also stimulated by relatively low doses of neurotensin.

Motility

Many of the motility effects of neurotensin mimic the motility changes that occur following the conversion from the fed to the fasted state. Neurotensin or ingestion of a fat meal reduces lower esophageal sphincter pressure, slows gastric emptying and intestinal transit, and inhibits the interdigestive migratory complex. As with other effects of neurotensin, an interaction with vagal cholinergic components is required. Once fat reaches the ileum, there is a further inhibition of gastric and intestinal motility, and this appears to be mediated by the distal small intestine peptide YY (PYY) together with neurotensin. *In vitro* studies performed to determine the mechanism of the motility effects of neurotensin have been difficult to interpret because the responses are dose, region, and species dependent. Neurotensin *in vitro* has both a direct relaxant and an indirect contractile action, with the relaxant effect being tetrodotoxin resistant and the contractile effect dependent on cholinergic and substance P-mediated mechanisms. Studies with both neurotensin antiserum and antagonists suggest that neurotensin is one of the noncholinergic, nonadrenergic mediators of relaxation in the small intestine. Overall, the consequence of these motility changes is that the chyme from a meal rich in fat is retained longer in the stomach and intestine, which should aid digestion and absorption of nutrients.

Growth

Many of the peptides produced by the intestine are growth factors. These include epidermal growth factor, transforming growth factor-α (TGF-α), insulin-like growth factor-1 (IGF-1), and glucagon-like peptide-2 (GLP-2). Neurotensin also has a trophic effect on the gastrointestinal tract and pancreas, but the specific contribution of neurotensin among the constellation of growth factors has not been resolved.

Animal studies have shown that neurotensin infusion is trophic for the pancreas, stomach, and intestine. However, relatively high doses are required. Neurotensin enhances the trophic effect of GLP-2, whereas the trophic effects of IGF-1 and TGF-α are mediated in part by increases in neurotensin production. The hypoplasia induced by feeding rats an elemental diet is reversed by neurotensin infusion. Similarly, the adaptive response following either small or large bowel resection is augmented by neurotensin administration.

PATHOLOGY

Neurotensin-producing pancreatic endocrine tumors are quite rare and are often associated with the overproduction of other bioactive peptides, such as vasoactive intestinal peptide. Because vasoactive intestinal peptide and neurotensin both stimulate intestinal secretion, it has been difficult to determine whether neurotensin is responsible for the diarrhea often associated with pancreatic endocrine tumors. Studies with neurotensin antagonists in patients with the watery diarrhea hypokalemia achlorhydria syndrome have not been reported. Hepatic fibrolamellar tumors and some prostatic tumors also overproduce neurotensin, often resulting in elevated blood neurotensin concentrations. Again, no specific symptoms have been associated with neurotensin overproduction in these tumors. The nature of the neurotensin produced is quite variable, ranging from intact neurotensin, proneurotensin, inactive neurotensin(1–8), and bioactive C-terminal fragments 6–13 or 9–13.

Neurotensin gene expression has been detected in 10 of 40 colorectal cancers tested. This expression was not detected in adjacent normal colonic mucosa. Interestingly, neurotensin gene and peptide are present in fetal colon, suggesting a recapitulation of the fetal phenotype under some circumstances. Using receptor autoradiography, only a small proportion of human colorectal cancers express NTR1, although the surrounding muscle and nerve cells are labeled. Whether the NTR3 subtype is present is unknown.

Neurotensin administration to rats increases the number and size but not the incidence of colon tumors induced by azoxymethane. The mechanism has been ascribed to an increase in proliferation, although the doses of neurotensin and azoxymethane were high.

Extensive studies with colon cancer cells either *in vitro* or *in vivo* after xenografting have confirmed a proliferative effect of neurotensin that is inhibited by NTR1 antagonists. However, NTR1 and NTR3 are both detected on colon cancer cell lines and interact in a cooperative manner. About half of colorectal cancer cell lines tested contain neurotensin receptors, determined either by binding studies or expression of receptor mRNA. The NTR1 receptor antagonist alone inhibits the endogenous growth of xenografted colon cancer cells, raising the possibility that neurotensin antagonists could be used therapeutically. The neurotensin receptor antagonist may function by inhibiting an autocrine regulatory loop, because many colon cancer cell lines contain neurotensin mRNA and peptide. Whether endogenous, meal-stimulated neurotensin has a stimulatory role on tumor growth has not been determined.

Similar to other peptide growth factors detected in tumors, processing efficiency is diminished and there is a preponderance of neurotensin precursor detected in colon cancer lines. However, proneurotensin is more stable than the fully processed neurotensin(1–13) and is able to activate NTR1 receptors in the nanomolar range.

Neurotensin receptors (both mRNA and binding) have been detected in nearly all pancreatic carcinomas. However, unlike normal colon, neurotensin receptors are also detected in normal pancreas, albeit at lower levels than in the tumors. In pancreatic cancer cell lines, the neurotensin antagonist SR 48692 inhibits both basal and neurotensin-stimulated proliferation, consistent with an endocrine or autocrine regulation of growth.

Patients with the dumping syndrome have exaggerated meal-stimulated release of neurotensin, probably as the result of the rapid passage of nutrients from the stomach to the small intestine. Neurotensin is not the responsible agent, because intravenous infusion does not mimic the symptoms. Another instance of exaggerated neurotensin release occurs in patients with severe chronic pancreatitis. The excess neurotensin response is probably the result of undigested fat products in the small intestine, because it is reversed by enzyme replacement therapy.

In terms of therapeutic value, the trophic effect of neurotensin could be of theoretical benefit in patients who have atrophy of the bowel associated with long-term parenteral feeding, or in patients who have had small intestine resection. However, a long-lasting analogue will be required for this to be tested in human clinical trials. Finally, the efficacy of the NTR1 subtype antagonist SR 48692 in moderating experimental pancreatic and colorectal carcinogenesis indicates a potential role for neurotensin antagonists.

Nitric Oxide

PAUL KUBES
University of Calgary, Canada

inflammation Body's response to infection or injury, including increased swelling, redness, heat, pain, and white cell infiltration (puss formation).
inflammatory bowel disease Chronic inflammation of the intestines.
nitric oxide Gas produced by cells of the brain, blood vessels, and immune system.
nitric oxide synthase-2 Protein that produces abundant bactericidal nitric oxide in response to inflammation.
nitric oxide synthase-3 Protein that continuously produces small amounts of nitric oxide to maintain normal blood pressure.

Nitric oxide is synthesized from a guanidino group of L-arginine and can be produced by virtually all mammalian cells, including endothelium lining the vasculature, epithelial cells, neurons of the central and enteric nervous systems, and cells of the immune system. Nitric oxide is constitutively produced by an enzyme normally present primarily in endothelium lining the vasculature (nitric oxide synthase-3; NOS3) and a neurally associated nitric oxide synthase found in neurons of the brain and enteric nervous system (NOS1). The constitutive forms of nitric oxide synthase, including neuronal NOS (NOS1) and endothelial NOS (NOS3), are critical to normal physiology. Nitric oxide produced from NOS3 maintains adequate perfusion, regulates microvascular permeability, modulates platelet homotypic aggregation as well as platelet adhesion to vessel walls, and regulates leukocyte–endothelial cell interactions. In the gastrointestinal tract, NOS3 appears to also regulate epithelial permeability. NOS1 is associated with the enteric nervous system and presently there is very limited information about its potential inflammatory/antiinflammatory function. Although NOS2, an inducible isoform of nitric oxide synthase, is not considered constitutive, small amounts of NOS2 message and protein have certainly been reported under normal conditions in the intestinal tract, and so a role for this isoform cannot be excluded in intestinal homeostatic function.

INTESTINAL INFLAMMATION

Acute and chronic inhibition of constitutive nitric oxide causes many of the hallmark features of intestinal inflammation, including increased neutrophil recruitment, increased oxidative stress, mast cell degranulation, and increased microvascular and epithelial permeability. Many studies of acute inflammatory models have documented that exogenous nitric oxide protects the gastrointestinal mucosa against noxious stimuli. Although improvement in blood flow associated with increased NO delivery would be an important factor in countering the compromised blood flow due to damaging effects of lumen-based insults such as HCl, ethanol, and indomethacin, NO can also protect at subdilatory levels.

NITRIC OXIDE SYNTHASE-2

Nitric oxide synthase-2 (NOS2) is an enzyme that requires protein synthesis for significant expression in endothelium, epithelium, and inflammatory cells; it is induced by cytokines and lipopolysaccharide (LPS) and produces large amounts of nitric oxide for extended periods of time. Three key observations underlie the hypothesis that NOS2 contributes to prolonged inflammation in a negative manner: (1) large quantities of nitric oxide are produced by NOS2, (2) expression patterns of NOS2 have correlated nicely with prolonged inflammation, and (3) many studies have shown that NO synthase inhibition reduces inflammation; this third observation is the most compelling evidence to suggest that NOS2 does contribute to intestinal inflammation. NO synthase inhibitors provide extremely beneficial results in a model of chemically induced (trinitrobenzenesulfonic acid; TNBS) guinea pig ileitis. Increased nitric oxide production from NOS2 has also been documented in a spontaneous, idiopathic, rhesus monkey colitis model. In that model, NOS2 inhibitor reduced the diarrhea but did not alter the morphological features of the disease. The TNBS-induced colitis was greatly improved in mice lacking NOS2 (NOS2−/− mice) and resulted in 90% mortality in wild-type mice and 38% mortality in the NOS2−/− counterparts.

It is important to note that not all studies support a detrimental role for NOS2. In a model of mucosal injury and repair not involving a chronic phase of inflammation,

 Copyright 2004, Elsevier (USA). All rights reserved.

the inducible NOS (iNOS)-deficient mice healed less effectively than did their wild-type counterparts, an observation recently noted in other tissues. In another study using TNBS-induced colitis in iNOS−/− mice, within the first 72 hours of TNBS-induced colitis the iNOS−/− mice had an approximately 50% greater damage score and increased neutrophilic infiltrate. By day 7, as the model entered the chronic phase of inflammation (mast cell hyperplasia and macrophage and lymphocyte infiltration), there was no difference in the various parameters of injury measured between iNOS−/− and iNOS+/+ mice. NOS2 deficiency is not important in interleukin-10 (IL-10)-deficient mice spontaneously developing chronic intestinal inflammation.

PEROXYNITRITE

Peroxynitrite, a potent nitrosating agent, may be the product that makes NOS2 detrimental. NO and superoxide react in essentially a diffusion-limited fashion to produce peroxynitrite. This product has a half-life of 1.9 seconds at pH 7.4 and exists in equilibrium with peroxynitrous acid. Peroxynitrous acid generates an excited isomer that acts as a hydroxyl-like oxidizing species, or, by direct homolysis of peroxynitrous acid, produces hydroxyl. In this fashion, peroxynitrite oxidizes a variety of molecules (sulfhydryls, thiols, and ascorbate) and triggers cytotoxic processes, including lipid peroxidation and DNA damage. Initial work suggests that peroxynitrite but not nitric oxide can also nitrosate tyrosine, to produce 3-nitrotyrosine. Because peroxynitrite is presently impossible to measure *in vivo* due to its high reactivity, 3-nitrotyrosine formation is used as a fingerprint of peroxynitrite formation. Intense immunostaining of nitrotyrosine has been detected in rodent and human colitis. It should be noted that that 3-nitrotyrosine could be formed from nitrite (NO_2^-) in the presence of hypochlorous acid or human polymorphonuclear leukocytes (a source of hypochlorous acid), suggesting this is not a specific marker of peroxynitrite. Although current work does question the specificity of nitrotyrosine, it does not necessarily refute the existence of peroxynitrite *in vivo*. A criticism levied against the formation of peroxynitrite per se has been the requirement for the simultaneous generation of equivalent amounts of nitric oxide and superoxide to generate optimal levels of peroxynitrite. Because the relative cellular concentration of superoxide is in the order of 1000 times lower than nitric oxide, the amount of peroxynitrite produced is limited, in a site-specific fashion, to areas of high superoxide anion generation or, alternatively, to low nitric oxide levels. Surprisingly, peroxynitrite under some conditions may function to prevent injury, an event that requires further investigation.

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

SALAHUDDIN KAZI
University of Texas Southwestern Medical Center, Dallas

cyclooxygenases Family of enzymes, of which at least two isoforms exist, cyclooxygenase-1 and cyclooxygenase-2. They act on arachidonic acid to produce a number of compounds, including prostaglandins and thromboxane.

prostaglandins One form of eicosanoids (biologically active lipids formed by the oxidation of 20-carbon fatty acids); produced by the cyclooxygenase pathway, they are responsible for a variety of physiologic and inflammatory reactions.

Non-steroidal Anti-inflammatory drugs (NSAIDs) are a heterogeneous group of chemical compounds that share common mechanisms of action, therapeutic effects, and toxicities. The prototypical drug is aspirin. There are over 20 NSAIDs currently available in the United States. Nearly 20 million persons in the United States use these drugs on a daily basis, making this group of drugs one of the most widely prescribed agents. Systematic reviews have not found important differences in efficacy between different NSAIDs, but differences in toxicity have been demonstrated.

HISTORY

Salicylic acid is the active ingredient in willow bark, the medicinal effects of which have been known for several centuries. Sodium salicylate was first used in 1875 for the treatment of rheumatic fever. Hoffman, a chemist working for the pharmaceutical company Bayer, synthesized acetylsalicylic acid in 1897. This compound was introduced into medicine in 1899 under the name of aspirin. Since the introduction of indomethacin in 1963, a number of similar agents have been synthesized. In 1971, John Vane established that aspirin inhibits the synthesis of prostaglandins. Within the past decade, it has become clear that inhibition of two enzymes is involved. With the elucidation of these two enzymes, cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2), increasingly sophisticated and specific compounds have been produced in attempts to improve efficacy and lower toxicity. Cyclooxygenase-3 (COX-3) is a recently described variant of COX-1.

NOMENCLATURE AND CLASSIFICATION

The NSAIDs are classified based on COX specificity and chemical structure. The nonselective COX inhibitors include salicylate derivatives such as aspirin, sodium salicylate, sulfasalazine, and diflunisal. The *para*-aminophenol derivatives include acetaminophen, and the indole acetic acid derivatives include indomethacin and etodolac. The heteroarylacetic acid derivatives are typified by diclofenac. Arylpropionic acids include ibuprofen and naproxen. The fenamates include mefenamic acid, and the enolic acids include piroxicam and meloxicam. Nabumetone is an alkalone. Some of the nonselective COX inhibitors (meloxicam, etodolac, and diclofenac) display COX-2 selectivity, especially at low doses. COX-2-selective inhibitors include nimuselide, rofecoxib, celecoxib, valdecoxib, etoricoxib, and lumiracoxib. Of these, rofecoxib, valdecoxib, and celecoxib are currently licensed in the United States.

MECHANISM OF ACTION

Non-steroidal Anti-inflammatory drugs act principally by inhibiting the synthesis of prostaglandins. This appears to be the basis of both the Anti-inflammatory and analgesic effects. This inhibition is mediated by competitively inhibiting the enzyme, cyclooxygenase, responsible for the synthesis of prostaglandins. Additionally, the NSAIDs also inhibit the formation of prostacyclin and thromboxane, both of which are involved in vascular permeability and platelet aggregation. This is the basis of the anticoagulant effect seen with the NSAIDs, especially that of aspirin, which irreversibly acetylates the COX enzymes.

As already noted, there appear to be two well-defined isoforms of the COX enzymes that differ both in their tissue distribution and their inducibility. COX-1 is widely expressed in most tissues, with a constitutive level of expression, being especially important in the upper gastrointestinal tract, where it helps maintain the integrity of the mucosa. COX-2 is considered an

 Copyright 2004, Elsevier (USA). All rights reserved.

inducible enzyme and is typically undetectable in most tissues. During states of inflammation, the levels of COX-2 are greatly increased. The targeting of COX-2 with concomitant sparing of COX-1 has been the driving force behind the development of COX-2-selective NSAIDs. It is increasingly recognized that the dichotomy of physiologic significance of COX-1 and COX-2 isoforms is not mutually exclusive, with COX-1 likely involved in the prevention of gastrointestinal ulcers and central perception of pain and COX-2 being critical to renal blood flow and electrolyte balance.

Both isoforms of the COX enzyme are inhibited to some degree by all currently available NSAIDs. Several traditional NSAIDs have been shown to be more selective for COX-2 than for COX-1, especially at low doses. This is typical of etodolac and meloxicam. At higher doses, this relative specificity is typically lost. The COX-2-specific inhibitors are much more likely to retain this selectivity even at higher doses. Large, prospective trials of the COX-2-specific inhibitors have suggested a decreased incidence of clinically important upper gastrointestinal events, although the influence on renal function and effects on the coagulation cascade remain to be fully elucidated. Prospective trials to understand the effects of COX-2-specific inhibitors on the coagulation pathway are underway.

An exciting new development has been the demonstration of a COX-1 variant, called COX-3, suggesting that multiple COX isoenzymes could be derived from just two distinct genes providing a COX continuum of enzymes and products. Other proposed mechanisms of action for NSAIDs are based on their lipophilic properties. Direct interruption of protein−protein interactions may underlie some of the effects attributed to NSAIDs.

PHARMACOLOGY

NSAIDs are well absorbed following oral administration. Once absorbed they are typically highly bound to serum albumin because they are weak organic acids. Most NSAIDs are metabolized predominantly in the liver and are subsequently excreted in the urine. This has important implications in patients with hepatic and/or renal dysfunction. Some NSAIDs (indomethacin, sulindac, and piroxicam) have prominent enterohepatic circulation. This may result in a prolonged half-life. NSAIDs with short half-lives achieve maximum plasma concentrations quickly whereas those with longer half-lives achieve this more slowly. Sulindac and nabumetone require conversion to an active compound after first-pass metabolism through the liver. Once steady-state pharmacokinetics have been achieved, tissue concentrations of NSAIDs do not vary greatly. Highly lipid-soluble NSAIDs can penetrate the central nervous system and may cause adverse effects such as headache; this is most frequently noted with indomethacin.

CLINICAL USES

Pain

NSAIDs have been widely used as single-dose therapy or as short-term intermittent therapy, to relieve mild to moderate pain. Most episodes of acute musculoskeletal pain, muscular headaches, dysmenorrhea, and postoperative pain respond well to NSAIDs, although there is a paucity of randomized controlled trials demonstrating improved efficacy over acetaminophen in acute musculoskeletal syndromes. NSAIDs are occasionally effective as monotherapy in chronic pain, but are typically used as an adjunct to opioids in the management of severe pain. They may be particularly effective in bony pain of malignant origin. NSAIDs are increasingly used for the management of postoperative pain, especially following day-surgery, because of the lack of sedative effects.

Fever

NSAIDs are effective antipyretic agents, comparable to acetaminophen. Aspirin is generally avoided in children with fever because of a possible link between its use and the development of Reye's syndrome. Ibuprofen is widely utilized in children with febrile illnesses.

Osteoarthritis

NSAIDs, because of their anti-inflammatory effects, are particularly attractive analgesics in patients with osteoarthritis. Systematic reviews have found that NSAIDs are effective in reducing the pain of osteoarthritis. No particular NSAIDs has been found more effective than the others have in this regard. Comparative trials of NSAIDs versus simple analgesics such as acetaminophen (which may act via COX-3) have not shown good evidence that NSAIDs are superior to simple analgesics in the treatment of osteoarthritis.

Rheumatoid Arthritis

NSAIDs are widely prescribed in the management of rheumatoid arthritis, especially in early disease, for which they are utilized as "bridge" therapy, because traditional disease-modifying antirheumatic drugs achieve benefits only after several weeks of therapy.

Other Uses

NSAIDs have been utilized for the management of biliary and renal colic, acute gout, the spondyloarthropathies, and as topical agents for the management of inflammatory ocular disorders. High doses of celecoxib have been utilized in the management of familial adenomatous polyposis (FAP).

ADVERSE EFFECTS

Gastrointestinal effects include an increased incidence of dyspepsia, peptic ulceration, intestinal ulceration, and blood loss. Renal effects must be considered with patients whose renal function is dependent on prostaglandin synthesis; such patients, who are especially vulnerable to renal side effects from NSAID therapy, include the elderly and patients with diabetes, cirrhosis, hypertension, congestive heart failure, and chronic renal insufficiency from any cause. Such patients on NSAID therapy have predictable increases in blood pressure and in peripheral edema and decreases in glomerular filtration rate. The COX-2-selective agents are as likely to cause nephrotoxicity (and therefore offer no renal advantage) when compared with nonselective NSAIDs.

Other adverse effects are much less common and include hepatotoxicity, photosensitivity eruptions, headache with or without meningitis, tinnitus (especially with aspirin), worsening of asthma and allergic rhinitis, and worsening of osteoarthritis (specifically with indomethacin). The antiplatelet effects of aspirin may manifest as easy bruisability. It remains to be determined definitively whether COX-2-selective NSAIDs have prothrombotic effects.

Nonalcoholic Fatty Liver Disease

PAUL ANGULO
Mayo Medical School, Clinic, and Foundation

acanthosis nigricans Disorder involving localized skin hyperpigmentation; appears as velvety hyperpigmentation, primarily in flexural areas. It is usually associated with obesity, type 2 diabetes mellitus, Cushing's syndrome, acromegaly, and the Stein–Leventhal syndrome.

insulin resistance Decreased ability of insulin to act effectively on peripheral target tissues, especially muscle and liver; resistance is relative, because supernormal levels of circulating insulin will normalize the plasma glucose.

oxidative stress Refers to increased generation of reactive oxygen species or free radicals, including superoxide anions, hydrogen peroxide, and hydroxyl radicals; occurs as a consequence of accumulation of fat within hepatocytes. The reactive oxygen species or free radicals seem to induce chemotaxis and accumulation of inflammatory cells in the liver.

truncal obesity Denotes waist/hip ratio (waist circumference divided by hip circumference) equal to or greater than 0.85 and 0.90 in women and men, respectively.

Nonalcoholic fatty liver disease is an increasingly recognized clinicopathological condition that may progress to end-stage liver disease. The pathological picture resembles alcohol-induced liver injury, but occurs in patients who do not abuse alcohol. This disease comprises a wide spectrum of liver damage, ranging from simple steatosis, to steatohepatitis, to advanced fibrosis and cirrhosis. Steatohepatitis (nonalcoholic) represents only a stage within the spectrum of nonalcoholic fatty liver disease. Nonalcoholic fatty liver disease and steatosis with or without hepatitis resulting from secondary causes should be differentiated (Table I) because they have distinctly different pathogeneses and outcomes.

RISK FACTORS

Obesity, type 2 (non-insulin-dependent) diabetes mellitus, and hyperlipidemia are comorbid conditions frequently associated with nonalcoholic fatty liver disease (NAFLD). The prevalence of obesity reported in several series of NAFLD studies varies between 30 and 100%; the prevalence of type 2 diabetes varies between 10 and 75% and the prevalence of hyperlipidemia varies

TABLE I Causes of Fatty Liver Disease

Nutritional	Drugs[a]	Metabolic/genetic	Other
Protein-calorie malnutrition	Glucocorticoids	Lipodystrophy	Inflammatory bowel disease
Starvation	Synthetic estrogens	Dysbetalipoproteinemia	Small bowel diverticulosis with bacterial overgrowth
Total parenteral nutrition	Aspirin	Weber–Christian disease	HIV infection
Rapid weight loss	Calcium channel blockers	Wolman's disease	Enviromental hepatotoxins
Gastrointestinal surgery for obesity	Amiodarone	Cholesterol ester storage	Phosphorus poisoning
	Tamoxifen	Acute fatty liver of pregnancy	Petrochemical exposure
	Tetracycline		Toxic mushrooms
	Methotrexate		Organic solvents
	Perhexiline maleate		*Bacillus cereus* toxins
	Valproic acid		
	Cocaine		
	Antiviral agents		
	Zidovudine		
	Didanosine		
	Fialuridine		

[a] Partial list of agents that produce fatty liver in humans. Some drugs produce inflammation as well. The association of fatty liver with calcium channel blockers and valproic acid is weak, whereas the association with amiodarone is strong. Drug-induced fatty liver may have no sequelae (i.e., corticosteroids), or can eventuate in cirrhosis (i.e., methotrexate and amiodarone).

 Copyright 2004, Elsevier (USA). All rights reserved.

between 20 and 92%. The prevalence of NAFLD increases by 4.6-fold in obese people. Regardless of body mass index, type 2 diabetes mellitus significantly increases the prevalence and severity of NAFLD. Truncal obesity seems to be an important risk factor for NAFLD, even in subjects with normal body mass index. About half of patients with hyperlipidemia were found to have NAFLD on ultrasound examination in one study. Hypertriglyceridemia rather than hypercholesterolemia may increase the risk of NAFLD. NAFLD may affect any age group and has been described in most racial groups.

PREVALENCE

NAFLD affects 10−24% of the general population worldwide. The prevalence of NAFLD, however, increases to 57.5−74% in obese people. NAFLD affects 2.6% of children and this figure increases to 22.5−52.8% in the obese pediatric population. NAFLD represents a common explanation for abnormal liver tests in blood donors, and it is the cause of asymptomatic elevation of aminotransferases in up to 90% of cases once other causes of liver disease are excluded.

The prevalence of NAFLD in the United States is unknown, although a good estimate can be derived from the known prevalence of obesity and type 2 diabetes mellitus in the general population. Obesity as defined by a body mass index (BMI) $\geq 30\ kg/m^2$ affects 22.5% of people aged 20 years or older. Steatosis, regardless of diabetic status, is found in over two-thirds of the obese population and in more than 90% of the severely obese (BMI $\geq 35\ kg/m^2$) individuals. Steatohepatitis affects about 3% of the lean population, 19% of the obese individuals, and almost half of severely obese people. Hence, when extrapolated to the 2002 United States population, an estimated 30.1 million obese adults in this country may have steatosis, and about 8.6 million may have steatohepatitis. Diabetes mellitus affects 7.8% of the United States adult population whereas 50% (range 21−78%) of diabetic patients have NAFLD.

CLINICAL FEATURES

Most patients with NAFLD have no symptoms or signs of liver disease at the time of diagnosis, although many patients complaint of fatigue or malaise and a sensation of fullness or discomfort in the right upper abdomen. Hepatomegaly is the only physical finding in most patients. Acanthosis nigricans may be found in children with NAFLD. Stigmata of chronic liver disease suggest advanced disease with cirrhosis. A high proportion of patients with cryptogenic cirrhosis shares many of the clinical and demographic features of patients with NAFLD, suggesting that cryptogenic cirrhosis was previously unrecognized NAFLD.

Mild to moderate elevation of serum aminotransferases is the most common and often the only laboratory abnormality found in patients with NAFLD. The aspartate aminotransferase/alanine transaminase (AST/ALT) ratio is usually less than 1, but this ratio increases as fibrosis advances, leading to a loss of its diagnostic accuracy in patients with cirrhotic stage. Serum alkaline phosphatase and/or γ-glutamyl transpeptidase are above the normal range in many patients. Other abnormalities, including hypoalbuminemia, prolonged prothrombin time, and hyperbilirubinemia, may be found in patients with cirrhotic stage NAFLD. Elevated serum ferritin levels are found in a half of patients and increased transferrin saturation is found in 6−11% of patients. Hepatic iron index and hepatic iron concentration, however, are usually in the normal range.

Fatty infiltration of the liver produces a diffusely increased echogenicity when compared to the kidney texture on ultrasonography. Cirrhosis regardless of etiology is associated with a similar appearance. Ultrasonography has a sensitivity of 89% and a specificity of 93% in detecting steatosis, and a sensitivity and specificity of 77 and 89%, respectively, in detecting increased fibrosis. Fatty infiltration of the liver produces a low-density hepatic parenchyma on a computer tomography (CT) scan. Magnetic resonance (MR) imaging can distinguish space-occupying lesions from focal fatty infiltration or focal fatty sparing.

LIVER HISTOLOGY

NAFLD is histologically indistinguishable from the liver damage resulting from alcohol abuse. Liver biopsy features include steatosis, mixed inflammatory cell infiltration, hepatocyte ballooning and necrosis, glycogen nuclei, Mallory's hyaline, and fibrosis. The presence of these features, alone or in combination, accounts for the wide spectrum of NAFLD. Fatty infiltration, necroinflammation, and hepatocyte ballooning are mostly seen in acinar zone 3, but their distribution is more diffuse in more severe cases of NAFLD. Mallory's hyaline is usually located in ballooned hepatocytes, but it is neither unique nor specific for NAFLD. Portal tracts are relatively spared from inflammation, although children with NAFLD may show a predominance of portal inflammation as opposed to a lobular infiltrate. Mallory's hyaline is notably sparse or absent in children with NAFLD.

Fibrosis in NAFLD suggests more advanced and severe liver injury. Some degree of fibrosis is found in up to 66% of patients at the time of diagnosis. Collagen is first laid down in the pericellular space around the central vein and in the perisinusoidal region in zone 3. This pattern of fibrosis helps to distinguish NAFLD and alcoholic liver disease from other forms of liver disease in which fibrosis shows an initial portal distribution. The combination of (a) steatosis; (b) mixed mononuclear and/or polymorphonuclear cell infiltration; and (c) hepatocyte ballooning and spotty necrosis is known as nonalcoholic steatohepatitis (NASH).

PATHOGENESIS

The pathogenesis of NAFLD has remained poorly understood since the earliest description of the disease. Much current thinking remains hypothetical and the mechanisms are still being worked out. It is not yet understood why some patients develop simple steatosis whereas others develop steatohepatitis and progressive disease; differences in body fat distribution or antioxidant systems, possibly in the context of a genetic predisposition, may be among the explanations. A net retention of lipids within hepatocytes, mostly in the form of triglycerides, is a prerequisite for the development of NAFLD. The primary metabolic abnormality leading to lipid accumulation, however, is not well understood, but it could potentially result from insulin resistance and alterations in the uptake, synthesis, degradation, or secretory pathways of hepatic lipid metabolism. Insulin resistance represents the most reproducible factor for the development of NAFLD. Increased intrahepatic concentration of fatty acids provides a source of oxidative stress, which may be in large part responsible for the progression from steatosis to steatohepatitis to cirrhosis. Mitochondria are the main cellular source of reactive oxygen species (ROS), which may trigger steatohepatitis and fibrosis by two main mechanisms: lipid peroxidation and cytokine induction.

Humans with steatohepatitis exhibit ultrastructural mitochondrial lesions, including linear crystalline inclusions in megamitochondria. This mitochondrial injury is absent in most patients with simple steatosis or in healthy subjects. After a fructose challenge, which causes acute hepatic ATP depletion, patients with steatohepatitis slowly resynthesize ATP *in vivo*. This impaired ATP recovery may reflect the mitochondrial injury found in patients with steatohepatitis. Thus, although obese, diabetic, or hyperlipidemic patients with fatty liver rarely develop symptoms of liver disease, the steatotic liver may be vulnerable to further injury when challenged by additional insults. This has led some to presume that progression from simple steatosis to steatohepatitis to advanced fibrosis results from two operating "hits." First, insulin resistance leads to accumulation of fat within hepatocytes, and second, mitochondrial ROS lead to lipid peroxidation and cytokine induction.

DIAGNOSIS

NAFLD is usually suspected in individuals with asymptomatic elevation of aminotransferases, radiological findings of fatty liver, or unexplained persistent hepatomegaly. Imaging studies help in determining the presence and amount of fatty infiltration of the liver, but the clinical suspicion of NAFLD and its severity can be confirmed only with a liver biopsy.

The diagnosis of NAFLD requires exclusion of alcohol abuse as the cause of liver disease; abuse involves a daily alcohol intake as low as 20 g in females and 30 g in males. Other etiologies, such as viral, autoimmune, metabolic/hereditary, and drug/toxin-induced liver disease, should be ruled out. Specific laboratory tests along with a number of histologic findings on liver biopsy make the diagnosis of these other liver diseases straightforward in most cases.

Given the lack of effective medical therapy for all patients with NAFLD, a liver biopsy may not be necessary for the simple purpose of making the diagnosis in a patient with clear risk factors (obesity, diabetes, or hyperlipidemia). However, a liver biopsy may provide the most useful diagnostic information for those patients who do not have any risk factors for NAFLD, as well as for those patients whose liver test results do not improve after weight loss and appropriate metabolic control. Some factors can help to identify the NAFLD patient for whom the liver biopsy may provide the most prognostic information. Age older than 45 years, presence of obesity or type 2 diabetes mellitus, and an AST/ALT ratio greater than 1 are noteworthy indicators of advanced liver fibrosis.

NATURAL HISTORY

The natural history of NAFLD is being defined, but it seems to be determined by the severity of histological damage. Out of 257 patients with NAFLD reported in five different series, 54 had subsequent liver biopsies performed during an average followup of 3.5–11 years. Of these patients, 28% had progression of liver damage, 59% remained essentially unchanged, and 13% showed improvement or resolution of liver injury. Thus, in many patients, NAFLD follows a

relatively benign course, whereas, in other patients, the disease progresses to cirrhosis and its complications. Patients with pure steatosis on liver biopsy seem to have the best prognosis within the spectrum of NAFLD, whereas features of steatohepatitis or more advanced fibrosis are associated with a worse prognosis.

MANAGEMENT

In patients with diabetes mellitus or hyperlipidemia, good metabolic control is always recommended, but is not always effective in reversing NAFLD. Improvement in liver tests is almost universal in obese adults and children after weight reduction. The degree of fatty infiltration usually improves with weight loss in most patients, although the degree of necroinflammation and fibrosis may worsen. How fast weight loss is achieved is important and may play a critical role in determining whether liver histology will improve or, in fact, worsen. A weight loss of about 500 g/week in children and 1600 g/week in adults has been advocated. The use of medications that can directly reduce or reverse liver damage independent of weight loss is a desired alternative. However, only small pilot studies lasting 1 year or less have been reported to date. Medications that have been tested in patients with NAFLD are summarized in Table II. These medications deserve further evaluation in carefully controlled powerful clinical trials that include clinically relevant end points.

TABLE II Medications Evaluated in the Treatment of Nonalcoholic Fatty Liver Disease

Medication type	Example
Insulin sensitizing	Metformin
	Troglitazone[a]
	Rosiglitazone
	Pioglitazone
Antioxidant	Vitamin E
	Vitamin C
	Betaine
	N-Acetylcysteine
Antiobesity	Orlistat
Hepatoprotective	Ursodeoxycholic Acid
Lipid lowering	Gemfibrozil
	Clofibrate
	Bezafibrate
	Atorvastain

[a] Troglitazone has been removed from the market because of its potential hepatotoxicity.

General Recommendations

An attempt at gradual weight loss along with appropriate control of serum glucose and lipid levels is a useful first step. Perhaps this should be the only treatment recommendation for patients with NAFLD with pure steatosis and no evidence of necroinflammation or fibrosis. Because most patients who develop problems from NAFLD have steatohepatitis, treatment is more likely to be aimed at those patients. Patients with steatohepatitis, particularly those with fibrosis on liver biopsy, should be monitored closely, make a greater effort for adequate metabolic control, and be offered enrollment in clinical trials. For the NAFLD patient with decompensated cirrhosis, liver transplantation is a potential therapeutic alternative. NAFLD, however, may recur in the allograft or develop after liver transplantation for cryptogenic cirrhosis.

Nosocomial Infections

ARMINE MARGARET SEFTON
Barts and the London, Queen Mary's School of Medicine and Dentistry, London

coliforms Gram-negative aerobic rods, which are part of the family *Enterobacteriacae* and which are found in normal bowel flora.
nosocomial Hospital acquired.

Nosocomial infections of the gastrointestinal (GI) tract include bacterial and viral diarrhea, sepsis relating to surgical and invasive procedures on the GI tract, hospital-acquired infective hepatitis, and nosocomial infections resulting from the colonization and/or infection of other areas of the body with organisms arising from the GI tract.

INTRODUCTION

A nosocomial infection is one that is hospital acquired. These infections can have significant morbidity and mortality and have a large financial impact on hospital resources. They lead to increased stay length of infected patients, resulting in decreased total throughput of patients. They also lead to increased utilization of antimicrobials and high-intensity beds for patients developing nosocomial infections. In addition, they lay the hospital open to the potential risk of litigation.

The three most common types of nosocomial infection are urinary tract infections, wound and soft tissue infections [including those resulting after procedures on the gastrointestinal (GI) tract], and nosocomial pneumonia, which frequently occurs due to aspiration of bacteria colonizing the oropharynx or upper gastrointestinal tract. However, nosocomial infections, per se, of the gastrointestinal tract are also a significant cause of morbidity and sometimes mortality in hospitals and nosocomial gastrointestinal infections can lead to multiple ward closures.

NOSOCOMIAL GASTROINTESTINAL INFECTIONS

Diarrhea is the most common nosocomial infection of the gastrointestinal tract. It can be bacterial or viral in origin and can sometimes result in multiple ward closures within a hospital.

Bacterial Infections

Antibiotic-Associated Diarrhea and Pseudomembranous Colitis

Giving a patient broad-spectrum antimicrobials changes his or her bowel flora and can lead to antibiotic-associated diarrhea. This is usually mild, is not associated with a particular organism, and resolves when the antibiotics are stopped. However, approximately 20% of cases of antibiotic-associated diarrhea are due to a specific bacterium, *Clostridium difficile*, that has a spectrum of disease ranging from an asymptomatic carrier state to fulminant colitis. It affects mainly the large bowel, and in severe disease, when the bowel is examined using a sigmoidoscope, sometimes pseudomembrane formation can be seen; hence the name pseudomembranous colitis.

C. difficile is a spore-forming, Gram-positive, anaerobic rod. It was given its name as it was initially found to be difficult to grow in culture and isolate. The spores are very hardy and can survive well in the ward environment. Hence, it can easily be transmitted by person-to-person contact within the hospital environment unless strict hand-washing and enteric precautions are used when dealing with infected patients. It is primarily a nosocomial infection and is thought to cause approximately three million cases of diarrhea or colitis each year in the United States.

Treatment of symptomatic *C. difficile* infection should begin with supportive measures and stopping the offending antimicrobial therapy if at all possible; if this is not possible, therapy should be changed to an antimicrobial not commonly implicated in causing *C. difficile* diarrhea. Specific therapy includes oral metronidazole or oral vancomycin. Metronidazole is usually given as first-line therapy because of the increasing incidence of vancomycin-resistant enterococci in hospitals and the worry that nonessential use of oral vancomycin might increase this incidence further. Very occasionally, the colitis caused by *C. difficile* does not respond to therapy and the patient must undergo a colectomy. Preventive measures to minimize the spread and acquisition of *C. difficile* diarrhea include the isolation of symptomatic patients to prevent

 Copyright 2004, Elsevier (USA). All rights reserved.

cross-infection and the judicious use of antibiotics such as broad-spectrum cephalosporins.

Other

In the past, there have been outbreaks of diarrhea in hospitals due to organisms such as *Salmonella* spp. and *Clostridium perfringens* resulting from the inadequate cooking or reheating of food. Salmonella infections may happen if inadequately cooked chicken or egg dishes are given to patients; if enteric precautions are not taken with infected patients, patient-to-patient transmission can then occur as well. Diarrheal illness due to *C. perfringens* is associated with poorly reheated meat dishes. These infections should not happen if food is properly prepared and stored.

Viral Infections

Small Round Structured Viruses

Small round structured viruses (SRSVs) are the most common cause of outbreaks of gastroenteritis in hospitals as well as in nursing homes, schools, hotels, etc. The norovirus (known as Norwalk virus until recently) is one of the most commonly implicated causes. Nosocomial outbreaks often lead to ward closures and can sometimes affect several wards in one hospital. This in turn leads to major disruption in the normal functioning of the hospital. Ward outbreaks tend to affect both patients and staff and sometimes have an attack rate in excess of 50%. This results in significant staffing problems and often staff aware of this situation try to return to work too early and while still infectious; this further compounds the problem. SRSVs may spread by a variety of routes including fecal–oral, vomit/aerosols, food, and water. Once the SRSVs have been introduced into the ward by any one of these routes, person-to-person spread then occurs. By the time an outbreak has been identified, most susceptible patients on the ward will have already been exposed to the virus. Hence, stringent attempts should be made to try and prevent spread to other wards and clinical areas by restricting patient and staff movements to other areas, enforcing good hand hygiene, and implementing effective environmental decontamination. It is important to prevent patients from becoming dehydrated but no specific therapy is available.

Rotavirus

Whereas SRSVs are the major cause of ward outbreaks of viral gastroenteritis in adults, rotaviruses are the most common cause of these outbreaks in pediatric wards. Outbreaks tend to occur in the winter months and the virus can spread within the ward environment very quickly. The virus is named for its characteristic wheel-like appearance when viewed under an electron microscope (see Fig. 1). The incubation period of rotavirus is approximately 2 days and the disease is characterized by vomiting and watery diarrhea for approximately 3–7 days. Diagnosis is by rapid antigen detection of rotavirus in the stools; electron microscopy of the stools, although less widely available, can also confirm the diagnosis. Prevention and minimization of spread are as for SRSVs, with the isolation and cohort nursing of infected patients. It is vital to ensure that the affected children are adequately rehydrated but no specific therapy is available.

SEPSIS RELATING TO SURGICAL PROCEDURES

Infections are a common complication after surgery on the gastrointestinal tract. They can range from mild superficial wound infections to a fatal septicemia resulting from generalized peritonitis. Many, but not all, of these infections can be prevented by appropriate chemoprophylaxis and/or optimal surgical technique. Patient factors and preoperative diagnosis are also

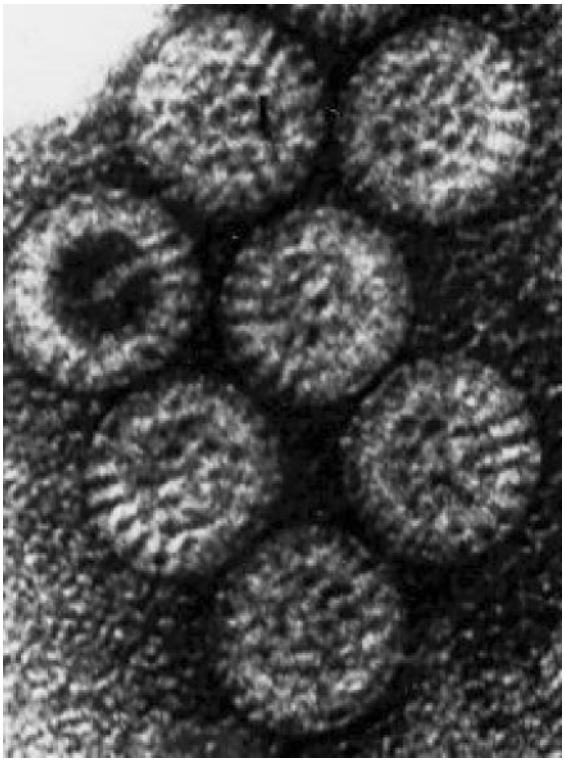

FIGURE 1 An electron micrograph of human rotavirus.

important factors in the likelihood of the patient developing a postoperative infection. Some examples of nosocomial infection post-GI surgery are given below.

Leaking of Anastomoses

Leaking of colonic or rectal anastomoses is more likely to occur than leaking of anastomoses in the small bowel. Sometimes anastomoses are noticed immediately postoperatively but often do not become apparent until several days later when bowel function has returned. A leaking anastomosis may lead to a generalized peritonitis, a local abscess, or fistula formation.

Abdominal Drains

Drains are often required postsurgery but should be removed as soon as they are no longer required because, like any foreign body in a person, they are a potential site of infection. The same applies to drains following biliary tract surgery.

Secondary Fungal Infections

Some patients who have had complicated abdominal surgery and who have presented with severe peritonitis require long courses of antimicrobials to get their bacterial sepsis under control. Unfortunately, this can dramatically change their normal flora, making them more susceptible to both local and systemic fungal infections.

Infection after Biliary Surgery

Operations in the presence of obstructive jaundice are not infrequently followed by wound infections most commonly due to *Escherichia coli*. Preoperative chemoprophylaxis will reduce infection rates, especially if the common bile duct is opened, if acute cholecystitis or obstructive jaundice is present, or if an intestinal anastomosis is performed. Cholangitis and septicemia due to coliforms sometimes occur after surgery for obstructive jaundice. The incidence of these conditions will also be reduced by appropriate preoperative chemoprophylaxis.

Septic Complications of Endoscopic Retrograde Cholangiopancreatography

Ascending cholangitis is a potential complication of endoscopic retrograde cholangiopancreatography (ERCP). Reported mortality rates in different series for post-ERCP cholangitis range between 10 and 16%. Ascending cholangitis results from bacterial infection of an obstructed biliary system, usually from enteric Gram-negative rods, resulting in bacteremia. Incomplete drainage of the biliary system after ERCP occurs in up to 10% of patients who require stenting. It has been suggested that appropriate early antibiotic therapy in this group of patients would probably reduce the frequency of cholangitis post-ERCP by 80%. Therapy should be continued until complete drainage has occurred. An antimicrobial such as ciprofloxacin, which achieves high levels in the biliary tract, should be started empirically but modification of therapy may be required following culture and sensitivity results of biliary fluid and blood, a local abscess, or a fistula.

Sepsis Postpancreatitis

One of the most important risk factors in patients suffering from acute necrotizing pancreatitis is pancreatic infection. The route of infection is probably via the colon and in patients with severe acute pancreatitis the infection rate is thought to be over 40% within the first 3 weeks. Not surprisingly, the bacteria most commonly implicated are those that reside in the gastrointestinal tract, such as *E. coli*, enterococci, and *Pseudomonas* spp. There is increasing evidence that patients with acute necrotizing pancreatitis benefit by starting antimicrobial therapy early, i.e., at initial presentation, as this has been found to decrease the infection rate at 3 weeks. Therapy should be broad spectrum; e.g., a carbapenem has often been recommended.

HEPATITIS

Hepatitis B and hepatitis C are both blood-borne viruses with the potential for nosocomial transmission in surgical or invasive procedures. To prevent this from occurring, all instruments involved in invasive techniques should be adequately sterilized and known carriers of the disease should be placed at the end of a list. All medical staff should be immunized against hepatitis B and in many countries hepatitis B carriers are not allowed to perform invasive procedures in order to prevent doctor-to-patient transmission.

NOSOCOMIAL INFECTIONS RESULTING FROM COLONIZATION OF OTHER AREAS OF THE BODY WITH ORGANISMS ARISING FROM THE GASTROINTESTINAL TRACT

Pneumonia

Pneumonia is the third most common nosocomial infection and is associated with substantial morbidity and mortality. It usually occurs in patients with severe

underlying disease, immunosuppression, or decreased conscious levels, due to either disease or anesthesia/analgesia, patients with underlying cardiac or respiratory disease, and those who have had thoracic or abdominal surgery. Nosocomial pneumonia usually occurs due to aspiration of bacteria colonizing the oropharynx or upper gastrointestinal tract of the patient. Both intubation and mechanical ventilation greatly increase the risk of developing nosocomial pneumonia as they breach the patient's first line of defense (the mucociliary escalator) against invasion of the respiratory tract by microorganisms. The risk of developing nosocomial pneumonia can be minimized by trying to decrease the risk of the patient aspirating, by preventing cross-infection of ventilator tubing, by good hygiene of medical personnel, and by adequate sterilization/disinfection of all devices associated with ventilating patients if they are not "single use." In some instances, there may be a place for reducing oropharyngeal and gastric colonization by potentially pathogenic microorganisms by a process known as "selective gut decontamination."

Sepsis Due to Resistant Organisms in the Bowel Flora

Patients who have received a lot of broad-spectrum antimicrobials for severe ongoing sepsis frequently become colonized with resistant organisms originating from the bowel flora, such as vancomycin-resistant enterococci and multi-resistant Gram negative rods, e.g., multi-resistant *Klebsiella* and *Acinetobacter* spp. Sometimes these colonizations can lead to bacteremias with these organisms, which can be difficult and expensive to treat. Hence, unnecessary antimicrobial treatment should be avoided.

NSAID-Induced Injury

BYRON CRYER

Department of Veteran's Affairs Medical Center and University of Texas Southwestern Medical Center, Dallas

cyclooxygenase Enzyme found throughout the body; responsible for the production of prostaglandins and thromboxane; inhibited by nonsteroidal antiinflammatory drugs.

diaphragm Specific type of stricture that develops in the small intestine or colon of chronic users of nonsteroidal antiinflammatory drugs.

leukotriene Fatty acid product of arachidonic acid that contributes to the proinflammatory response.

nonsteroidal antiinflammatory drugs Compounds that are therapeutically effective in reducing inflammation and treating pain and fever; cause injury to the gastrointestinal tract as their principal side effect.

prostaglandins Fatty acids produced by most of the body's cells; within the gastrointestinal tract, protect against injury.

thromboxane Product of cyclooxygenase metabolism in platelets; serum concentrations of thromboxane correlate with platelet activity.

Although nonsteroidal antiinflammatory drugs represent a very effective class of drugs, their use is associated with a broad spectrum of injury, especially in the gastrointestinal tract and kidney. Antiplatelet effects of nonsteroidal antiinflammatory drugs (aspirin particularly) are beneficial for cardiovascular disease prophylaxis, but excessive bleeding is an associated consequence. The upper gastrointestinal side effects constitute the greatest of the untoward effects of nonsteroidal antiinflammatory drugs.

INTRODUCTION

Nonsteroidal antiinflammatory drugs (NSAIDs) are prescribed more frequently than any other group of medicines. The 2002 edition of "The Physician's Desk Reference" lists 26 different NSAIDs, 6 of them salicylate-based compounds and 3 of them classified as cyclooxgenase-2 (COX-2)-specific inhibitors (Table I). A fourth COX-2-specific inhibitor, etoricoxib, is expected to be approved for use soon. All current NSAIDs are orally administered, with the exception of ketorolac, the only currently available parentally administered NSAID. It is anticipated that in the near future another parenterally administered NSAID, parecoxib (a COX-2-specific inhibitor) will be also available.

MECHANISMS OF GI TOXICITY

Irrespective of site of gastrointestinal (GI) damage, the mechanisms through which NSAIDs cause injury are similar throughout the GI tract. The general mechanisms can be grouped into two categories: (1) cyclooxygenase independent and (2) cyclooxygenase dependent. The former category consists largely of topical mucosal toxic processes.

Cyclooxygenase-Independent Toxicity (Topical Damage)

Within a few minutes of ingestion, NSAIDs accumulate at very high concentrations in gastric mucosal cells, causing denudation of surface epithelial cells and increased mucosal permeability to luminal contents. A second topical mechanism of NSAID injury is a reduction of the phospholipid content and surface hydrophobicity of the gastric mucus gel layer. Topical effects of NSAIDs are likely the major mechanism responsible for acute subepithelial hemorrhages and erosions that can be observed soon after NSAID challenge, although such lesions rarely cause clinical problems. Enteric-coated NSAIDs produce considerably less acute topical erosive and hemorrhagic injury compared to plain (non-enteric-coated) formulations during short-term administration (i.e., 1–2 weeks), an observation in support of a local toxic effect of NSAIDs. However, with long-term administration of enteric-coated formulations, gastric ulcers develop at rates that are not different than with non-enteric-coated preparations, presumably as a result the systemic mechanism of injury.

Cyclooxygenase-Dependent Toxicity

The beneficial effect of NSAIDs of decreasing systemic inflammation and their deleterious effects in the GI tract are both, in part, related inhibition of the enzyme cyclooxygenase. Within the GI tract, NSAID-associated reduction in gastroduodenal mucosal prostaglandin concentrations is the major contributor toward NSAID mucosal toxicity. Most NSAIDs (with the exception of cyclooxygnease-2-specific inhibitors)

TABLE I List of NSAIDs Available by Prescription in the United States[a]

Nonsalicylates	Salicylates	COX-2 inhibitors
Diclofenac (Voltaren)[b]	Aspirin[c] (Zorprin, Easprin)	Celecoxib (Celebrex)
Etodolac (Lodine)	Diflunisal (Dolobid)	Rofecoxib (Vioxx)
Fenoprofen (Nalfon)	Salsalate (Disalcid, Salflex)	Valdecoxib (Bextra)
Flurbiprofen (Ansaid)	Choline salicylate (Trilisate)	Etoricoxib[d]
Ibuprofen (Motrin)[c]	Magnesium salicylate (Magan)	Parecoxib[e]
Indomethacin (Indocin)		COX-189[f]
Ketoprofen (Orudis)[c]		
Ketorolac (Toradol)[e]		
Mefenamic acid (Ponstel)		
Meloxicam (Mobic)		
Nabumetone (Relafen)		
Naproxen (Naprosyn, Anaprox)[c]		
Oxaprozin (Daypro)		
Piroxicam (Feldene)		
Sulindac (Clinoril)		
Tolmetin (Tolectin)		

[a] Data from "The Physician's Desk Reference" (2002), 53rd Ed., Montvale, New Jersey.
[b] Combination tablet of diclofenac and a synthetic prostaglandin E1 (misoprostol) is also available.
[c] Also available as over-the-counter preparations in the United States in 2002.
[d] Expected to be available soon.
[e] Parenterally administered.
[f] Orally administered COX-2 inhibitor in clinical development by Novartis (East Hanover, New Jersey).

inhibit GI cyclooxygenase, which reduces gastroduodenal mucosal prostaglandin concentrations, thus removing a major mechanism for protection against mucosal injury. Aspirin, by acetylation of cyclooxygenase, inhibits cyclooxygenase irreversibly, whereas all other NSAIDs inhibit cyclooxygenase in a reversible, concentration-dependent manner. With aspirin, when cyclooxygenase is irreversibly inhibited, the capacity for prostaglandin synthesis does not return to normal for several days, until new enzyme can be synthesized. A recent study has demonstrated that after low daily doses of aspirin, gastric prostaglandins do not fully recover for approximately 5–8 days; in the platelet, prostaglandin synthesis does not return to normal for 14 days. This may explain why aspirin, in comparison to the other NSAIDs, remains one of the most potent inhibitors of prostaglandin and thromboxane synthesis.

In the early 1990s, two structurally related cyclooxygenase isoforms were identified in mammalian cells, cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). COX-1 is found in most body tissues, including the stomach and platelets. COX-2, by contrast, is the principal COX isoform that participates in inflammation. There is little COX-2 activity present in the normal stomach. This concept has led to development and clinical introduction of COX-2-specific NSAIDs. Recent animal data indicate that for gastric ulceration to occur, both COX-1 and COX-2 must be inhibited. Interestingly, in one model, selective inhibition of COX-1 alone did not cause gastric damage. Thus, the actual explanation for the COX-2 specific inhibitor association with improved GI toxicity may more closely relate to the lack of dual COX isoform inhibition rather than simply the COX-1 sparing effects.

ADVERSE GI EFFECTS OF NSAIDS

NSAID-induced adverse GI effects can have variable presentations, including GI symptoms such as nausea and upper abdominal pain (dyspepsia), asymptomatic mucosal lesions that can be visualized through an endoscope, and, most importantly, ulcers, which are sometimes accompanied by serious GI complications. Serious upper GI complications are most relevant to the clinical morbidity of NSAIDs. Symptomatic GI ulceration (that is, ulcers associated with pain, perforation, bleeding, or obstruction) occurs in approximately 2–4% of patients treated with a NSAID for 1 year.

Low-dose aspirin increases risks of GI bleeding and increases the likelihood of hospitalization for ulcers. Aspirin doses as low as 75 or 300 mg/day have been associated with a two- to fourfold increased risk of GI bleeding. Buffered or enteric-coated aspirin preparations, although probably associated with a reduced incidence

of dyspepsia when compared to plain aspirin, have risks of upper GI bleeding that are similar to those of plain aspirin. There is probably no orally administered dose of aspirin that is both efficacious for cardiovascular disease prophylaxis and is free of GI toxicity.

RISK GROUPS FOR NSAID-INDUCED GI ULCERS

Certain groups of patients taking NSAIDs are at greater risk for development of NSAID ulcer complications (Table II) and should be given greater consideration for strategies to prevent or to reduce ulceration.

THERAPY FOR NSAID-INDUCED ULCERS

Prior to the clinical availability of safer classes of NSAIDs, reduction in NSAID-induced GI toxicity was primarily accomplished by prescribing drugs that, when coadministered with NSAIDs, would protect against mucosal ulceration. Because the majority of patients who chronically take NSAIDs will never develop clinically significant ulceration, the ideal candidates for cotherapy are those considered as high risk for NSAID-induced ulcers (Table II). Various cotherapies have shown to be effective. Misoprostol, a synthetic prostaglandin E1 (PGE1) analogue, reduces NSAID-induced serious GI adverse events. A combination tablet of misoprostol and the NSAID diclofenac has a relatively low ulceration rate.

There are no placebo-controlled studies evaluating whether any proton pump inhibitors (PPIs), including omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole, can prevent the complications of NSAID-induced ulcers.

TABLE II Definite and Possible Risk Factors for NSAID-Induced Ulcers[a]

Definite	Possible
Prior peptic ulcer disease	*Helicobacter pylori* infection
Prior GI ulcer complication	Cigarette smoking
Advanced age[b]	
Concomitant use of corticosteroids	
Concomitant use of anticoagulants	
Concomitant use of ethanol	
Comorbid diseases (e.g., heart disease, rheumatoid arthritis)	

[a] Risk is also related to dose of NSAID used and to number of NSAIDs used.

[b] Participants in some studies, >65 years old; in others, >75 years old.

When attempting to treat an ulcer that has formed during NSAID use, the first step is always to stop the NSAID. Once the NSAID is stopped, rapid ulcer healing can be achieved by treatment with standard doses of histamine-2 receptor antagonists (H2RAs) or PPIs. With patients for whom NSAIDs cannot be discontinued, use of a PPI will allow ulcer healing, even while NSAID use continues.

NSAIDS WITH IMPROVED GI SAFETY PROFILES

COX-2 Specific Inhibitors

Treatment with rofecoxib or celecoxib is associated with significantly lower incidences of serious upper GI adverse clinical events than treatment with comparator NSAIDs. Two trials of ~8000 arthritis patients each reported a reduction of ~50% in upper GI events with celecoxib and rofecoxib when compared to nonselective NSAIDs. Concurrent use of low-dose aspirin eliminated the GI protective benefit of the COX-2 inhibitor celecoxib.

Older and Safer NSAIDs

In addition to the recently marketed COX-2-specific NSAIDs, several other established NSAIDs (or products in development) have safety evaluations superior to those of conventional NSAIDs. These include etodolac, nabumetone, diclofenac, and nonacetylated salicylates such as salsalate. Salsalate and etodolac have no measurable effects on gastric COX activity.

Nitric Oxide-Releasing NSAIDs

Nitric oxide is a critical mediator of GI mucosal defense, exerting many of the same beneficial actions as prostaglandins within the GI tract. In addition to other properties, nitric oxide increases mucosal blood flow and prevents neutrophil adherence to the vascular endothelium. These observations have led to the development of nitric oxide (NO)-releasing NSAIDs in which the native NSAID has been coupled to a nitric-oxide-releasing moiety. However, NO—NSAIDs are associated with less NSAID-induced gastric and intestinal toxicity than has been associated with the parent compounds. Such drugs are currently in clinical development.

Phospholipid NSAIDs

NSAIDs reduce hydrophobicity of the gastric mucosa by chemically associating with and destabilizing phospholipids (in particular, phosphatidylcholine) within the mucus gel layer. Newer NSAIDs have been

developed in which the native NSAID moiety has been coupled with synthetic phosphatidylcholine (PC). Short-term courses of PC–aspirin are associated with less acute gastric injury when compared with plain aspirin. Should subsequent clinical studies show continued safety and efficacy, PC–NSAIDs may be another future class of safer NSAIDs available to clinicians.

SMALL INTESTINAL AND COLONIC EFFECTS OF NSAIDS

Small Intestine

Ulcers (which may bleed or perforate), strictures (which may obstruct), and an enteropathy have all been described in the small intestines of chronic NSAID users. The pathology of strictures ranges from nonspecific broad-based strictures to intestinal diaphragms. These diaphragms are usually located in the jejunum. Their histology reveals submucosal fibrosis with normal overlying epithelium, except for the central tip of the diaphragm, which contains acute and chronic inflammatory cells. NSAIDs can cause diffuse intestinal inflammation and increased intestinal mucosal permeability, a condition known as "NSAID enteropathy"; this is characterized clinically by occult blood loss, iron deficiency anemia, malabsorption, and a protein-losing enteropathy.

Colon

NSAIDs may also cause ulcers, strictures, and diaphragms, and inflammation in the colon, especially on the right side. Ulceration may be complicated by bleeding or perforation, especially ulcers occurring in the cecum. Cases of eosinophilic, collagenous, pseudomembranous, and nonspecific colitis have been associated with NSAIDs. A disproportionately high number of colitis cases have occurred in patients taking mefenamic and flufenamic acid. Histology usually reveals a nonspecific mild colitis unless one of the other variants is present (eosinophilic, pseudomembranous, or collagenous). Rectal administration of NSAIDs in the form of suppositories has been frequently associated with inflammation, ulcers, and strictures of the anus and rectum.

There are individual case reports and small studies suggesting that NSAIDs are the cause of colonic diverticular perforation and diverticular bleeding. Many cases of diverticular perforation involve a sustained-release preparation of indomethacin, with the perforations attributed to a mechanical effect of the capsule being caught in a diverticulum.

In patients with inflammatory bowel disease (IBD), NSAIDs may exacerbate disease or activate IBD that has been previously quiescent. These occurrences are more frequently observed in ulcerative colitis than in Crohn's disease. One postulated mechanism through which NSAIDs may exacerbate colonic inflammation is by inhibiting cyclooxygenase and shunting arachidonic acid metabolism toward the proinflammatory leukotrienes. Of all patients with IBD, only a subset experience symptomatic flares when placed on a NSAID. These patients, when they relapse, will do so within a few days of receiving a NSAID. It is unknown whether the COX-2-specific inhibitors, compared with the older NSAIDs, are associated with fewer or greater intestinal problems in patients with IBD.

Nuclear Medicine Imaging

MOHAN R. RAMASWAMY AND RANDALL A. HAWKINS
University of California, San Francisco

gamma camera A device capable of detecting and localizing gamma rays, forming an image of the underlying radiopharmaceutical distribution within a patient. Most gamma cameras are capable of producing both planar and tomographic images.

positron emission tomography A technique that utilizes a system especially designed to produce tomographic images of positron-emitting radionuclides (such as ^{18}F and ^{11}C).

radionuclide An atom with an unstable nucleus, which achieves stability by emitting excess energy in the form of gamma rays and subatomic particles (e.g., positrons). The radionuclide most commonly utilized in nuclear medicine is technetium-99m.

radiopharmaceutical A biologically active molecule labeled with a radionuclide.

scintigraphy The process of obtaining images with a gamma camera.

Nuclear imaging techniques rely on a spectrum of radiopharmaceuticals, which are biologically active molecules or cells labeled with radioactivity. By following these radioactive tracers as they are taken up, metabolized, and excreted by various organs and tissues, one is able to obtain a qualitative (and sometimes quantitative) assessment of a wide array of functional disorders of the gastrointestinal tract. Such functional information is often not available from the more conventional anatomic imaging techniques, such as radiography, computed tomography, magnetic resonance imaging, and ultrasound.

GASTROINTESTINAL TRACT SCINTIGRAPHY

Gastrointestinal Bleeding

Using *in vitro* labeling methodology, technetium-99m-pertechnetate ($^{99m}TcO_4^-$) can be introduced into red blood cells, where it binds to the β-subunit of hemoglobin. After withdrawal of a small blood sample, such labeling can be performed within 30 min. This blood is then reinjected into the patient and scintigraphic imaging of the abdomen and pelvis is obtained for a period of 60 to 90 min. Typically, the images are acquired digitally in 1 min frames, which can then be displayed dynamically on a computer screen in a cinematic loop.

Normally, there is uniform distribution of activity within the largest reservoirs of blood: the liver, spleen, and great vessels. Any unbound ^{99m}Tc-pertechnetate is excreted via the kidneys into the bladder. Any other focus of activity developing during the course of the study in the expected location of bowel is usually indicative of an active gastrointestinal bleed (Fig. 1). Due to its irritative effect, such intralumenal blood produces peristalsis and is rapidly conveyed along the gastrointestinal tract. By imaging the transit of activity over time, it is generally possible to determine the site of origin.

To be most useful, labeled erythrocyte studies must be performed at a time when the patient is suspected to be actively bleeding. In this situation, the study is quite sensitive, detecting bleeding rates as low as 0.05 to 0.1 ml/min. When performed properly, scintigraphy will serve to both confirm the presence of active gastrointestinal bleeding and establish the site of origin. This information can be quite useful in guiding subsequent angiographic, endoscopic, or surgical therapy.

Ectopic Gastric Mucosa

When administered in its unbound form, ^{99m}Tc-pertechnetate has a strong affinity for gastric mucosa, both within the stomach and in ectopic sites. This test can be used to localize gastric mucosa within a bleeding Meckel's diverticulum, an enteric duplication, Barrett's esophagus, and a retained gastric antrum after partial gastrectomy. It is reported that at least 2 cm^2 of mucosa must be present for reliable scintigraphic detection. Pretreatment with pharmacologic agents such as cimetidine, pentagastrin, and glucagon may help improve visualization.

Gastric Emptying

A solid meal (e.g., fried eggs) may be easily labeled by cooking with ^{99m}Tc-sulfur colloid. Similarly, a liquid meal (e.g., water or juice) may be labeled by mixing with ^{99m}Tc-sulfur colloid or ^{111}In-DTPA. Images of the upper gastrointestinal tract obtained over a period of 1 to 2 h following oral administration of such a meal

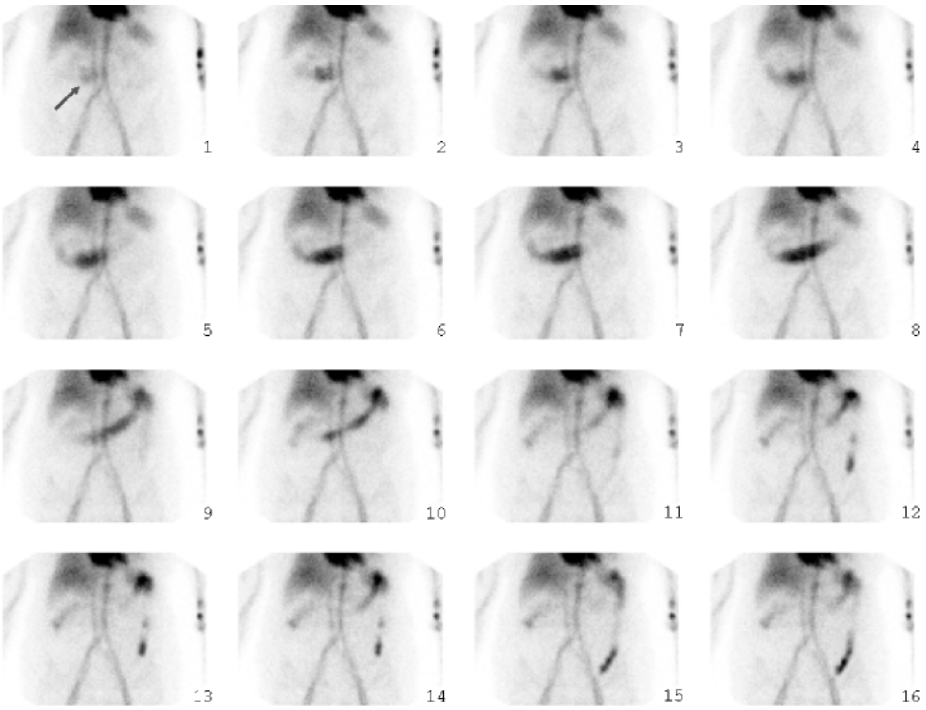

FIGURE 1 Sixteen 1 min frames from a ^{99m}Tc-labeled erythrocyte study performed in an 84-year-old woman presenting with hematochezia. The early images demonstrate a focus of radioactivity developing in the right upper quadrant, roughly in the region of the proximal transverse colon (arrow). Later images demonstrate peristalsis of activity through the distal transverse and descending colon, confirming the site of origin (correlated by subsequent angiography). Note the normal activity in the heart, liver, spleen, and great vessels.

allow for qualitative assessment of solid and/or liquid gastric emptying.

By drawing a region of interest around the stomach, it is possible to quantitate the amount of activity within the stomach. From this value, a quantitative estimate of gastric emptying can be obtained, usually expressed in the form of an emptying half-time (in minutes) or an emptying rate (expressed as the percentage per minute). The rate of gastric emptying may vary greatly with the type of meal (i.e., its quantity, consistency, and nutritional content), the imaging technique, and the method of quantitative analysis. It is therefore imperative for each laboratory to rigorously standardize its imaging protocol and to establish appropriate normal values specific to that protocol.

Gastric emptying studies are most often utilized in assessing the severity of diabetic gastroparesis (Fig. 2), although they can be useful in a wide range of functional gastroparetic disorders. They may also be used to detect rapid gastric emptying, as may be seen in dumping syndromes following upper gastrointestinal tract surgery, and to assess the response to medical or surgical therapies of gastroparesis.

Other Studies

Scintigraphic techniques exist for the detection of gastroesophageal reflux and aspiration and the

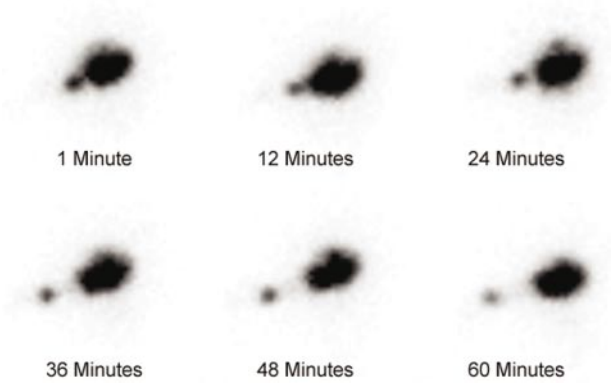

FIGURE 2 Selected images from a ^{99m}Tc-sulfur colloid solid gastric emptying study performed in a 43-year-old woman with a long history of diabetes and early satiety. Very little emptying of the radiolabeled scrambled egg meal is identified within the first 60 min of the study, consistent with the suspected diagnosis of diabetic gastroparesis.

assessment of esophageal, small bowel, and colonic motility. However, these studies are not well standardized and are not widely available.

HEPATOBILIARY SCINTIGRAPHY

Technique

The primary radiopharmaceuticals utilized in hepatobiliary scintigraphy are the ^{99m}Tc-labeled iminodiacetic acid (IDA) derivatives, disofenin and mebrofenin. Following intravenous administration, these agents are taken up by the hepatocytes through the same membrane transport mechanism as bilirubin and, like bilirubin, are then promptly secreted into the bile (without conjugation). This radiolabeled bile then fills the gallbladder through the cystic duct and empties into the duodenum through the common duct.

Immediately following the intravenous administration of one of the ^{99m}Tc-IDA agents, consecutive 1 min scintigraphic images are acquired over the abdomen for a period of 60 to 90 min. Typically, the images are acquired digitally and then displayed dynamically on a computer screen in a cinematic loop. In a normal study, there is prompt extraction of activity from the blood by the hepatocytes in the liver. Secreted activity is identified within the major bile ducts within 10 min, with filling of the gallbladder and transit into the small bowel within 60 min after injection.

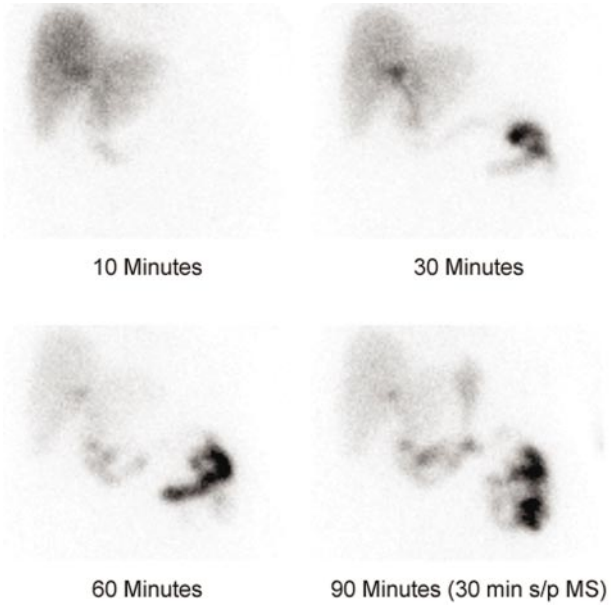

FIGURE 3 Selected images from a ^{99m}Tc-IDA study performed in a 76-year-old woman with right upper quadrant pain and an equivocal ultrasound evaluation. Early images demonstrate uptake of tracer by the liver, with subsequent excretion into the biliary tree and small bowel. Note the lack of gallbladder uptake, even following the intravenous administration of morphine sulfate. Acute gangrenous cholecystitis was found at surgery.

Acute Cholecystitis

Filling of the gallbladder indicates patency of the cystic duct and virtually excludes the possibility of acute cholecystitis. Failure of the gallbladder to fill within 4 h is usually indicative of acute cholecystitis. Morphine sulfate's ability to contract the sphincter of Oddi can be used to shorten the time required to make the diagnosis. Specifically, lack of gallbladder filling within 30 min following the intravenous administration of 0.04 mg/kg of morphine is considered indicative of acute cholecystitis (Fig. 3).

Many studies have found hepatobiliary scintigraphy to have both a sensitivity and a specificity of greater than 90% for the detection of acute cholecystitis. An important cause of false-positive studies is fasting for less than 4 h prior to the study, as a recent meal induces gallbladder contraction and thereby prevents filling. On the other hand, fasting for more than 24 h leads to a sludge-filled gallbladder, which is also unlikely to fill. Other important causes of a false-positive study include poor liver function and severe chronic cholecystitis. False-negative studies are unusual, but may occasionally be seen in the setting of acute acalculous cholecystitis. In this setting, the use of labeled leukocyte imaging may be considered (discussed below).

Chronic Cholecystitis

Fibrotic changes associated with chronic inflammation of the gallbladder can lead to diminished contractile ability, eventually resulting in pain. Contractility of the gallbladder may be assessed as part of a hepatobiliary study by comparing the amount of radioactivity in the gallbladder before and after the induction of gallbladder contraction. This is usually expressed quantitatively, in the form of an ejection fraction:

$$\frac{\left[\begin{array}{l}\text{Radioactive counts in gallbladder before contraction} \\ -\text{Radioactive counts in gallbladder after contraction}\end{array}\right]}{\left[\text{Radioactive counts in gallbladder before contraction.}\right]}$$

Gallbladder contraction is induced physiologically by duodenal secretion of the hormone cholecystokinin. This may be simulated by administration of the active terminal octapeptide of cholecystokinin, sincalide (Kinevac, Bracco Diagnostics, Princeton, NJ), administered intravenously over several minutes at a dose of

0.02 μg/kg. In properly selected patients with recurrent right upper quadrant pain, a gallbladder ejection fraction below 35% provides evidence of chronic cholecystitis or biliary dyskinesia. Furthermore, such patients often demonstrate symptomatic improvement following elective cholecystectomy.

Other Applications

In the jaundiced newborn, hepatobiliary scintigraphy plays an important role in the differentiation of biliary atresia from neonatal hepatitis. Specifically, normal transit of activity from the liver into the small bowel virtually excludes the diagnosis of biliary atresia. Another interesting role is in the differentiation of hepatic masses. Focal nodular hyperplasia tends to demonstrate prompt radiotracer uptake and delayed secretion, whereas many hepatocellular carcinomas tend to demonstrate both delayed uptake and delayed secretion. Most other hepatic tumors fail to demonstrate any radiotracer uptake (although some uptake may be seen in adenomas). Hepatobiliary scintigraphy may also be used to detect enterogastric reflux of bile and sphincter of Oddi dysfunction and may serve as an adjunct to other imaging modalities in the evaluation of biliary obstruction, biliary leaks, and choledochal cysts.

LIVER AND SPLEEN SCINTIGRAPHY

Sulfur Colloid Imaging

^{99m}Tc-sulfur colloid is a particulate radiopharmaceutical, with particle diameters on the order of 100 to 1000 nm. Following intravenous administration, these particles are rapidly phagocytized by the Kupffer cells of the liver (85%) and the macrophages of the spleen (10%) and bone marrow (5%). Although ^{99m}Tc-sulfur colloid imaging of the liver has largely been supplanted by cross-sectional imaging, a small role still exists. A characteristic pattern may be identified in the setting of alcoholic cirrhosis, consisting of a decrease in hepatic uptake with a corresponding increase in splenic and bone marrow uptake (the so-called "colloid shift"). ^{99m}Tc-sulfur colloid can also play a role in the differentiation of hepatic tumors, in that most regenerating nodules, two-thirds of focal nodular hyperplasia, and a small number of adenomas maintain enough Kupffer cell activity to take up the tracer, whereas most other hepatic lesions usually do not.

Hemangioma Imaging

^{99m}Tc-pertechnetate-labeled erythrocytes may be used to differentiate cavernous hemangiomas from other liver masses. This test makes use of the classic blood flow pattern of such hemangiomas, which initially appear as cold defects on images obtained immediately after injection, progressively filling-in to an intensity greater than that of the liver background on subsequent delayed images obtained at 1 to 2 h postinjection. Lesions over 2 to 3 cm in size can be detected with an accuracy of greater than 95%. Somewhat smaller lesions may be detected with high-quality tomographic techniques.

Damaged Erythrocyte Imaging

Although ^{99m}Tc-sulfur colloid may be used for splenic imaging, heat-damaged or chemically damaged ^{99m}Tc-pertechnetate-labeled erythrocytes demonstrate a much stronger affinity for the spleen. This latter imaging method obviously takes advantage of the spleen's role in removing damaged erythrocytes from the blood. Radionuclide imaging of the spleen is most often utilized in detecting recurrent splenic tissue in patients with continuing laboratory abnormalities after splenectomy for thrombocytopenia. It is also useful in differentiating a left upper quadrant mass from an accessory spleen, establishing the diagnosis of splenosis, and evaluating congenital asplenia/polysplenia syndromes.

Hepatic Arterial Infusion Pump Imaging

^{99m}Tc-macroaggregated albumin is a particulate radiopharmaceutical, with particle diameters on the order of 10 to 90 μm (compared to a capillary diameter on the order of 5 μm). When administered through a hepatic arterial chemotherapy infusion pump, these particles will flow through the arterial system until they lodge in the first capillary bed they encounter. Thus, subsequent imaging will demonstrate the arterial system subtended by the pump catheter. This study is often performed after pump placement, to ensure that the entire liver is perfused and that there is no extrahepatic perfusion or significant systemic arteriovenous shunting. Follow-up imaging is often obtained if the patient develops symptoms suggestive of pump occlusion or migration.

INFECTION AND INFLAMMATION SCINTIGRAPHY

Labeled Leukocytes

Using *in vitro* labeling methodology, a mixed population of a patient's white blood cells can be labeled with ^{111}In-oxine or ^{99m}Tc-HMPAO. Following reinjection of the labeled blood sample, the leukocytes are

drawn to areas of active infection and inflammation through the usual chemotactic mechanisms. ^{111}In-labeled leukocytes are typically imaged 18 to 24 h after injection, with normal distribution in the spleen, liver, and bone marrow. Because of better imaging characteristics, ^{99m}Tc-labeled leukocytes provide greater image quality and allow for earlier imaging (at 4 h). Unfortunately, ^{99m}Tc-labeled leukocytes also undergo normal biliary and bowel clearance, somewhat limiting their use in the abdomen.

Labeled leukocytes are not usually the first agent of choice in the imaging of intra-abdominal infection, due to the expense and long imaging delays involved. However, they may be used to detect intra-abdominal abscesses when computed tomography (CT) imaging is unrevealing or equivocal and to verify the presence of cholecystitis when ultrasound and hepatobiliary scintigraphy are equivocal. Other infections that may be investigated with this technique include aortic graft infections, peritonitis, and diverticulitis.

Labeled leukocytes may also play an important role in inflammatory bowel disease, by assessing its extent and severity, by detecting complications (such as abscess formation), and by determining response to therapy. It is possible for leukocytes to be shed into the bowel lumen at sites of active bowel inflammation. These leukocytes may then undergo peristalsis to other parts of the bowel, confounding image interpretation. It is therefore important to perform early imaging in this setting—at 4 h for ^{111}In-labeled leukocytes and at 1 to 2 h for ^{99m}Tc-labeled leukocytes.

Gallium

^{67}Gallium-citrate is an analogue of iron, which tends to accumulate at sites of infection and inflammation through a variety of complex mechanisms. One mechanism appears to involve binding to lactoferrin, an acute-phase reactant released by activated neutrophils. Typically imaged at 48 h, the widespread normal distribution of gallium (which includes the liver, spleen, bowel, bone, and bone marrow) tends to limit its use in the abdomen. However, gallium may have a higher sensitivity for chronic infections (i.e., greater than 1 or 2 weeks old) and may be preferable in this situation.

TUMOR SCINTIGRAPHY

[^{18}F]Fluorodeoxyglucose Positron Emission Tomography Imaging

Like glucose, the radiolabeled glucose analogue [^{18}F]fluorodeoxyglucose (FDG) is taken up in cells through the glucose membrane and undergoes the first step of glycolysis (phosphorylation). However, phosphorylated FDG is unable to pass through the remainder of the glycolytic cycle and remains trapped within the cytoplasm of the cell. Because of the increased glycolysis needed to support rapid mitosis, most malignant tumors appear as "hot spots" on FDG positron emission tomography (PET) imaging.

The current indications for FDG PET imaging supported by Medicare in the gastrointestinal tract are the staging and restaging of esophageal and colorectal carcinoma. In terms of initial staging, PET is limited in its ability to detect the depth of local invasion or the involvement of locoregional lymph nodes. However, it is quite powerful in the detection of distant metastases, with an accuracy of approximately 86% in esophageal carcinoma and 92% in colorectal cancer. This is superior to CT, with accuracies of approximately 62 and 71%, respectively.

FDG PET is also quite useful in detecting suspected residual or recurrent tumor after the completion of therapy. In one recent study, PET identified 79% of recurrences (both local and distant) in patients with an elevated carcinoembryonic antigen (CEA) level after therapy for colorectal carcinoma (Fig. 4).

An exciting new area of investigation in PET is the prediction of tumor response to chemotherapy. By comparing the decline in FDG uptake within a tumor on studies performed before chemotherapy and again following one or two cycles, it may be possible to predict the response to the complete course of chemotherapy. This would allow for midcourse adjustments in the therapeutic regimen for nonresponders.

FDG PET also appears to be quite promising in the imaging of pancreatic adenocarcinoma and gastrointestinal stromal tumors. Results have been mixed in the setting of hepatocellular carcinoma, however, with some studies identifying only 55% of tumors. The development of new PET tracers, such as [^{11}C]choline for potential imaging of primary and metastatic prostate carcinoma, will further increase the power of PET in oncologic imaging.

Other Agents

Radiopharmaceuticals such as ^{67}Ga-citrate, ^{201}Tl-chloride, ^{99m}Tc-sestamibi, and ^{99m}Tc-tetrofosmin tend to accumulate in tumors through a variety of mechanisms. As such, they may be used as nonspecific markers for a variety of tumors. However, the extensive normal physiologic uptake of these tracers in the bowel and/or biliary system tends to limit their use in the abdomen. Nonetheless, they may be of value when PET imaging is unavailable. In-DTPA-Pentreotide (OctreoScan,

FIGURE 4 Image from a FDG PET study performed in a 51-year-old man with a rising CEA value approximately 1 year following surgery and chemotherapy for colorectal adenocarcinoma. Note the prominent focus of radiotracer uptake at the dome of the liver (arrow), subsequently found at surgery to represent a metastasis.

Mallinckrodt, St. Louis, MO) is a radiolabeled analogue of somatastatin. Typically imaged at 24 h, its normal distribution includes the pituitary, thyroid, liver, spleen, bowel, kidneys, and bladder. This agent has a strong affinity for a variety of somatostatin receptor-bearing tumors, including pancreatic islet cell tumors (with the possible exception of insulinoma) and carcinoid tumors. In this specific setting, OctreoScan has been shown to be as effective as all other imaging modalities combined.

There has been a considerable amount of excitement surrounding the use of radiolabeled antibodies in oncologic imaging. Two agents that are currently commercially available are OncoScint, an ^{111}In-labeled antibody to the antigen TAG-72, and CEA-Scan, a ^{99m}Tc-labeled antibody to the antigen CEA. Both are useful in the imaging of colorectal carcinoma, although FDG PET imaging has largely supplanted their use at the authors' institution.

MISCELLANEOUS SCINTIGRAPHIC STUDIES

Peritoneal Imaging

Direct introduction of a ^{99m}Tc-labeled tracer into the peritoneal cavity allows the assessment of peritoneal flow. This is most useful in detecting the presence of a pleuro-peritoneal leak or in establishing the patency of a peritoneovenous (i.e., LaVeen or Denver) shunt.

Salivary Gland Imaging

In addition to its role as a gastric mucosal agent, ^{99m}Tc-pertechnetate also has an affinity for the salivary glands. By assessing the uptake of this radiopharmaceutical, one can estimate the relative function of the major (parotid and submandibular) salivary glands. Dynamic imaging performed after the administration of a sialagogue (e.g., lemon juice) allows estimation of an ejection fraction for each gland.

CONCLUSION

This has been just a brief overview of the wide range of nuclear techniques available for structural and functional assessment of the gastrointestinal system. The constant development of new radiotracers and imaging techniques will further expand the applications of nuclear imaging in the field of gastroenterology.

The rate of nutrient transport is ultimately regulated by the energy content, the essential nature, or the toxic potential of nutrients. The absorption rate of a nutrient utilized mainly for its energy content increases with dietary concentration, whereas the absorption rate of a nutrient that is essential but otherwise contains little energy will increase only when dietary concentration or body stores decrease. Regulation of nutrients that are both essential and energy yielding or potentially toxic may be complex and may depend on still unidentified factors.

INTRODUCTION

The nutrients that are released from digested foods are absorbed by enterocytes or intestinal absorptive cells. Because many nutrients from food are hydrophilic and cannot diffuse through the lipid bilayer membrane, absorption requires transport systems in the brush border and basolateral membranes of the enterocytes. These transport systems are synthesized by intestinal cells so nutrients can be transferred from the lumen across the brush border into the cytosol, and from the cytosol across the basolateral membrane into the blood.

Why regulate? Regulation of absorption ensures that nutrients are not only completely absorbed but also absorbed in the appropriate regions. Nutrients that are not absorbed eventually reach the large intestine, potentially inducing borborygmi and osmotic diarrhea. Under normal conditions, however, nutrients are completely absorbed when intestinal contents reach the distal small intestine. Even when absorption is complete,

The rate of nutrient transport is ultimately regulated by the energy content, the essential nature, or the toxic potential of nutrients. The absorption rate of a nutrient utilized mainly for its energy content increases with dietary concentration, whereas the absorption rate of a nutrient that is essential but otherwise contains little energy will increase only when dietary concentration or body stores decrease. Regulation of nutrients that are both essential and energy yielding or potentially toxic may be complex and may depend on still unidentified factors.

INTRODUCTION

The nutrients that are released from digested foods are absorbed by enterocytes or intestinal absorptive cells. Because many nutrients from food are hydrophilic and cannot diffuse through the lipid bilayer membrane, absorption requires transport systems in the brush border and basolateral membranes of the enterocytes. These transport systems are synthesized by intestinal cells so nutrients can be transferred from the lumen across the brush border into the cytosol, and from the cytosol across the basolateral membrane into the blood.

Why regulate? Regulation of absorption ensures that nutrients are not only completely absorbed but also absorbed in the appropriate regions. Nutrients that are not absorbed eventually reach the large intestine, potentially inducing borborygmi and osmotic diarrhea. Under normal conditions, however, nutrients are completely absorbed when intestinal contents reach the distal small intestine. Even when absorption is complete,

 Copyright 2004, Elsevier (USA). All rights reserved.

regulation is important because the rate of absorption and the intestinal region where a nutrient is absorbed determine the time course of appearance of that nutrient in the blood, and therefore of that nutrient's availability to other organs. The pathological consequences of abnormal plasma glucose levels in diabetes are an example of the importance of plasma nutrient concentrations. Obesity in humans may be correlated with chronically elevated rate of uptake of nutrients in the small intestine.

Patterns of Regulation

Although there is an enormous number of types of nutrients and therefore an equally impressive number of transporters, regulatory mechanisms can only increase, decrease, or not change when dietary concentrations or body stores of nutrients change. The patterns of regulation for various nutrients can be predicted, based on four considerations related to the metabolic costs and benefits of nutrient absorption. First, if the metabolic cost of transporter synthesis exceeds the benefits (e.g., in the form of metabolic energy) the transporter provides, the number of transporters should decrease. Conversely, if transporter synthesis will yield energy in terms of quantity of nutrients absorbed, the number of transporters should increase. Hence, for virtually all nonessential nutrients used as calorie source, absorption rate is directly proportional to dietary substrate concentrations (see Fig. 1). Third, for essential nutrients that do not yield calories but are needed at some minimum amounts in the body for essential metabolic reactions, decreases in dietary levels should result in increases in the number of transporters, because transport will yield its greatest benefits when dietary concentrations are low (Fig. 1). Finally, transporter activity should decrease with increasing dietary substrate levels for nutrients that are toxic at high dietary concentrations or body stores. Because the transport step across the brush border is typically the limiting step, and because basolateral transporters also function to obtain nutrients from the blood for enterocytes, these considerations apply mainly to brush border transporters.

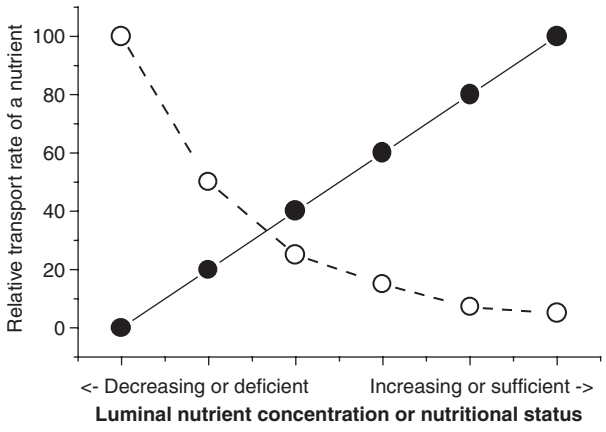

FIGURE 1 Effect of dietary concentration or body stores of a nutrient on intestinal uptake of that nutrient. ●, Nonessential nutrient, calorie source; ○, essential nutrient, not a calorie source.

Regulation can be induced by endogenous signals such as those coming from the blood, or by luminal signals such as those found in the food. These external signals use intracellular signal transduction mechanisms to alter cellular function.

Mechanisms of Regulation

Specific

Changes in absorption rates can be accomplished by specific or nonspecific mechanisms. Specific mechanisms such as changes in affinity for a substrate or in number of transporters are those that increase the absorption rate of a single nutrient or category of nutrients sharing a single transport system. Changes in number of transporters can be accomplished by changes in transporter synthesis and degradation rates or by alterations in rates of translocation of transporters to and from membranes.

Nonspecific

A wide variety of nonspecific mechanisms can alter absorption rate, including number of absorptive cells, ratio of absorptive to nonabsorptive cells, phospholipid composition, fluidity and permeability of the plasma membrane, and permeability of the paracellular pathway. In addition, for nutrients that are cotransported with the sodium or hydrogen ions, changes in electrochemical potential of these ions will also alter transport rate. Different types of mechanisms can be combined to alter nutrient transport rates. The time course of regulation can be brief, in seconds or minutes, or long, measured in hours and days. Rapid rates of regulation are thought to be a response to rapid changes in luminal nutrient concentrations such as those occurring during meals. A longer time course is thought to be caused by alterations in the average luminal concentrations of nutrients initiated by changes in diet, and is the type of regulation emphasized in this article. Diet-induced changes in nutrient absorption typically utilize specific mechanisms to alter transporter activity. There is a caveat regarding the discussion here: a significant number of studies on molecular mechanisms underlying substrate regulation of nutrient transport involve use of

cell cultures or *Xenopus* oocytes expressing the transporter of interest. Unfortunately, regulation of nutrient transporters in these artificial systems may differ from transporter regulation *in vivo* or in animal models. Studies from cell culture systems are therefore excluded from discussion in this article, unless their findings have been replicated *in vivo*. Most of this article is based on knowledge obtained from studies utilizing small animal models.

MACRONUTRIENTS

Carbohydrates

The final products of carbohydrate digestion are glucose, galactose, and fructose. Glucose and galactose enter the intestinal cells across the brush border membrane via the sodium/glucose-dependent cotransporter 1 (SGLT1), whereas fructose is absorbed by the glucose transporter (GLUT5). In mammals with omnivorous diets, the number of SGLT1 and GLUT5 copies typically varies by two- to fourfold, and is correlated with dietary carbohydrate concentrations. In carnivores, the abundance of SGLT1 is low, and little regulation occurs. In most vertebrates, site density of SGLT1 and therefore glucose transport rate increase within 24 hours after increases in levels of dietary carbohydrate.

The proposed mechanism involves an increase in the number of brush border glucose transport systems in young cells located in the lower regions of intestinal villi. Intestinal glucose transport rate gradually increases as these cells migrate up the villus and replace cells that have a lower number of glucose transporters. The change in transport rate is complete when cells with more transporters have replaced all cells with few transporters.

The magnitude of diet-induced changes in site density of GLUT5 is typically greater than that of SGLT1, suggesting that average luminal fructose concentrations undergo wider fluctuations. The proposed mechanism underlying changes in intestinal fructose transport involves changes in the number of GLUT5 copies in all cells lining the villus. Although changes in the time course of glucose transport are dependent on transporter synthesis and cell migration rate, the time course of changes in fructose transport is dependent only on transporter synthesis. As a consequence, the time course of a diet-induced change in fructose transport is typically more rapid, in the range of 4–8 hours.

Changes in number of SGLT1 are brought about by increases in concentrations of many types of sugars, including galactose, fructose, mannose, xylose, glucose, and even some nonmetabolizable analogues of glucose. Because Na^+ is also a substrate of SGLT1, increases in dietary Na^+ concentration have been shown to increase glucose absorption. The signal to increase GLUT5 transporter number is only dietary fructose (or sucrose, which contains fructose) and is therefore quite specific.

Glucose, galactose, and fructose all share the basolateral sugar transporter GLUT2, which mediates the exit of sugars from the cytosol to the blood. Although there is no transepithelial glucose transport in the absence of SGLT1, there is glucose and fructose transport in GLUT2 −/− mice, indicating that an alternative basolateral pathway for sugars exists and that SGLT1 is the rate-limiting step in transepithelial glucose transport. Like GLUT5, site density of GLUT2 transporters also increases within a few hours following increases in dietary carbohydrate, but the mechanisms underlying dietary regulation are not known. Both luminal glucose and fructose can up-regulate GLUT2 mRNA and activity in all enterocytes located in the low to upper regions of the villus, and changes in transporter number have been shown to be dependent mainly on transporter synthesis and subsequent translocation to the basolateral membrane.

Proteins

Amino Acids

Transport of amino acids is accomplished by at least seven families of transporters, each family having several types or isoforms with overlapping specificities for different substrates. Many of these transporters are heterodimeric, such that a heavy-chain subunit is linked by disulfide bridges to a light-chain subunit. There are two known families of heavy subunits and at least five families of light subunits, and any light subunit can pair with any heavy subunit. The result is a large variety of amino acid transporters with overlapping specificities so that many types of amino acids can be transported by a single transporter, and thus a single type of amino acid can be transported by different transporters.

There are two typical ways of categorizing amino acid transporters, including by a transporter's dependence on the Na^+ gradient and by its substrates. Imino and acidic amino acids each have a carrier family with subtypes dedicated to transport these substrates, but basic and neutral amino acids are thought to share several transport systems. The large number of amino acid transporters complicates any study related to their regulation.

Although sugar absorption rates typically vary in parallel with luminal concentration of carbohydrate digestion products, the absorption of amino acids does not always vary monotonically with dietary protein

concentration. There are several explanations for this observation, and they involve the fact that all amino acids can yield energy and that some amino acids are required (essential) nutrients whereas others are toxic at high concentrations. At concentrations above minimum dietary requirements, absorption of essential amino acids increases with dietary protein, unless those amino acids are potentially toxic. Absorption of potentially toxic amino acids either does not increase or increases only modestly with dietary protein levels. Below minimum dietary requirements, absorption of essential amino acids typically increases, suggesting a regulatory mechanism that compensates for deficient dietary levels of a required nutrient. Intestinal absorption rates of nonessential amino acids that are usually not toxic are directly proportional with dietary protein levels. Because the molecular mechanisms of amino acid transporters have just been elucidated, the molecular mechanisms of their regulation are still being studied.

Peptides

Di- and tripeptides are absorbed from the intestinal lumen into the cell by the PEPT transporter family, which relies on the electrochemical gradient of hydrogen to supply the energy required for transport. Dietary free amino acids and dipeptides stimulate the transcription of the PEPT gene and increase PEPT mRNA as well as protein abundance, leading to enhanced peptide absorption rates. Increases in luminal dipeptide concentration have also been shown to increase PEPT mRNA stability. Hence, increases in dietary protein levels typically increase peptide transport across the brush border membrane. Regulation of peptide transport across the basolateral membrane, however, is not known.

Fatty Acids and Bile Acids

After digestion, dietary lipids that are sufficiently hydrophobic are likely to be incorporated into micelles and then passively absorbed by the intestinal cell. Passive transport is dependent on concentration gradients and hence cannot be regulated. However, fatty acids from pancreatic lipase digestion of triglycerides are thought to cross the brush border membrane by carriers that have not yet been extensively characterized at the molecular level. High-fat diets increase fatty acid transporter expression.

Bile acids, though not considered nutrients, are essential for fat digestion and absorption. Synthesis of bile acids is not sufficient to absorb the amount of fat consumed in a typical meal, hence bile acids need to be recycled. Bile acids are amphipathic molecules and require the Na^+-dependent bile acid transporter (ASBT) for transport across the brush border membrane of enterocytes in the distal small intestine. ASBT expression and activity decrease when luminal bile acid concentrations decrease.

MICRONUTRIENTS

Minerals

Iron

Iron is used as a catalytic center in fundamental metabolic reactions, but can be toxic at high concentrations because of its ability to oxidize many cell components. Iron deficiency is primarily caused by lack of dietary iron, whereas iron overload is mainly genetic and in some individuals is attributed to a deficiency in functional hematochromatosis protein. Body iron stores are controlled by regulating intestinal iron absorption via unidentified signals that sense the level of body iron and that communicate body iron status to intestinal crypt cells. Crypt cells are then somehow programmed to absorb dietary iron at rates appropriate for the individual.

The small intestine absorbs both elemental and heme iron. Absorption of elemental iron across the brush border membrane occurs by way of the proton-dependent divalent metal transporter (DMT1). Dietary and body iron deficiency increases mRNA and protein abundance of DMT1 as well as rates of insertion into the apical membrane of enterocytes, resulting in an increase in absorption rate for iron. High dietary levels of iron decrease brush border absorption rate. Expression of the basolateral iron transporter ferroportin 1 (IREG1) either is not affected by dietary iron levels or decreases with dietary iron. In humans with hematochromatosis, regulation of iron absorption is compromised, such that there is increased protein and mRNA expression of DMT1 in spite of excess body iron stores. Both DMT1 and IREG1 mRNA have iron response elements in the 3′ and 5′ untranslated regions that bind iron-response proteins, suggesting that posttranscriptional regulation is important in iron absorption. Hephaestrin, a copper containing iron oxide necessary for basolateral exit of iron, responds to systematic signals of iron status.

The molecular mechanisms of heme iron transport are not well known, but heme iron transport rate is also down-regulated by body iron stores, decreasing in rate when stores are high.

Calcium

Calcium is required for skeleton formation and also plays an important role as intracellular messenger in

virtually all cells. Almost all calcium in the body is stored in the skeleton. Calcium transport in the small intestine is tightly regulated by vitamin D, and is also modulated by dietary calcium levels. Active, transepithelial transport of dietary calcium increases when dietary calcium intake is low and decreases when dietary calcium intake is high.

Calcium enters the cell down an electrochemical gradient via calcium channels. Regulation of these channels is not known. The rate-limiting step of dietary calcium absorption is the intracellular movement of calcium from the apical pole of the enterocyte to the basolateral pole. Intracellular calcium movement is mediated by cytosolic calcium-binding protein (calbindin). When plasma calcium concentration decreases below normal (about 2.5 m*M*), vitamin D increases the synthesis of calbindin, which increases the transfer of dietary calcium from the apical to the basolateral pole, where calcium is extruded against an electrochemical gradient by Ca-ATPase. Vitamin D also increases the rate of entry and the rate of exit of dietary calcium across the brush border and basolateral membranes, respectively.

Phosphate

Like calcium, phosphate is also a major component of bone. Phosphate is absorbed against an electrochemical gradient in the small intestine by a Na^+-dependent phosphate transport system called NaPi, which has many subtypes; NaPi2b is expressed in the small intestine of humans and of many other vertebrates. Phosphate transport rate and the number of NaPi2b transporters increase with chronic consumption of a diet low in phosphate or by increases in plasma vitamin D. Although transporter protein abundance and transport rates increase dramatically, NaPi2b mRNA abundance does not change, indicating that NaPi2b regulation does not involve alterations in transcription rate. Unlike that of the renal phosphate transporter NaPi2a, which adapts within hours following a change in dietary phosphorus concentrations, the time course of adaptation of NaPi2b to changes in dietary phosphorus levels is slow, and typically runs over several days. Exit of phosphate from the enterocyte to the blood occurs by way of a facilitated carrier in the basolateral membrane. Regulation of this transport system is not known.

Vitamins

Most water-soluble vitamins are absorbed by transporters across the brush border and basolateral membranes of intestinal cells, but the molecular mechanisms are not known. Only those vitamins with well-characterized transport systems are mentioned here.

Ascorbic acid is absorbed across the brush border membrane by SVCT1, a high affinity, Na-dependent transporter expressed only in the small intestine and kidney. Chronic consumption of ascorbic acid reduces the rate of intestinal ascorbic acid transport. Low concentrations of dietary ascorbic acid, however, do not increase intestinal transport.

Biotin shares a Na^+-dependent brush border transporter, SMVT, with pantothenic acid. Biotin deficiency leads to a marked increase in intestinal biotin transport, whereas biotin consumption at pharmacological levels decreases biotin transport rate. The regulation of pantothenic acid transport is not known but is likely influenced by dietary or systemic levels of both biotin and pantothenic acid.

Folate is absorbed across the brush border membrane by hIFC-1, located mainly in the enterocytes lining the upper villus regions. Dietary folate deficiency leads to specific increases in intestinal folate transport and in hIFC-1 protein and mRNA abundance. A related thiamine transporter, ThT1, absorbs thiamine across the brush border. In the cell, the thiamine is phosphorylated as it crosses the cytosol. Basolateral exit seems to involve a transphosphorylation process. A thiamine-deficient diet increases transepithelial transport of thiamine.

bioimpedance analysis Measurement of body resistance and reactance by the use of a fixed high-frequency alternating current.
bioimpedance spectroscopy Measurement of a range of body resistance and reactance by the use of variable high-frequency alternating current.
body mass index The body weight in kilograms divided by the height expressed in meters squared (17 kg/m^2).
nutrition-associated complications Disease complications that can be influenced by the nutritional status.

Nutritional status is conventionally associated with body mass. This is a concept derived from agricultural science, where the objective was to develop, through nutritional means, large and meaty animals. In humans, the objective of nutritional assessment is to identify individuals who, because of their nutritional status, are at increased risk of disease complications or death. It is hoped that persons likely to benefit (in terms of reduced complications) can be identified by such an assessment.

INTRODUCTION

Nutritional health is maintained by a state of equilibrium in which nutrient intake and requirements are balanced. Malnutrition occurs when net nutrient intakes (nutrient intakes corrected for abnormally large fecal or urinary losses) are less than requirements. The obvious effect of the above processes is a change in body and blood composition and changes in body and blood composition have traditionally been used to assess nutrition. Traditional nutritional science was first developed in the field of agriculture, where the effect of nutrition was entirely judged by animal growth, mass of muscle and fat, and the production of proteins by the liver. It is therefore not surprising that nutritional assessment methods hitherto used were based on changes in body and blood composition.

The prime question when faced with a patient is how can the physician alter the outcome of the disease in a favorable (to the patient) manner. The question is whether measurement of body composition and blood components allows a prediction of outcome and whether these measurements can be used to help devise treatment that is beneficial? To answer these questions, it is necessary to examine the evolution of malnutrition and the ability of nutritional assessment techniques to predict outcome and aid treatment knowing the evolution.

Malnutrition leads to a succession of metabolic abnormalities, physiological changes, reduced organ and tissue function, and loss of body mass. Concurrent stress such as trauma, sepsis, inflammation, and burns accelerates the loss of tissue mass and function. Ultimately, critical loss of body mass and function occurs, resulting in nutrition-associated complications (NAC) and even death.

The assessment of the nutritional status, to be of clinical importance, should be able to predict whether the individual would have increased morbidity and mortality in the absence of nutritional support. In short, can it predict the occurrence of NAC and thus predict outcome? Disease and nutrition interact so that disease in turn may cause secondary malnutrition or malnutrition may adversely influence the underlying

***INDY* gene** Recently discovered "I'm not dead yet" gene locus, mutation of which can slow senescence and extend longevity; encodes for a protein that down-regulates cellular energy utilization.

life expectancy Predicted number of years that will pass until only half of any cohort of people will still be alive.

longevity Length of time an individual survives; for humans, 120 years is considered the maximal life span.

sarcopenia Age-dependent loss of skeletal muscle fibers and their replacement by intramuscular fat in the elderly, leading to reduced strength of gait and predisposition to falls.

senescence Age-dependent decline in physiological capacities and anatomic integrity that proceeds throughout adulthood.

The elderly represent a rapidly growing segment of populations around the world. Physiological senescent changes impact on the ability of individuals to feed and nourish themselves, and aging and chronic disease are conducive to both over- and undernutrition. A better understanding of specific nutrient requirements for older persons requires refining the recommendations for selection of foods, food groups, and specific dietary supplements for the aging population.

DEMOGRAPHIC CONSIDERATIONS

Sixty years of age or more is considered to be the criterion for being classified as elderly by the World Health Organization, whereas 65 years is the threshold in North America and the United Kingdom. The number of people over 65 years of age is growing worldwide at an unprecedented rate of 800,000 per month, according to a recent report of the United States Census Bureau and National Institute on Aging. The fastest growing segments of the population are people over 85 years and the centagenarians. Life expectancy at birth, i.e., the expected median survival of a birth cohort, has been advancing steadily in all nations. In developed nations, it now ranges from 75 to 81 years, always with a greater expectancy for women than men. Currently, for instance, 18% of the Italian population is over 65 years of age. Despite much lower life expectancies, the larger total populations in Africa, Asia, and Latin America mean that the majority of people over 60 years of age now live in low-income developing countries.

CHRONOLOGICAL AND BIOLOGICAL AGING

Chronological age refers to the number of years an individual has lived. Survival to 120 years is considered to be the maximum life span for *Homo sapiens*. Biological aging is a process that begins at conception and continues throughout life, first as developmental changes, then, in adulthood, as "senescence." It involves the anatomical changes in tissues and a decline in the capacity for physiological functions of most organ systems.

A series of theories regarding the nature and mediation of the aging process have been advanced, all of which can be rationalized on the basis of an evolutionary advantage to maximize reproductive efficiency at the expense of the mechanisms for genetic and cellular repair. Some theories frame the mechanism as oxidative stress and cumulative mutations associated with the cumulative cellular utilization of metabolic energy. Calorie restriction in animals reduces the rate of senescence and prolongs longevity. A *Drosophila* gene associated with longevity, *INDY*, when mutated to mimic caloric restriction, leads to a longer life span. Thus, longevity may have some genetic basis.

Successful Aging

The classical public health goal for gerontology has been expressed as "adding life to years, rather years to life." This involves the so-called compression of morbidity, in which physical and cognitive capacities are maintained and individuals succumb rapidly in old age after a minimum period of disability and dependency. Such a life evolution has been termed "successful aging," in which chronological age advances more rapidly than biological aging and people maintain normal health and

 Copyright 2004, Elsevier (USA). All rights reserved.

adequate physical and cognitive function. A majority of survivors to the "Third Age," however, exhibit "usual" (normative) aging, in which chronic diseases and some disability intercede. The most burdensome format for individuals, their relatives, and the community is the evolution to "fragile aging," characterized by disease, debility, heavy dependence on caretakers, and the need for institutional care.

Changes in Body Composition with Advancing Age

Basic senescent processes and diseases common to advanced age impact the elemental, molecular, and tissue and organ composition of the body. Conversely, body composition influences resistance and susceptibility to disease and disability. Primary among senescent changes is a progressive decrease in height, beginning around age 30 and continuing thereafter. It is proportionately greater in aging women as compared to men. Settling and desiccation of intervertebral disks combines with compression of vertebral bodies to diminish the length of the spinal column. Curvatures produced by uneven vertebral compression can further reduce stature.

On the aggregate, body weight increases up through the seventh decade and then stabilizes or decreases in later life. The composition of this weight follows a stereotyped modification in the last third of the life span, with an increased percentage of body mass as fat, a decreased percentage of body water, and a lower total cell mass. The deposition of fat added in later life is to some extent visceral, but is largely intramuscular. The term "sarcopenia" (scarcity of muscle) has been assigned to this age-related loss of muscle fibers and marbling of the skeletal muscle, which may be mediated by inflammatory cytokines, e.g., interleukin-6. Sarcopenia contributes to loss of strength in gait and predisposes to falls. Osteopenia (scarcity of bone) is the progressive demineralization of bone and loss of skeletal mass, common in both sexes. A rapid, involutional bone demineralization occurs with menopause, making women more susceptible (but not exclusively so) to a critical reduction in bone mineral density and loss of architecture that leads to pathological fractures of the vertebral bodies, wrists, and hips (osteoporosis).

CAVEATS IN ASSESSING NUTRITIONAL STATUS IN THE ELDERLY

The senescent processes confound the assessment of nutritional status of the elderly to the extent that conventional standards derived from younger adults are employed. As a consequence of the aforementioned body composition changes, anthropometric indicators are confounded. When elderly patients are bedridden or undergo partial amputations, two proxy measurements—arm span and knee height—have been advanced to produce an estimate for height. Moreover, because true (original) height cannot be assessed from the stature of an elderly patient, these same proxy measures can be used to interpolate to what was the likely length in youth. This senescent shortening of stature has implications for the calculation of Quetlet's body mass index (BMI) (weight in kilograms divided by the square of height in meters) in individuals and in groups of elderly individuals. By international BMI standards, underweight begins with a BMI equal to or less than 18.5 kg/m^2. Overweight is a state of BMI from 25 to 29.9 kg/m^2 and obesity ensues at or greater than 30 kg/m^2. The measured BMI for an older person is inevitably higher than what would have been measured for the same weight earlier in life, because of a distortion in the denominator term. This produces an underestimation of true underweight and an overestimation of overweight states in an elderly population. Substituting the arm span or a height term derived from knee height into the BMI formula improves the validity of the diagnostic classification. As a caveat, both arm span and knee height vary in relation to true height across ethnic groups, and this must be compensated for in the clinic or in surveys.

Caliper assessment of skinfolds are confounded both in their measurement and their interpretation in the elderly. Laxity of skin makes the dermis more compressible between the jaws of the calipers, producing a falsely low value. Moreover, because fat deposition shifts from subcutaneous distribution to intramuscular marbling, the relation of skinfolds to total body fat is distorted in measurements made in the elderly, and the formulas for total body fat from skinfolds do not apply.

A global estimation of total body water, from which fat mass and fat-free mass can be derived, applying certain assumptions, can be assessed by bioelectric impedance analysis (BIA). Most investigations have found that nomograms for interpreting BIA data in terms of body composition require an age term.

The Mini-Nutritional Assessment is a four-component diagnostic tool, combining anthropometric indices, dietary intake, examiner's global assessment, dietary evaluation, and patient's subjective assessment points, to be used in general practice to assess the nutritional status of the elderly. Less than a score of 17 out of a 30-point total signifies undernutrition, whereas a score of 17−23 points implies "nutritional risk." When the opportunity for laboratory assessment

comes into play, low albumin and cholesterol concentrations and lymphocyte counts of <1500/μl provide additional evidence of poor geriatric nutritional status.

There is no validity to the oft-cited belief that red cell concentrations are normally reduced with aging. Inflammation and decreased renal mass can reduce erythropoiesis rates, however, independent of any constraints on hematinic nutrients. Hepatic secretion rates of proteins, including albumin, are reduced with increasing age, but also with chronic inflammatory illness. It is not clear if age is an independent variable.

FACTORS INFLUENCING NUTRITIONAL STATUS IN AGING

A generic roster of mechanisms devised by Herbert, which, alone or in combination, can explain all nutrient deficiency states, is useful for understanding undernutrition in the elderly when aging-specific factors are weighed within this framework (Table I). The elderly are also susceptible to overnutrition involving energy and certain micronutrients (Table II).

Undernutrition in the Elderly

Malnutrition (undernutrition) has variously been reported to affect one-fourth of community-dwelling elders, one-half of hospitalized elderly, and up to two-thirds of the residents of long-term chronic-care facilities. Of course, chronic and terminal illness contribute to these statistics, and not all such undernutrition can (or should) be addressed by specific nutritional measures. Taste enhancement with flavorings or monosodium glutamate increases eating satisfaction in the healthy elderly and energy consumption in the sick elderly. Both inappetence and sensory dulling may distort the dietary intake of older persons, i.e., the balance and adequacy of micronutrients are better for dependent institutionalized elderly, fed by caretakers, than for ambulatory persons who select an *ad libitum* diet.

Older persons are much more sensitive to dehydration due to immobility, dysregulated thirst, fear of incontinence, diuretic use, and increased solute loads. For hospitalized and institutionalized elderly, weight loss and dehydration increase risk of pressure sores; nutritional supplementation is generally useful when intake is low, but has not been demonstrated to improve resistance to pressure sores and ulcers.

With respect to micronutrients, the lower energy needs of the elderly oblige the diet to have a higher nutrient density to fulfill the normal intakes of vitamins and minerals. Gastric atrophy (due to *Helicobacter pylori* infection) and increased intraintestinal pH predispose to bacterial overgrowth and decreased absorption of certain micronutrients, such as iron, folic acid, beta-carotene, and vitamin B_{12}. Deficiency of the latter is a threat to the elderly, and its delayed recognition by masking with folic acid may be increasing in risk as public health organization folate fortification policies advance.

Increased requirements for vitamin D collide with reduced food intake and decreased outdoor activities, contributing to vitamin deficiency and greater bone loss. Insufficient intake of zinc and of vitamin K_1 to maximize bone mineralization are also consequences of dietary constraints typical with advancing years.

TABLE I Six Possible Causes of All Nutrient Deficiencies, as Applied to Specific Factors of Chronological Aging[a]

Decreased intake	
	Depression, dementia, economic constraints, immobility, illness, taste and smell deficits, oral disease, edentulousness, decreased thirst sensitivity, altered intestinal motility, medications, alcohol abuse
Decreased absorption	
	Hypochlorhydria, drug interactions, recurrent diarrhea, bacterial overgrowth
Increased wastage	
	Chronic inflammation, glucose intolerance and diuresis, diuretic use, "programmed" tissue remodeling
Decreased utilization	
	Drug interactions, chronic inflammation, alcohol abuse
Increased destruction	
	Drug interactions, chronic inflammation
Increased requirements	
	Possibly for calcium, vitamin D, and vitamin B_6

[a] Modified and adapted from Herbert (1973).

TABLE II Five Possible Causes of All Nutrient Excesses as Applied to Specific Factors or Chronological Aging

Increased intake	
	Depression, self-supplementation, medications
Increased absorption	
	No case examples known
Increased retention	
	Decreased physical activity; lower basal metabolism rates; reduced nephron number, decreased renal blood flow, and diminished glomerular filtration; reduced biliary flow
Decreased mobilization or destruction	
	Decreased postprandial clearance of chylomicrons
Decreased requirements	
	Accumulated lifetime storage of nutrient reserves

Overnutrition in the Elderly

Overweight and obesity are risk factors for cardiovascular disease, hypertension, stroke, type 2 diabetes, osteoarthritis, depression, and certain cancers. Decreased activity and lower basal metabolism contribute to risk in later life. There is ongoing debate, however, as to whether the body mass index associated with lowest all-cause mortality, around 22 kg/m^2, applies to all age groups of adults equally, or whether a higher BMI level is more protective in older age.

Vitamin A toxicity is an issue for the elderly, not by body burden, per se, but because retinyl esters persist an inordinately long time in the circulation. Iron stores increase progressively throughout life in healthy men, and in women after menopause. The upper segment of the population distribution may accumulate sufficient iron to constitute an oxidative burden. Manganese and copper may accumulate in the liver and in other tissue sites if cholestatic conditions are present.

DIETARY REQUIREMENTS, RECOMMENDATIONS, AND FOOD SELECTION PATTERNS FOR THE ELDERLY

In past editions of the Recommended Dietary Allowances (RDAs), all adults above 51 years of age formed a common group; it has only been in the past 10 years that sufficient information to make age-specific recommendations for persons 75 years and older has been developed. Dietary guidelines for the selection of foods and food groups have also proliferated, and differentiation for the specific needs and expectations for the elderly is emerging.

Nutrient Requirements and Recommendations in Later Life

It has long been established, and verified by community survey data, that the energy requirements of the elderly are about two-thirds of what they are in active, young, and middle adulthood. In the United States' and Canada's *Dietary Reference Intakes*, differential increases in recommended levels, higher than those for younger adults, exist for three nutrients: calcium, vitamin D, and vitamin B_6. For two additional nutrients relevant to aging—vitamin B_{12} and vitamin K_1—the general adult recommendations have almost doubled over the previous RDA.

Diet, Function, and Chronic Disease Risk

Alongside the concerns for adequate—but not excessive—intakes of macro- and micronutrients are another series suggestions constituting "dietary guidelines," which are related to selection of and servings of various foods and food groups. A variant Food Pyramid, taking the specific needs of the elderly to consume extra liquid to maintain hydration and more dietary fiber to increase colonic transit, stool frequency, and fecal weight, has been advanced for geriatric preventive nutrition. Most aspects of the conventional Food Pyramid relate to a long-term dietary pattern to avoid the genesis of chronic disease. Doubt surrounds the potential for the *de novo* institution of these healthful eating patterns to prevent or reverse disease processes once an individual has reached advanced age.

Dietary constituents for improved performance of physiological function and disease resistance are being identified. Improved immunoresponsiveness has been documented with chronic intakes of suprarequirement amounts of zinc and vitamin E, levels that could never be achieved from dietary sources alone. Nonnutrient substances such as phytochemicals and carotenoids may also have emerging roles in maintaining health in later life, such as lutein and zeaxanthin for macular degeneration. Reduced incidences of most forms of cataracts are associated with higher dietary intakes and supplements of antioxidant vitamins and some carotenoids. Cognitive function of elderly can be improved by routine use of balanced vitamin and mineral supplements without iron.

nutrition-associated complications Disease complications that can be influenced by the nutritional status.

Nutritional status is conventionally associated with body mass. This is a concept derived from agricultural science, where the objective was to develop, through nutritional means, large and meaty animals. In humans, the objective of nutritional assessment is to identify individuals who, because of their nutritional status, are at increased risk of disease complications or death. It is hoped that persons likely to benefit (in terms of reduced complications) can be identified by such an assessment.

INTRODUCTION

Nutritional health is maintained by a state of equilibrium in which nutrient intake and requirements are balanced. Malnutrition occurs when net nutrient intakes (nutrient intakes corrected for abnormally large fecal or urinary losses) are less than requirements. The obvious effect of the above processes is a change in body and blood composition and changes in body and blood composition have traditionally been used to assess nutrition. Traditional nutritional science was first developed in the field of agriculture, where the effect of nutrition was entirely judged by animal growth, mass of muscle and fat, and the production of proteins by the liver. It is therefore not surprising that nutritional assessment methods hitherto used were based on changes in body and blood composition.

The prime question when faced with a patient is how can the physician alter the outcome of the disease in a favorable (to the patient) manner. The question is whether measurement of body composition and blood components allows a prediction of outcome and whether these measurements can be used to help devise treatment that is beneficial? To answer these questions, it is necessary to examine the evolution of malnutrition and the ability of nutritional assessment techniques to predict outcome and aid treatment knowing the evolution.

Malnutrition leads to a succession of metabolic abnormalities, physiological changes, reduced organ and tissue function, and loss of body mass. Concurrent stress such as trauma, sepsis, inflammation, and burns accelerates the loss of tissue mass and function. Ultimately, critical loss of body mass and function occurs, resulting in nutrition-associated complications (NAC) and even death.

The assessment of the nutritional status, to be of clinical importance, should be able to predict whether the individual would have increased morbidity and mortality in the absence of nutritional support. In short, can it predict the occurrence of NAC and thus predict outcome? Disease and nutrition interact so that disease in turn may cause secondary malnutrition or malnutrition may adversely influence the underlying

Copyright 2004, Elsevier (USA). All rights reserved.

disease. Thus, patient outcomes are multifactorial and attempting to formulate the influence of malnutrition based on outcomes of single parameters or simple models fails to consider the many interacting factors. Measurements of body composition and blood components are a snapshot in time and cannot predict the direction of change. Three major factors alter the direction of malnutrition, namely, intake, disease-induced stress, and absorption or losses of nutrients. The progression or regression of these factors ultimately determines whether critical malnutrition will occur in the absence of nutritional support.

Although there are reliable methods to identify patients who will develop NAC, none of the methods or tools can clearly identify patients in whom nutritional support will reduce NAC.

TRADITIONAL NUTRITIONAL ASSESSMENT INDICES

Nutritional status has been traditionally defined by body composition, plasma protein concentrations, immune competence, and multivariate analysis. Assessment of nutritional status based on body composition involves detecting the loss (or gain) of body components relative to previous measurements and relating the values in a given patient to normal standards. The reproducibility and error in the measurements themselves affect the former and the latter is dependent on the normal range of values. A person who starts off at the upper end of the normal range may be classified as "normal" despite considerable changes in the measured value. Therefore, it is possible for a person to be in a negative nutritional state for a long time before anthropometric measurements fall below normal.

Body Weight and Weight Loss

Body weight is a simple measure of total body components and is compared to an "ideal" or desirable weight. This comparison can be made by using formulas or tables. However, a simple approach that gives as much information as these tables is the calculation of the body mass index (BMI) or Quetelet index. Body mass index is calculated as weight in kilograms divided by height in meters squared. A BMI below 14–15 is associated with significant mortality. However, measurements of body weight in patients in hospitals, especially those in intensive care units (ICUs), and of patients with liver disease, cancer, and renal failure are confounded by changes in body water due to underhydration, edema, ascites, and dialysate in the abdomen. Furthermore, the nutritional significance of changes in body weight can again be confounded by changes in hydrational status.

Anthropometry

Triceps and subscapular skinfold thicknesses provide an index of body fat and midarm muscle circumference provides a measure of muscle mass. Although these measurements seem to be useful in population studies, their reliability in individual patients is less clear. The most commonly used standards for triceps skinfold thickness and midarm muscle circumference are not universally applicable. The use of these standards to identify malnutrition in many patients is problematic because of the restricted database and the absence of correction factors for age, hydrational status, and physical activity on anthropometric parameters. Several studies have demonstrated that 20–30% of healthy control subjects would be considered malnourished based on these standards. These measurements do not reflect muscle and fat mass in sick patients, especially those in ICU and those with liver and renal disease, where edema is a major problem in assessing skin folds and arm circumference.

Creatinine–Height Index

The excretion of creatinine in the urine is related to muscle mass. Normalized for height the 24 h creatinine excretion is an index of muscle mass. In theory, it is a good and simple way of assessing the lean body mass. However, it is dependent on complete 24 h urine collections, and urinary losses or oliguria may result in an inappropriate diagnosis of malnutrition. Patients on diuretics such as those with cardiac and liver failure and those with renal disease are especially likely to have low levels of excretion of creatinine.

Serum Albumin

Serum albumin is one of the most extensively studied proteins and there are approximately 20,000 citations referring to this protein in the literature from the past 30 years. Several studies have demonstrated that a low serum albumin concentration correlates with an increased incidence of medical complications. Disease rather than nutrition in adults mainly influences serum albumin.

The concentration of serum albumin represents the net sum of albumin synthesis, degradation, losses from the body, exchange between intra- and extravascular albumin compartments, and the volume in which albumin is distributed. Albumin is highly water soluble and resides in the extravascular space. The total body pool of

albumin in a normal 70 kg man is ~280 g (3.5–5.3 g/kg). Approximately one-third of the total pool constitutes the intravascular compartment and two-thirds constitutes the extravascular compartment. The concentration of albumin in blood is greater than that in lymph or other extracellular fluids and the ratio of intravascular to extravascular albumin concentration varies from tissue to tissue. During steady-state conditions, ~14 g of albumin (200 mg/kg) is produced and degraded daily. Each day, ~5% of the total albumin pool is degraded and replaced by newly synthesized albumin. Protein-calorie malnutrition causes a decrease in the rate of albumin synthesis because adequate nutrient intake is important for polysomal aggregation and maintenance of cellular RNA levels needed for protein synthesis. Within 24 h of fasting, the rate of albumin synthesis decreases markedly. However, a short-term reduction in albumin synthesis has little impact on albumin levels because of a compensatory decrease in albumin degradation and a transfer of extravascular albumin to the intravascular compartment. Prolonged protein-calorie restriction induced experimentally in human volunteers or observed clinically in patients with anorexia nervosa causes marked reductions in body weight but little change in plasma albumin concentration. A protein-deficient diet with adequate calories in elderly persons causes a decrease in lean body mass and muscle function without a change in plasma albumin concentration.

Hospitalized patients may have low levels of plasma albumin for several reasons. Inflammatory disorders cause a decrease in albumin synthesis, an increase in albumin degradation, and an increase in albumin transcapillary losses. Gastrointestinal diseases and some cardiac diseases increase albumin losses through the gut and renal diseases may cause considerable albuminuria. Wounds, burns, and peritonitis cause major losses from the injured surface and in certain circumstances cause an increase in albumin losses through the gut, kidneys, or damaged tissues. Because the exchange between intra- and extravascular albumin is so large, even small changes in the percentage of exchange can cause significant changes in plasma albumin levels.

Prealbumin

Prealbumin is a transport protein for thyroid hormones and exists in the circulation as a retinol-binding–prealbumin complex. The turnover rate of this protein is rapid, with a half-life of 2–3 days. It is synthesized by the liver and is catabolized partly in the kidneys. Protein-energy malnutrition reduces the levels of prealbumin and refeeding restores levels. However, prealbumin levels fall without malnutrition in infections and in response to cytokine and following hormone treatment. Renal failure increases levels and liver failure may cause decreased levels. Although prealbumin is responsive to nutritional changes, it is influenced by several disease-related factors, making it unreliable as an index of nutritional status.

Immune Competence

Immune competence, as measured by delayed cutaneous hypersensitivity (DCH), is affected by severe malnutrition. While it is true that immune competence as measured by DCH is reduced in malnutrition, several diseases and drugs influence this measurement, making it a poor predictor of malnutrition in sick patients. The following factors nonspecifically alter DCH in the absence of malnutrition: (1) infections; (2) uremia, cirrhosis, hepatitis, trauma, burns, and hemorrhage; (3) steroids, immunosuppressants, cimetidine, warfarin, and perhaps aspirin; and (4) general anesthesia and surgery. Hence, in the critically sick patient, many factors can alter DCH and render it valueless in assessing the state of nutrition.

MEASUREMENT OF BODY COMPOSITION

The body consists of compartments or components. There are over 35 well-recognized components and these are organized into five levels of increasing complexity: atomic, molecular, cellular, tissue-system, and whole body. In healthy weight-stable subjects, there are relatively constant relationships among these components, which are correlated with one another.

Isotope Dilution

Total body water, measured by isotope dilution, is usually the largest molecular-level component. Water maintains a relatively stable relationship to fat-free body mass and thus measured water isotope dilution volumes allow prediction of fat-free body mass and fat (i.e., body weight minus fat-free body mass). The relationship between total body water and other body composition components may change with disease and this should be considered when interpreting data from hospitalized or chronically ill patients. The usual approach is to measure a dilution volume using isotopes such as tritium-, deuterium-, or ^{18}O-labeled water and then calculate fat-free mass by assuming that the proportion of fat-free body mass as water is constant at 0.732. However, there are no data about the relationship of fat-free mass and clinical outcome.

Bioimpedance Analysis

Bioimpedance analysis (BIA) is a method of estimating body fluid volumes by measuring the resistance to a high-frequency, low-amplitude alternating electric current (50 kHz at 500 to 800 mA). The amount of resistance measured (*R*) is inversely proportional to the volume of electrolytic fluid in the body and to a lesser extent on the proportions of this volume. A regression equation is then developed based between a reference measurement of fat-free body mass (i.e., isotope dilution) and the measured *R*, height, and other variables.

Recently, the difference in the conductive properties of extra- and intracellular fluid has resulted in the development of bioimpedance spectroscopy (BIS). Direct current will pass through extracellular fluid but will not traverse the lipid membrane of cells. As the frequency of the applied current increases, the cell membrane acts as the dielectric of capacitors and the alternating current will pass partly and easily through the extracellular fluid and with greater resistance through the cells. The total impedance to the current is defined by an equivalent circuit of a resistance and a reactance through a capacitor. As the frequency of the alternating current increases, the reactance at first increases and then decreases until at very high frequencies there is little impedance to the passage of the current through cells. An analysis of the reactance to different frequencies is used to calculate extra- and intracellular water. In healthy adults, it is possible to predict total body water within 2 to 3 liters. Much more variable results are observed in diseased patients, owing in part to the population-specific nature of BIA. BIA measures total body water from which the lean body mass is calculated using the assumption that all tissues have the same degree of hydration. Such an assumption will give erroneous results in patients with edema and ascites. Again, the relationship between body composition, as determined by BIA, and clinical outcome in hospitalized patients has not been established.

Dual-Energy X-Ray Absorptiometry

Dual-energy X-ray absorptiometry (DXA) is a method developed originally for the measurement of bone density and mass. DXA can also be used to measure soft tissue composition. DXA can measure total and regional fat, bone mineral, and bone mineral-free lean components. The method is based on the attenuation characteristics of tissues exposed to X rays at two peak energies. Mathematical algorithms allow calculation of body components using various physical and biological models. The method provides an accurate measurement of bone mineral mass and also of soft tissue mass. Again, there are no data indicating whether DXA can predict outcome in hospital patients.

Whole-Body Counting/Neutron Activation

K, N, P, H, O, C, Na, Cl, and Ca can be measured with a group of techniques referred to as whole-body counting/*in vivo* neutron activation analysis. Shielded whole-body counters can count the gamma-ray emission of naturally occurring ^{40}K. The method is safe and can be used in children and pregnant women. The ^{40}K counts can be used to estimate total body potassium, which in turn can be used to calculate body cell mass and fat-free body mass. Prompt gamma neutron activation analysis can be used to measure total body N and H. Nitrogen can be used to calculate total body protein. Delayed gamma neutron activation measures total body Ca, Na, Cl, and P. These elements can be used to calculate bone mineral mass and extracellular fluid volume. Finally, inelastic neutron-scattering methods measure total body O and C. Carbon is useful in models designed to quantify total body fat. Whole-body-counting/neutron activation methods are important because they provide a means of estimating all major chemical components *in vivo*. These methods are considered the standard for evaluating the body composition components of nutritional interest, including body cell mass, fat, fat-free body mass, skeletal muscle mass, and various fluid volumes. Refeeding the malnourished subject by mouth or by TPN results in a rapid increase in TBK but not TBN. In animal studies, it has been shown that this increase in TBK is the result of improved cell membrane voltage and an increase in the intracellular ionic potassium. The findings are consistent with improved cell energetics demonstrated by nuclear magnetic resonance spectroscopy and the improved muscle function shown concurrently. Loss of TBK is a good predictor of poor outcome in a variety of conditions associated with malnutrition.

Computerized Axial Tomography and Magnetic Resonance Imaging

These methods measure components at the tissue-system level of body composition, including skeletal muscle, adipose tissue, visceral organs, and brain. A large number of studies in phantoms, cadavers, and *in vivo* validate these methods. There are no studies of imaging methods that show that they can predict clinical outcome in hospital patients.

TABLE I Nutritional Indices

Index	Features	Classes
Prognostic Nutritional Index (PNI)	PNI = 158 − 1.6 × albumin (g/dl) − 0.78 × TSF (mm) − 0.2 transferrin (mg/dl) − 5.8 × DCH	<40 predicts sepsis
Nutritional Risk Index	NRI = 1.519 × albumin (g/dl) + 41.7 × present weight/usual weight	Normal nutrition >100 Severe malnutrition <83.5
Maastricht Index	MI = 20.68 − 0.24 × albumin (g/liter) − 19.21 × prealbumin (g/liter) − 1.86 × lymphocyte count (10^6/liter) − 0.04 × ideal body weight	>0 Malnourished

Note. Reprinted from Schneider, S. M., and Hebuterne, X. (2000). Use of nutritional scores to predict clinical outcome in chronic disease. *Nutr. Rev.* **58**, 31–38, with permission.

Body Composition and Outcomes

Although the above methods of body composition can accurately assess different components, they are difficult to apply in the clinical setting except in special units. The only methods of nutritional assessment available for wide application in populations are BIA and BIS. There are few data to show that these methods can predict outcome in hospital patients. In patients on renal dialysis, it has been shown that a reduction of the reactance from 70 to 43 Ω increased morbidity by 9% and a reduction of reactance to 31 Ω increased morbidity by 14%. In cancer patients, a lean body mass below the normal range as indicated by BIA was associated with increased morbidity.

NUTRITIONAL INDICES

There are a number of nutritional indices based on measurements of serum proteins, immune competence, and anthropometry. These are the Prognostic Nutritional Index (PNI), a simplified version of the PNI called the Nutritional Risk Index, and the Maastricht Index, all of which predict postoperative complications (Table I).

SUBJECTIVE GLOBAL ASSESSMENT

A clinical method for evaluating nutritional status, termed subjective global assessment (SGA), encompasses historical, symptomatic, and clinical parameters as given below. This approach defines malnourished patients as those who are at increased risk for medical complications and who will presumably benefit from nutritional therapy. The basis of this assessment is to determine whether nutrient assimilation has been restricted because of decreased food intake, maldigestion, or malabsorption, whether reduction in intake has adversely influenced organ function and body composition, and whether the patient's disease has altered nutrient requirements. The specific features of the history and physical examination used in the SGA are listed in Table II.

History

The nutritional history should evaluate the following questions:

1. Has there been a recent change in body weight and was the change intentional or unintentional? The percentage of body weight lost in the previous 6 months is characterized as mild (<5%), moderate (5–10%), or severe (>10%). The pattern of loss is also important and it is possible for a patient to have significant weight loss but still be considered well nourished if body weight (without edema or ascites) recently increased. For example, a patient who has had a 10% body weight loss but regained 3% of that weight over the past month would be considered well nourished.

2. Is dietary intake adequate? The patient should be questioned about his or her habitual diet and any change in diet pattern. Have the number, size, and contents of meals changed? Are nutrient supplements being taken? A diary documenting food intake may be useful when the history is inconclusive.

3. What is the reason(s) for the change in dietary intake? Has appetite changed? Is there a disturbance in taste, smell, or the ability to chew or swallow food? Has there been a change in mental status or increased depression? Has there been a change in the ability to prepare meals? Are there gastrointestinal symptoms, such as early satiety, postprandial pain, nausea, or vomiting? Is the patient taking medications that affect food intake?

4. The presence of persistent gastrointestinal symptoms, such as anorexia, nausea, vomiting,

TABLE II Subjective Global Assessment

A. History
  1. Weight and height
    Current height ____ cm, weight ____ kg
    Overall weight loss in past 6 months: ____ kg, ____%
    Change in weight in past 2 weeks (use + or −): ____ kg, ____%
  2. Dietary intake change (relative to usual intake)
    No change
    Change: Duration = ____ days
      Type: Suboptimal solid diet
        Hypocaloric liquids
        Starvation
        Supplement (circle): Nil, vitamin, minerals
  3. Gastrointestinal symptoms that persisted for >2 weeks
    None
    Nausea
    Vomiting
    Diarrhea
    Pain (circle): At rest, on eating
  4. Functional capacity
    No dysfunction
    Dysfunction: Duration ____ days
      Type: Working suboptimally
        Ambulatory but not working
        Bedridden
  5. Disease and its relation to nutritional requirements
    Primary diagnosis: ____
    Metabolic demand (stress)
      No stress
      Moderate stress
      High stress (burns, sepsis, severe trauma)
B. Physical status (for each trait specify: 0 = normal, 1 = mild deficit, 2 = established deficit)
    Loss of subcutaneous fat
    Muscle wasting
    Edema
    Ascites
    Mucosal lesions
    Cutaneous and hair changes
SGA Grade ____

diarrhea, and abdominal pain, which have occurred almost daily for at least 2 weeks is recorded. Is there evidence of malabsorption?

5. The patient's functional capacity is defined as bedridden, suboptimally active, or full capacity. Are there symptoms of specific nutrient deficiencies including macrominerals, micronutrients, and water?

6. The metabolic demands of the patient due to the underlying disease state should be determined. Examples of high-stress illnesses are burns, major trauma, and severe inflammation, such as acute colitis. Moderate-stress diseases might be a mild infection or limited malignant tumor.

Physical Examination

The physical examination corroborates and adds to the findings obtained by history:

Anthropometric Assessment

Current body weight should be compared with previously recorded weights, if available. Weight for height should be compared with standard normal values. A search for evidence demonstrating depletion of body fat and muscle mass should be made. Clearly defined bony, muscular, and venous outlines and loose skin folds can judge a general loss of adipose tissue. A fold of skin, pinched between the forefinger and thumb, can detect the adequacy of subcutaneous fat. The presence of hollow cheeks, buttocks, and perianal area suggests body fat loss. An examination of the temporalis, deltoids, and quadriceps muscles should be made to search for muscle wasting.

Assessment of Muscle Function

Strength testing of individual muscle groups should be made to evaluate generalized and localized muscle weakness. In addition, a general evaluation of respiratory and cardiac muscle function should be made.

Fluid Status

An evaluation for dehydration (hypotension, tachycardia, postural changes, mucosal xerosis, dry skin, and swollen tongue) and excess body fluid (edema, ascites) should be made.

Evaluation for Specific Nutrient Deficiencies

Rapidly proliferating tissues, such as oral mucosa, hair, skin, and bone marrow, are often more sensitive to nutrient deficiencies than are tissues that turn over more slowly.

In contrast to the traditional approach, the SGA identifies the initial nutritional state and the interplay of the factors influencing the progression or regression of nutritional abnormalities. Therefore, SGA is a dynamic process that is not limited to a single snapshot at the moment of measurement but provides a picture of current nutritional status and insight into the patient's future status. The clinical assessment of nutritional status involves a focused history and physical examination. The information is then used as a composite observation to judge whether the intake and quality of food eaten, the status of the gastrointestinal tract, metabolic requirements, and existing habitus are critical or would result in critical malnutrition in the future if nutritional support is not given.

It is a mistake to create many subcategories of nutritional status. The findings from the patient history and physical examination are used to categorize patients as follows: being well nourished and not having risk factors for progressive malnutrition (category A); currently having no significant wasting or minimal weight loss but having changes in intake, absorption, stress, and function, as judged globally, that will induce, and cause the patient to progress toward, increased weight loss and functional deficit (category B); or significant weight loss, functional deficit and risk factors for progression (category C). The rank is assigned on the basis of subjective weighing. Equivocal information is given less weight than definitive data. Fluid shifts related to onset or treatment of edema or ascites must be considered when interpreting changes in body weight. In general, a patient who has experienced weight loss and muscle wasting but is currently eating well and is gaining weight is classified as well nourished. A patient who has experienced moderate weight loss, continued compromised food intake, continued weight loss, and progressive functional impairment and who has a "moderate-stress" illness is classified as moderately malnourished. A patient who has experienced severe weight loss and who continues to have poor nutrient intake, progressive functional impairment, and muscle wasting is classified as severely malnourished independent of disease stress. Several studies have shown that the use of SGA in evaluating hospitalized patients gives reproducible results and there was more than 80% agreement when two blinded observers assessed the same patient.

Such a structured approach allows an assessment of whether there is a role for nutritional support or whether the weight loss and fatigue are entirely due to disease. For example, for a patient with thyrotoxicosis, increased appetite, and no gastrointestinal symptoms restricting intake but only signs of hypermetabolism, the role of nutritional support is minimal. In contrast, a person with marked weight loss due to obstruction caused by upper gastrointestinal cancer with compromised swallowing, marked functional deficit, and poor intake will benefit from nutritional support. On the basis of a technical review of the literature, the American Gastroenterological Society stated that "preoperative parenteral nutrition has a more profound effect in reducing the rate of major postoperative complications in patients undergoing major surgery for cancer of the esophagus or stomach." On the basis of the same review, they concluded that "[p]reoperative parenteral nutrition should also be considered in those patients who are severely malnourished (as defined in the technical review). A retrospective subgroup analysis of one large RCT suggests that it does have a greater therapeutic effect in decreasing postoperative complications in this group."

Illustrative Cases

Case 1: A 60-year-old woman was admitted to the hospital for elective resection of a colon carcinoma. She had lost 10% of her initial weight over 8 months before admission. However, she recently gained weight after therapy with nutritional supplements was initiated. She continued to work and was active. On physical examination, there was no loss of muscle or fat. She is SGA A.

Case 2: A 40-year-old man with an acute exacerbation of Crohn's disease had lost 10% of his body weight within the previous 2 weeks and was ingesting mostly liquids to avoid gastrointestinal discomfort. He was ambulatory but was not going to work. On physical examination, he had slight loss of subcutaneous tissue manifested by a reduced buccal fat pad and loose skin folds over the arms. He is SGA B.

Case 3: A 67-year-old man with esophageal cancer had minimal food intake for almost 3 months. He lost 15% of his body weight during the previous 4 months and is continuing to lose weight. He was able to move around the house but had marked muscle weakness and fatigue and did not walk outdoors. On physical examination, he lacked subcutaneous tissue and had hollow temples, deltoid wasting, and mild pitting edema. He is SGA C.

SGA has been shown to be a better predictor of postoperative infectious complications than serum albumin, serum transferrin, delayed cutaneous, hypersensitivity, anthropometry, creatinine–height index, and the prognostic nutritional index. How does SGA perform in predicting complications in conditions other than preoperative patients? SGA has been shown to predict complications in general surgical patients, cancer patients, patients on dialysis, and liver transplant patients. Two recent large-scale studies by Perman *et al*. and Pirlich *et al*. have shown that SGA independently identifies the increased mortality and morbidity from malnutrition even when the data are statistically adjusted for other factors influencing survival and complications.

GERIATRIC NUTRITIONAL ASSESSMENT

SGA is a reliable tool for the assessment of malnutrition in the elderly. In addition, two other tools have been developed for the assessment of the nutritional status in the elderly. They are the Mini Nutritional Assessment (MNA) and the Malnutrition Risk Scales (SCALES). The MNA consists of 18 items. Weight, height, and weight

loss are recorded. Questions are asked regarding lifestyle, medications, and degree of mobility. Then, a diet history of number of meals, food and fluid intake, and ability to self-feed is recorded. Finally, a self-assessment of health and nutritional status is noted. The answers to these questions are converted into a score. A score ≥ 24 is considered well nourished, a score of 17–24 indicates a risk of malnutrition, and a score <17 indicates that the patient is malnourished. A score below 17 has been associated with increased mortality and a longer hospital stay. SCALES is composed of sadness, cholesterol, albumin <40 g/liter, loss of weight, eating problems, and shopping problems. Each component that is abnormal is given a point. If the sum of the points is ≥ 3, then there is a high risk of malnutrition.

FUNCTIONAL TESTS OF MALNUTRITION

It was shown that muscle function and mitochondrial function are very sensitive to nutritional manipulations and are influenced before changes in body composition. The measurement of muscle function has been shown to predict complications in a number of studies. The association between outcome and muscle function was shown by Klidjian using hand-grip strength and by Windsor and Hill using stimulated and respiratory muscle function. Elderly subjects with a hand-grip strength of <5 kg have a very high mortality. Functional tests (the simplest in practice is the test of hand grip strength) have been shown to predict NACs. They are also a snapshot in time and are best used to follow the effects of nutritional support. Since they improve before changes in body composition, they could be used to determine whether the individual is progressively responding to nutrition before there are changes in body composition. They could be used to examine corroborate the functional changes observed during evaluation of SGA.

Obesity, Treatment of

GEORGE A. BRAY
Pennington Biomedical Research Center, Baton Rouge, Louisiana

body mass index A measure of normal weight and overweight [weight (in kilograms)]/[height (in centimeters)]^2.
gastric bypass Construction of a small (10–30 ml) proximal gastric pouch by stapling across the stomach or complete resection from the rest of the stomach, connected to a segment of jejunum brought up at a Roux-en-Y limb.
obesity Body mass index is >30 kg/m^2.
overweight Body mass index in the range of 25–29.9 kg/m^2.

Obesity produces complications that involve nearly all major organ systems. The major gastrointestinal medical complications associated with obesity include gallstones, nonalcoholic fatty liver disease, and possibly gastroesophageal reflux disease.

INTRODUCTION

As the epidemic of obesity has grown over the past 20 years, the need to understand its causes and apply this knowledge to the treatment of obesity has become ever more urgent. As medical science's understanding of obesity increases, novel ideas about techniques, strategies, molecules, and procedures that can be used to curtail the devastating effects of this epidemic will emerge. This article will focus on five different approaches to the treatment of obesity. These are behavioral therapy, diet, exercise, medications, and surgery. As there is only space for a brief discussion of each, the reader is referred to other sources for more details (see Further Reading). Since obesity is an imbalance between the energy that is ingested and the energy that is expended, any treatment must have an effect on one or both sides of the energy balance equation. This concept is easily applied to diet, which aims to reduce food intake, and exercise, which aims to raise energy expenditure. The subtleties of this concept, when applied to medications, are more complex.

BEHAVIOR THERAPY

Over the past 30 years, there has been a steady improvement in behavioral techniques that were originally introduced only in 1967 by Stuart in a classic paper. The basic elements of any behavioral program focus on three things: identifying the antecedents to eating and changing them; characterizing an individual's eating style and improving it; and providing rewards for improved eating behavior. With programs that last up to 24 weeks, the retention is usually more than 75% and weight losses can be up to 10% of initial body weight.

Retrospective analysis has shown that several strategies are particularly useful. These include self-monitoring of one's eating habits, eating a lower fat diet, being more physically active, and developing a support system to help reward successful behavior. Providing structured meal plans has proven to be an additional useful strategy. These can be meal plans, written menus, or portion-controlled foods. The use of the internet has also proven to be a potentially valuable approach to delivering behavioral therapy. The major problem with behavioral strategies is that patients tend to regain weight after leaving the program. Recent focus has concentrated on ways of continuing the impact of the program over longer periods of time.

Overweight adolescents are a good target for preventive strategies using behavior therapy, because good 10-year data show that intervention for this group can reduce the degree of overweight into adult life. Data on the efficacy of behavior programs carried out in controlled settings show that weight losses average nearly 10% in trials lasting more than 16 weeks. The problem with behavioral therapy is that regaining weight once the behavior treatment ends is frequent. At least one long-term study showed that behavioral therapy could provide long-term weight loss, providing it was continued.

DIET

Calories

The essential element of any diet is that it reduces the total caloric intake. Many different diets have been recommended over the past 150 years since Mr. Banting published his famous pamphlet in 1863. One of the most

 Copyright 2004, Elsevier (USA). All rights reserved.

popular themes has been the low-carbohydrate diet. The fact that new diets continue to appear suggests that none of them have a magic formula because if one did, none of the others would have succeeded in the marketplace.

Fat

There are a number of elements of an effective diet that anyone can incorporate with potential benefit. The observation from behavioral therapy that a low-fat diet is what successful patients adopt suggests that this would be a useful strategy. Several reviews have shown that low-fat diets are associated with weight loss. The initial weight is one variable predicting the magnitude of the response (overweight people lose more than do normal weight people). A second variable is the amount of fat removed from the diet—the greater the reduction, the more weight is lost. Palatability of the diet may be another factor. A recent study showed that replacing fat with olestra, a nondigestible fat substitute, reduced body weight by 6% and body fat by nearly 20% over 9 months, whereas a standard reduced-fat diet with the same available fat was relatively ineffective. However, a very-low-fat diet can be difficult for many people to adhere to. For this reason, the best advice is to reduce saturated and *trans*-fatty acids and to lower total fat to as near 25% as possible for the individual.

Carbohydrate and Fiber

Carbohydrate and both digestible and indigestible fiber intake can affect food intake. Although recent studies show that substituting starch for sugar does not produce greater weight loss, the type of digestibility of that carbohydrate may play a role. The glycemic load, which is the glycemic index times the carbohydrate intake, may be important. In the Nurses Health Study, the glycemic load was related to the risk of developing heart disease and diabetes. Diets with a low glycemic index, i.e., with a lower rise in glucose, produce more satiety than do diets with a high glycemic index.

Breast Feeding

Several recent studies suggest that the length of breastfeeding affects childhood obesity. In a large German study of more than 11,000 children, von Kries *et al*. showed that the duration of breastfeeding as the sole source of nutrition was inversely related to the incidence of obesity, defined as a weight above the 95th percentile, when children entered the first grade. In this study, the incidence was 4.8% in children with no breastfeeding, falling in a graded fashion to 0.8% in children who were fed solely from the breast for 12 months or more. A second large report also showed that breastfeeding reduced the incidence of overweight adolescents. The third report with fewer subjects and more ethnic heterogeneity failed to show this effect. However, the possibility that lengthening the duration of breastfeeding could reduce the future risk of obesity is another reason to recommend breastfeeding for at least 6 to 12 months.

Dietary Calcium

Nearly 20 years ago, McCarron *et al*. reported that there was a negative relationship between body mass index and dietary calcium intake in the data collected by the National Center for Health Statistics. More recently, in 1999, Zemel *et al*. found that there was a strong inverse relationship between calcium intake and the risk of being in the highest quartile of body mass index. These studies have prompted a reevaluation of clinical trials that have given calcium supplements orally. In the prospective trials, subjects receiving calcium had a greater weight loss than did subjects receiving placebos. Increasing calcium from 0 to nearly 2000 g/day was associated with a reduction in body mass index (BMI) of approximately 5 BMI units. These data might suggest that low calcium intake plays a role in the current epidemic of obesity.

EXERCISE

Exercise is an obvious way to increase energy expenditure. This is desirable for all Americans and would be beneficial for reducing cardiovascular risks. However, for many people who are overweight, exercise can be a challenge, because they are already expending more energy doing everyday activities. Thus, for many such patients, a simple walking program can be the best approach. That this is valuable is shown by the Diabetes Prevention Program, where a lifestyle program of diet and exercise produced a 58% reduction in the conversion of patients with impaired glucose tolerance to diabetes mellitus.

With substantial amounts of supervised exercise, significant weight loss can be obtained. However, for many people, exercise adds little extra weight loss to a dietary program aimed at weight loss, probably because people do not maintain the amount of exercise that is prescribed. Some reports suggest that exercise may conserve body protein during dieting, but others do not.

The most beneficial part of an exercise program comes when trying to maintain a lower body weight. In a survey of people who were successful at maintaining

weight, exercise was maintained at a level significantly above that in people without a weight problem.

MEDICATIONS

Medication should be seriously considered for clinically overweight individuals, defined as individuals with a body mass index above 30 kg/m^2, or those with diabetes, impaired glucose tolerance, hypertension, or heart disease combined with a BMI above 27 kg/m^2. Two strategies can be used to treat individuals who are clinically overweight. If they have co-morbidities, individual drugs can be used to treat each co-morbidity; i.e., patients can be treated for their diabetes, hypertension, dyslipidemia, and sleep apnea. Alternatively, or in addition, patients with a BMI > 30 kg/m^2 could be treated with anti-obesity drugs. Current drugs include appetite suppressants that act on the central nervous system and orlistat, which blocks pancreatic lipase. The availability of these agents differs from country to country and any physician planning to use them should be familiar with the local regulations. Most of the drugs on the market were reviewed and approved more than 20 years ago and are approved for short-term use only. The basis for the short-term use is twofold. First, almost all the studies of these agents are short-term. Second, the regulatory agencies are concerned about the potential for abuse and thus have restricted their prescription to "only a few weeks," which is usually interpreted as up to 12 weeks. The withdrawal of fenfluramine and dexfenfluramine from the market in 1997 following the development of valvular heart disease in patients treated with these drugs further compounds the concern of health authorities about the safety of appetite suppressants. Because of the regulatory limitations and the lack of longer-term data on safety and efficacy, the use of the drugs approved for short-term treatment must be carefully justified. These drugs may be useful in initiating treatment and in helping a patient who is relapsing, but only for a few weeks.

Sibutramine (Meridia; Reductil) is approved in many countries for long-term use. The evidence shows that weight loss of 10% or more can be produced with this drug. The side effect profile includes dry mouth, asthenia, insomnia, and constipation. It also produces a small increase in heart rate of 2–5 beats per minute and a small rise in blood pressure of 2–4 mm Hg. Clinical data show no evidence of valvulopathy. Blood pressure should be followed carefully and the drug may be inappropriate in patients with stroke, congestive heart failure, or recent myocardial infarction. It should not be used with other serotonergic drugs or drugs that inhibit monoamine oxidase.

Orlistat (Xenical), a drug that blocks intestinal lipase, has been approved for long-term use in many countries. In clinical trials lasting up to 4 years, orlistat was associated with a mean weight loss of up to 10% at the end of 1 year in patients who were prescribed a 30% fat diet. As might be expected, because the drug blocks pancreatic lipase in the intestine, fecal fat loss is increased. Major side effects related to the release of undigested triglyceride occurred in some patients, usually within the first month, and were reported with reduced frequency over time, indicating that patients learned to use the drug effectively in relation to dietary intake of fat. The effective use of this medication requires that physicians and their staff members provide good dietary counseling to patients.

The combination of ephedrine and caffeine is a third compound for which a randomized clinical trial has been published by Astrup *et al*. Over 6 months, the patients treated with ephedrine and caffeine lost more weight than did the placebo-treated group or the two groups treated individually with ephedrine or caffeine. This research has been used for marketing of herbal preparations that contain ephedra alkaloids with or without caffeine. Two clinical trials by Boozer *et al*. have shown significantly greater weight loss with an herbal ephedra/caffeine preparation than with placebo.

The epidemic of obesity, the discovery of genes that produce obesity, and a slim armamentarium for treatment of obesity have spurred many pharmaceutical companies to search for new agents. These agents can be divided into two categories: compounds that are in clinical trials with suggestive data and new molecules just entering the clinical arena. In the former category are bupropion, leptin, and topiramate. Bupropion is approved by the Food and Drug Administration (FDA) as an antidepressant. Two recent studies show that it produces weight loss. Leptin is the peptide produced primarily in adipose tissue. When deficient, it produces massive obesity. Leptin-deficient patients respond to leptin with weight loss, suggesting that leptin might be clinically useful if the proper way of delivering it can be found. The third molecule, topiramate, is an anticonvulsant approved by the FDA for this purpose. Several studies now suggest that topiramate produces weight loss in patients receiving it for their epilepsy. Clinical trials with this compound are currently under way.

A number of other molecular targets could serve as the basis for clinically useful drugs. These molecules can be divided into those that have a peripheral mechanism of action and those that act on the brain. Thermogenic β-adrenergic receptors are one target that have been investigated for more than 15 years, but as yet

no clinically useful molecule has been identified. Cholecystokinin reduces food intake in animals and humans. To date, no useful molecules that work through this receptor have been identified. Glucagon-like peptide 1 (GLP-1) is processed from the enteroglucagon molecule by gastrointestinal (GI) cells. Infusion of GLP-1 into lean and obese human beings reduces food intake and molecule agonists to this receptor system are under development. Ghrelin, produced primarily in the stomach, has been recently identified and shown to increase food intake when given peripherally or centrally. Antagonists to this receptor system offer potential for future molecules with which to treat obesity. Finally, the pentapeptide enterostatin, cleaved from pro-colipase in the intestinal lumen, reduces food intake and primarily fat intake. This molecule or similar molecules might have interesting potential for modulation of clinical fat intake.

Neuropeptide Y is one of the most potent stimulators of food intake when it is injected into the brain. Several abstracts suggest that this may be a useful target, with molecules aimed at either the Y-1 or the Y-2 receptor. Loss of the melanocortin-4 receptor produces massive obesity in mice, suggesting that molecules aimed at this receptor could be useful. The endogenous signal for this system is probably α-melanocyte-stimulating hormone (α-MSH), which is produced from proopiomelanocortin. Another endogenous molecule, agouti-related peptide (AGRP), inhibits the effect of α-MSH. Modulation of the receptors for AGRP or α-MSH would be two potential targets. The peptides mentioned above are under the control of circulating leptin acting on receptors in the arcuate nucleus of the hypothalamus. Cocaine–amphetamine-regulated transcript (CART) is a fourth molecule in the brain that modulates, and reduces, food intake. A receptor agonist that mimicked CART might also be an attractive target. At least two other hypothalamic peptides need to be considered in this discussion. The first is melanocortin-concentrating hormone. Animals overexpressing this peptide are heavier than controls and disabling the production of this peptide produces leanness. Other hypothalamic peptides are corticotropin-releasing hormone (CRH) and urocortin, two variants that differentially bind to CRH R1 and CRH R2. CRH reduces food intake and modulating its activity would be another potential mechanism to reduce food intake.

SURGERY

Surgical intervention was initiated more than 40 years ago with operations that shortened the absorptive surface available to GI contents by various bypass operations. At present, the principal operations are the gastric bypass, the vertical banded gastroplasty, and the gastric band, which allows a constrictive band around the stomach to be expanded by injecting saline into a subcutaneous reservoir. With the introduction of laparoscopic surgery and advancement in the skill of surgeons using this surgery during the 1990s, the safety of these procedures improved. Although originally recommended for people with a body mass index above 40 kg/m^2, the studies showed marked benefits to patients having this surgery, which suggests that the BMI should be reduced to 35 kg/m^2 or even lower if there are significant risks associated with the obesity.

BENEFITS OF INTENTIONAL WEIGHT LOSS

Because the weight loss after gastric surgery is more sustained than after other methods of weight reduction, much of the data on the benefits of weight loss are derived from those patients. Although the data are not entirely clear, studies indicate that intentional weight loss $\geq$20 pounds has been associated with an approximately 25% reduction in obese and overweight patients who have an obesity-related illness, especially type 2 diabetes mellitus. Other benefits of modest sustained weight loss include improved cardiovascular function, better control of type 2 diabetes mellitus, dyslipidemia, and hypertension. Improved respiratory function with less obstructive sleep apnea and improved reproductive and urinary tract function in women require considerably more weight loss.

Although the relationship between obesity and factors that dispose to gastroesophageal reflux disease is not clear, significant weight loss after gastric surgery caused resolution of symptoms, even before significant weight loss occurred. Gallstones may increase in incidence in obesity and rapid weight loss increases bile cholesterol supersaturation, increasing the risk of new gallstones. Nonalcoholic fatty liver disease (NAFLD) is associated with the metabolic syndrome (increased insulin, hypertension, and hyperlipidemia), perhaps as an earlier stage before obesity or diabetes mellitus develops. A gradual weight loss may improve hepatic chemistries and liver size, but rapid weight loss (e.g., after gastric surgery) may exacerbate NAFLD.

capsule wireless endoscopy Use of a small camera containing a capsule that is ingested to evaluate the gastrointestinal tract. Typically used to investigate bleeding sources in the small intestine.

hematemesis Vomiting of blood; indicates an upper gastrointestinal site of bleeding.

hematochezia Bright red blood per rectum; may or may not be mixed with stool.

Meckel's diverticulum A 2- to 6-cm outpocketing of the ileum along the antimesenteric border, usually located 50 to 180 cm proximal to the ileocecal valve.

melena Tarry, foul-smelling black stools.

Gastrointestinal bleeding is one of the most common problems in medicine. Bleeding from the upper and lower gastrointestinal tracts is recognized as a major source of disease-related morbidity and, on occasion, mortality. Occult gastrointestinal bleeding is even more common than upper and lower gastrointestinal bleeding. Patients may present with bleeding that is truly hidden (occult); this form of bleeding is extremely common and can even be considered to be pervasive. Patients may instead have clinically obvious bleeding, but the blood is from a source in the gastrointestinal tract that is difficult to identify; this type of occult bleeding has been termed "obscure gastrointestinal bleeding." The clinical spectrum of occult gastrointestinal bleeding is therefore expansive and may encompass any of a number of clinical scenarios. Because patients may present with massive obvious bleeding or may be entirely unaware that they are bleeding, gastrointestinal bleeding afflicts inpatients as well as outpatients.

INTRODUCTION

issues surrounding acute gastrointestinal bleeding remain unchanged. First, attention must be directed at the patient's hemodynamic status. Subsequently, the source of bleeding should be determined, any active bleeding should be stopped, and recurrent bleeding should be prevented.

CLINICAL PRESENTATION

Types of Manifest Bleeding

Clinical signs of gastrointestinal bleeding reflect the site, etiology, and rapidity of bleeding. Clinically obvious bleeding from the gastrointestinal (GI) tract is usually manifest as hematemesis, melena, melenemesis, or hematochezia (coffee-ground emesis). Hematemesis is defined as the vomiting of blood and indicates an upper gastrointestinal site of bleeding—essentially a site proximal to the ligament of Treitz. Such blood may be fresh (bright red) or old (with the appearance of coffee grounds). Melena describes black stools that are tarry and foul smelling. The black, tarry character of melena is classic and must not be confused with the greenish character of ingested iron or the black, non-foul-smelling stool typical of that caused by ingestion of bismuth (i.e., as in bismuth salicylate compounds such as Peptobismol); it is important to review the patient history. Hematochezia refers to bright red blood per rectum that may or may not be mixed with stool. Occult bleeding (bleeding that is not noted by the patient) is usually diagnosed by tests that detect small amounts of blood in the stool (i.e., guaiac tests) or because of iron deficiency anemia.

Directed History

A directed history helps localize the source of bleeding and is critical in making a preliminary diagnosis (Table I). Hematemesis and melena are the most common symptoms and signs of gastrointestinal bleeding. Melena is caused by at least 50 ml of blood in the upper gastrointestinal tract (although larger volumes of blood can be clinically silent). Although vomiting of bright red blood usually signifies aggressive bleeding, vomiting of small amounts of blood can be alarming to patients and care providers alike; therefore, a careful history about volumes of vomited blood is important (as is assessment of vital signs). Patients exhibiting coffee-ground emesis typically have had a recent or remote bleed. Hematochezia can result from bleeding anywhere in the gastrointestinal tract. When upper gastrointestinal tract bleeding results in hematochezia, bleeding is brisk and often hemodynamically significant. Chronic, occult blood loss may lead to end-organ symptoms such as lightheadedness and orthostasis, dyspnea, and angina (or symptoms of myocardial infarction).

TABLE I Historical Features Important in Assessing the Etiology of Gastrointestinal Bleeding

History	Diseases suggested
Age	Malignancy, vascular ectasia
Prior bleeding	Vascular ectasia, ulcer disease, diverticula
Previous surgery	Ulcer disease
Liver disease	Varices, portal hypertensive gastropathy
Renal failure	Vascular Ectasia
NSAIDs/ASA[a]	Ulcer disease
Abdominal pain	Ischemia
Change in bowel habits	Colon Malignancy, celiac sprue
Weight loss/anorexia	Malignancy, celiac sprue
Dysphagia, odynophagia	Esophageal malignancy, achalasia

[a] NSAIDs, nonsteroidal antiinflammatory drugs; ASA, acetylsalicylic acid.

An important historical feature in gastrointestinal bleeding is age. Elderly patients are at risk for bleeding from a number of disorders that are less common in younger patients. Bleeding in very young patients is most often due to Meckel's diverticula (which does not occur in patients older than 25 to 30 years). A history of liver disease raises the possibility of bleeding associated with portal hypertension. A history of prior bleeding raises the likelihood of ulcer disease or diverticular bleeding. A history of aspirin or nonsteroidal antiinflammatory drug usage raises the possibility of bleeding from gastric or gastroduodenal ulceration. A history of reflux points to the esophagus as a potential site of bleeding. Other important historical features include the presence of abdominal pain (mesenteric ischemia), retching (Mallory–Weiss tear), change in bowel habits (malignancy), anorexia, and weight loss (the latter two can indicate malignancy).

The Physical Examination

Like the patient history, simple physical examination provides important information. Cutaneous spider angiomata and Dupytren's contractures should suggest the presence of liver disease; other signs of liver disease (splenomegaly, ascites, caput) may suggest the possibility of portal hypertension. Acanthosis nigricans raises the possibility of underlying cancer (especially gastric cancer), cutaneous spider angiomata in the absence of liver disease raises the possibility of hemorrhagic telangiectasia (Osler–Weber–Rendu syndrome), pigmented

lip lesions may be seen with Peutz–Jeghers syndrome, cutaneous tumors suggest neurofibromatosis, and purpura are consistent with vascular disease (Henloch–Schönlein syndrome or polyarteritis nodosa). Abdominal pain (peptic ulcer, pancreatitis, ischemia), abdominal masses, lymphadenopathy (malignancy), and splenomegaly (cirrhosis, splenic vein thrombosis) are important to detect.

Initial Patient Assessment

The first step in all forms of gastrointestinal bleeding is to assess the urgency of bleeding. Therefore, hemodynamics are the initial focal point and remain the gold standard for assessment of the overall clinical well being of the patient. Features of the history and physical examination provide critical clues not only about the cause of bleeding, but also about the severity of bleeding. "Bedside" tools are critical in initial assessment of the patient. Vital signs are essential in helping to gauge the severity of bleeding. Additionally, features of the history and physical exam provide critical information. For example, patients with brown stool are unlikely to have aggressive bleeding. Patients passing numerous stools containing melena—even in the absence of a positive nasogastric lavage—are likely to have aggressive ongoing bleeding. Patients with infrequent stools are unlikely to be actively bleeding. Patients with a history of coffee-ground emesis or even hematemesis, normal appearing stools, and normal vital signs have had a trivial bleed.

Laboratory Evaluation

The laboratory evaluation most often focuses on the hematocrit. However, it is important to recognize that the hematocrit, particularly when determined soon after the onset of bleeding, may not accurately reflect blood loss. Equilibration with extravascular fluid and subsequent hemodilution require several hours. In contrast, patients who bleed small amounts of blood over long periods of time develop iron deficiency, and despite the presence of a low hematocrit may be entirely hemodynamically stable. The mean corpuscular volume (MCV) is often an important clue in these patients; additionally, the ferritin level is used to establish a diagnosis of iron deficiency. It is important to emphasize that ferritin levels of even 50 μg/ml are consistent with iron deficiency anemia.

The blood urea nitrogen (BUN) may be mildly elevated in patients with upper GI bleeding. The elevation is typically out of proportion to elevation in serum creatinine, due to breakdown of blood proteins to urea by intestinal bacteria as well as from a mild reduction in glomerular filtration rate.

Clinical Localization of Bleeding

It is useful to determine the source of bleeding so as to direct investigation; this can often be accomplished with a careful history and physical examination. Hematemesis indicates an upper gastrointestinal source of bleeding. Melena indicates that blood has been in the gastrointestinal tract for extended periods of time. Melena is usually the result of upper gastrointestinal bleeding, but can be a result of distal small bowel and even right-sided colonic bleeding. The latter occurrence, which is relatively uncommon, requires the volume of bleeding to be too small to cause hematochezia but sufficient to supply enough hemoglobin for degradation. Hematochezia typically is a result of colonic bleeding, although an upper gastrointestinal lesion may bleed briskly enough to cause hematochezia. Somewhere around 10% of all patients with rapid bleeding from an upper source will pass bright red blood per rectum. Other clues to an upper gastrointestinal source of bleeding include hyperactive bowel sounds and an elevation in BUN out of proportion to creatinine. The use of nasogastric lavage can further help localize bleeding.

OCCULT BLEEDING

Obscure Bleeding

A standard diagnostic evaluation with upper and lower endoscopy, tagged red blood cell (RBC) scintigraphy, and visceral angiography is able to identify the source of bleeding in the majority of patients. However, in approximately 5% of patients, the source will remain obscure after a diagnostic evaluation. Even more problematically, some of these patients experience recurrent gastrointestinal bleeding that can not be easily ascribed to a definite site. These patients represent a considerable management challenge.

Differential Diagnosis

The differential diagnosis in patients with obscure gastrointestinal bleeding encompasses all of the lesions that can bleed in the upper and lower gastrointestinal tracts. The most common causes of obscure gastrointestinal bleeding are highlighted in Table II. The most common lesion is vascular ectasia. These lesions are often found in the small intestine, but can be identified in any location.

TABLE II Causes of Obscure Gastrointestinal Bleeding[a]

Vascular ectasias[b]
Small bowel neoplastic lesions
Hemosuccus pancreaticus
Hemobilia
Aortoenteric fistula
Dieulafoy's ulcer (stomach more frequently than other sites)
Meckel's diverticulum
Extraesophageal varices (gastric, small bowel, colonic)
Diverticula (especially small intestinal)

[a] From Rockey, D.C. (2002). Used with permission from W. B. Saunders.

[b] Small intestinal lesions are particularly important.

Evaluation

The approach to evaluation should proceed along a standard algorithm (Fig. 1). Initially, easily "overlooked" lesions should be considered. Such lesions include Dieulafoy's lesions, gastric and duodenal varices, diverticula, aortoenteric fistula, hemobilia, hemosuccus pancreaticus, and, in young patients, Meckel's diverticulum. Thus, repeat endoscopy directed at the most likely site of bleeding is usually warranted. Reexamination of the upper gastrointestinal tract within reach of a standard gastroscope will identify lesions in a substantial proportion of patients. Importantly, however, familiarity with rare and/or subtle bleeding lesions is required. If a lesion cannot be identified, further evaluation depends on the briskness of bleeding. In those with active bleeding, technetium-99 radionuclide scanning or angiography should be performed. Technetium scanning, although sensitive (reportedly, as little as 0.1 ml/minute can be detected), is useful only to confirm the site of bleeding, and available literature assessing its impact on management has been disappointing. Mesenteric angiography is less sensitive (requiring a bleeding rate >0.5 ml/minute) than technetium scanning but reportedly more often identifies the site of bleeding, perhaps due to selection bias in published studies. In selected situations, other diagnostic tests (computed tomography, Meckel's scan) may be helpful. In those with subacute bleeding in whom repeat endoscopies are negative, the focus of investigation should be broadened to include the small intestine. The lesions most commonly identified as bleeding sites in the small bowel

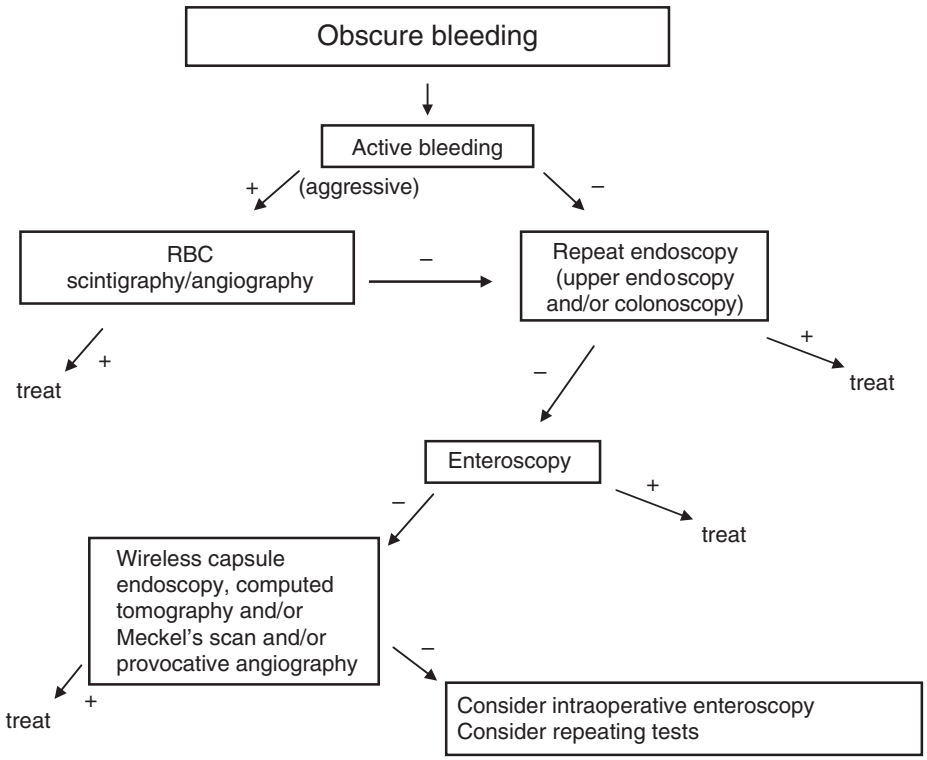

FIGURE 1 Scheme for evaluation of obscure gastrointestinal bleeding. RBC, Red blood cell. Adapted with permission from Rockey, D. C. (2002). Gastrointestinal bleeding. *In* "Sleisenger & Fordtran's Gastrointestinal and Liver Disease" (M. Feldman *et al.*, eds.), 7th Ed. W. B. Saunders, Philadelphia.

include tumors and vascular ectasias, which vary in frequency depending on age. In patients less than 25 years of age, Meckel's diverticula are the most common source of small bowel bleeding; in those between 30 and 50 years old, tumors are the most common abnormalities, and vascular ectasias predominate in the elderly.

Once the upper and lower gastrointestinal tracts have been excluded as a source of bleeding, the focus of evaluation should shift to the small bowel. This can be accomplished with standard small bowel follow-through, enteroclysis, push enteroscopy, sonde enteroscopy, intraoperative enteroscopy, or, most recently, wireless capsule endoscopy. We prefer endoscopic evaluation over radiologic evaluation because of the ability to identify flat lesions such as vascular ectasia, which may be missed by barium studies. Push enteroscopy should probably be the first test; several recent reports suggest that push enteroscopy is able to identify a substantial number of gastrointestinal lesions in patients with obscure gastrointestinal bleeding. Sonde enteroscopy is limited by the inability to biopsy lesions or make therapeutic interventions. Wireless capsule endoscopy is rapidly gaining favor. Initial results with this test are encouraging and demonstrate that it is capable of identifying lesions that could be considered a source of bleeding in up to 30–40% of patients.

An alternative approach to the diagnosis of recurrent, obscure bleeding is to reactivate or augment bleeding with the use of vasodilators, anticoagulants, and/or thrombolytics in association with tagged RBC scintigraphy or visceral angiography. This approach is attractive in principle, but may be dangerous in practice and needs to be studied further.

Treatment and Outcome

Specific treatment for the obscure bleeder depends on the abnormality identified. Enteroscopy, which often demonstrates putative bleeding lesions, has not always led to improved outcomes. Enteroscopic cauterization of vascular ectasias has been shown to lead to an improvement in hemoglobin and a reduction in blood transfusion requirements, and can be effective in selected patients. Additionally, only about 50% of patients treated at the time of intraoperative enteroscopy will stop bleeding, indicating that this intervention is not always ideal. Finally, wireless capsule endoscopy is an attractive diagnostic approach in patients with obscure bleeding. However, it and other diagnostic interventions in obscure bleeding have yet to be shown to improve meaningful outcomes. It is important to emphasize that care of these patients requires an experienced and dedicated team.

Small bowel vascular ectasias are the single most common source of bleeding in patients with obscure gastrointestinal bleeding. In general, specific endoscopic and surgical therapy is most successful in those with large focal vascular ectasias. However, because vascular ectasias are often diffuse, endoscopic and surgical interventions are often limited. Hormonal therapy with estrogen/progesterone compounds has been advanced as a medical alternative; whereas some clinicians have reported positive experiences with such pharmacological therapy, controlled trials have failed to show an advantage.

Fecal Occult Blood

Occult gastrointestinal bleeding is not clinically apparent but rather is manifest by biochemical evidence of blood in the stool or by laboratory evidence of iron deficiency. In these situations, blood loss is often entirely unknown to the patient. When iron deficiency occurs in men or postmenopausal women, it is usually due to occult gastrointestinal blood loss. Occult bleeding can occur from any location in the gastrointestinal tract.

Fecal occult blood is the most common form of occult gastrointestinal bleeding; when fecal occult blood tests have been applied to large populations, up to 16% of those tested are positive. Although fecal occult blood tests were designed to detect colonic bleeding, they detect blood from other lesions in the gastrointestinal tract. The likelihood that these tests will detect blood resulting from gastrointestinal bleeding varies and is dependent on the mechanistic features of the test as well as the anatomic level of bleeding (which influences whether hemoglobin is degraded; Fig. 2). A further critical issue, unrelated to characteristics of fecal occult blood tests per se, is the biology of bleeding gastrointestinal tract lesions, many of which bleed in an irregular fashion. Thus, multiple factors contribute to the ability of fecal occult blood tests to detect bleeding lesions.

Types of Fecal Occult Blood Tests

The prototypical fecal occult blood tests are guaiac based and take advantage of the fact that hemoglobin possesses pseudoperoxidase activity. Guaiac tests are more sensitive for detecting bleeding from the lower than from the upper gastrointestinal tract because hemoglobin is degraded in the gastrointestinal tract (Fig. 2). The likelihood that occult blood will be detected by a positive guaiac test is generally proportional to the quantity of fecal heme, which in turn is related to the size and location of the bleeding lesion.

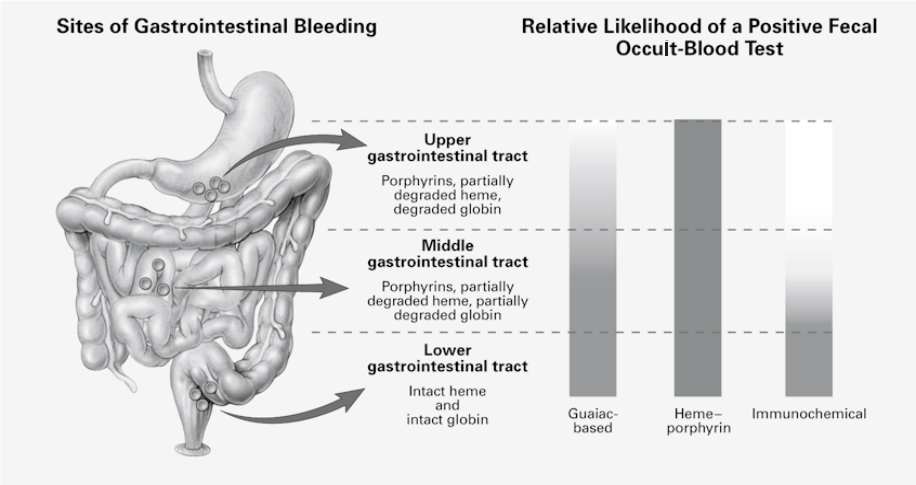

FIGURE 2 Intraluminal hemoglobin metabolism and fecal occult blood tests. In the upper gastrointestinal tract, hemoglobin is degraded by gastric pepsin and/or pancreatic proteases in the proximal small intestine, resulting in heme and globin. Some (generally $<15\%$) intraluminal heme is reabsorbed in the small intestine. A portion of heme that is not absorbed is converted to porphyrins and iron via poorly understood mechanisms; this portion of heme has been termed the "intestinal converted fraction" of heme. This fraction is not detected by guaiac tests but is detected by the heme–porphyrin assay (HemoQuant), which measures both heme and porphyrins, and is therefore a highly accurate indicator of bleeding, regardless of level. Globin in the upper gastrointestinal tract is digested by pepsin and pancreatic and intestinal proteases and is thus not detected by immunochemical fecal occult blood tests. Used with permission from Rockey (1999). Occult gastrointestinal bleeding. *N. Engl. J. Med.* **341**, 38–46.

Thus, guaiac-based tests are best at detecting large, more distal lesions. Fecal hemoglobin levels must exceed 10 mg/g (approximately 10 ml daily blood loss) before most guaiac tests are positive at least 50% of the time. It is important to emphasize that a number of other factors, many of which are dietary (Table III), influence guaiac test results. Another factor affecting the reactivity of guaiac-based tests is fecal rehydration, which markedly raises sensitivity but significantly reduces specificity. It is commonly believed that oral iron causes false positive guaiac tests. Care must be taken not to confuse the dark-green or black appearance of iron in stool with the typical blue color of a positive guaiac reaction; it has been confirmed that orally administered iron, even in large amounts, does not cause false positive guaiac reactions. Bismuth-containing antacids and antidiarrheals cause the stool to become black and may confound reading of guaiac-based tests, or may even cause confusion with melena.

Immunochemical tests (using antibodies directed against human globin) readily detect colonic blood and do not detect small quantities of blood from upper gastrointestinal sources (Fig. 2). Thus, they are more specific than guaiac-based tests. However, they are

TABLE III Factors Affecting Fecal Occult Blood Tests[a]

Variable	Guaiac	Heme–porphyrin	Immunochemical
False positives			
Animal hemoglobin	++++	++++	0
Dietary peroxidases	+++	0	0
False negatives			
Hemoglobin degradation	++	0	++
Storage	++	++++	++
Vitamin C	++	0	0

limited by technical problems such as loss of hemoglobin antigenicity at room temperature and the requirement for laboratory processing. Finally, the heme–porphyrin test (HemoQuant, Mayo Medical Laboratories, Rochester, MN) measures porphyrin spectrofluorometrically and therefore allows precise determination of total stool hemoglobin. Substances that may interfere with or cause false positive guaiac tests (i.e., vegetable peroxidases) do not affect this test. However, this test detects myoglobin, an important source of nonhuman heme found in red meats. This test is the most sensitive method to detect occult gastrointestinal bleeding.

Differential Diagnosis and Approach to Evaluation

Fecal occult blood tests are widely used to screen the colon for cancer, but also help to investigate symptoms. Virtually any gastrointestinal lesion can bleed and cause a positive fecal occult blood test result (Table IV). Once a patient is determined to have fecal occult blood, investigation is initially focused on the colon. However, the choice of colonic imaging modality (colonoscopic or radiographic) is controversial, both in terms of diagnostic accuracy and in terms of cost. Flexible sigmoidoscopy is necessary for patients undergoing air-contrast barium enema to fully evaluate the rectosigmoid colon. Air-contrast barium enema can accurately detect colonic malignancy and large adenomas; however, under certain circumstances, it may also be inaccurate. Colonoscopy is generally considered to be more accurate but may also miss important lesions. Computed tomography and computerized rendering of the colon (virtual colonoscopy or colonography) may eventually play a role in colon evaluation, but are currently not widely available. At present, it is generally believed that the best choice for evaluation of the colon in patients with fecal occult blood is colonoscopy.

Patients with fecal occult blood but a normal colon often harbor upper gastrointestinal pathology. A number of studies have addressed this issue and have emphasized that upper endoscopy will detect abnormalities in around one-third of patients. This finding is somewhat surprising because the guaiac-based tests used in these studies have a relatively low sensitivity for detecting upper gastrointestinal blood. Nonetheless, guaiac-based tests are clearly capable of detecting even small amounts of upper gastrointestinal tract blood, and many of the types of lesions identified in the upper gastrointestinal tract in these studies bleed enough to produce positive guaiac-based tests. The cost-effectiveness of upper gastrointestinal tract investigation in patients with fecal occult blood and normal colons is unknown.

Whether patients with occult blood found in the stool after digital rectal examination should be evaluated is controversial; anorectal trauma and/or dietary factors may lead to false positive tests. However, in both symptomatic and asymptomatic patients with fecal occult blood detected by digital rectal examination, the number of new lesions identified by gastrointestinal

TABLE IV Differential Diagnosis of Occult Gastrointestinal Bleeding[a]

Mass lesions	**Vascular**
Carcinoma (any site)[a]	Vascular ectasia (any site)[b]
Large (>1.5 cm) adenoma (any site)	Portal hypertensive gastropathy/colopathy
Inflammation	Watermelon stomach
Erosive esophagitis[b]	Hemangioma
Ulcer (any site)[b]	Dieulafoy's ulcer[d]
Cameron lesions[c]	**Infectious**
Erosive gastritis	Hookworm
Celiac sprue	Whipworm
Ulcerative colitis	Stronglyoidiasis
Crohn's disease	Ascariasis
Colitis (nonspecific)	Tuberculous enterocolitis
Idiopathic cecal ulcer	Amebiasis
Miscellaneous	**Surreptitious**
Long-distance running	Hemoptysis
Fictitious	Oropharyngeal (including epistaxis)
	Pancreaticobiliary

[b] Most common abnormalities.

[c] Linear erosions within a hiatus hernia.

[d] Large superficial artery underlying mucosal defect.

evaluation is substantial and therefore evaluation is indicated; if symptoms are present, further evaluation should be directed accordingly. Whether testing stool obtained by digital rectal examination is a viable cancer screening option is an important question and would be influenced by variables such as improved compliance versus inadequate dietary preparation.

Occult gastrointestinal bleeding generally should not be attributed to anticoagulant or aspirin therapy. Indeed, fecal blood levels in patients therapeutically anticoagulated have been reported to be normal and low-dose aspirin alone does not result in significantly elevated fecal blood levels. Further, neither warfarin nor low-dose aspirin alone appears to cause positive guaiac-based fecal occult blood tests. Thus, a positive fecal occult blood test should not be attributed to the effect of anticoagulation or aspirin alone, but rather should lead to standard evaluation.

Treatment and Outcome

Treatment of patients with fecal occult blood varies and depends on the abnormalities identified. Likewise, outcomes are directly related to specific findings. Non-steroidal antiinflammatory drugs cause mucosal injury and should be discontinued if possible. Patients with vascular ectasias are problematic, and if they bleed chronically should be managed carefully (see earlier discussion of obscure gastrointestinal bleeding). The prognosis of patients with positive fecal occult blood tests but no identifiable gastrointestinal pathology is generally favorable, but long-term outcome data on this subject are lacking.

Iron Deficiency Anemia

Iron deficiency anemia is the most common form of anemia in the world. In the United States, 5–11% of adult females and 1–4% of adult males are iron deficient whereas approximately 5 and 2% of adult women and men, respectively, have iron deficiency anemia. Although iron deficiency anemia in women of reproductive age is typically assigned to menstrual- and pregnancy-associated iron losses, in groups other than premenopausal women, iron deficiency anemia is assumed to be due to chronic occult gastrointestinal bleeding, resulting depletion of the iron pool and ultimately anemia (Fig. 3).

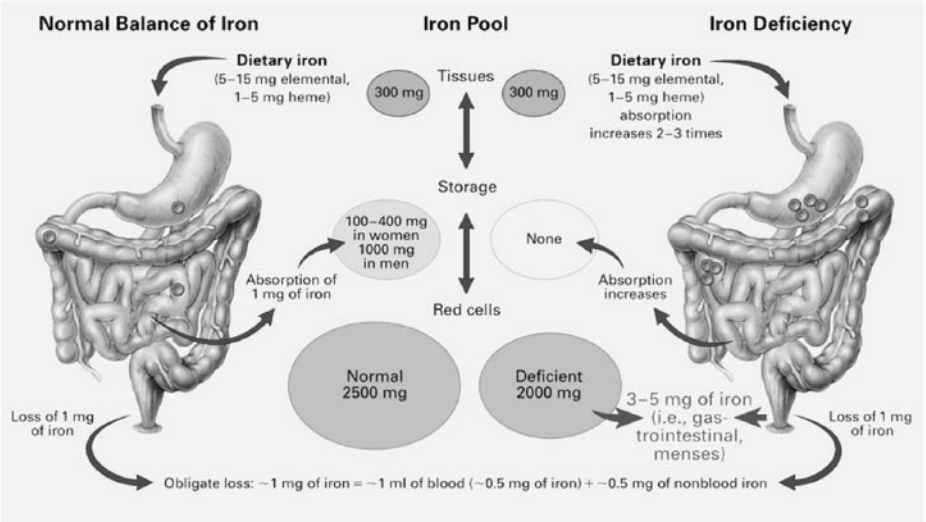

FIGURE 3 Gastrointestinal blood loss and iron balance. Normal obligate daily iron loss is from (1) blood loss (presumably from gastrointestinal mucosal microerosions or microulcerations) and (2) iron in sloughed gut epithelial cells. Total daily iron loss is thus approximately 1 mg. The usual Western diet contains mostly elemental iron, of which about 10% is absorbed. Heme-iron, derived primarily from myoglobin in meats, is preferentially absorbed and accounts for 60–80% of the iron absorbed per day. Under normal circumstances, iron homeostasis is tightly regulated and daily iron loss is precisely balanced by iron absorption. Iron deficiency results only when the dynamic, but limited, absorptive capacity of the small intestine is exceeded by iron loss. The time required to develop iron deficiency depends on the size of initial iron stores, the rate of bleeding, and intestinal iron absorption. Iron deficiency generally occurs only with increased loss of over 5 ml of blood daily. Importantly, anemia is a late manifestation of the iron-depleted state. With permission from Rockey (1999). Occult gastrointestinal bleeding. *N. Engl. J. Med.* **341**, 38–46.

Differential Diagnosis and Approach to Evaluation

The diagnosis of iron deficiency and iron deficiency anemia is most often confirmed by a low serum ferritin level or a bone marrow examination. Effort should be made to verify the diagnosis in equivocal cases, because a diagnosis of iron deficiency anemia leads to extensive and often costly evaluation. Iron deficiency without anemia is often also associated with significant gastrointestinal tract abnormalities.

As with all occult gastrointestinal bleeding, virtually any gastrointestinal tract lesion can bleed in an occult fashion and lead to iron deficiency anemia (Table IV). Although the colon is traditionally viewed as the source of bleeding in most patients with iron deficiency anemia, a number of studies have now documented prominent abnormalities in the upper gastrointestinal tract in patients without colonic lesions. The most common abnormalities have been erosive disease of the esophagus, stomach, and duodenum (i.e., severe esophagitis, presumably reflux mediated, gastric, or duodenal ulcer). Colon cancers and large adenomas are the most commonly identified lesions in the colon. Importantly, only about 5% of patients have had simultaneous pathology identified in both upper and lower gastrointestinal sites.

A large body of literature has helped change the way patients with iron deficiency anemia are currently managed. The emphasis is on the importance of evaluation of the upper gastrointestinal tract. It is important to emphasize that although mass lesions and large ulcerative upper gastrointestinal lesions can lead to significant blood loss (up to 20 ml/day), it is unlikely that trivial lesions such as mild inflammation and small adenomas bleed enough to lead to iron deficiency. Thus, care must be taken when attributing iron deficiency anemia to lesions not expected to cause significant bleeding.

Gastrointestinal symptoms in patients with iron deficiency anemia typically help focus gastrointestinal tract evaluation. Directed gastrointestinal tract evaluation is practical and desirable as a cost- and risk-containing strategy. Although many patients with iron deficiency anemia are entirely asymptomatic, those with classic symptoms (change in stool caliber, epigastric pain, or heartburn) should undergo site-directed investigation. The initial investigation should be directed toward the location of specific symptoms, if present (Fig. 4). Because dual lesions are rare, identification of an abnormality clearly consistent with bleeding (mass lesion, large ulceration, severe inflammation) makes further evaluation unnecessary. In the absence of symptoms, particularly in elderly patients, evaluation should

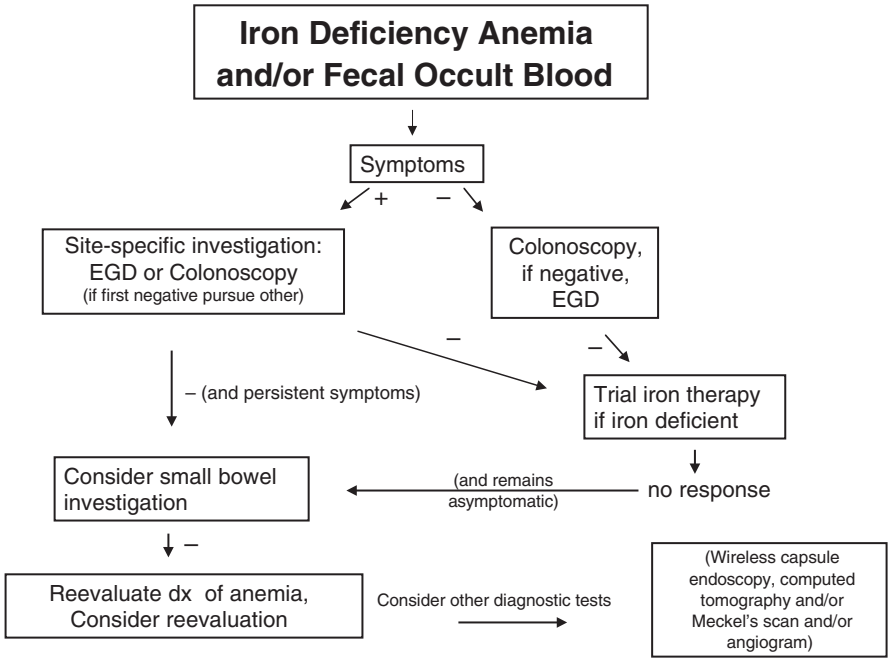

FIGURE 4 Scheme for evaluation of fecal occult blood and iron deficiency anemia. EGD, Esophagogastroduodenoscopy. From Rockey, D. C. (2002). Gastrointestinal bleeding. *In* "Sleisenger & Fordtran's Gastrointestinal and Liver Disease" (M. Feldman *et al.*, eds.), 7th Ed. W. B. Saunders, Philadelphia). Used with permission.

begin with the colon, but if this is negative, evaluation of the upper gastrointestinal tract is indicated.

The degree of gastrointestinal evaluation in premenopausal women with iron deficiency anemia is controversial. On one hand, few iron deficiency anemia premenopausal women undergo evaluation. However, in studies focusing on those referred to gastroenterologists, it has been reported that up to 20% of patients will have significant gastrointestinal tract abnormalities, including important lesions such as colon cancer, celiac sprue, and inflammatory bowel disease. Clearly, a management algorithm is required for these patients. A practical approach is as follows: for those with specific gastrointestinal symptoms, weight loss, fecal occult blood, or perhaps severe anemia, evaluation is indicated. For asymptomatic women or those with abnormal menses, whether to pursue gastrointestinal tract evaluation should be individualized.

The small bowel is an important potential site of bleeding in patients with negative colon and upper gastrointestinal tract examinations. For example, celiac sprue, a classic small bowel disorder, can not only lead to malabsorption of iron, but may cause occult bleeding and should be considered. This is especially true in patients of Northern European descent. Radiographic examination of the small bowel (enteroclysis or small bowel follow-through) is of limited value and is generally not recommended. On the other hand, push enteroscopy has a greater sensitivity for mucosal abnormalities and detects abnormalities in approximately 25% of patients. However, it remains unknown whether push enteroscopy leads to improved outcomes. Likewise, the use of wireless capsule endoscopy in patients with iron deficiency anemia remains unsettled.

Nearly one-third of patients with iron deficiency anemia have no identifiable gastrointestinal tract abnormality by routine endoscopic examination. In these patients, explanations for iron deficiency anemia include non-gastrointestinal blood loss, misdiagnosis of the type of anemia, missed lesions, or nutritional deficiency. Additionally, these patients may have gastric achlorhydria and atrophy, suggesting that lack of acid in this subgroup could contribute to iron malabsorption.

Treatment and Outcome

All patients with iron deficiency anemia should be started on iron therapy. Oral ferrous sulfate is the best option because it is inexpensive and effective (the recommended dose is 300 mg three times daily). Intolerance to ferrous sulfate is common; in these patients, ferrous gluconate and fumarate are acceptable alternatives. Parenteral iron therapy is reserved only for patients with severe malabsorption or intolerance to all iron supplements. The prognosis for patients with iron deficiency anemia and readily treatable lesions (i.e., duodenal ulcer, esophagitis, large adenoma) is excellent. Likewise, the prognosis for patients who do not have lesions identified during gastrointestinal evaluation is favorable; long-term followup of patients in this group suggests that significant lesions do not surface at a later date. In patients who do not respond to iron therapy, the diagnosis of iron deficiency anemia should be reevaluated and repeat gastrointestinal evaluation should be contemplated. A careful reexamination of the gastrointestinal tract for easily missed lesions (in the esophagus, for Cameron lesions within hiatus hernia; in the stomach, for atrophic gastritis; in the small bowel, celiac sprue) is indicated when evaluating persistent unexplained iron deficiency anemia.

CONCLUSIONS

Occult gastrointestinal bleeding is most often manifest as occult blood in the stool, typically by the use of guaiac-based fecal occult blood tests. Occult gastrointestinal bleeding may also be manifest as iron deficiency anemia, which often results from chronic occult gastrointestinal bleeding. These forms of occult gastrointestinal bleeding are common. In contrast to fecal occult blood and iron deficiency anemia, obscure gastrointestinal bleeding is uncommon but represents a considerable diagnostic and therapeutic challenge. Evaluation of patients with fecal occult blood and iron deficiency anemia often parallels similar algorithms and in asymptomatic patients should usually begin with investigation of the colon. Colonoscopy is the preferred method, but flexible sigmoidoscopy plus air-contrast barium enema may be acceptable. If evaluation of the colon does not reveal a bleeding site, evaluation of the upper gastrointestinal tract should be considered, and in patients with iron deficiency anemia, this is mandatory. In patients with iron deficiency anemia, the role of small bowel investigation is controversial and is probably best reserved for those with persistent gastrointestinal symptoms or those who fail to respond to appropriate therapy. Celiac sprue should be considered as a potential cause of iron deficiency anemia in certain epidemiological groups. The treatment and prognosis of patients with occult blood in the stool and/or iron deficiency anemia depends on the gastrointestinal tract abnormalities identified. Those without identifiable bleeding sites generally respond to conservative management and have a favorable prognosis. For patients with obscure gastrointestinal bleeding, investigation is typically focused on the small bowel, typically with enteroscopy,

but perhaps also with wireless capsule endoscopy. In these patients, vascular ectasias are a major consideration. The prognosis for these patients is less clear, and outcome studies are required. This group requires a committed and experienced team approach to diagnosis and therapy.

acid-neutralizing capacity Amount of acid (mEq) neutralized by a unit dose (teaspoonful or tablet) of an antacid.

antacids Soluble and/or insoluble substances capable of buffering or neutralizing gastric (stomach) acid.

antiflatulents Drugs effective for the relief of painful bloating or sensations of pressure and fullness, commonly referred to as gas in the digestive tract.

constipation Commonly defined as related to decreased bowel movement frequency, difficulty in initiating passage of feces, passage of firm or small-volume feces, or a feeling of incomplete evacuation.

diarrhea Symptom of several gastrointestinal disorders affecting water and electrolyte transport; characterized by alteration of the frequency and consistency of stools.

dyspepsia Mild pain present in the upper abdomen.

heartburn Specific symptom of gastroesophageal reflux disease, typically manifested by a burning sensation in the upper abdomen, behind the chest, and as high as the throat.

histamine-2 (H2) receptor antagonists Drugs that block action of histamine at a specific histamine (type 2) receptor located in the stomach, which results in effective inhibition of gastric acid secretion.

Increasing numbers of drugs are obtainable without a prescription, i.e., over the counter (OTC), for self-treatment of mild gastrointestinal symptoms. The consumer must be able to recognize the symptoms of the condition that the product can treat easily, without medical assistance. Unlike prescription-based drugs, the ingestion of which requires physicians' supervision and management for treating the underlying disease process, OTC drugs are primarily used for self-treatment of well-recognized symptoms by consumers. It is increasingly important to review the therapeutics of gastrointestinal drugs specifically available for self-use and to remain vigilant about the safe use of drugs sold on an OTC basis in the United States.

INTRODUCTION

The availability of OTC drugs lessens the economic burden to our health care system and clearly provides much needed convenience to consumers. However, despite these advantages, there are clear risks related to the use of OTC drugs. For example, aspirin and acetaminophen are still associated with serious gastrointestinal toxicity despite their availability as OTC drugs for many years. In addition, chronic use of antacids and OTC gastric antisecretory drugs can delay the diagnosis of gastric cancer. Therefore, it is most essential that consumers are made aware of the indications and limitations of OTC drugs through improved education by the pharmaceutical manufacturers and easily understood labels, affixed to the containers, which should explain the desired uses, treatment duration, dosage, and adverse effects of these drugs. Clear drug labeling, as mandated by the Food and Drug Administration (FDA), and perhaps pharmacist counseling are most essential for the safe use of OTC drugs.

AGENTS BUFFERING OR INHIBITING GASTRIC ACIDITY

Antacids

Antacids are drugs capable of buffering stomach acid. Antacids raise the pH of the stomach contents toward neutrality. An antacid that raises the pH from 1.5 to 3.5 produces a 100-fold reduction in the concentration of gastric acid. Furthermore, the reduction of acidity is accompanied by inhibition of pepsin activity, another important component of the digestive juice. According to their approved labeling, the only symptoms that can be safely diagnosed and self-treated with OTC antacids are those caused by excess stomach acid. These symptoms have been described as burning sensations in the upper abdomen, behind the chest, and high as the throat. The official FDA-approved claims for antacids are for the relief of "heartburn, sour stomach, acid indigestion, and upset stomach." Based on the many years that OTC antacids have been used for heartburn, it is apparent that a consumer who has heartburn can determine when he or she has heartburn, and in most cases can predict what foods, situations, or life stresses can cause heartburn.

Great disparity exists in the acid-neutralizing capacity (ANC) of various antacids (Table I). The more

TABLE I Acid-Neutralizing Capacity of Selected Antacids[a]

Product	Acid-neutralizing capacity in mEq acid/dose	Standard dose to neutralize 152 mEq acid/dose
Alka-Seltzer (tablet)	10.6 tablets	15 tablets
Amphogel (liquid)	6.5 tsp	25 tsp
Amphogel (tablet)	9 tablets	17 tablets
Maalox (liquid)	13.5 tsp	11 tsp
Maalox Therapeutic Concentrate (liquid)	28.5 tsp	5 tsp
Mylanta (liquid)	12.5 tsp	12 tsp
Mylanta II (liquid)	25.5 tsp	6 tsp
Mylanta II (tablet)	23 tablets	7 tablets
Titralac (liquid)	19 tsp	8 tsp
Tums (tablet)	10 tablets	16 tablets

[a] The amount of acid (mEq) being neutralized by a unit dose (teaspoonful or tablet) of an antacid; tsp, teaspoonful.

Note: Data adapted from Zimmerman, 1983.

potent antacids (e.g., Mylanta II) require a smaller dose, compared to a weaker product (e.g., Amphogel), and this is advantageous for treating ulcers. However, ulcer treatment is clearly outside the scope of OTC product labeling and should be treated only by physicians, not by self-treatment. The dose of antacid that will relieve pain in a patient with gastric ulcer must provide an ANC of 152 mEq. A weaker product, such as Amphogel, would require 25 teaspoonfuls to neutralize gastric acid, whereas a stronger product, such as Mylanta II, requires only 6 teaspoonfuls (Table I).

It should be noted that liquid antacid preparations generally provide faster buffering action than do tablet preparations. However, from a therapeutic perspective, there is a dissociation between the duration of buffering capacity of antacids, which is relatively short (30 minutes), and the duration of the pain relief required for heartburn or peptic ulcer (approximately 4 hours). Thus, on the basis of pain relief, antacids administered at a low frequency of about three times daily would not be therapeutically sufficient for healing gastric or duodenal ulcers. However, this low frequency of administration does provides pain relief in mild to moderate heartburn.

The neutralization of gastric contents by antacids promotes antral gastrin release, which promotes gastric emptying and hence contributes to the short duration of their buffering action. Due to the gastrin-induced gastric emptying, the more potent antacids have durations of buffering action essentially similar to those of weaker antacids. Therefore, the increased potency of an antacid should not be a criterion for a patient's product selection for the self-treatment of heartburn.

Several principal ingredients are present in antacids: bicarbonate (sodium, potassium, and calcium), aluminum, magnesium, phosphate, and silicates. Bismuth subsalicylate (Pepto-Bismol), which is marketed for the treatment of heartburn, has minimal antacid action and therefore is not pharmacologically classified as an antacid. All antacid products contain at least one ingredient; most contain at least two ingredients. Sodium bicarbonate and calcium carbonate are more potent antacids, compared to magnesium compounds. Magnesium compounds are more potent than aluminum compounds. Sodium and potassium bicarbonate are soluble antacids that are readily absorbed into the blood, and thus are particularly risky for patients with impaired kidney function. Calcium compounds (calcium carbonate and calcium phosphate) are potent and fast-acting antacids that are readily absorbed. However, these drugs may form calcium kidney stones. Paradoxically, calcium antacids promote antral gastrin release to a greater degree than do noncalcium antacids, which in turn stimulate gastric acid production. The aluminum compounds induce constipation and the magnesium compounds induce diarrhea, thus these two ingredients are combined together, although the net effect of the combined product is laxation. This is especially noted when the combined drugs are taken at increased dosages. The silicate antacids (e.g., magnesium trisilicate) interfere with the absorption of some drugs and this needs to be considered by patients and health care providers. For specific details about all available antacid products and their pharmacological characteristics, the readers are encouraged to consult the *Physicians' Desk Reference for Nonprescription Drugs*.

TABLE II Pharmacological Characteristics of Selected OTC Histamine-2 Receptor Antagonists

Drug	Trade name	Doses	Half-life (hours)	Drug interactions
Cimetidine	Tagamet HB 200, others	200 mg up to twice daily	2.0	Yes[a]
Ranitidine	Zantac 75, others	75 mg up to twice daily	2.1	No
Famotidine	Pepcid AC	10 mg up to twice daily	2.6	No

[a] The OTC dosage of cimetidine has a small potential for pharmacokinetic interaction with theophylline. Prescription dosage of cimetidine has shown pharmacokinetic interactions with phenytoin, theophylline, and warfarin.

Histamine-2 Receptor Antagonists

Histamine-2 (H2) receptor antagonists were previously marketed as prescription-based products for the healing and prevention of gastric ulcers and duodenal ulcers, and for the management of gastroesophageal reflux disease (GERD) due to their well-known gastric antisecretory actions. However, patients with GERD represent a spectrum ranging from mild to severe disease states and many patients with heartburn symptoms have been accustomed to the use of OTC antacids and H2 receptor antagonists. Therefore, three of the four H2 receptor antagonists that were previously marketed as prescription-based products were switched to OTC use at reduced doses, which are one-half of their prescription doses (Table II). The currently available OTC drugs, cimetidine, ranitidine, and famotidine, have essentially two similar medical claims in their labeling: (a) "for the relief of heartburn associated with acid indigestion and sour stomach" and (b) "for the prevention of heartburn associated with acid indigestion and sour stomach brought on by certain foods or beverages." The H2 antagonist nizatidine, which is currently available as a prescription-based product, has not yet been switched to an OTC status.

The frequency of the administration of all three H2 antagonists is one to two doses per day and the duration of self-use should not exceed 2 continuous weeks, except under the advice and supervision of a physician. All three drugs have similar biological half-lives of about 2 hours (Table II). However, as is the case with prescription-based products, ranitidine and famotidine, but not cimetidine, are marketed at doses that exceed their median effective gastric antisecretory doses (ED_{50}). Thus, when administered at the recommended OTC dosage of twice daily, it is expected that ranitidine and famotidine would provide a much longer duration of gastric antisecretory action than would cimetidine. However, despite the differences in the magnitude of their doses, all three drugs appear to have similar degree of efficacy for the treatment and prevention of heartburn.

Unlike antacids, which provide immediate relief of heartburn, there is some delay (15–30 minutes) in the onset of pain relief provided by H2 antagonists, because they are systemically acting drugs and require absorption into the bloodstream. However, one H2 antagonist combines famotidine with the antacids calcium carbonate and magnesium hydroxide (Pepcid Complete) to provide both immediate and prolonged gastric antisecretory action.

The tolerability of the three drugs appears to be similar. However, given the fact that cimetidine is known to inhibit various P450-metabolizing isoenzymes, which could affect metabolism of other drugs and thereby increase their blood concentration, patients should consult with their physicians if they are taking theophylline, warfarin, and phenytoin with cimetidine.

ANTIFLATULENT (ANTIGAS) AGENTS

An antiflatulent is a drug that expels gas from the stomach and intestines. Simethicone (contained in products such as Mylicon, Phazyme, GAS-X, Gas Aid, and others) is the only drug approved as antiflatulent by the FDA. The drug reduces the surface tension of small gas bubbles and is often combined with antacids. The approved OTC indication for the product is "for the relief of painful bloating, and the sensation of pressure and fullness, commonly referred to as gas in the digestive tract." Such gas is frequently caused by excessive swallowing of air or by eating certain foods. The antiflatulent property is useful in conditions in which the retention of gas may be problematic, such as air swallowing, functional dyspepsia, postoperative gaseous distension, peptic ulcers, spastic or irritable colon, or diverticulosis. Tablet or liquid formulations of the drug are used in dosages of 80 to 125 mg, six times daily after meals and at bedtime, or as directed by a physician.

ANTIDIARRHEAL AGENTS

Diarrhea is well recognized by ordinary individuals to be a disorder of "too rapid evacuation of too fluid stools." Diarrhea is a symptom of several gastrointestinal (GI) diseases affecting water and electrolyte transport. Several types of drugs exist for the treatment of diarrhea.

In some situations, diarrhea is an adaptive and defensive process that expedites the removal of toxins, bacteria, fungi, viruses, and protozoa from the GI tract. Under these conditions, it is probably best not to interfere with their removal using an antidiarrheal drug, because this might prolong disease. Moreover, antidiarrheal drugs do not affect the underlying GI disease process, but rather provide control of symptoms.

Antipropulsive Drugs

Loperamide hydrochloride (e.g., Imodium A-D) was previously available only as a prescription-based drug; after about 10 years, it was introduced for OTC use. Loperamide is the only available OTC antidiarrheal drug; it works by inhibiting intestinal propulsive activity and by affecting water and electrolyte transport by the bowel, probably secondary to the inhibition of propulsive motility. Loperamide is an opiate receptor agonist similar to morphine and specifically binds to receptors in the brain and in the gut (myenteric plexus). Loperamide stimulates intestinal circular muscle contractile activity to induce segmentation or mixing, but, unlike morphine, it has reduced ability to cross the blood–brain barrier.

Loperamide is indicated for the symptomatic relief of acute nonspecific diarrhea and should not be used if diarrhea is accompanied by high fever (greater than 101°F), or if blood is present in the stool, suggesting an infectious etiology. The dosage for adults is 4 mg (two caplets or four teaspoonfuls) after the first loose bowel movement. If needed, 2 mg can be used after each additional loose bowel movement. An adult should not exceed a total of 8 mg in a 24-hour period unless directed by a physician. A lower dosage is recommended for children. Warnings appear on the package label and instruct the user not to take the drug for more than 2 days unless directed by a physician. Following systemic absorption, loperamide has a long half-life of 18 hours, and the recommended dosage must therefore be adhered to in order to avoid potential toxicity.

Overdose of loperamide may result in constipation, central nervous system depression, and nausea. A slurry of activated charcoal administered promptly after ingestion may reduce the amount of the drug that is absorbed. In the event of overdosage, patients should be monitored for signs of central nervous system (CNS) depression for at least 24 hours. In addition, children may be more sensitive to the CNS effect of loperamide. If CNS depression is observed, the opiate antagonist naloxone should be used. If responsive to nalaxone, vital signs must be monitored carefully for the recurrence of symptoms of drug overdose for at least 24 hours after the last dose of naloxone.

Bismuth Drugs

Bismuth subsalicylate (Pepto-Bismol) is the only colloidal bismuth salt drug approved for OTC use in multiple GI conditions, including "diarrhea, heartburn, indigestion without constipation, nausea, and upset stomach." The mechanism of action of bismuth subsalicylate in these gastrointestinal disorders is not completely understood. Although colloidal bismuth compounds have no significant acid-neutralizing capacity, they inhibit the action of pepsin, increase the secretion of mucus, and interact with protein in necrotic ulcer craters, presumably forming a barrier to the diffusion of acid. Bismuth colloids have an antibacterial action, which is relevant for the treatment of infectious diarrhea and peptic ulcers (e.g., *Helicobacter pylori*). The salicylate component of bismuth subsalicylate may exert intestinal antiinflammatory and antisecretory actions. Thus, the combined antibacterial and intestinal antisecretory action of bismuth subsalicylate is relevant for the OTC treatment of mild to moderate diarrhea. Pepto-Bismol controls diarrhea within 24 hours, and also relieves associated abdominal cramps.

Pepto-Bismol is available in two liquid suspension forms (262 and 525 mg per 15 ml) and in a tablet dosage form (102 mg per tablet). The recommended dosage for adults is 262 to 1050 mg, to be repeated every hour, if needed, to a maximum of four doses in 24-hour period. Lower dosages are provided for children of various age groups. Pepto-Bismol should not be used in patients who have a known allergy to aspirin. Caution is also advised when administering to patients taking medications for anticoagulation, diabetes, and gout. A warning statement advises caution in the administration of the drug to children, including teenagers, during or after recovery from chicken pox or flu. In addition, the medication may cause a temporary and harmless darkening of the tongue and/or stool.

Adsorbent Drugs

Adsorbents have been so named because of their potential to adsorb intestinal luminal toxins and bacteria associated with some types of infectious diarrhea, and theoretically they should enhance fecal elimination of the toxins or bacteria. Although this adsorption principle has been demonstrated in *in vitro* studies, there have been no meaningful confirmatory *in vivo* studies. Furthermore, adsorbents are of little or no value for the treatment or prevention of acute infectious diarrhea. Clearly, additional clinical studies are needed to

support the utility of these drugs for the treatment of diarrhea. Several types of adsorbent drugs are commercially available for OTC use and include kaolin (e.g., Kaopectate, Donagel), attapulgite (e.g., Diasorb, Rheaban), and pectin (e.g., Kaopectate, Donagel). The official claim for these products is "for the relief of diarrhea and cramps."

Oral Rehydration Therapy

Although healthy adults with episodes of mild to moderate diarrhea do not need extensive oral hydration therapy, they are advised to eat easily digested food and to drink noncarbonated beverages such as fruit juices. Fruit juices contain easily digested sugars and water. It is well established that glucose promotes the intestinal absorption of water, sodium, and other electrolytes, thus overcoming the losses associated with diarrhea. In patients with severe diarrhea, however, and especially young children, the use of oral hydration solutions containing glucose, electrolytes, and amino acids in proportions similar to the World Health Organization formula is advised. Such solutions are available OTC for use in infants and children when recommended by physicians (e.g., Pedialyte).

LAXATIVES

Laxatives are drugs or fibers that relieve the symptoms of constipation. Constipation is understood by lay individuals to be related to decreased fecal frequency, difficulty in initiating fecal passage, the passage of firm or small-volume feces, or a feeling of incomplete evacuation. Although there are several types of laxatives, most laxatives increase intestinal water content via distinct pharmacological mechanisms (summarized in Table III). All laxatives have a general warning statement that they should not be used if abdominal pain, nausea, or vomiting is present.

TABLE III Pharmacological Classifications of Major Drugs Used for the Treatment of Constipation

Pharmacological class	Drug examples
Bulk-forming agents	Hydrophillic colloids, fibers
Osmotic agents	Nonabsorbable magnesium salts
Emollient agents	Mineral oil
Nonspecific stimulants or irritants	Docusate salts, anthraquinone (senna, cascara, aloe), diphenylmethane (bisacodyl), castor oil

Bulk-Producing Laxatives

Bulk-forming hydrophilic colloids such as psyllium husk derived from the plantago seed (e.g., Metamucil), methylcellulose (e.g., Citrucel), and calcium polycarbophil (Fibercon) are most popular with consumers. Psyllium is one of the oldest bulk laxatives, with more than 70 years of clinical application. Psyllium is available in various oral dosage forms, including powder and cookies. The bulking effect of the psyllium husk is due both to the water-holding capacity (gel formation) of the undigested fibers and to an increased bacterial mass following extensive colonic bacterial fermentation (about 85%) of the undigested fibers. Colonic fermentation of undigested psyllium fibers and other natural dietary fibers leads to the formation of short-chain fatty acids, which are osmotically active and add water to the bulk of the stools. This fermentation results in the formation of intestinal gases, which some individuals may find objectionable. However, with dose adjustments, most individuals are able to tolerate chronic treatment with psyllium and other natural dietary fibers. In contrast, the synthetic bulk laxatives methylcellulose and calcium polycarbophil act to increase colonic water content primarily by gel formation, because they are poorly fermentable (15%).

All bulk laxatives produce bowel movements after 12 to 72 hours, and are well tolerated with good safety records. Furthermore, the approved labeling indications for Metamucil (3.4 g psyllium/dose) and Citrucel (2 g/dose) are rather broad, and include the treatment of occasional constipation and, when recommended by a physician, chronic constipation and constipation associated with irritable bowel syndrome, diverticulosis, hemorrhoids, convalescence, senility, and pregnancy. In contrast, the approved labeling for calcium polycarbophil (625 mg/dose) is more limited to "the relief of constipation and to help restore and maintain regularity."

Osmotically Active Agents (Saline Laxatives)

This group contains the drugs magnesium hydroxide (e.g., Phillips Milk of Magnesia, others), magnesium sulfate, magnesium citrate (e.g., Citrate of Magnesia), and sodium biphosphate (e.g., Fleet Phospho-Soda, Fleet Enema). Their cathartic action results from osmotically mediated water retention in the bowel. The increased intestinal volume stimulates intestinal peristalsis and promotes defecation. The magnesium-containing cathartics stimulate release of the intestinal hormone cholecystokinin, which promotes intestinal secretion and increased intestinal motility. The usual adult dose of magnesium hydroxide is 800 to 1600 mg at bedtime, which produces a bowel movement

within 6 hours. Phosphate salts are better absorbed than are magnesium salts and therefore require higher dosage to effect catharsis. Saline cathartics should not be used for more than 1 week unless directed by a physician. Both magnesium- and phosphate-containing preparations are reasonably well tolerated, but they need to be used with caution in patients with renal insufficiency or cardiac disease.

Emollient Laxatives

Mineral oil is the only drug available as an indigestible emollient. When used for 2 to 3 days, mineral oil (e.g., Fleet Mineral Oil Enema, 118 ml/dose; or as an oral liquid) can soften very dry stools. However, its poor taste and possible oil leakage from the anus precludes its regular use. Furthermore, the chronic use of mineral oil could result in foreign body reactions and interference with the absorption of fat-soluble substances, such as some vitamins.

Nonspecific Stimulants (Irritant Laxatives)

Stimulant laxatives induce bowel movement by virtue of their ability to alter intestinal mucosal permeability and stimulate intestinal water and electrolyte secretion in the bowel. This pharmacological class of drugs constitutes four distinct subgroups:

1. Surfactants: Anionic surfactants containing the docusate salts dioctyl sodium sulfosuccinate or dioctyl calcium sulfosuccinate (e.g., Surfak Liqui-Gels, Colace, Doxinate) are mild stimulant laxatives. These surfactants were initially believed to act by lowering the surface tension of stool to allow mixing of aqueous and fatty substances in the stool, thereby permitting easier defecation. However, more recent evidence indicates that these drugs act in a manner similar to that of other stimulant drugs in this class, by stimulating intestinal water and electrolyte secretion. However, despite their widespread use, these surfactants have marginal, if any, efficacy in most cases of constipation.

2. Diphenylmethane derivatives: Bisacodyl (e.g., Dulcolax, 10-mg tablets or 5-mg rectal suppositories) is the only currently available drug in this class, and when taken orally once daily it produces a bowel movement in about 6 hours. A suppository form, however, can produce a bowel movement within 30 to 60 minutes. Bisacodyl is a prodrug and requires *in vivo* hydrolysis for its activation. To avoid activation of the drug in the stomach and consequential gastric irritation, enteric-coated tablets should be swallowed whole without chewing. The laxative effects may be accompanied with cramps and excessive fluid loss. The drug should not be used for more than 10 days, unless advised by a physician.

3. Anthraquinone laxatives: These are plant-derived drugs that have been used as laxatives since ancient times. This group includes senna (e.g., Senokot, Nature Remedy, Ex-Lax), cascara sagrada, and aloe. All of these drugs act by inducing a low-grade inflammatory state in the small and large bowel; this inflammation induces the secretion of water and electrolytes and this is accompanied by giant migrating colonic contractions. The drugs are poorly absorbed in the small intestine and require metabolic activation by colonic bacteria to form monoanthrone derivatives. The usual dose of sennosoides, derived from senna, is 8.6 to 15 mg, which produces a bowel movement in 6 to 12 hours. The chronic use of these drugs may results in laxative dependence and a "cathartic colon" manifested by dilatation of the colon, a relative absence of myenteric plexus neurons, atrophy of the muscularis propria, and the inability to evacuate without their use. This condition is observed typically in women following chronic use of these drugs. Given this colonic pathology, anthraquinone laxatives cannot be recommended for chronic use. In fact, the official labeling for this pharmacological class mandates that these products should not be used for more than 1 week, unless directed by a physician.

4. Castor oil: Castor oil (Neoloid, Purge) is derived from the castor bean plant and contains two noxious ingredients, an extremely toxic protein, ricin, and an oil composed of the triglycerides of ricinoleic acid. In the upper intestine, the triglycerides are hydrolyzed by the pancreatic lipase enzyme to liberate ricinoleic acid, which acts in the small intestine to stimulate fluid and electrolyte secretion and thereby reduce intestinal transit time. Catharsis is produced within 1 to 3 hours. However, due to its unpleasant taste and the potential for toxicity toward the intestinal epithelium and myenteric neurons, similar to the senna, castor oil is now seldom used.

ANTIEMETIC DRUGS

Dimenhydrinate (Dramamine, 50 mg/dose) and meclizine hydrochloride (Bonine, 25 mg/dose) are centrally acting histamine-1 (H1) receptor antagonists that are effective for the "prevention and treatment of nausea, vomiting, or dizziness associated with motion sickness." Although their mechanism of action is not well understood, it is believed that these drugs act by blocking muscarinic receptors in the brain rather than by the blockade of central histamine receptors. These drugs

possess central nervous depressant activity and consumers should be warned not to take these drugs when driving motor vehicles or operating machinery, or when taking sedatives, tranquilizers, or alcohol.

Emetrol, a phosphorylated carbohydrate solution, is an oral preparation formulated for the "relief of nausea associated with upset stomach." Each 5-ml of solution contains 1.87 g of glucose, 1.87 g of fructose, and 21.5 mg of phosphoric acid. The mechanism of the beneficial action is not fully understood, although the official labeling states that this product "has a local action on the hyperactive GI tract." The product should not be diluted. The adult dosage is 15 to 30 ml to be taken every 15 minutes until distress subsides. However, not more than five doses should be taken per hour without consulting a physician.

Of interest is the observation that bismuth subsalicylate (Pepto-Bismol) is also indicated for the treatment of "upset stomach and nausea."

GASTROINTESTINAL DIETARY SUPPLEMENTS

Dietary supplements, which are available on an OTC basis, are frequently used for GI disorders. Unlike drugs, for which there are requirements addressing the proof of safety, efficacy, and good manufacturing practices (GMPs) to assure quality and standardization, dietary supplements do not have these legal requirements. Dietary supplements are therefore marketed on the basis of the 1994 Dietary Supplement Health and Educational Act (DSHEA) passed by the United States Congress. The DSHEA requires that the label state that the product "must not be intended to diagnose, treat, cure, or prevent any disease." Furthermore, dietary supplements do not need premarket approval or review by the FDA, as is the case for drugs, and hence their use by consumers is not based on solid scientific evidence. However, a premarket safety notification by the manufacturers is required for new ingredients. The sponsor can only claim the role of the nutrient or the dietary ingredient "intended to affect structure and function in humans."

Several digestive products and probiotics are available OTC; however, these products have not been evaluated for their clinical efficacy in controlled, double-blind studies. Digestive products are substances that promote the process of digestion in conditions characterized by lack of one or more of the specific substances that digest food. Two digestive (lactase enzyme and α-galactosidase) and one probiotic (*Lactobacillus reuteri*) products are commercially available.

Lactase Enzymes

Lactaid and other similar preparations represent a family of products that contain a lactase enzyme derived from *Aspergillus oryzae*. Lactase aids in the digestion of lactose present in dairy products and converts it to the simple sugars, glucose and galactose. Many adults, particularly those from specific ethnic groups, such as African-Americans or Asian-Americans, have low levels of intestinal lactase. If lactose is not fully digested, it can be fermented by colonic bacteria to induce gas, bloating, cramps, and diarrhea. In such patients, ingestion of lactase may be desirable. Caplets or chewable tablets of Lactaid must be taken with the first bite of dairy food and the dosage needs to be adjusted depending on the desired response. The labeling instructs the user to seek medical attention should he/she experience any unusual symptoms, or symptoms seemingly unrelated to the condition for which the product was taken. As a dietary supplement, lactase enzyme is also added to milk to yield finished products for use by individuals who have lactose intolerance.

α-Galactosidase

The product Beano contains the enzyme α-galactosidase, which is derived from *Aspergillus niger* and aids in the digestion of the sugars raffinose, stachyose, and/or verbascose. These sugars are present in almost all legumes (e.g., beans, peas, chickpeas, lentils, oats) and all or most of the cruciferous vegetables (e.g., cabbage, broccoli). Adverse reactions listed on the label of Beano include cramping and diarrhea as well as allergic-type reactions.

Lactobacillus reuteri

The product Probiotica is a digestive product containing the bacteria *Lactobacillus reuteri*. The product label indicates that this dietary supplement provides "friendly bacteria" to the digestive system. However, there is no specific information on the label to indicate how this product provides improved digestive health. In fact, the mechanisms of action of probiotic bacteria in a variety of intestinal disorders, while supported by anecdotal clinical reports, remain the subject of investigation.

SUMMARY AND CONCLUSIONS

The availability of drugs on an over-the-counter basis provides patients with improved access to effective therapies. However, optimal therapy with OTC drugs

requires that consumers correctly diagnose the underlying condition and safely use a desirable drug.

The OTC gastrointestinal drugs comprise six broad therapeutic categories consisting of antacids and gastric antisecretory agents, antiflatulents, antidiarrheals, laxatives, antiemetics, and dietary supplements. Antacids and histamine (H2) receptor antagonists are effective for the resolution of mild symptoms of occasional heartburn. However, H2 antagonists have a longer duration of action than do antacids when used for the self-treatment of heartburn. The product bismuth subsalicylate, which is not an antacid, is also indicated for the treatment of heartburn. Simethicone is the only approved antiflatulent drug used for the relief of painful bloating, commonly referred to as gas, in the digestive tract. The antidiarrheal drugs loperamide and bismuth subsalicylate are effective for the resolution of diarrheal symptoms. However, adsorbent antidiarrheal drugs are of no value for the treatment and prevention of acute infectious diarrhea. Laxatives of various pharmacological classes are effective for the treatment of constipation. The bulk laxatives have the most physiologic action on the colon, whereas stimulant laxatives have potential for inducing intestinal toxicity and their use should be restricted to short time periods. The histamine (H1) receptor antagonists dimenhydrinate and meclizine are effective antiemetics for the prevention and treatment of nausea and vomiting associated with motion sickness. Since 1994, diverse dietary supplements have become available and consist of either digestive enzymes (e.g., lactase, α-galactosidase) or probiotics.

Clearly, as drug patents expire for prescription-based drugs, many such drugs will likely be switched to an OTC status, thus benefiting consumers and reducing the burden of health care costs. However, it is essential that continuous vigilance is maintained to verify that consumers are safely using OTC drugs and dietary supplements.

Pancreas, Anatomy

NINA W. FLAY AND FRED S. GORELICK
Yale University and Veterans Affairs Medical Center

ampulla of Vater A common channel receiving the contents of the main pancreatic duct and the common bile duct.
common bile duct Vessel that receives the drainage of the cystic duct of the gallbladder and common hepatic duct of the liver; it drains into the ampulla of Vater.
duct of Santorini A small accessory pancreatic duct located cephalad to the main pancreatic duct.
duct of Wirsung The main pancreatic duct.
pancreatic islet–acinar portal system An arterial supply network that connects the islet cells with the exocrine cells.
sphincter of Oddi Smooth muscle surrounding the major duodenal papilla, where the ampulla of Vater releases its contents into the descending portion of the duodenum.
uncinate process That portion of the pancreas that lies between the descending aorta posteriorly and the superior mesenteric artery anteriorly.

The pancreas is a mixed endocrine and exocrine gland that crosses the midline at the transpyloric plane (L1), extending between vertebral level T10 on the left and L2 on the right. In humans, the pancreas weighs approximately 85 ± 15 g in the adult female, 90 ± 16 g in the adult male, and approximately 5 g in the newborn. Located just posterior to the stomach, the pancreas is mainly a retroperitoneal organ and not readily palpated. Imaging techniques can demonstrate pancreatic anatomy and pathology. Computed tomography (CT) and ultrasound detect inconsistencies in the pancreatic texture or masses (as observed with inflammation or tumors) and define its relationships to neighboring structures. CT, magnetic resonance imaging, and intravenous dyes that can be visualized by X-ray are used to define blood flow and vascular abnormalities. Endoscopic retrograde cholangiopancreatography is a combined endoscopic and X-ray technique in which dye is injected into the pancreatic and/or bile ducts.

ANATOMICAL RELATIONSHIPS

In cross section, the pancreas forms an anterior convex curve, with the central portion of the pancreas located on the midline ridge formed by the upper lumbar vertebrae (Fig. 1). Abdominal trauma can lead to fracture of the pancreatic duct at two sites: where the pancreas crosses the lumbar vertebrae (the most common site) and in the pancreatic tail, where it is attached to the splenic hilum by the splenorenal ligament.

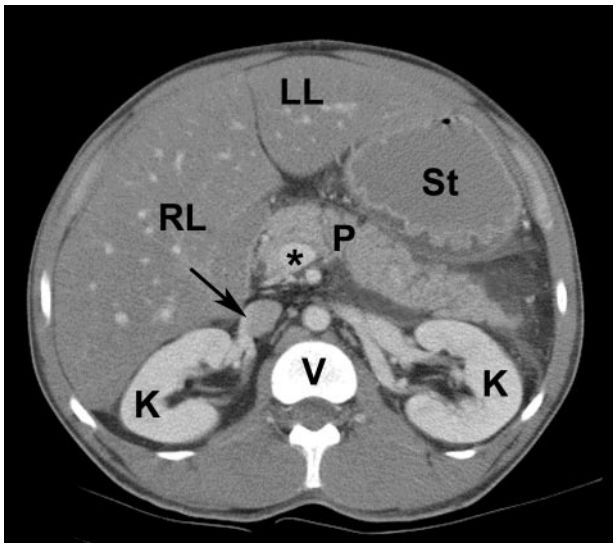

FIGURE 1 CT scan. This axial view reveals relationships of the pancreas (P) to neighboring major structures: liver (right lobe, RL, and left lobe, LL), stomach (St), kidneys (K), vertebral body of lumbar vertebra (V), portal confluence (*), and inferior vena cava (arrow). The body of the pancreas crosses the midline and the tail of the pancreas lies in close proximity to the spleen (not seen) on the left. The distal part of the body and the tail of the pancreas are anterior to the left kidney. The body of the pancreas is anterior to the inferior vena cava and the vertebral body. Note that the pancreas is posterior to the stomach and left lobe of the liver. The portal confluence, visible in the head of the pancreas, is in close approximation to the right lobe of the liver.

The pancreas is related to the duodenum (Fig. 2). The head and uncinate process of the pancreas rest against the duodenal bulb and descending duodenum. Rarely, ulcers may penetrate the duodenal wall and cause pancreatitis. Pancreatic tumors, inflammation, or fibrosis may cause obstruction of the duodenum. The anterior surfaces of the pancreas and duodenum are covered with peritoneum, with the exception of

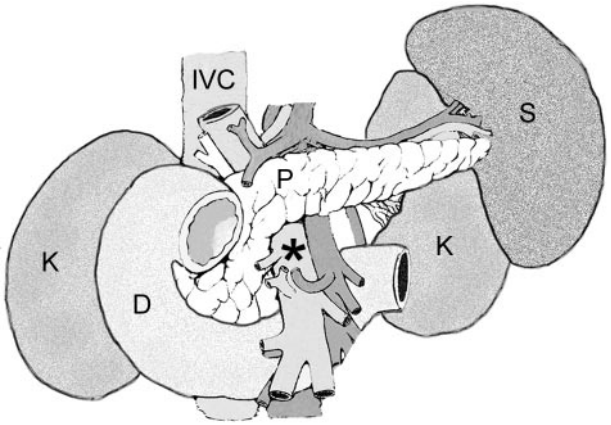

FIGURE 2 *In situ* view of the pancreas. The body of the pancreas (P) crosses the midline of the abdomen anterior to the superior mesenteric vein (*) and artery. The head of the pancreas is in the bulb of the duodenum (D) and its tail is on the left, in the splenorenal ligament that extends between the spleen (S) and the kidney (K). The inferior vena cava (IVC) is the most posterior structure.

the area at the midline where the transverse mesoderm originates.

Structures anterior to the pancreas include the stomach, omental bursa, and transverse colon. The omental bursa (lesser peritoneal sac) lies between the peritoneal coverings of the stomach (anterior) and the pancreas (posterior). The transverse colon crosses anterior to the descending duodenum and the head of the pancreas. The transverse mesocolon is formed by the peritoneal reflections off the posterior abdominal wall and anterior surfaces of the duodenum and pancreas. Pancreatic inflammation may extend into the colon and result in obstruction or bleeding. Gas in the overlying colon or small intestine may obscure visualization of the pancreas by ultrasonography.

Many structures lie posterior to the pancreas (Fig. 2). The tail and distal part of the body of the pancreas are anterior and to the right of the left kidney, with the tail encased in the splenorenal ligament. The splenic vein passes through, or is adjacent to, the pancreas. Chronic pancreatic inflammation can lead to splenic vein thrombosis, causing engorgement of the splenic vessels that connect to the stomach through the left gastric vessels. Enlargement of veins connected to the left gastric vein can result in gastric varices, which are prone to spontaneous rupture and life-threatening bleeding. The superior and inferior mesenteric vessels pass adjacent to the pancreas. If they are involved in pancreatic cancer, resection of the tumor is precluded. The portal vein originates at the junction of the splenic vein and the superior mesenteric veins. In some cases, it originates at a junction composed of three veins: the splenic vein, the superior mesenteric vein, and the inferior mesenteric vein. In either case, the portal vein drains directly into the liver. The common bile duct passes through the head of the pancreas and usually joins the main pancreatic duct to form a common channel that empties into the duodenum. Tumors, inflammation, or fibrosis within the head of the pancreas can obstruct the intrapancreatic portion of the common bile duct. This can cause jaundice and secondary biliary cirrhosis. Since the pancreas does not have a capsule, and there is no peritoneum between the dorsal part of the pancreas and structures posterior to it, tumor cells can spread to all of the structures located posterior to the pancreas.

REGIONS OF THE PANCREAS

The pancreas has four parts: the head, neck, body, and tail. The head of the pancreas is located in the cap of the duodenum. The uncinate process is an extension of the pancreatic head that is located between the superior mesenteric artery and the abdominal part of the descending aorta. Constriction of these vessels compresses the uncinate process. The neck lies anterior to the origin of the portal vein. The body crosses the midline and lies anterior to the aorta, the splenic vein, the left suprarenal gland, the left renal vessels, the left kidney, and the left crus of the diaphragm. The tail is the only intraperitoneal part of the pancreas and lies within the splenorenal ligament.

PANCREATIC DEVELOPMENT AND THE DUCT SYSTEM

The structure of the adult pancreatic duct system is directly related to the dual embryonic origin of the pancreas. The dorsal bud is larger than the ventral bud and gives rise to the major portion of the pancreas. It supplies all of the tail and the body and some of the head and the uncinate process. Initially, the ventral bud is a paired structure, with the left portion atrophying and the right portion continuing to grow. After rotation of the duodenum and the pancreatic buds, fusion of the dorsal and ventral ducts occurs at approximately 6 weeks of human gestation. The main pancreatic duct, called the duct of Wirsung, is surrounded by its own smooth muscle sphincter and arises from the ventral bud. It generally becomes the main conduit in the pancreas. It supplies parts of the head and the uncinate process. Approximately 80% of the time, the main pancreatic duct fuses with the common bile duct, which also

has a smooth muscle sphincter, forming a common channel called the ampulla of Vater. The ampulla of Vater releases its contents into the descending portion of the duodenum at the major duodenal papilla, which is surrounded and innervated by the smooth muscle of the sphincter of Oddi (Fig. 3). Most pancreatic duct contents are released into the duodenum at the major duodenal papilla. In addition to the main pancreatic duct, there is a small accessory duct, the duct of Santorini, which is located cephalad. In the majority of cases, it connects to the main pancreatic duct, but in a small percentage of cases, it has a separate opening into the minor duodenal papilla. The small minor duodenal papilla is cephalad to the major duodenal papilla (Fig. 3).

The pancreatic duct diameter becomes smaller from the head to the tail. Increases in the diameter of the main pancreatic duct are observed with some pathologic processes, such as obstruction by tumors or in chronic pancreatitis. However, the diameter of the pancreas may also increase with age.

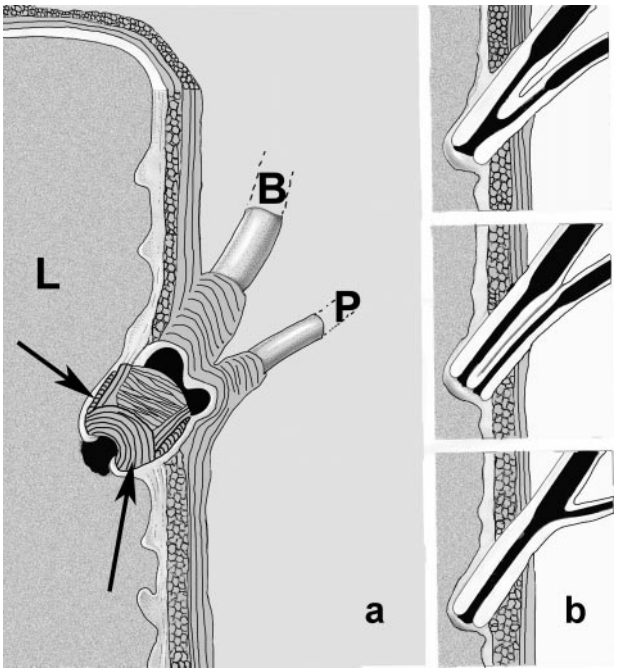

FIGURE 3 Pancreatic duct system. (a) The common bile duct (B) and the main pancreatic duct (P) join to form a common duct (ampulla of Vater). The ampulla of Vater empties its contents into the lumen (L) of the descending portion of the duodenum at the major duodenal papilla, which is surrounded by the sphincter of Oddi (arrows). Note that the main pancreatic duct and the common bile duct are surrounded by their own sphincters. (b) Three variations of the common bile duct and main pancreatic duct system. (Top) Short common channel of the two ducts. (Middle) Two separate ducts. (Bottom) Long common channel of the two ducts. FIGURE 4 Comparison between normal pancreatic duct structure (A) and pancreas divisum (B). Note that in pancreas divisum, there are separate dorsal and ventral pancreatic ducts. There are several variations on this duct pattern.

Variations in the scheme of the pancreatic ducts are frequent. Most often, there is a small accessory duct. However, in approximately 10% of individuals, the dorsal and ventral pancreatic ducts do not fuse. This is called pancreas divisum. Most pancreatic secretions drain though a small minor papillae in pancreas divisum. In a small minority of patients, this may cause relative obstruction of the pancreatic duct that occasionally leads to pancreatitis (Fig. 4). Annular pancreas, a rare condition, may lead to obstruction in the duodenum. It is caused by the lack of atrophy of one of the portions of the ventral bud and the resulting emergence of a bifid ventral pancreatic bud that can surround and constrict the descending duodenum.

VASCULATURE AND LYMPHATICS

Arterial supply to the pancreas is provided by the splenic artery, the pancreatic branches of the gastroduodenal and superior mesenteric arteries, the superior posterior pancreaticoduodenal artery (a branch of the gastroduodenal artery), and the inferior pancreaticoduodenal artery (a branch of the superior mesenteric artery). The splenic artery, a branch of the celiac trunk, lies along the upper border of the pancreas and forms

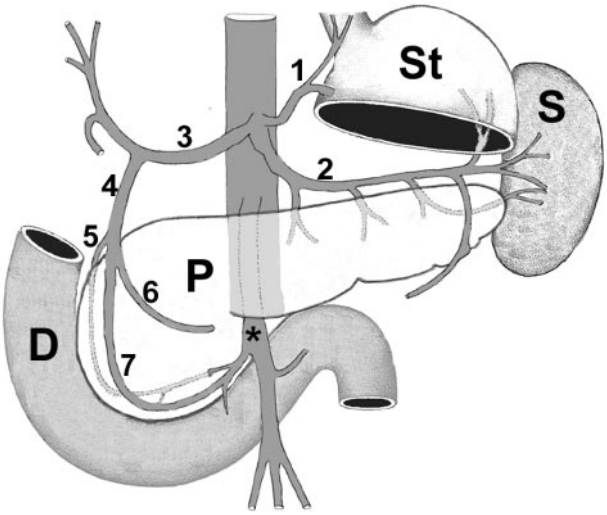

FIGURE 5 Arterial supply to the pancreas. The major arterial supply to the pancreas is from the splenic artery (2) on the superior border of the pancreas and the posterior (5) and anterior (7) superior pancreaticoduodenal arteries, which are branches of the gastroduodenal artery (4). Other vessels in the region include the left gastric (1), common hepatic (3), right gastroepiploic (6), and superior mesenteric (asterisk) arteries.

arcades with the pancreatic branches of the gastroduodenal and superior mesenteric arteries (Fig. 5). The arcades supply the body and tail of the pancreas. The intimate association of the pancreas with critical vascular structures often leads to direct involvement of pancreatic cancer with these blood vessels. This is often the reason that pancreatic cancers cannot be removed surgically. A pancreatic portal system connects the endocrine and exocrine pancreas, allowing arteries supplying the islets to flow directly to the acini located in the immediate vicinity of the islets. Venous drainage of the pancreas occurs by way of the splenic vein, which lies posterior to the pancreas. Venous blood exiting the pancreas flows directly into the liver through the portal vein.

Lymphatic drainage from the pancreas is carried to the pancreaticosplenic, pancreaticoduodenal, subpyloric, and hepatic lymph nodes. Lymph from these nodes flows through the celiac lymph nodes into the intestinal lymphatic trunk and the thoracic duct, ultimately draining into the junction of the left jugular and the left subclavian veins.

NERVOUS INNERVATION

The autonomic nervous system (ANS) plays a major role in the sensory and motor innervations of the pancreas. Nerve fibers are unevenly distributed throughout the pancreas, with the ANS supply being richer in the head of the pancreas than in the tail. The right celiac, hepatic, and superior mesenteric nerve plexuses innervate the head and neck of the pancreas. The celiac plexus and splanchnic neurological networks supply the pancreatic body and tail.

General sensation from the pancreas is carried by visceral afferent fibers of the vagus nerve. Pancreatic visceral pain carried by sympathetic fibers is referred to dermatomes T5–T10, which mark the upper abdomen in the area of the stomach. Severe abdominal pain is a characteristic of both acute and chronic pancreatitis. With chronic disease, the pain is associated with changes in neuronal architecture and changes in neurotransmitter content. Disruption of the perineural sheath may allow toxic substances to come into direct contact with nerve fibers. In patients suffering from chronic pancreatitis, inflammatory cells (lymphocytes, granulocytes, and macrophages) are found around nerves and ganglia supplying the pancreas and the size of nerves is greatly increased. In pancreatic cancer, tumor cells disrupt the perineural sheath and invade the underlying nerve fibers. Severe back pain may be due to the activation of nerve fibers located in the posterior abdominal wall. Changes in neurotransmitter content include the release of increased amounts of two pain transmitter substances: calcitonin gene-related peptide (CGRP) and substance P.

Recent research suggests that some pancreatic pain may be the result of proteolytic activation of the protease-activated receptor PAR-2, a member of the G-protein-coupled receptor family. PAR-2 expression has been detected on a subset of peripheral peptidergic neurons and is involved in the neurogenic component of inflammation. In pancreatitis, PAR-2 may be activated by pathologically generated trypsin from acinar cells or tryptase from mast cells. Pancreatic pain can also be generated by edema, pancreatic duct distension, or ischemia.

Pancreatic secretion is controlled by the parasympathetic and sympathetic nerve fibers as well as peptidergic nerve fibers. Nerve fibers secrete neurotransmitters (acetylcholine from parasympathetic fibers, norepinephrine from sympathetic fibers, and various peptides from peptidergic fibers) along the length of their axons. The neurotransmitters diffuse to target cells, bind to cell surface receptors, and work through signal transduction pathways to stimulate or inhibit pancreatic secretion. Since sympathetic terminals are predominantly associated with blood vessels, decreased blood flow is also related to decreased secretion. Corticotropin-releasing factor (CRF) and CGRP also exert effects on pancreas secretion indirectly, through sympathetic pathways. CRF and CGRP cause the decreases in pancreatic secretion associated with stress. Vagal parasympathetic fibers are also major regulators of

interdigestive secretion, supplying pancreatic acini and islets. They stimulate secretion by releasing acetylcholine, which interacts with the M3 receptor on the acinar cell. A major component of pancreatic secretion stimulated by either cholecystokinin (CCK) or secretin is probably indirect. In response to a meal, CCK is released from I cells and secretin is released from S cells, in the duodenum. These ligands bind to neural pathways and release neurotransmitters that stimulate receptors on acinar and duct cells. They also may have direct effects on exocrine cells. Acetylcholine plays a major role in this pathway. Another major pathway regulating pancreatic secretion is mediated by serotonin, released when food is in the duodenum and interacts with 5-hydroxtryptamine receptors.

Peptidergic nerves in the pancreas exert effects on exocrine tissue but are vulnerable to proteases, so they act in a paracrine manner by releasing peptides that stimulate secretion by neighboring acinar cells. Somatostatin, enkephalin, and pancreastatin are examples of peptides that act in a paracrine manner.

In summary, the pancreas is a mixed endocrine and exocrine gland that crosses the midline at the transpyloric plane (L1) of the abdomen. It consists of four parts: the head, neck, body, and tail. Except for the tail, which is intraperitoneal, the gland is retroperitoneal. This fact, combined with the absence of a capsule, explains the various pathological conditions that arise due to the spread of pancreatic tumors to other retroperitoneal organs. The duct system, of dual embryonic origin, releases its contents into the descending portion of the duodenum. Anastomosis of several major arteries supplies the pancreas. Venous blood drains into the portal vein. Innervation to the pancreas is supplied by the vagus nerve and the ANS. Imaging techniques used to examine the pancreas include computed tomography, ultrasound, endoscopic retrograde cholangiopancreatography, and X-rays.

homeobox/homeodomain Specific sequences of transcription factor nucleotides and amino acids that confer a DNA binding patterning/regulation capacity.
lateral inhibition Process by which a single, centrally located cell self-determines its differentiation and, in doing so, inhibits a similar fate selection by adjacent lateral cells.
lineage selection Process by which developmental fate choices are made during organogenesis between different cell lineage types.
Pdx-1 Patterning transcription factor required for early development of the embryonic pancreas.
protodifferentiated Early state of differentiation wherein cells exhibit low-level expression of lineage-specific genes, but have not acquired the higher expression levels characteristic of fully differentiated cells.

The pancreas develops through the evagination of early endoderm. Cells then remain in the epithelium to become the ductal–acinar network or migrate out of the epithelium to give rise to the endocrine cells. These processes are controlled through a complex array of intracellular and extracellular molecular influences. Defects in these pathways can lead to various pathologic states.

INTRODUCTION

The pancreas develops from the caudal foregut, where endodermal cells give rise to a ventral and dorsal pancreatic bud. These two buds then fuse and mesenchymal factors induce the early pancreatic epithelium to undergo a complex pattern of cellular differentiation and lineage selection to yield both epithelial exocrine (acinar and ductal) and nonepithelial endocrine cells. Studies of pancreatic organogenesis have identified several morphogenetic signals, patterning transcription factors, and pathogenetic mechanisms of pancreatic abnormalities. The following overview is a description of the present knowledge of pancreatic organogenesis and morphogenesis.

EMBRYONIC ANATOMY

At approximately 5 weeks of gestation in the human, the pancreatic dorsal and ventral buds evaginate from the endodermal lining of the caudal foregut. The ventral bud moves with the axial rotation of the gut tube during week 6, as the C-loop of the duodenum takes its final position and comes to lie behind and below the dorsal bud. By gestational week 7, fusion of the two pancreatic buds occurs (see Fig. 1).

The most clinically relevant gross anatomy of the exocrine pancreas is the duct system. The main

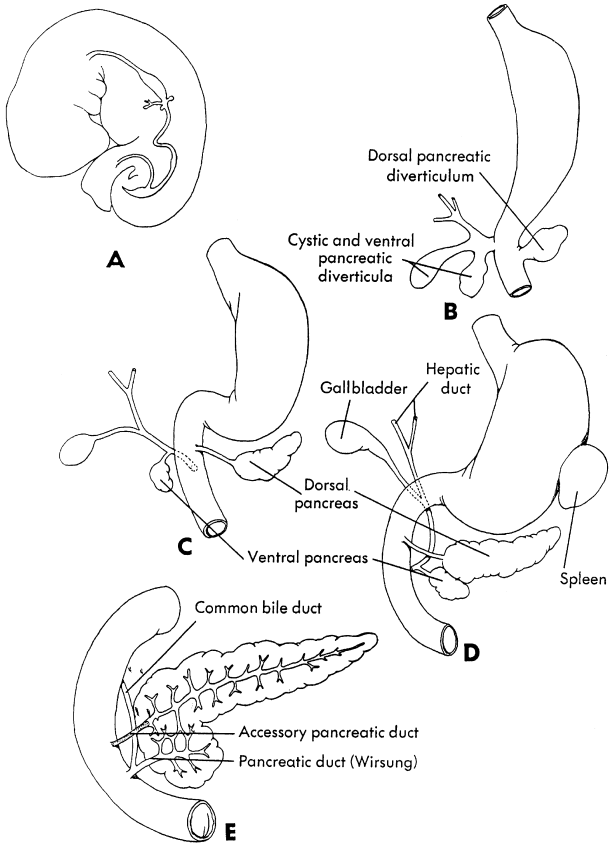

FIGURE 1 Development of the derivatives of the human caudal foregut. (A) Orientation of the gut within a human embryo at about 30 days of gestation. pancreatic duct (duct of Wirsung) is formed by fusion of the distal dorsal duct with the entire ventral duct. This main pancreatic duct drains into the duodenum via the ampulla of Vater. The proximal dorsal duct usually persists as an accessory duct, communicates with the main duct, and opens into the duodenum at the minor papilla. When present, this accessory duct is called the duct of Santorini. Approximately 10% of humans with otherwise normally developed pancreata do not have duct fusion, and the entire dorsal duct drains via the minor papilla. The ventral bud develops into the inferior head and uncinate process of the mature pancreas; the dorsal bud provides the remainder. The pancreas is highly vascular and has extensive lymphatic drainage. The connective tissue, septae, and lymphatics of the adult gland are derived from the splanchnic mesoderm.

Histologically, the pancreas is composed of two distinct tissue types, exocrine and endocrine. The exocrine pancreas consists of lobules of acinar cells at the tips of branched ducts. The acinar cells develop zymogen granules containing proenzymes for over 20 digestive enzymes. Zymogens release these proenzymes (nucleases, proteases, amylase, and lipase), into the gastrointestinal tract, where they are activated and participate in digestion. The function of the healthy exocrine pancreas is under complex regulation by hormones, including cholecystokinin (CCK), neurohormones, and secretin.

The cells of the endocrine pancreas constitute only 1–2% of the adult gland, but early in differentiation these represent a major component of the developing pancreas. Clusters of endocrine cells, the islets of Langerhans, form from cells that bud off of the exocrine ducts. Four types of endocrine cells secrete their peptide hormones into the bloodstream from the islets. The majority of pancreatic endocrine cells are beta cells, which produce insulin and amylin (an insulin antagonist). The other three cell types are glucagon-secreting alpha cells, somatostatin-producing delta cells, and the pancreatic polypeptide (PP)-secreting cells. These islets do not arise from a single progenitor cell, and the cellular content of islets is variable. For example, islets with a higher concentration of pancreatic polypeptide-producing cells are found in the head of the pancreas, which derives from the embryologic ventral bud.

CELLULAR DIFFERENTIATION AND MORPHOGENESIS

The normal structural development of the embryonic pancreas during early gestation has been well described. Specifically, Wessells and Cohen in 1967 and Pictet and Rutter in 1972 delineated the morphogenesis of the pancreas in the rat. The first morphologic evidence of the embryonic pancreas, an evagination of the foregut dorsal and ventral endoderm, forms the dorsal and the ventral pancreatic buds, respectively. Dorsal bud evagination occurs first and requires previous contact with overlying notochord, followed by dorsal aorta. The process of evagination and subsequent further growth and differentiation of the pancreatic buds seems to require the presence of the overlying splanchnic mesoderm. This early evagination occurs at 9–10 days of gestation in the mouse.

The developing pancreatic bud starts as a simple sheet of epithelium, which then quickly becomes highly folded. Progressive growth and branching lead to the exocrine (ducts and acini) network. This ductal–acinar structure of the pancreas is evident by 14.5 days in the mouse. Detected throughout the early development of the pancreas, endocrine cells appear to break away and form nonepithelial clusters of endocrine cells that will become vascularized and form the islets of Langerhans.

Pancreas-specific cytodifferentiation has been described by Pictet and Rutter as beginning with a "protodifferentiated" epithelial cell. Exocrine and endocrine cell lineages both originate from these morphologically undifferentiated cells. Expression of lineage-specific mRNA, such as insulin and amylase RNA in these cells, suggests an early commitment to a lineage. Insulin and glucagon genes are expressed prior to dorsal pancreatic bud evagination at embryonic day 9.5 in the mouse. Amylase and other acinar enzyme genes are first expressed around days 11–12 in the mouse.

MOLECULAR INFLUENCES

Although the morphologic and functional development of the pancreas has been well described, the details of the molecular influences regulating pancreatic cell proliferation and differentiation remain elusive. As mentioned previously, contact of early endoderm with the notochord is necessary to induce evagination and subsequent pancreatic differentiation. This interaction is mediated through notochord production of fibroblast growth factor-2 (FGF-2) and activin B, which inhibit the production of sonic hedgehog (SHH) by the endodermal cells that form the pancreas. This SHH suppression is specific to the prepancreatic area. This backdrop of extracellular signaling, accompanied by expression of patterning transcription factors (Pdx-1 and Hlbx9), leads to the early development of the embryonic pancreas. Differentiation pathways determined by homeodomain proteins such as Pdx-1 and Hlbx9 are further modulated by the expression of secondary patterning genes. For example, neurogenin 3, a helix–loop–helix

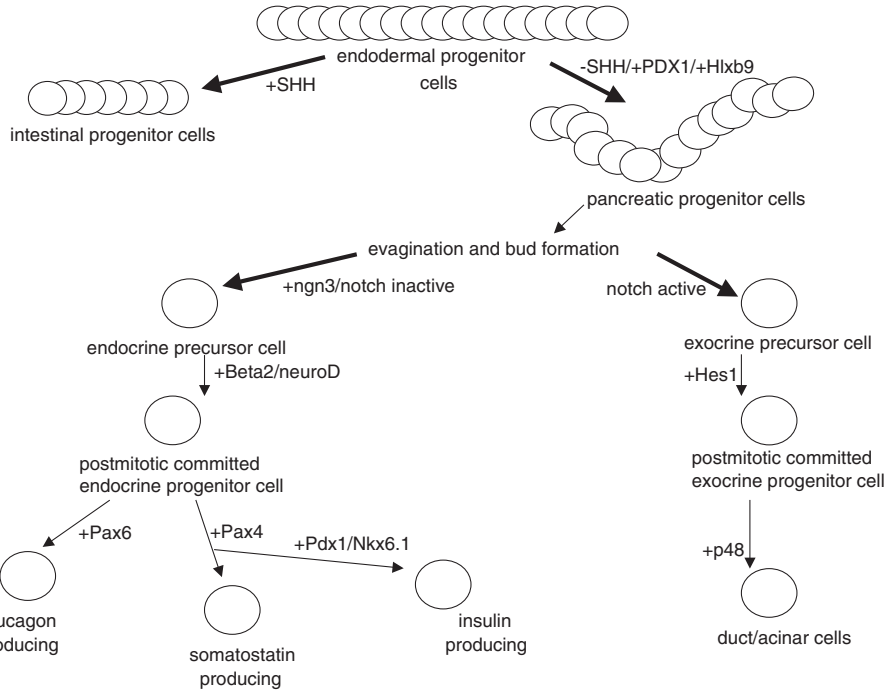

FIGURE 2 Molecular influences and cell lineage map for differentiation of the pancreas. SHH, Sonic hedgehog; ngn3, neurogenin 3.

(HLH) protein, has been found to be necessary for the commitment of Pdx-1-positive cells to become pancreatic endocrine cells. Notch signaling, through mechanisms similar to pathways of neurogenesis called "lateral inhibition," opposes neurogenin 3 signaling and leads to exocrine differentiation. Further levels of lineage selection occur after these events (see Fig. 2).

In endocrine differentiation, Pax4 and Pax6 confer specific differentiation of the glucagon cell (alpha cell) and the insulin cell (beta cell), respectively. In exocrine differentiation, p48 is an HLH protein that is necessary for exocrine differentiation and activates acinar genes. Much of this secondary differentiation beyond the initial pancreatic commitment is mediated by factors in the surrounding pancreatic mesenchyme. FGFs and laminins are examples of such critical mesenchyme-derived factors.

DEVELOPMENTAL ABNORMALITIES

A rare embryologic abnormality of the pancreas is complete agenesis; this has been associated with mutation of the Pdx-1 gene and is frequently fatal in the newborn. A heterozygous Pdx-1 mutation leads to one form of mature-onset diabetes of the young (MODY). Partial pancreatic agenesis describes an otherwise normal pancreas with a portion absent, typically the dorsal pancreas. Hypoplasia of the pancreas, or "lipomatous pseudohypertrophy of the pancreas," is the congenital absence of secondary exocrine structure development. The pancreas has normal islets, but the ductal structures have been replaced by fat.

Pancreas divisum is noncommunication of the ducts in the dorsal and ventral pancreas. Failure of fusion between the main duct (ventral) and the accessory duct (dorsal) results in most of the pancreas draining through the minor papilla via the persistent duct of Santorini. Pancreas divisum is the most common anomaly of the pancreas (~5–10%), and may be more prominent in patients with pancreatitis (16–25%).

Failure of proper pancreatic rotation is thought to lead to a complete ring of pancreatic tissue around the second portion of the duodenum (annular pancreas). Annular pancreas is frequently associated with other anomalies, such as trisomy 21 and duodenal atresia.

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI), also termed nesidioblastosis, is a condition wherein the insulin cells have faulty glucose sensing and thus overproliferate and overproduce insulin. PHHI is often due to mutations in the sulfonylurea receptor 1 (SUR1) () or Kir6.2, and is sometimes associated with the Beckwith–Wiedemann syndrome and multiple endocrine neoplasia type 1(MEN 1). Duct–endocrine proliferation, with new

islet formation from the pancreatic duct epithelium, characterizes nesidioblastosis, but these findings can be seen in the normal neonate as well. Frequently a difficult clinical and pathologic diagnosis, nesidioblastosis requires prompt medical and surgical treatment to avoid brain damage from severe hypoglycemia.

Pancreas, Nutritional Effects on

C. S. PITCHUMONI

St. Peter's University Hospital, New Brunswick, New Jersey

kwashiorkor Protein deficiency state with adequate caloric intake.

marasmus Deficiency state resulting from deprivation of both proteins and calories.

nutritional pancreatitis Form of nonalcoholic chronic pancreatitis prevalent in India and other tropical countries.

Inadequate nutrition, especially of protein, may lead to pancreatic atrophy or in some cases chronic pancreatitis or diabetes. Both the exocrine and endocrine components of the pancreas can be injured. Factors causing injury to the pancreas directly or indirectly interfere with both components to a varying degree, although pancreatic exocrine and endocrine components have considerable functional reserve and malabsorption is not seen until 90% of the pancreas is lost.

MALNUTRITION AND EXOCRINE PANCREATIC INJURY

Protein Deficiency

Among the specialized organs of the body, the pancreas (along with liver and small intestine) has the highest rate of protein synthesis. The acinar cells synthesize and secrete between 6 and 20 g of digestive enzymes in 24 hours. Consequently, the pancreas is extremely vulnerable to short- or long-term protein deficiency. Protein energy malnutrition (PEM) is the most important public health problem in developing countries. Malnutrition in affluent nations is often occult, resulting from chronic alcoholism, drug abuse, immunodeficiency states, and problems associated with old age.

Pancreas, Nutritional Effects on

C. S. PITCHUMONI

St. Peter's University Hospital, New Brunswick, New Jersey

kwashiorkor Protein deficiency state with adequate caloric intake.

marasmus Deficiency state resulting from deprivation of both proteins and calories.

nutritional pancreatitis Form of nonalcoholic chronic pancreatitis prevalent in India and other tropical countries.

Inadequate nutrition, especially of protein, may lead to pancreatic atrophy or in some cases chronic pancreatitis or diabetes. Both the exocrine and endocrine components of the pancreas can be injured. Factors causing injury to the pancreas directly or indirectly interfere with both components to a varying degree, although pancreatic exocrine and endocrine components have considerable functional reserve and malabsorption is not seen until 90% of the pancreas is lost.

MALNUTRITION AND EXOCRINE PANCREATIC INJURY

Protein Deficiency

Among the specialized organs of the body, the pancreas (along with liver and small intestine) has the highest rate of protein synthesis. The acinar cells synthesize and secrete between 6 and 20 g of digestive enzymes in 24 hours. Consequently, the pancreas is extremely vulnerable to short- or long-term protein deficiency. Protein energy malnutrition (PEM) is the most important public health problem in developing countries. Malnutrition in affluent nations is often occult, resulting from chronic alcoholism, drug abuse, immunodeficiency states, and problems associated with old age.

Copyright 2004, Elsevier (USA). All rights reserved.

Severe nutritional deficiency causes initially reversible and finally irreversible changes. In an experimental study on Bonnet monkeys, animals on protein-deficient, normal carbohydrate diets showed atrophy of pancreatic tissue with replacement with adipose tissue. Animals on low-protein, high-carbohydrate diets showed severe changes. The additional carbohydrate seemed to harm the pancreas more than normal carbohydrate consumption. The low-protein, high-carbohydrate diet mimics the usual diet of the population groups in most developing nations. Other experimental studies have shown recovery of pancreatic function when protein deficiency is corrected, depending on the severity and duration of malnutrition. Clinical observations support experimental studies. Children dying of kwashiorkor have small fibrosed pancreases along with atrophic intestinal mucosa. In children suffering from marasmus and kwashiorkor, pancreatic enzyme output is decreased with no change in HCO_3^- output. The pancreatic ductules, which produce HCO_3^-, are usually well preserved in kwashiorkor.

Micronutrient Deficiencies

Clinical malnutrition is seldom a pure protein deficiency state. Multiple deficiencies of trace elements and vitamins occur. Unopposed free radicals (FRs) are potential mediators of injury to many organs, including the pancreas. The roles played by antioxidant enzymes, which include a mineral in their structure (metalloenzymes), and antioxidant vitamins (such as vitamins A, E, C, and β-carotene) are increasingly clear. Zinc, an essential micronutrient, is a component of enzymes such as DNA polymerase, RNA polymerase, and reverse transcriptase, which are involved in protein synthesis. Experimental studies have shown that zinc deficiency promotes acinar cell degeneration. Clinical zinc deficiency occurs in chronic alcoholism, cirrhosis of the liver, sickle cell disease, and other conditions. Similarly, selenium is an important trace element because it is a component of the enzyme glutathione peroxidase. A selenium-deficient diet in chicks causes pancreatic atrophy. Clinical selenium deficiency occurs in chronic alcoholics and cigarette smokers.

There is no pancreatic disease that can be solely attributed to malnutrition. However, a form of nonalcoholic chronic pancreatitis, prevalent in India and other tropical countries, known as tropical or nutritional pancreatitis, is reported to occur in children and young adults of low-income groups. Although the etiology for tropical pancreatitis is not yet elucidated, experimental data coupled with epidemiological observations have indicated that malnutrition might play a major role in its pathogenesis.

Malnutrition and Endocrine Pancreatic Injury

The role of malnutrition as a cause for endocrine pancreatic injury has only recently been recognized. Although diabetes is often recognized to be a complication of being overweight, abnormal glucose tolerance is a feature of malnutrition. A reduction in insulin secretory capacity is noted in malnourished animals in experimental studies. The functional damage to B cells in malnutrition initially starts as high levels of insulin (hyperinsulinemia) in early stages of subclinical malnutrition and progresses to low levels of insulin (hypoinsulinemia) with the onset of frank malnutrition. In kwashiorkor, there is islet cell hypertrophy in early stages, followed by atrophy. Malnutrition-related diabetes mellitus is recognized to be a subtype of diabetes. It is not clear whether protein deficiency is the sole cause of this diabetes.

Pancreatic Anomalies

THEODORE R. LIN AND MICHAEL W. MULHOLLAND
University of Michigan Medical Center, Ann Arbor

endoscopic retrograde cholangiopancreatography A procedure whereby pancreatic and biliary ducts are visualized by endoscopic injection of contrast medium.
stenosis An area of narrowing.

The pancreas develops during the fourth week of gestation, arising from the endodermal lining of the duodenum. From this anlage, two pancreatic pouches, dorsal and ventral, develop, which ultimately give rise to the body/tail and head/uncinate processes of the pancreas, respectively. By the sixth week of gestation, the ventral pouch assumes a position adjacent to the dorsal pouch through the process of clockwise migration as the primitive duodenum rotates to assume its characteristic C-shaped configuration. Fusion of the dorsal and ventral primordia and their ductal systems is achieved by the eighth week. At the time of birth, the pancreatic parenchyma is unified and the accessory and main pancreatic ducts are fused. Malformations of pancreatic embryology include annular pancreas, pancreas divisum, and heterotopic pancreas.

ANNULAR PANCREAS

Annular pancreas occurs when the ventral pancreatic pouch fails to properly rotate clockwise posteriorly around the duodenum (see Fig. 1). Thus, the ventral pouch lies anterior to the duodenum in this anomaly. The duodenum can become partially or completely obstructed by the encircling pancreatic ring (Fig. 2). The band of pancreatic tissue commonly lies proximal to the major duodenal papilla. Microscopically, pancreatic tissue often is found to invade the duodenal wall into the muscularis layer. Other congenital defects associated with annular pancreas include duodenal atresia, Down's syndrome (trisomy 21), intracardiac defects, intestinal malrotation, and tracheoesophageal fistula. Annular pancreas is the most common anomaly obstructing the duodenum in infants, who may present with feeding intolerance and vomiting. On examination, visible peristalsis and distension may be appreciated due to the obstruction. Less commonly, the existence of annular pancreas may not become manifest until adulthood. Patients may complain of bloating, pain, or vomiting. Upper gastrointestinal obstruction, peptic ulceration, and pancreatitis may result from annular pancreas. Diagnosis is facilitated by plain abdominal radiograph, which classically reveals the "double-bubble" sign characteristic of gastric and duodenal dilation secondary to duodenal obstruction. Often, however, upper gastrointestinal contrast study is necessary to document obstruction. Endoscopic retrograde cholangiopancreatogram (ERCP) may also be useful in demonstrating ductal anomalies found with this condition.

Treatment is operative when obstructive symptoms develop. Bypass of the obstruction by duodenojejunostomy is preferred over resection of the annular pancreatic tissue due to the high predisposition to develop pancreatic and duodenal fistulas.

PANCREAS DIVISUM

Failure of the ventral and dorsal pancreatic ductal systems to fuse results in pancreas divisum. In this disorder, the majority of the pancreas is drained through the accessory pancreatic duct (duct of Santorini) into the minor duodenal papilla (Fig. 3). Pancreatic secretions from the uncinate process and portions of the pancreatic head, derived from the ventral anlage, drain via the major duodenal papilla (via the duct of Wirsung), separate from the remainder of the pancreas. Pancreas divisum is relatively common, demonstrated in 5 to 10% of subjects by autopsy or by ERCP.

Manifestations of pancreas divisum occur uncommonly in childhood. Controversy exists as to whether pancreas divisum has a causative role in recurrent idiopathic acute pancreatitis, chronic pancreatitis, and chronic abdominal pain. Some investigators believe that stenosis of the minor duodenal papilla must coexist with pancreas divisum for pancreatitis to develop. Diagnosis of pancreas divisum is made by ERCP; on cannulation of the accessory papilla, the duct of Santorini is found to span the length of the pancreas without communicating with the duct of Wirsung.

Given the uncertainty of a causal relationship between pancreas divisum and pancreatitis, no specific intervention is advised for mild or single episodes of pancreatitis. Severe or recurrent bouts of pancreatitis may warrant therapeutic invention. Both endoscopic and surgical approaches have been

HETEROTOPIC PANCREAS

When pancreatic tissue develops outside of the main pancreatic body, these aberrant rests of tissue are referred to as heterotopic pancreas. Heterotopic pancreatic tissue may be found anywhere along the gastrointestinal tract, most commonly in the stomach, duodenum, small bowel, and Meckel's diverticulum. Rarely, ectopic pancreatic tissue may be found in the gallbladder, omentum, umbilicus, colon, or lungs. The etiology of heterotopic pancreas is unclear. Aberrations in stem cell differentiation or migration of the pancreatic pouches during development are thought to be involved in this anomaly.

Heterotopic pancreas is usually an asymptomatic condition found incidentally at autopsy or surgery. Bowel obstruction may result when rests serve as lead points for intussusception or as space-occupying lesions. Other complications include hemorrhage and ulceration. Upper endoscopy is helpful in diagnosis. Submucosal nodules with central depression characteristic of heterotopic pancreas may be discerned. Biopsy is required to distinguish these lesions from polyps, leiomyomas, and lymphoma. Treatment is indicated for patients with complications from heterotopic pancreas. Excision with histologic examination is required to exclude malignancy.

Pancreatic Bicarbonate Secretion

R. MAYNARD CASE*, HIROSHI ISHIGURO†, AND MARTIN C. STEWARD*
*University of Manchester, United Kingdom and †Nagoya University, Japan

cholecystokinin A peptide hormone produced by endocrine cells of the upper small intestine.
vasoactive intestinal peptide A polypeptide from the small intestine with cardiovascular and gastrointestinal effects.

Following appropriate stimulation, the pancreas secretes a bicarbonate (HCO_3^-)-rich fluid that is derived largely from duct cells. Understanding how the pancreatic ductal epithelium is able to secrete HCO_3^- at a concentration five- to sixfold greater than that in plasma is of intrinsic interest. Moreover, it is important from a clinical viewpoint: defects in ductal secretion underlie the pancreatic pathology that characterizes cystic fibrosis and perhaps certain forms of pancreatitis, whereas 90% of pancreatic cancers are of ductal origin.

INTRODUCTION

Pancreatic juice is the product of two distinct secretory processes: protein (enzyme) secretion and electrolyte secretion. Enzymes are secreted by exocytosis. Electrolyte secretion is achieved by the vectorial transport of ions across the secretory epithelium accompanied by water in isotonic proportions. The most significant of these ions is bicarbonate (HCO_3^-). Each day, these two secretory processes result in the human pancreas delivering 6–20 g of digestive enzymes to the duodenum in approximately 2.5 liters of HCO_3^--rich fluid. Although the role of pancreatic enzymes is defined, that of pancreatic HCO_3^- secretion is less precise. Clearly, the fluid acts as a vehicle for transporting enzymes to the duodenum where the HCO_3^- neutralizes gastric acid. Pancreatic HCO_3^- may also aid disaggregation of secreted enzymes following their exocytosis.

PATTERNS OF BICARBONATE SECRETION

The regulation of pancreatic electrolyte secretion and the volume and composition of the secreted fluid differ considerably from species to species (Table I). It is important to recognize these differences for two reasons: (1) observations made in one experimental species, especially those involving models of disease, cannot be assumed to be relevant to humans; (2) a regulatory or secretory mechanism dominant in one experimental species may be present to a small, perhaps unrecognized, extent in humans where it could account for otherwise inexplicable symptoms and/or be explored therapeutically. The major differences and their relevance are as follows:

TABLE I Species-Dependent Patterns of HCO_3^- Secretion

Species	Stimulus	Volume	Maximum $[HCO_3^-]$ (mM)
Dog, cat, and human	Spontaneous	0 (+)	—
	+ Secretin	+++++	145
	+ CCK	+	60
	+ Vagus	+	?
Rat	Spontaneous	+	25
	+ Secretin	++	70
	+ CCK	+++	30
	+ Vagus	++	?
Guinea pig	Spontaneous	+	95
	+ Secretin	+++++	150
	+ CCK	+++	140
	+ Vagus	+++	120

Note. This table gives an idea of the response to stimuli given alone: potentiation often occurs when stimuli are given together. Most data were obtained from studies on anesthetized animals: quantitative differences may occur in conscious animals, especially in the rat, in which secretion is increased fivefold in conscious animals. CCK, cholecystokinin.

1. In all species, secretin evokes the secretion of HCO_3^--rich pancreatic juice. However, the amount of fluid that is secreted varies; an especially small amount is secreted in the rat (approximately fivefold less than that in cat, per gram of tissue). During maximal stimulation, HCO_3^- concentration reaches

 Copyright 2004, Elsevier (USA). All rights reserved.

130 mmol/liter or more in all species except the rat, in which 70 mmol/liter is approximately the maximum value observed.
2. There is a reciprocal relationship between juice HCO_3^- and Cl^- concentrations: as flow rate increases, so does HCO_3^- concentration, with a corresponding reduction in Cl^- concentration. This reciprocal relationship results from a flow rate-dependent loss of HCO_3^- from the primary secretion in exchange for Cl^- as the fluid passes down the ductal tree.
3. The effect of cholecystokinin (CCK) on fluid secretion is very variable. In rat, it evokes a relatively large volume of Cl^--rich fluid that is secreted by acinar cells. In guinea pig, it evokes a HCO_3^--rich fluid. Studies on duct segments isolated from guinea pig pancreas indicate that the ducts are a source of this secretion, but do not exclude an acinar component. In other species, the effect of CCK lies somewhere between these two extremes. Where CCK is a weak stimulant of HCO_3^- secretion, it usually potentiates the action of secretin.
4. The influence of vagal stimulation is also complex. In some species, muscarinic cholinoceptor activation evokes HCO_3^- secretion. In some species (notably pig and guinea pig), vagal stimulation evokes a copious HCO_3^--rich secretion because in these species the vagus nerves contain many VIPergic neurons and the vasoactive intestinal peptide released from these neurons acts in a manner similar to secretin.

In addition to these classical stimulatory mechanisms, many other candidate stimulatory and inhibitory control mechanisms undoubtedly influence pancreatic HCO_3^- secretion to a greater or lesser extent.

ORIGIN OF BICARBONATE SECRETION

Studies on isolated pancreatic duct segments confirm the generally held view, first proposed 50 years ago, that pancreatic duct cells are the principal site of HCO_3^- secretion, without necessarily excluding a possible contribution from acinar cells. Given that duct cells constitute approximately 5% of gland mass, if all pancreatic fluid secretion was derived from duct cells, they would secrete their own volume of fluid in approximately 2 min. This assumes that all duct cells contribute equally to secretion. However, there is some evidence that the terminal duct cells (centroacinar cells) and small ducts contribute disproportionately to secretion, in which case the fluid secretory rate in that region is even faster.

MECHANISM OF DUCTAL BICARBONATE SECRETION

The "textbook" model of HCO_3^- secretion by pancreatic ducts has the following components: (1) generation of intracellular HCO_3^- by the hydration of CO_2 under the influence of carbonic anhydrase; (2) extrusion from the cell of the residual protons by means of a Na^+/H^+ exchanger in the basolateral membrane; (3) secretion of HCO_3^- across the apical (lumenal) membrane in exchange for Cl^- on an anion exchanger working in parallel with an anion channel that allows entry of Cl^- into the lumen. This lumenal anion channel is usually regarded as being the cystic fibrosis transmembrane conductance regulator protein (CFTR).

This model arose from early studies on perfused whole glands and, more recently (and more importantly), from experiments on isolated duct segments from rat pancreas. Although the model can successfully generate the HCO_3^- concentrations observed in the rat (i.e., approximately 70 mmol/liter), on thermodynamic grounds it seems most unlikely to be able to generate the higher concentrations (up to 150 mmol/liter) seen in other species. However, recent observations have suggested a number of modifications to the model, which help to explain how the ducts of these species achieve such high secretory HCO_3^- concentrations.

At the basolateral membrane, the situation is relatively clear. Although the Na^+/H^+ exchanger may be involved to a small extent in HCO_3^- accumulation across the basolateral membrane, experimental studies on duct segments isolated from guinea pig pancreas show that it is largely achieved by a $Na^+-HCO_3^-$ co-transporter (NBC) located in this membrane. Furthermore, the electrogenicity of the NBC contributes to the driving force for HCO_3^- secretion across the lumenal membrane. Immunohistochemical studies confirm that NBC is expressed in the basolateral membrane of human duct cells. However, since NBC is also present in rat ducts, its presence alone cannot account for the much higher HCO_3^- concentrations secreted by the guinea pig pancreas.

At the lumenal membrane, the situation is less clear. Although spontaneous secretion in guinea pig ducts involves anion exchange across the lumenal membrane (Fig. 1A), secretin-evoked secretion can occur in the nominal absence of lumenal Cl^- or when the activity of the anion exchanger is blocked. Furthermore, raising the lumenal HCO_3^- concentration (as occurs during secretin stimulation) actually inhibits lumenal anion exchanger activity, thereby helping to prevent the reabsorption of secreted HCO_3^-. There must, therefore, be an

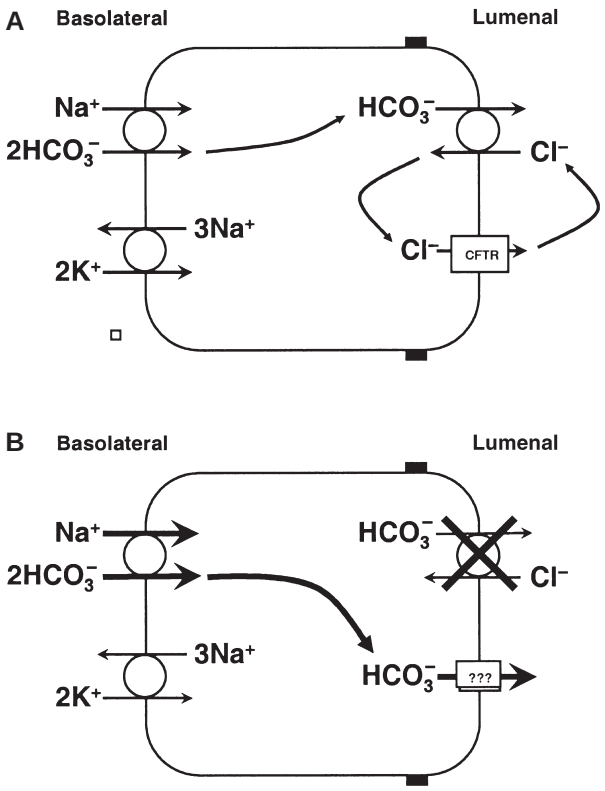

FIGURE 1 HCO_3^- secretion in guinea pig pancreatic duct. (A) During spontaneous secretion, HCO_3^- enters the lumen by anion exchange with Cl^-, which recycles across the lumenal membrane via the CFTR Cl^- channel. (B) Following stimulation with secretin, the anion exchanger becomes inhibited by the high lumenal HCO_3^- concentration and HCO_3^- secretion occurs mainly by diffusion through a lumenal anion channel, probably CFTR. In both situations, HCO_3^- uptake across the basolateral membrane is achieved by Na^+–HCO_3^- co-transport and, to a lesser extent, through H^+ extrusion by Na^+/H^+ exchange (not shown). Both processes derive their energy from the inward Na^+ gradient maintained by the basolateral Na^+,K^+-ATPase.

alternative pathway for HCO_3^- secretion across the lumenal membrane under these conditions.

In contrast to its effect in rat ducts, secretin does not greatly depolarize cells in guinea pig ducts; instead the membrane potential remains at approximately −60 mV. Therefore, even at a lumenal HCO_3^- concentration of 125 mmol/liter and a cytoplasmic HCO_3^- concentration calculated to be 20 mmol/liter, the electrochemical gradient for HCO_3^- would favor diffusion from the cell to the lumen via an anion channel. Furthermore, under these conditions intracellular Cl^- dips to very low values (approximately 7 mmol/liter). Consequently, a HCO_3^--rich secretion is favored by the lack of driving force for Cl^- provided that the anion conductance at the lumenal membrane also conducts HCO_3^- (Fig. 1B). Whether CFTR or another anion conductance provides such a pathway for HCO_3^- remains to be clarified.

In other words, given a large enough HCO_3^- conductance at the lumenal membrane and a low intracellular Cl^- concentration, there may be no need to invoke any other membrane transport protein in the lumenal membrane to explain the high HCO_3^- concentration observed in pancreatic juice from the guinea pig. If so, what is true for the guinea pig may presumably be true of other species, including humans, that show a similar pattern of HCO_3^- secretion.

Finally, why does the rat not achieve such high HCO_3^- concentrations? The answer may lie in the basolateral rather than the lumenal membrane. In rat (and mouse) ducts, fluid secretion can be inhibited by bumetanide. It thus seems likely that a Na^+–K^+–$2Cl^-$ co-transporter is present on the basolateral membrane of these species, which acts to increase intracellular Cl^- concentration. As a result, there are driving forces for both Cl^- and HCO_3^- secretion via the lumenal anion conductance. This causes the production of a secretion containing comparable concentrations of the two anions. The absence or inactivity of this co-transporter in the guinea pig (and other species?) ensures that the secretion is HCO_3^--rich.

Pancreatic Cancer

CHARLES E. BINKLEY AND DIANE M. SIMEONE
University of Michigan Medical Center, Ann Arbor

CA 19–9 Widely used serum marker for pancreatic cancer; has limited specificity because it is also expressed in other malignancies as well as in pancreatitis, hepatitis, and biliary obstruction.

chemical splanchnicectomy Chemical blockage of the celiac nerve plexus, performed either intraoperatively or percutaneously, in order to palliate pain associated with pancreatic adenocarcinoma.

double duct sign Dilation of the distal pancreatic and common bile ducts, with proximal stricturing of both structures evident on endoscopic retrograde cholangiopancreatography and highly suggestive of adenocarcinoma affecting the head of the pancreas.

endoscopic ultrasonography Imaging technique whereby an ultrasound probe attached to an endoscope is used to assess structures through the gastric and duodenal wall.

gemcitabine Chemotherapeutic agent and potent radiosensitizer that has recently been added to the multimodality treatment regimen for pancreatic adenocarcinoma.

hereditary pancreatitis Autosomal dominant trait, leading to recurrent acute pancreatitis and a 40-fold increased risk of pancreatic adenocarcinoma.

K-ras Oncogene; the mutated form is found in over 90% of pancreatic cancers.

laparoscopic staging Minimally invasive means of evaluating the resectability of pancreatic adenocarcinoma by visualization through a tube inserted into the abdomen.

neoadjuvant therapy Strategy of preoperative administration of chemoradiation aimed at increasing the number of patients able to complete multimodality therapy.

palliation Treatment of symptoms such as abdominal pain to optimize quality of life, limit morbidity, and increase survival.

pancreatic intraepithelial neoplasia Areas of focal ductal proliferation adjacent to infiltrating pancreatic cancers that may be precursor lesions to pancreatic adenocarcinoma.

pancreaticoduodenectomy Surgical excision of the head and uncinate process of the pancreas by en bloc resection of the distal stomach and duodenum to the ligament of Treitz, common bile duct, and head of the pancreas. Also known as a Whipple procedure.

Pancreatic adenocarcinoma is one of the deadliest known human malignancies, with an overall 5-year survival rate of less than 5%. Among gastrointestinal malignancies, pancreatic adenocarcinoma is second to colorectal cancer in terms of incidence in the United States, with 30,300 estimated new cases in 2002. Pancreatic cancer deaths in the United States in 2002 were estimated to approach 29,700, making pancreatic cancer the fifth most common cause of cancer-related mortality. Delayed diagnosis, relative chemotherapy and radiation resistance, and an intrinsic biologic aggressiveness all contribute to the abysmal prognosis associated with pancreatic adenocarcinoma. The risk of pancreatic adenocarcinoma is twice as great in men compared to women, and African Americans as well as Japanese Americans have a higher incidence compared to other ethnic groups, suggesting an as-yet undetermined specific genetic or environmental association.

EPIDEMIOLOGY

Many risk factors for pancreatic adenocarcinoma have been identified, with cigarette smoking having the strongest overall association and thought to account for one-quarter of all patients diagnosed. This may also in part explain the greater number of men diagnosed with pancreatic adenocarcinoma. The mechanism believed to be responsible for the association between cigarette smoking and pancreatic cancer involves the *N*-nitroso compounds present in cigarette smoke. Exposure to these agents leads to pancreatic ductal hyperplasia, a possible precursor to adenocarcinoma.

Other factors associated with increased risk of pancreatic adenocarcinoma include saturated fat intake, exposure to nonchlorinated solvents, and the pesticide dichlorodiphenyl trichloroethane (DDT), although the overall contribution of these is likely small. The risk of pancreatic adenocarcinoma increases with age, with most patients diagnosed between 60 and 80 years old. Studies examining the risk between alcohol consumption and pancreatic adenocarcinoma are equivocal, except in the case of heavy alcohol use leading to chronic pancreatitis. Chronic pancreatitis clearly increases the risk of pancreatic adenocarcinoma, although the direct or indirect role of alcohol is not yet defined.

 Copyright 2004, Elsevier (USA). All rights reserved.

MOLECULAR GENETICS

Genetic analysis has shown two distinct patterns of inherited risk for developing pancreatic adenocarcinoma: those inheriting mutations specifically in the *PRSS1* gene, which leads to hereditary pancreatitis, and those inheriting mutations in general cancer susceptibility genes. Hereditary pancreatitis is an autosomal dominant trait, with complete penetrance. Individuals inheriting a mutated *PRSS1* gene, which codes for cationic trypsinogen, develop recurrent acute pancreatitis, frequently beginning in childhood. These individuals have a 40-fold increased risk of developing pancreatic adenocarcinoma when compared to the general population. The mechanism seems to involve recurrent bouts of acute pancreatitis, with increased pancreatic ductal cell turnover, leading to increased rates of DNA synthesis and accompanying random mutations. It is believed that the accumulation of random genetic mutations in key oncogenes and tumor suppressor genes finally leads to the development of pancreatic adenocarcinoma.

Increased risk for developing pancreatic adenocarcinoma also occurs when individuals inherit germ-line mutations in cancer susceptibility genes. A germ-line mutation in the *BRCA2* gene is present in approximately 5–10% of pancreatic adenocarcinomas and predisposes an individual to pancreatic as well as breast and ovarian cancer. The p16 tumor suppressor gene is mutated in over 95% of the cases of pancreatic adenocarcinoma, usually by a somatic mutation, yet germ-line mutations have been described and are associated with an increased risk of both pancreatic malignancy and melanoma.

Inherited mutations in the *LKB1/STK11* gene leads to Peutz–Jeghers syndrome, which is associated with the development of benign gastrointestinal polyps as well increased risk of gastrointestinal cancers, including pancreatic adenocarcinoma. Other familial cancer syndromes involving increased risk of pancreatic adenocarcinoma include hereditary nonpolyposis colorectal cancer (Lynch II), Gardner's syndrome, and familial and atypical multiple mole melanoma (FAMMM). In all of these familial cancer syndromes, one of the two genes inherited at birth is mutated, with cancer arising after the loss of the remaining normal gene.

In contrast to inherited or germ-line gene mutations, several genes have been found to be commonly spontaneously mutated in pancreatic adenocarcinoma. Mutations in the oncogene *K-ras* confer constitutive activation of the gene and are found in over 90% of pancreatic cancers. Mutations in *K-ras* have also been detected in hyperplastic foci within the duct of patients with chronic pancreatitis, and may predict which of these patients is at risk to develop pancreatic adenocarcinoma. As might be expected, mutations in tumor suppressor genes, both spontaneously arising and inherited, are common in pancreatic tumors, with over 95% of cases harboring mutations in p16, 50–75% with p53 mutations, and approximately 55% with mutations in Smad4/DPC4 (deleted in pancreatic cancer, locus 4). Other less frequent mutations occur in tumor suppressors *MKK4* (4%), transforming growth factor-β (TGF-β) receptors I or II (<5%), and *RB1* (<5%).

PATHOLOGY

The pancreas has both exocrine and endocrine cell types, and as such, neoplasms can arise from multiple cellular structures. Approximately 90% of tumors of the exocrine pancreas have a ductal phenotype, whereas less than 1% have an acinar cell phenotype, with the balance being of uncertain histogenesis. Overall, 75% of pancreatic neoplasms are ductal adenocarcinoma, 65% of which arise from the head, neck, or uncinate process, 15% from the body or tail, and 20% are diffuse. Hallmarks of pancreatic adenocarcinoma include an intense desmoplastic reaction and perineural invasion (Fig. 1).

Areas of focal ductal proliferation have been noted both adjacent to infiltrating pancreatic cancers and in the setting of chronic pancreatitis. Molecular analysis of these lesions, termed pancreatic intraepithelial neoplasia (PanIN), has shown progressive accumulation of genetic changes with increasing severity of histologic atypia. The genetic alterations in PanIN lesions are similar to those seen in pancreatic adenocarcinomas,

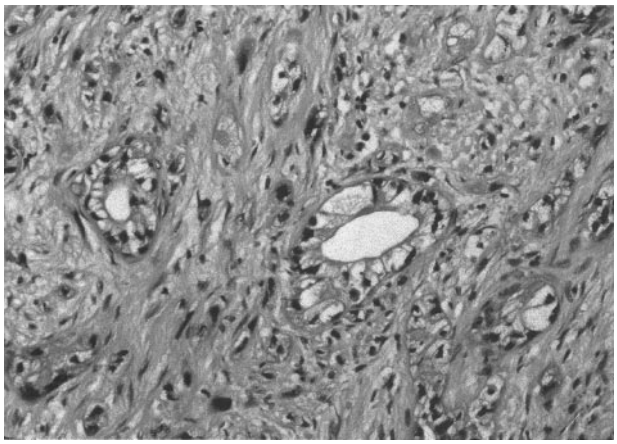

FIGURE 1 Histologic section of an adenocarcinoma of the pancreas, revealing the characteristic appearance of tumor cells embedded in dense regions of fibrosis.

supporting the hypothesis that they are precursor lesions. There appears to be a step-wise accumulation of specific genetic alterations in the continuum from normal tissue to infiltrating carcinoma, with mutations in K-ras and Her-2/neu occurring in low-grade lesions, mutations in p16 present in intermediate-grade lesions, and p53, DPC4, and BRCA2 mutations present in high-grade lesions. Although the progressive accumulation of genetic alterations has been identified, some controversy remains as to whether these lesions originate from fully differentiated duct cells or metaplastic conversion of either islet or acinar to ductal cells.

CLINICAL PRESENTATION

The early symptoms associated with pancreatic adenocarcinoma are nonspecific and therefore patients often delay seeking medical attention until the disease is advanced. A common presenting symptom, present in over 90% of patients with pancreatic cancer, is cachexia, which usually precedes a diagnosis of pancreatic adenocarcinoma by many months. A major contributor to eventual mortality, cachexia is due to weight loss from local obstructive factors causing nausea, vomiting, and anorexia as well as to elaboration of tumor factors such as tumor necrosis factor α (TNFα) and cytokines such as interferon α (IFNα).

Abdominal pain is reported at presentation in 75–90% of patients with pancreatic cancer. The pain is believed to be caused by compression of, or invasion into, perineural and splanchnic neuronal structures as well as contiguous organs and the retroperitoneum. Because of the proximity of the common bile duct and duodenum to the pancreas, tumors located in the head of the organ may grow and compress these structures. Bile duct compression leads to obstructive jaundice in 70–85% of patients with pancreatic head lesions. Compression of the duodenum leads to delayed gastric emptying and early satiety, contributing to nausea and vomiting, which is initially present in 35–45% of patients. Up to 5% of patients present with advanced tumors causing complete duodenal obstruction.

The onset of diabetes mellitus is also associated with pancreatic adenocarcinoma, with 10–15% of patients developing glucose intolerance 6–12 months prior to cancer diagnosis. The onset of diabetes appears to be due to tumor elaboration of a yet undefined factor that stimulates islet cells to secrete the prodiabetic polypeptide amylin. Amylin levels are higher in patients with pancreatic adenocarcinoma compared to patients with diabetes and other gastrointestinal malignancies, and serum amylin levels and insulin resistance abate after tumor resection.

DIAGNOSIS AND STAGING

Although the constellation of symptoms of abdominal pain, weight loss, nausea, vomiting, and obstructive jaundice is highly suggestive of pancreatic malignancy, other processes that can mimic these symptoms must also be considered. Benign biliary strictures and common bile duct stones as well as carcinoma of the bile ducts or gallbladder can cause these symptoms, as can ampullary and duodenal tumors. The possible diagnosis of pancreatic cancer is often proposed during the evaluation of obstructive jaundice by transabdominal ultrasonographic imaging. Because of multiple variables, including skill of the examiner, patient habitus, and overlying loops of gas-filled bowel limiting complete imaging, the sensitivity of transabdominal ultrasound for diagnosing pancreatic cancer has ranged from 44 to 94% in different studies. Even with optimal results, transabdominal ultrasound is not able to stage patients or determine resectablity, thus it must always be accompanied by another imaging modality.

Once a diagnosis of pancreatic cancer is suspected, the modality of choice for confirmation is a helical computed tomography (CT) scan of the abdomen with dual-phase scan acquisition. Dual-phase scans, acquired during both the arterial and the portal phases, allow for pancreatic parenchymal and arterial enhancement during the former phase, and hepatic parenchymal as well as peripancreatic venous enhancement during the later phase (Fig. 2). Enhancement of the pancreatic parenchyma allows for detection of small, hypodense

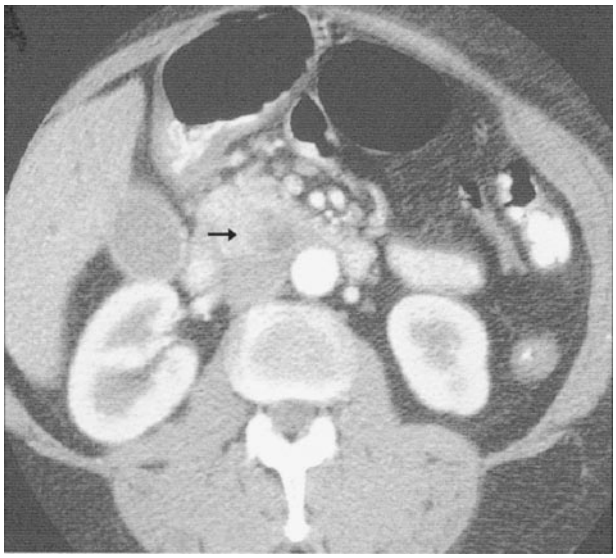

FIGURE 2 Dual-phase computer tomography scan of a patient with a mass in the head of the pancreas (arrow) representing an adenocarcinoma.

carcinomas as well as arterial involvement by the tumor, which directly affects resectability and possible cure. Tumor involvement of venous vessels and liver metastasis are delineated during the portal phase. The sensitivity of helical CT scanning to detect lesions greater than 2 cm in diameter is approximately 89%, decreasing to approximately 71% for lesions less than 2 cm in diameter, with an overall diagnostic accuracy of 97% for pancreatic adenocarcinoma.

Besides providing a diagnosis, CT scanning is useful to determine resectability of the tumor. The criteria for resectability include absence of extrapancreatic disease, the absence of tumor extension to the superior mesenteric artery and celiac axis, and a patent superior mesenteric–portal vein confluence. The accuracy of CT for predicting unresectability approaches 100%, but the accuracy for predicting resectability is only approximately 30% due to the limited ability to detect small metastases to the surface of the liver, peritoneum, lymph nodes, and peripancreatic soft tissue.

Other modalities may be used to better define resectability prior to laparotomy. However, magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) offer no diagnostic advantage over CT, having an accuracy of 90–100% in several small series. The only role for magnetic resonance imaging in evaluating for potential pancreatic malignancy is in patients allergic to the iodinated contrast material used for CT imaging, because the contrast agent used, gadolinium, is associated with a lesser incidence of severe allergic reactions. Positron emission tomography (PET) scanning with fluodeoxyglucose F 18 offers promise for delineating inflammatory from neoplastic pancreatic processes, although experience is limited and data are unavailable for assessing overall accuracy.

Endoscopic ultrasonography (EUS) is highly sensitive for diagnosing pancreatic cancer, with an overall sensitivity of approximately 93% when combining data from various studies. EUS is particularly useful for detecting small (< 2 cm) pancreatic tumors that may not be well visualized by CT, as well as in assessment of local vascular involvement. Combining EUS with fine needle aspiration (FNA) of the tumor increases the specificity of EUS alone for diagnosing pancreatic cancer.

ERCP allows for visualization of the biliary and pancreatic ductal structures and may be useful for diagnosing the cause of biliary obstruction when no mass is evident by CT scanning, such as in ampullary tumors or cholangiocarcinoma, and for differentiating focal pancreatitis from neoplasm. Dilation of the distal pancreatic and common bile ducts with proximal stricturing of both structures, the "double duct sign," is highly suggestive of adenocarcinoma affecting the head of the pancreas (Fig. 3). Data summarized from 16 studies suggest that ERCP has a sensitivity of 92% and a specificity of 96% for diagnosing pancreatic cancer. Bile aspiration for cytologic evaluation and tissue sampling by biopsy and ductal brushing can also be performed at the time of ERCP. Biliary decompression can also be achieved at ERCP if a tumor has been deemed unresectable or if a patient with symptomatic biliary obstruction will have a delay prior to resection. Multiple studies have failed to show a benefit from routine preoperative biliary decompression, and some studies have shown increased operative morbidity related to infectious complications.

In addition to radiographic and endoscopic assessment, laparoscopy has been proposed as an accurate means of evaluation for resectability prior to laparotomy. Evaluation begins with a thorough inspection of the abdomen, including the liver and peritoneal surfaces. Any suspicious nodules should be biopsied for histological assessment. Metastatic disease not identified by spiral CT can be detected in as many as 30% of patients undergoing laparoscopic staging of pancreatic cancer. The addition of laparoscopic ultrasonography to evaluate for intrahepatic and lymph node metastasis as well as unrecognized vascular invasion may further alter the management of additional patients.

Because of the limitations of detecting very early pancreatic cancers, development of a biological marker that could detect these early lesions may translate into

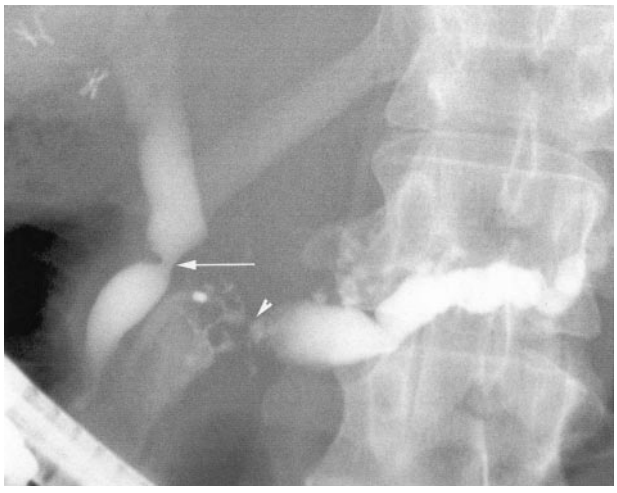

FIGURE 3 The "double duct sign." Endoscopic retrograde cholangiopancreatography of a patient with adenocarcinoma of the head of the pancreas reveals that both the common bile duct (arrow) and the pancreatic duct (arrowhead) are compressed by the tumor.

decreased mortality. Although many tumor markers have been investigated, currently none exists with acceptable specificity either for confirmation of pancreatic adenocarcinoma in equivocal cases or for routine screening.

CA 19-9 is presently the most widely used serum marker for pancreatic cancer. CA 19-9 is a sialylated Lewis^a antigen associated with circulating mucins and is expressed in normal pancreatic, biliary, and gastric epithelial cells. Although it is most frequently elevated in pancreatic adenocarcinoma, it may also be expressed in biliary, gastric, and colonic malignancies as well as in acute and chronic pancreatitis, hepatitis, and biliary obstruction. Marked elevations are found in acute cholangitis and hepatic cirrhosis. The reported sensitivities and specificities of CA 19-9 for diagnosing pancreatic adenocarcinoma are related to the serum cutoff level selected. A cutoff of 15 U/ml produces a sensitivity of 92% and a specificity of 60%, whereas a cutoff of 1000 U/ml yields a sensitivity of 40% and a specificity of 99%. When using the usual cutoff of 37 U/ml, combined studies have shown a sensitivity of 81–85% and a specificity of 81–90%.

Carcineoembryonic antigen (CEA) is commonly used as a serum marker for colon cancer. It has been investigated as a marker for pancreatic adenocarcinoma, but its sensitivity and specificity from combined studies is 58 and 75%, respectively. A higher diagnostic accuracy of 83% is observed when measuring CEA levels in pancreatic juice rather than in serum. The oncogene *K-ras* is mutated in more than 90% of pancreatic adenocarcinomas and can be detected in the pancreatic juice from 55–77% of these patients. Several reports retrospectively examining pancreatic juice specimens from patients subsequently diagnosed with pancreatic adenocarcinoma have suggested that screening for *K-ras* mutations may be effective for the early detection of pancreatic cancer, but the utility of this is limited by the finding that *K-ras* mutations are also present in some cases of chronic pancreatitis. Whether *K-ras* mutations in the setting of chronic pancreatitis predict those who are at increased risk for developing pancreatic adenocarcinoma is currently unknown.

In some cases, even after multiple diagnostic modalities have been applied, it is still impossible to differentiate pancreatic adenocarcinoma from some other inflammatory process, often chronic pancreatitis, prior to laparotomy. In these instances, particularly when a pancreatic mass is identified in the setting of antecedent chronic pancreatitis, a tissue diagnosis is not necessary prior to resection. Although this approach risks overtreating a benign process, the greater concern is undertreating a potentially curable malignancy.

SURGICAL TREATMENT

Only approximately 20% of pancreatic tumors are resectable at the time of diagnosis due to local vascular invasion in 40% of patients and metastatic disease present in 40%. Currently, the only potential cure for pancreatic adenocarcinoma is surgical resection. Because lesions originating in the head and uncinate process of the pancreas obstruct the bile duct and cause jaundice, they tend to present at an earlier stage and have a higher resectability rate than do cancers in the tail and body. The uncommon lesion in the pancreatic body or tail that is resectable may be treated by distal or subtotal pancreatectomy and splenectomy, whereas pancreatic head and uncinate lesions are treated by pancreaticoduodenectomy.

Although survival rates following pancreaticoduodenectomy are approximately 25% at 5 years with negative margins of resection, given the low postoperative mortality of 1–4% and the chance for cure, most patients with resectable disease and no prohibitive comorbidities undergo this operation. The procedure involves division of either the distal stomach, in the classic Whipple operation, or the proximal duodenum 2–3 cm distal to the pylorus in the pylorus-preserving modification, with en bloc resection of the distal common bile duct and involved portion of the pancreas along with the duodenum to the ligament of Treitz. Reconstruction consists of pancreatic, biliary, and either gastro- or duodenoenteric anastomoses, usually in that anatomical order. Typically, the proximal jejunum is used to reestablish pancreatic–enteric continuity, although the stomach is preferred by some surgeons, with roughly equivalent results.

Several important controversies surround the technical aspects of this operation. In Whipple's original description, the stomach was transected proximal to the antrum, whereas in the pylorus-preserving modification, the duodenum is transected 2–3 cm distal to the pylorus. The more extensive gastric resection was performed not only on oncologic grounds, but also to reduce the acid burden and subsequent incidence of marginal ulceration. Pylorus preservation maintains normal gastrointestinal physiology, specifically in terms of acid production, gastric reservoir and emptying functions, and hormone secretion. The rates of early postoperative delayed gastric emptying are similar for the two procedures, and pyloric preservation shortens operative time and is associated with no adverse early or late sequelae.

The extent of peripancreatic dissection is also the source of some controversy. The extended or radical pancreaticoduodenectomy entails en bloc wide

retroperitoneal lymphadenectomy and often resection of the superior mesenteric vein–portal vein confluence along with the tumor. Arguments that favor this approach claim improve resectability and cure rates, yet sufficient data are currently lacking to make a final determination. Although operative mortality rates associated with pancreaticoduodenectomy are typically 1–4%, up to half of the patients undergoing this operation will experience a complication. Approximately 30% of patients undergoing a pancreaticoduodenectomy will experience delayed gastric emptying, though to be related to decreased motilin levels, removal of the duodenal pacemaker and disruption of gastroduodenal neural connections. Erythromycin, a motilin agonist, has been found to improve gastric emptying of both solids and liquids when administered intravenously during the postoperative period.

Pancreatic fistula resulting from failure of healing at the pancreatic–enteric anastomosis, with subsequent intraperitoneal leakage of pancreatic secretions, can usually be managed conservatively if there is no evidence of abdominal sepsis. Isolated fluid collections should be drained, percutaneously if possible, and the patient should have nutrition provided parenterally and remain without oral intake. Intraoperatively, a drain is usually placed in the vicinity of the pancreatic–enteric anastomosis and should be maintained as the fistula is allowed to heal.

Intraabdominal abscesses can result from leakage at the pancreatic–enteric, gastroenteric, or hepaticoenteric anastomoses. Patients with evidence of systemic infection should be evaluated for an intraabdominal abscess and the collection should be drained, preferably percutaneously, with the initiation of appropriate antibiotics. In addition, hepaticoenteric anastomotic leaks may require a transhepatic catheter to allow for external biliary drainage.

PALLIATION OF UNRESECTABLE PANCREATIC ADENOCARCINOMA

At the time of diagnosis, 80% of patients are not candidates for potentially curative resection, narrowing their options to medical palliation for the primary disease and treatment of specific complications of pancreatic cancer. The majority of patients diagnosed with pancreatic adenocarcinoma will experience one or more of its complications, including biliary obstruction, gastric outlet obstruction, and severe abdominal pain. As well, with improvements in determining preoperative resectability of pancreatic cancer, fewer patients undergo exploratory laparotomy during which palliative procedures are performed. Palliation of the complications of pancreatic cancer may be achieved nonsurgically in most cases.

Up to 70% of patients with pancreatic cancer will develop obstructive jaundice and accompanying pruritis with an increased risk of cholangitis. In patients deemed unresectable intraoperatively, a biliary–enteric bypass may be performed for decompression. The preferred procedures involve hepatico- or choledocojejunostomy; cholecystoenterostomy is associated with a rate of recurrent jaundice of 20%. In patients deemed unresectable who do not undergo an operation, endoscopic or transhepatic radiographic placement of a biliary stent may be accomplished. Radiographically placed transhepatic catheters with exclusive external biliary drainage result in large fluid and electrolyte losses and are less desirable for palliation of obstructive jaundice in patients with pancreatic cancer. This procedure is reserved for patients who fail internal endoscopic drainage. Biliary decompression prior to planned resection should be limited to cases with severe symptoms of obstructive jaundice in which surgery is delayed.

Gastric outlet obstruction from duodenal compression will affect up to 25% of patients with pancreatic cancer and may require surgical gastric bypass for palliation. Controversy exists as to whether patients deemed unresectable at exploratory laparotomy should undergo a prophylactic gastroenteric bypass. Proponents cite the higher mortality rate, approaching 25%, for patients requiring a second operation for palliation of gastric outlet obstruction following exploratory laparotomy, as well as no increase in mortality when gastric bypass is performed at the initial operation. Increased morbidity associated with gastric bypass, most notably delayed gastric emptying, as well as increased hospital stay and overestimation of the need for gastric bypass at the time of exploration is cited by its opponents. A confounding factor in the discussion of pancreatic cancer-related gastric outlet obstruction is whether common symptoms of nausea and vomiting represent gastroparesis or true mechanical obstruction. Clearly, any patient with radiographically confirmed gastric outlet obstruction associated with pancreatic adenocarcinoma who is fit for surgery should undergo gastroenterostomy, using either an open or laparoscopic technique. Limited data are available regarding the use of endoscopically deployed duodenal stents in this setting.

Severe, debilitating abdominal pain and back pain are a frequent complication of pancreatic

adenocarcinoma, often requiring significant analgesia for adequate palliation. Chemical splanchnicectomy with 50% ethanol, performed either at the time of exploration or subsequently through the percutaneous route, has been shown to palliate pain associated with pancreatic adenocarcinoma, although its duration is limited. When performed intraoperatively, this procedure has not been accompanied by increases in morbidity, mortality, return to oral intake, or length of hospital stay.

Thoracoscopic splanchnectomy, using video-assisted thoracoscopy, transects the pain fibers in the posterior mediastinum as they course cephalad through the sympathetic chain. The short-term efficacy is clear, with 99% of patients reporting excellent analgesia and 50% reporting a sustained effect at 4 months. This procedure does involve a general anesthetic, a hospital stay, and an associated risk of complications that occur more often and are more severe compared to chemical splanchnicectomy. The role of palliative radiotherapy for pain control has been used, but has several limitations, including extended length of time for pain control to be achieved and need for repeated hospital visits.

For the 80% of patients deemed unresectable, palliative chemoradiation has been shown to increase survival and possibly to reduce severity of pain compared to untreated patients. In 1981, the Gastrointestinal Tumor Study Group (GITSG) published results of a trial in which patients surgically staged to confirm unresectability and no evidence of peritoneal or liver metastases were randomized to receive either external beam radiation alone or external beam radiation with 5-fluorouracil (5-FU). Patients treated with chemoradiation fared better in terms of median survival (49 weeks) than did those receiving radiation alone (22 weeks). Other studies have confirmed the benefit of multimodality therapy over either radiotherapy or chemotherapy alone. In a subsequent GITSG trial, patients received either combined streptozotocin, mitomycin C, and 5-FU (SMF) alone or radiotherapy with 5-FU followed by SMF. The median survival in patients receiving chemoradiation was 42 weeks, compared with 32 weeks in those assigned to the chemotherapy alone group, and 1-year survival was 41% in the chemoradiation group and 19% in the SMF alone group.

A recent advance in the chemotherapeutic regimen to treat pancreatic adenocarcinoma is the use of gemcitabine, a potent radiosensitizer. Gemcitabine has been shown to improve survival when compared to 5-FU, with reported 1- year survival rates of 18 and 2%, respectively. As well, gemcitabine appears to confer clinical benefit in terms of decreased pain intensity and analgesic consumption with improvement in overall functional status.

NEOADJUVANT THERAPY

The observation that 25–30% of patients do not receive adjuvant therapy following pancreatic resection due to prolonged recovery, perioperative complications, or patient refusal has led to the investigation of preoperative chemoradiation. Besides increasing the number of patients able to complete multimodality therapy, neoadjuvant therapy has been studied for its ability to convert locally unresectable pancreatic cancer to resectable disease. Other advantages of this modality include more effective radiation therapy to well-oxygenated cells not devascularized by surgery, reducing tumor dissemination during surgical manipulation, and targeting retroperitoneal margins of excision that may not be adequately treated surgically. As well, preoperative chemoradiation would allow an interval window for restaging prior to surgical resection so that previously occult metastatic disease could be detected, thus saving patients an unnecessary laparotomy. The utility of this approach is currently under intense investigation.

ADJUVANT THERAPY FOR RESECTABLE PANCREATIC ADENOCARCINOMA

The basis for adjuvant therapy following surgical resection with negative margins comes from a GITSG study that showed a median survival nearly twice as long for patients treated postoperatively with radiation and concurrent 5-FU compared to those randomized to observation alone (20 vs. 11 months, respectively). Single-institution studies investigating the benefit of postoperative chemoradiation compared to observation have also shown a survival benefit. Thus, the current data support the use of postoperative adjuvant chemoradiation in patients who undergo surgical resection.

FUTURE STRATEGIES

Although many recent advances have been made in the treatment of pancreatic adenocarcinoma, including lower postoperative mortality rates, neoadjuvant therapy, and addition of gemcitabine to the multimodality armamentarium, none is expected to dramatically alter the high mortality associated with this disease. The single advance that offers the most promise is elucidation of the molecular events involved in pancreatic oncogenesis, metastasis, and resistance to radiation and chemotherapy.

Understanding pancreatic adenocarcinoma on a molecular level allows for the development of targeted therapies that may be employed either alone or in combination with traditional chemoradiation. The finding that the *K-ras* oncogene is mutated and activated in over 90% of pancreatic adenocarcinomas, and that this is an early event in the accumulation of genetic damage, has prompted investigation into strategies that would block its activation. SCH 66336, a farnesyl transferase inhibitor that renders *K-ras* functionally inactive, as well as *K-ras* antisense therapy, are currently being investigated.

The p53 tumor suppressor is often mutated and functionally inactive in pancreatic adenocarcinoma, causing inhibition of a major apoptotic pathway induced by most chemoradiation therapies. Strategies to correct functional losses are more challenging than are those that inhibit gene expression or function, but one promising method is to use genetically modified adenoviruses that replicate only in p53-deficient cells. An additional challenge for pancreatic cancer is delivering the virus to the tumor target, although intratumoral injection using endoscopic ultrasound is an area of investigation. Other molecular therapeutic targets are angiogenic factors such as vascular endothelial growth factor (VEGF), which is up-regulated in pancreatic adenocarcinoma, growth stimulatory factor receptors such as the epidermal growth factor receptor and human growth factor receptor 2 (HER2), as well as matrix metalloproteinases that degrade the extracellular matrix, allowing cancer cells to metastasize. Strategies to antagonize these factors and their function have been developed and are currently being tested in clinical trials. Although the prognosis of pancreatic adenocarcinoma remains abysmal, the outlook for novel molecular strategies that would significantly reduce the mortality and suffering associated with this disease is very promising.

University of Michigan, Ann Arbor

translational control The regulation of protein synthesis at the level where the mRNA sequence is translated into the amino acid sequence on the ribosome.
zymogen granules Pancreatic acinar cell secretory granules.
zymogens Inactive precursors of certain pancreatic digestive enzymes that are activated by proteolytic cleavage.

The pancreatic digestive enzymes are a mixture of approximately 20 enzymes synthesized by pancreatic acinar cells and secreted into the pancreatic ducts. These enzymes are responsible for almost all of the activity during the lumenal phase of digestion in the intestine.

INTRODUCTION

Pancreatic digestive enzymes can be divided into four groups according to the major class of macronutrients upon which they act (Table I). There is only one major form of amylase, DNase, and RNase, possibly due to the relatively limited number of distinct chemical bonds to cleave. There is a much more diverse array of proteases, due to the increased complexity of peptide bonds as a result of the larger number of amino acids. Multiple closely related forms, termed isoenzymes, are present for many proteases, such as trypsinogens 1, 2, and 3. The biological significance of these multiple gene products is not clear. All of the pancreatic proteases, as well as phospholipase A2 and colipase, are synthesized as inactive precursors known as zymogens and designated by either the prefix "pro" or the suffix "ogen." These have little or no enzymatic activity in the pancreatic juice but are activated in the intestinal lumen by a cascade in which the intestinal enzyme enterokinase cleaves and activates trypsinogen and the released trypsin rapidly activates the other enzymes. This article addresses the general features of pancreatic digestive enzymes.

TABLE I Human Pancreatic Digestive Enzymes

Enzyme	Molecular weight (daltons)
Proteases	
Trypsinogen 1	25,000
Trypsinogen 2	25,000
Trypsinogen 3	23,400
Chymotrypsinogen	24,000
Proelastase 1	33,000
Proelastase 2	26,600
Kallikreinogen	35,000
Procarboxypeptidase A1	44,500
Procarboxypeptidase A2	47,000
Procarboxypeptidase B1	47,300
Procarboxypeptidase B2	47,300
Glycosidase	
Amylase	57,000
Lipases	
Triglyceride lipase	48,000
Colipase	10,000
Carboxyl ester hydrolase	100,000
Phospholipase A2	14,000
Nucleases	
DNase I	30,000
RNase	15,000

SYNTHESIS AND PACKAGING OF DIGESTIVE ENZYMES

All of the digestive enzymes contain a sequence in the nascent peptide that induces translation on ribosomes attached to the endoplasmic reticulum (ER). The nascent peptide is inserted through a protein channel into the lumen of the ER. There the proteins are processed and folded with the help of intralumenal chaperone proteins. The proenzymes move to the Golgi by vesicular transport and in the *trans*-Golgi network are sorted into newly forming secretory granules, termed condensing vacuoles, which are distinguishable in electron microscopic images by their lower density. With the possible help of granule membrane proteins, such as GP-2, the contents become more densely packed and lose some of their water. Mature zymogen granules then move from the Golgi to the apical region of the cell in a microtubule-dependent manner, where they await the signal for exocytosis, the process by which their contents are released into the acinar lumen. Although the concept was somewhat controversial in the past, all the different digestive enzymes synthesized in each cell are believed to be packaged in the same granules. When granules differ in enzyme content, it is believed to be due

 Copyright 2004, Elsevier (USA). All rights reserved.

to different levels of mRNA being expressed in different cells. For example, the acinar cells surrounding the islets of Langerhans have larger amounts of certain enzymes such as amylase, possibly due to locally high concentrations of insulin. The stimulation of secretion from such different regions of the gland can result in the phenomenon of "nonparallel secretion," in which the composition of secreted digestive enzymes changes in response to a physiological stimulus.

REGULATION OF DIGESTIVE ENZYME SYNTHESIS BY DIET AND HORMONES

The synthesis of digestive enzymes is regulated at several levels. Dietary adaptation occurs when the pancreas modifies its composition of different digestive enzymes in response to changes in the level of dietary protein, fat, and carbohydrate. In general, enzyme levels increase in response to an abundance of their specific dietary substrate. Thus, a high-starch diet induces the presence of more amylase and a high-protein diet induces the presence of more proteases. This effect takes 2–10 days to occur and is accompanied by changes in mRNA levels for the individual digestive enzymes. Some of these effects are well established as being hormonally mediated. Thus, insulin, which increases in response to a high-carbohydrate diet, increases amylase mRNA levels through enhanced gene transcription. Cholecystokinin (CCK) has similarly been related to a high-protein diet and secretin to a high-fat diet. These changes have been studied primarily in rodents and their relevance to the human pancreas is unknown.

The second type of regulation is the increased rate of protein synthesis due to enhanced mRNA translation that occurs following a meal. In this case, because mRNA levels are relatively unchanged, synthesis of all the digestive enzymes increases in parallel and the main function is to increase the amount of new enzyme in the cell to be ready for the next meal. This effect is mediated by the pancreatic secretagogues, CCK and acetylcholine (the latter is released from the vagal nerve), insulin, and dietary amino acids, particularly branched chain amino acids such as leucine. These all activate a biochemical pathway that involves protein kinase B (Akt) and mTOR (mammalian target of rapamycin) and leads to the activation, by phosphorylation or dephosphorylation, of specific translation factors and ribosomal proteins that are involved in the initiation and elongation stages of translation.

Pancreatic Disease, Pediatric

MARK E. LOWE
Washington University, St. Louis and St. Louis Children's Hospital

acute pancreatitis An acute condition due to inflammatory disease of the pancreas that typically presents with abdominal pain and elevated pancreatic enzymes in the blood.

chronic pancreatitis A persistent inflammatory disease of the pancreas characterized by irreversible morphological change that often causes pain or loss of exocrine function or both.

exocrine pancreas The portion of the pancreas that synthesizes and secretes the components of pancreatic juice. The juice contains digestive enzymes, water, and bicarbonate. The pancreatic acinar and ductal cells constitute the cellular components of the exocrine pancreas.

pancreatic insufficiency Decreased secretion of digestive enzymes or insulin to the extent that malabsorption or diabetes mellitus appears. Malabsorption typically manifests with steatorrhea, the presence of more than 7% of dietary fat in the stool.

Disorders of the exocrine pancreas represent a small segment of pediatric disease, but are common enough that all physicians caring for children should have a working knowledge of the pancreatic diseases that affect children. Cystic fibrosis is the most common ailment of the exocrine pancreas in children, but there are many other causes of pancreatic dysfunction and inflammation in pediatrics that present difficult diagnostic challenges. This article focuses on the disorders of the exocrine pancreas that affect children except for the pancreatic dysfunction associated with cystic fibrosis.

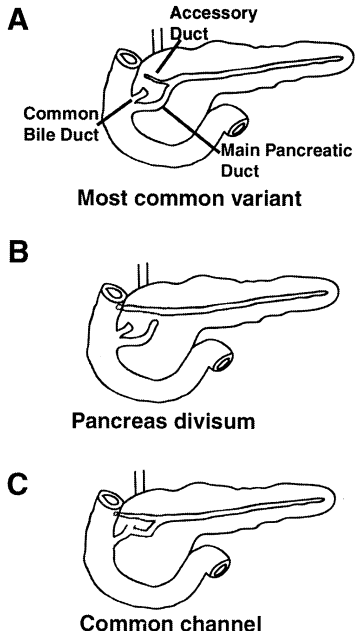

FIGURE 1 Three variations in ductal anatomy. (A) In 40–50% of people, the main pancreatic duct enters the duodenum with the common bile duct and the accessory duct regresses. (B) Five to 10% of people have pancreas divisum. The main and accessory pancreatic ducts do not connect and each duct drains into the duodenum through its own papilla. (C) The main pancreatic duct enters the common bile duct approximately 5 to 15 mm before the ampulla of Vater in approximately 5 to 10% of individuals.

CONGENITAL ANOMALIES

Pancreas Divisum

Incomplete fusion of the dorsal and ventral pancreas may result in the substitution of the dorsal pancreatic duct, which empties through the relatively small accessory papilla, for the ventral duct as the main conduit for pancreatic fluids (Fig. 1). This anatomical variant, pancreas divisum, is the most common congenital anomaly of the pancreas and the most controversial. Some believe that an anatomic or functional stenosis at the accessory papilla produces increased ductal pressure, which, in turn, causes bouts of acute and recurrent pancreatitis. Others point out that there is no causal relationship between pancreas divisum and pancreatitis and that there is disagreement among clinical studies about the incidence of pancreatitis in patients with pancreas divisum. Some studies have found an increased incidence, whereas other studies have failed to confirm those findings.

The diagnosis of pancreas divisum is best made by endoscopic retrograde cholangiopancreatography (ERCP). The role of magnetic resonance cholangiopancreatography (MRCP) has not been established in pediatric patients. Once pancreas divisum is diagnosed,

 Copyright 2004, Elsevier (USA). All rights reserved.

the decision to treat, and how to treat, is not straightforward. If the patient has had recurrent episodes of pancreatitis, most gastroenterologists opt for ERCP therapies, such as sphincterotomy with or without stenting, particularly if objective evidence of papillary stenosis exists. Rarely, a surgical drainage procedure is offered.

Common Channel Syndrome

Abnormal junctions of the common bile duct and the main pancreatic duct represent another frequently encountered ductal anomaly. In these cases, the common bile duct joins the main pancreatic duct 5 to 15 mm before the ampulla of Vater to create a common channel, which has been associated with pancreatitis, choledochal cysts, and, in adults, bile duct or gallbladder cancer. Because the juncture occurs before the sphincter of Oddi, bile can reflux into the main pancreatic duct and cause pancreatitis. Similarly, pancreatic juice can reflux into the common bile duct, a situation that may cause some choledochal cysts. Animal models support both relationships. The presentation of these patients relates to the symptoms of pancreatitis or of choledochal cysts. The latter presents with right upper quadrant pain, jaundice, and, sometimes, a palpable mass below the liver. The diagnosis can be made by ERCP, MRCP, or intraoperative cholangiogram. Treatment for choledochal cysts is excision of the cysts with a Roux-en-Y hepatojejunostomy. Therapy for an isolated common channel has traditionally been surgical, but, recently, ERCP treatments have been advocated although long-term studies of outcome after ERCP therapy are lacking.

Annular Pancreas

Annular pancreas is an uncommon developmental anomaly that is generally associated with other congenital malformations and has a particularly high incidence in patients with trisomy 21. The exact pathogenesis of annular pancreas remains unclear although most theories invoke a failure in one of the steps leading to fusion of the ventral and dorsal pancreatic buds. Symptoms of partial or complete upper gastrointestinal obstruction present at any age, but newborns represent the largest group. Radiographic studies, such as upper gastrointestinal series, ultrasound, and ERCP, can suggest the diagnosis of annular pancreas, but definitive diagnosis occurs at surgery. During surgery, the obstruction is bypassed by a duodenoduodenostomy or duodenojejunostomy.

Pancreatic Agenesis and Aplasia

Disorders of pancreatic development are rare and range from complete to partial agenesis of the pancreas. Only two cases of pancreatic agenesis and five cases of partial agenesis were described in an autopsy series of 2000 fetuses. These disorders almost certainly arise from mutations in the genetic or signaling pathways responsible for the early development of the fetal pancreas. In one patient with pancreatic agenesis, a homozygous mutation in the PDX1 gene was identified. PDX1 is a transcription factor that is required for pancreatic development in rodents and almost certainly contributed to the lack of pancreatic development in this patient.

Complete absence of the pancreas is incompatible with life and is usually diagnosed at autopsy. Newborns with this disorder have significant intrauterine growth retardation and insulin-dependent hyperglycemia. In contrast, most cases of partial pancreatic agenesis remain asymptomatic and may be diagnosed at surgery or autopsy. Only those with less than approximately 5% of normal tissue will manifest evidence of exocrine dysfunction with poor growth and fat malabsorption or evidence of endocrine dysfunction with hyperglycemia and low glucagon levels and response. With treatment of the endocrine insufficiency with pancreatic enzymes and fat-soluble diets and insulin if required, these patients may do well.

HEREDITARY DISORDERS

Shwachman–Diamond Syndrome

Shwachman–Diamond syndrome (SDS) is the second most commonly recognized cause of pancreatic insufficiency in children. Estimates of incidence for this autosomal recessive disease range from 1 in 10,000 to 1 in 50,000 live births. Although the constellation of pancreatic insufficiency and hematological abnormalities in the face of normal sweat electrolytes typifies this disorder, many other organ systems may be affected (Table I). Among these, the prominent features include short stature, skeletal abnormalities, and learning or behavioral abnormalities.

The pancreas varies in size from normal to small and has a prominent fatty infiltration, which replaces acinar tissue and can be appreciated in computed tomography of the abdomen. The ducts appear normal and pancreatic secretions have relatively normal volume with normal levels of bicarbonate and chloride. The primary defect is in the acinar cells and may involve a defective transcription factor or growth factor, which would also account for the wide range of organ involvement in SDS.

TABLE I Features of Shwachman–Diamond Syndrome

Pancreatic exocrine insufficiency
Short stature
Hematological changes
Neutropenia
Thrombocytopenia
Anemia
Myelolymphoproliferative disorders
Skeletal changes
Metaphyseal chondrodysplasia
Short or flared ribs
Clinodactyly
Delayed bone age
Recurrent infections
Liver changes
Elevated serum aminotransferases
Periportal fibrosis
Miscellaneous
Psychomotor retardation
Icthyosis
Dental abnormalities

Linkage studies suggest that the defective gene or genes locate in the peri-centrometric region of chromosome 7. At present, a specific gene has not been identified.

Most patients present in infancy with symptoms of pancreatic insufficiency. Interestingly, pancreatic exocrine function improves with age and as many as 50% of patients have normal fecal fat excretion by 4 years of age. Even so, these patients still have decreased secretion of pancreatic enzymes in pancreatic stimulation tests. This is also true of the patients who do not have steatorrhea. Analysis of pancreatic secretions in this group still reveals deficient secretion of pancreatic enzymes but at levels that permit efficient digestion of dietary fats. Thus, normal fecal fat excretion does not exclude the diagnosis of SDS.

Likewise, the bone marrow dysfunction, generally neutropenia, anemia, or thrombocytopenia, is not always found initially. Both the neutropenia and thrombocytopenia can be intermittent and multiple blood counts should be performed to aid diagnosis. The anemia is less common than the other two abnormalities and is often mild. Bone marrow biopsies in patients with SDS vary considerably and may be normal or show decreased cellularity, fat infiltration, and myeloid maturation arrest.

Therapy is symptomatic and includes optimal pancreatic enzyme replacement, fat-soluble vitamin supplementation, and aggressive treatment of febrile episodes, particularly during periods of neutropenia. Even with optimal treatment, SDS patients may not reach normal adult height. Growth hormone therapy does not appear to alter this outcome. Complications of bone marrow failure produce the most morbidity and mortality in SDS. Infections may be life-threatening in patients with neutropenia, and myelodysplasia, aplastic anemia, and acute myeloid leukemia may be significantly increased in SDS patients.

Johansson Blizzard Syndrome

This syndrome also causes pancreatic lipomatosis, but it is considerably less common than SDS, with fewer than three dozen cases described. Like SDS, the exocrine pancreatic insufficiency in this syndrome most likely results from a defect in acinar cell development, whereas duct function remains intact. In addition to exocrine pancreatic insufficiency, the syndrome includes imperforate anus, hypoplastic alae nasi, hypothyroidism, ectodermal scalp defects, deafness, and mental retardation. Other endocrine abnormalities and genitourinary defects have also been described. Unlike SDS, this syndrome does not include hematological or skeletal abnormalities.

Pearson's Marrow–Pancreas Syndrome

Described in 1979, this syndrome consists of refractory sideroblastic anemia with vacuolization of erythroid and myeloid precursors. The described patients all required repeated blood transfusions and all had failure to thrive. With increased age, many organs, such as the liver, kidney, intestine, skin, and nervous system, show abnormalities. The patients who survived infancy underwent pancreatic stimulation testing, which showed deficient secretion of digestive enzymes, decreased volume, and low bicarbonate concentrations, indicating defects in both acinar and duct cell function in distinction from SDS. At autopsy, fibrosis and acinar cell atrophy were found. Fatty infiltration was not present. Mutations, often deletions, in mitochondrial DNA have been consistently found in patients with this syndrome. The connection between mutations in mitochondrial DNA and pancreatic dysfunction has not been established, but may relate to impaired energy production in the pancreas, which must meet the high energy requirements required to produce large amounts of proteins.

Jeune Syndrome

Pancreatic insufficiency, abnormalities of the thorax, short-limbed dwarfism, cystic dysplasia of the kidneys, and hepatic portal lesions characterize this rare syndrome. The skeletal abnormalities in the thorax may

produce respiratory distress in neonates. Fibrosis and cystic lesions are found in the pancreas.

Isolated Enzyme Deficiencies

A small number of papers report patients with deficiencies of individual pancreatic digestive enzymes and of enterokinase, an intestinal brush-border enzyme that is required for activation of pancreatic zymogens. The patients with decreased levels of triglyceride lipase or of colipase, an essential cofactor for triglyceride lipase, all had evidence of fat malabsorption that was improved by pancreatic enzyme supplementation. These patients presented with oily bowel movements, but otherwise had no other symptoms and were well grown. In contrast, the two reported patients with decreased trypsin activity presented with severe growth failure, hypoproteinemia, and edema. Although the authors speculated that the patients had trypsin deficiency, the report lacked any supporting evidence for a defect in trypsin. A later report of patients with identical clinical symptoms and similarly decreased protease levels raised additional questions about the existence of isolated trypsin deficiency. In these patients, enterokinase was deficient in small bowel biopsies, endogenous enterokinase corrected the protease deficiencies, and the symptoms resolved with pancreatic enzyme supplementation. No gene defects have been described in patients with any of these purported deficiencies and until that time the existence of these isolated enzyme deficiencies is uncertain.

Hereditary Pancreatitis

First described in 1952, hereditary pancreatitis is a rare disorder causing recurrent episodes of acute pancreatitis and, in approximately 75% of patients, chronic pancreatitis. Multiple pedigrees have been well described and it is clear that hereditary pancreatitis has an autosomal dominant inheritance pattern with approximately 80% penetrance and a variable clinical course even among family members.

Recently, mutations in the cationic trypsinogen gene were linked to the development of hereditary pancreatitis in most kindreds. Two mutations, R122H and N29I, are the most prevalent and have been described in families from North America, Europe, and Japan. A few patients have other substitutions at these same amino acid positions. Additional mutations in the same gene, A16V, D22G, and K23R, have been described in a small number of patients, but these are weakly associated with pancreatitis.

The mechanism behind the increased incidence of pancreatitis in patients with mutations in the cationic trypsinogen gene remains speculative. After the description of the R122H mutation, it was speculated that the mutation interfered with the normal protective mechanisms of the acinar cells against premature activation of trypsinogen (Fig. 2). Intracellular activation of trypsinogen would permit the activation of other zymogens,

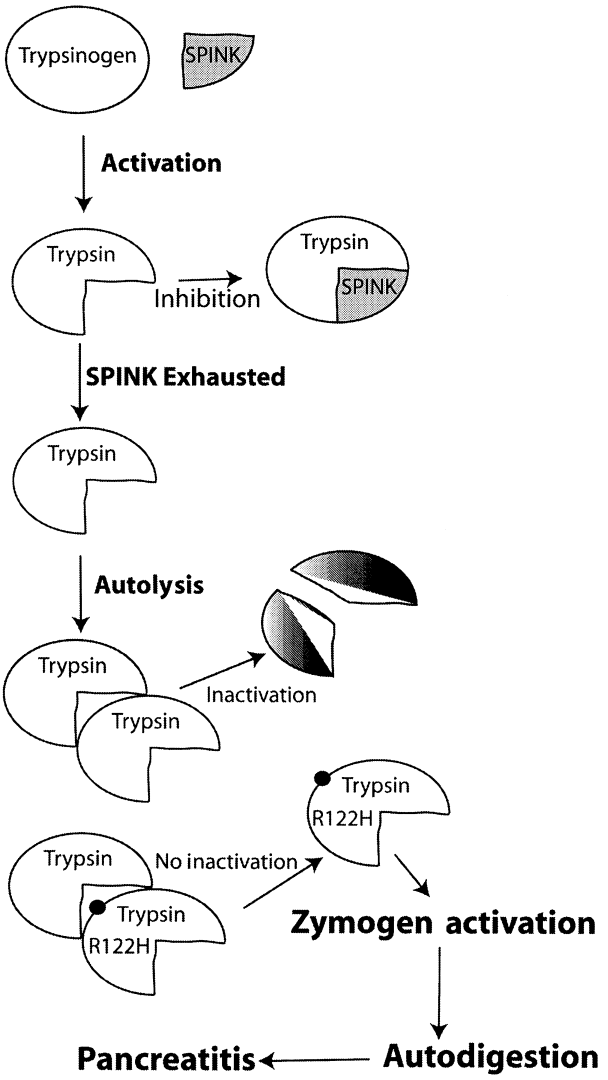

FIGURE 2 Mechanisms that protect the pancreas from premature trypsinogen activation. Acinar cells synthesize and package trypsinogen and SPINK1 or pancreatic secretory trypsin inhibitor at a 5 to 1 ratio. When trypsinogen is activated to trypsin, the first line of defense is inhibition by SPINK1. If there is enough trypsinogen activation to overwhelm the capacity of SPINK1, then trypsin autolysis provides a second line of defense. Autolysis begins with cleavage of the bond after arginine 122. In hereditary pancreatitis, the R122H mutation slows autolysis and allows trypsin to activate other zymogens. Once the zymogen activation cascade begins, autodigestion of the pancreatitis can occur and produce pancreatitis.

resulting in damage to the acinar cells. To protect against premature trypsinogen activation, the acinar cell contains an inhibitor of trypsin. This first line of defense is limited and can be overwhelmed by excessive trypsin activation. In that case, the acinar cell has a second line of defense, trypsin autolysis. Degradation begins with hydrolysis at Arg-122. In hereditary pancreatitis, the histidine substitution at position 122 prevents autolysis. *In vitro* studies on human cationic trypsinogen confirm the increased autolytic resistance of the R117H mutant and also demonstrate that the mutation interferes with multiple protective mechanisms. For instance, the mutation increases trypsinogen autoactivation. Similar studies on the R29I human cationic trypsinogen reveal that the mutation results in faster autoactivation and increased trypsin stability. Thus, both mutants can increase the trypsin levels in the acinar cells and cause increased activation of other zymogens.

Episodes of pancreatitis begin before the age of 20 in approximately 80% of patients. Pain is generally the presenting symptom and may be accompanied by nausea and vomiting. Although some authors suggest that fasting, fatty meals, alcohol, and stress may precipitate pancreatitis, the triggers for individual episodes remain ambiguous, despite the considerable progress made in understanding the pathophysiology of hereditary pancreatitis in the past 5 years. The attacks occur with variable frequency and may become less frequent and less severe with age, but this progression is not universal.

With time, the pancreas atrophies and calcifications develop in approximately 50% of patients. Pancreatic insufficiency develops in a sizable proportion of patients, perhaps as many as 75%. Diabetes mellitus is also relatively common. In some, glucose intolerance may be more troublesome during episodes of pancreatitis. As in other causes of pancreatitis, pseudocysts and hemorrhage can complicate the clinical course. Importantly, the risk of pancreatic cancer is increased above that for the general population and the cumulative risk may be 40% by age 70. The incidences of these complications have not been clearly established, in part because, until recently, identification of patients was limited to clinical diagnoses.

Treatment of acute episodes is supportive, as discussed later. Little can be done to prevent episodes. If triggers for acute pancreatitis are identified, they should be avoided. In most patients, the triggers are elusive. Even so, patients should be advised to avoid alcohol and medications known to cause pancreatitis. Antioxidant cocktails have been suggested as a way to prevent attacks, but no study has demonstrated clear benefit. Regular monitoring for complications is an important facet of patient management. Patients who develop pancreatic insufficiency should receive pancreatic enzyme and fat-soluble vitamin supplementation. Some may require insulin. Chronic pain develops in many patients and presents difficult management decisions. Narcotic analgesia may be required for long periods of time. Treating structural complications may relieve pain in some patients. Pseudocysts can be observed over time for spontaneous resorption or they may require drainage (Fig. 3). Currently, endoscopic internal drainage and external drainage by interventional radiologists offer viable options to surgery. The chronicity, size, location, and complexity of the pseudocyst all contribute to decisions about the best treatment. Generally, pancreatic duct strictures and pancreatic stones can be treated by balloon dilation and stent placement during ERCP. In some patients, surgical drainage procedures, such as a modified Puestow (longitudinal pancreaticojejunostomy), are performed in an attempt to relieve chronic pain. The success of these procedures is difficult to assess because available reports group hereditary pancreatitis with other forms of chronic pancreatitis.

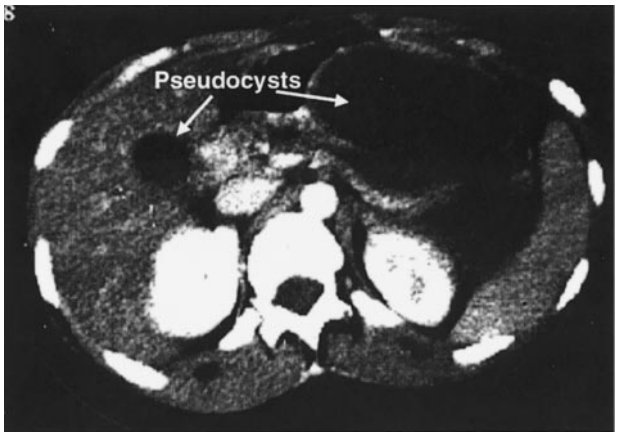

FIGURE 3 Pancreatic pseudocysts. Fluid collections are common complications of acute and chronic pancreatitis. Larger collections may persist and develop a pseudomembrane. These collections can become infected, obstruct other organs, and be a source of hemorrhage.

ACUTE PANCREATITIS

Pancreatitis in children is not common, although the true incidence has never been reliably determined. Earlier published series reported 2 to 9 cases per year in each institution. A more recent series from a large children's hospital shows a steady increase in incidence from 5 cases per year to 113 cases per year 5 years later. Whether this change represents an actual increase in incidence or in diagnosis is uncertain.

TABLE II Etiology of Pancreatitis in Childhood

Trauma
Multisystem disease
Shock
Sepsis
Rheumatological disease
Inflammatory bowel disease
Infection
Pancreaticobiliary abnormalities
Gallstones

Metabolic or genetic
Hyperlipoproteinemia I, IV, or V
Cystic fibrosis
Hereditary pancreatitis
Hypercalcemia
Protein-calorie malnutrition
Miscellaneous
Juvenile tropical pancreatitis
Perforated duodenal ulcer
Spinal surgery
Idiopathic fibrosing pancreatitis
Enteric duplication cysts
Idiopathic

There are multiple causes of acute pancreatitis in children. Trauma has always been mentioned as a leading cause of pancreatitis and accounts for approximately 20% of acute pancreatitis in childhood. The largest proportion of cases, approximately 50%, occur in patients with associated systemic illness. Approximately 15–20% of patients have idiopathic pancreatitis, 10% have pancreaticobiliary disease such as gallstones or duct anomalies, and approximately 5% of pancreatitis cases are associated with medications. Other causes contribute a small percentage of cases (Table II). Even though hereditary pancreatitis affects a small fraction of patients, these patients account for a disproportionate number of episodes and hospital admissions.

As in adults, the predominant symptom of acute pancreatitis in children is pain. Although the pain can be severe, it may be mild or even absent. Radiation to the back may occur. Nausea and vomiting may be present and sometimes the diagnosis is first suspected because of feeding intolerance when feeding is introduced in patients with systemic illness. Transient fever or jaundice can also be present. Jaundice should raise concerns about biliary tract involvement. Rarely, patients present with an abdominal mass or ascites.

The diagnosis of acute pancreatitis can be difficult because no readily available test confirms the diagnosis. Most patients are screened with serum amylase and lipase levels. There are no studies of the diagnostic performance of either amylase or lipase levels in children. Although there have been multiple attempts to determine the sensitivity and specificity of elevations in both enzymes in adults, the studies all suffer from the absence of a method to separately and absolutely document pancreatitis. It is clear that both enzymes can be normal when there is radiographic and clinical evidence of pancreatitis. Also, both enzymes can be elevated by other conditions unrelated to pancreatitis (Table III). The level of elevation is also not diagnostic although the higher the level is above the upper reference limit, the more likely there is to be pancreatic inflammation. Levels just above the upper reference limit may still be secondary to pancreatitis especially in patients who present several days after the onset of symptoms. Other pancreatic products, such as phospholipase A2, trypsin, trypsinogen activation peptide, and elastase, are also elevated in pancreatitis, but none has found widespread use in the clinical laboratory. Serum transaminases are elevated in some patients and the combination of elevated amylase or lipase and elevated serum transaminases may be more predictive of pancreatitis than elevated amylase or lipase alone.

Radiographic studies help in the diagnosis of acute pancreatitis and in defining complications of acute pancreatitis. Both ultrasound and computed tomography (CT scan) have been used to document pancreatitis. Ultrasound findings include enlargement of the pancreas, altered echogenicity of the pancreas, dilated main pancreatic duct, gallstones, pancreatic calcifications, choledochal cysts, and fluid collections, either peripancreatic or cystic. CT scan will show similar findings,

TABLE III Causes of Elevated Amylase or Lipase

Pancreatic disease	Nonpancreatic causes
Acute pancreatitis	Salivary adenitis
Chronic pancreatitis	Salpingitis
Pseudocyst	End-stage renal disease
Pancreatic ascites	Burn injury
Pancreatic cancer	Acute cholecystitis
	Upper GI endoscopy
	Diabetic ketoacidosis
	Macroamylasemia
	Macrolipasemia

TABLE IV Complications of Acute Pancreatitis

Local	Systemic
Edema	Shock
Inflammation	Pulmonary edema
Fat necrosis	Pleural effusions
Phlegmon	Acute renal failure
Hemorrhage	Coagulopathy
Abscess	Hypocalcemia
Fluid collections	Hyperglycemia
Extension to nearby organs	Distant fat necrosis

except that abnormal attenuation, rather than altered echogenicity, is seen. If the pancreas does not perfuse with intravenous contrast during the CT scan, pancreatic necrosis is likely. MRCP may be helpful in defining abnormalities of the ductal system, but its utility in pediatric patients has not been carefully studied. ERCP should be reserved for patients with unexplained recurrent episodes of pancreatitis, a prolonged episode of pancreatitis, or gallstone pancreatitis.

Medical management of acute pancreatitis is supportive and consists of providing adequate fluids and analgesia and of monitoring for metabolic complications (Table IV). Nutritional therapy should be started early in the hospitalization. Until recently, parenteral nutrition was considered the only option, but several studies show that adult patients with acute pancreatitis tolerate jejunal feeding with fewer complications than those given parenteral nutrition.

Fortunately, pancreatitis is generally not severe in children. Hemorrhagic pancreatitis and infected pancreatic necrosis can occur, but the incidence has not been adequately established. Hypovolemic shock and severe underlying systemic illness are risk factors for severe pancreatitis in children. Typically, patients with severe pancreatitis develop ominous clinical findings such as peritoneal signs, respiratory distress, or circulatory collapse. The utility of either the Ranson or APACHE II scoring system for the severity of pancreatitis has not been tested in pediatrics. The prophylactic use of broad-spectrum antibiotics in severe pancreatitis remains an unsettled issue because current evidence supporting this approach has many uncertainties and leaves unanswered a number of questions about details of therapy. Still, many clinicians would commence a course of broad-spectrum antibiotics in critically ill patients. Surgical debridement is rarely required in children, but should be considered in patients with necrosis who are deteriorating or failing to progress despite maximal supportive care.

Other complications of pancreatitis may require specific treatment. Pancreatic pseudocysts occur frequently in children and are managed as discussed earlier. Abscesses can often be treated with external drainage and intravenous antibiotics and surgical drainage is rarely necessary. Surgery may be necessary for traumatic rupture of the duct although endoscopic stenting across the disrupted duct is another option.

CHRONIC PANCREATITIS

The distinction between acute and chronic pancreatitis may present diagnostic problems, particularly in the early stages of chronic pancreatitis. To make a diagnosis of chronic pancreatitis, irreversible morphological changes in the pancreas must be present. These changes are most often determined by radiographic studies or by ERCP (Fig. 4). The presence of permanent exocrine insufficiency and diabetes mellitus in association with the morphological changes greatly aids the diagnosis. Patients with recurrent pancreatitis that is secondary to ductal obstruction may show radiographic changes similar to those seen in chronic pancreatitis and may even have evidence of decreased function, but these can improve on correction of the obstruction.

In pediatrics, cystic fibrosis is by far the commonest cause of chronic pancreatitis. Other causes, hereditary pancreatitis and SDS, have been discussed. The remaining causes occur quite infrequently. Many cases remain idiopathic despite advances in the diagnosis of genetic and structural defects. In a few affected patients, biopsy of the pancreas reveals marked fibrosis of the parenchyma with relative sparing of islets. This entity has been called juvenile idiopathic fibrosing pancreatitis and may lead to pancreatic or bile duct obstruction by fibrotic tissue. Other identifiable causes of chronic pancreatitis include hyperparathyroidism (in which the hypercalcemia is thought to cause repeated episodes of pancreatitis) and hyperlipidemias, in particular types I, IV, and V. Tropical pancreatitis is found only in tropical areas including south India and Africa and its etiology remains unknown. Autoimmune pancreatitis causes chronic pancreatitis associated with increased serum gamma globulin, autoantibodies, enlargement of the

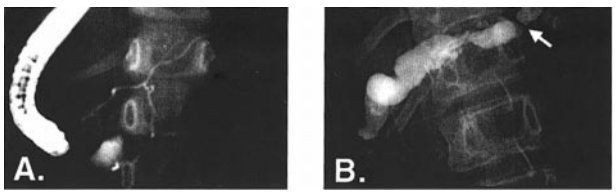

FIGURE 4 ERCP in chronic pancreatitis. (A) Normal ductal anatomy is visualized by contrast injection. (B) The dilated and tortuous main pancreatic duct in a patient with chronic pancreatitis. A stricture is present near the tail (arrow).

pancreas, which may be diffuse or localized, and a narrow main pancreatic duct. Although rare, the diagnosis is important because these patients respond to steroid therapy. To date, there have been no reports of autoimmune pancreatitis in children. The diagnosis and treatment of childhood chronic pancreatitis are the same as discussed for hereditary pancreatitis.

Pancreatic ductal adenocarcinoma is a malignancy of the exocrine pancreas that is the fifth leading cause of cancer-related deaths. Although the exact cause of this disease is unknown, factors thought to contribute its etiology include cigarette smoking and other environmental risks. The molecular mechanisms involved in the pathogenesis of these tumors include mutations in the K-ras oncogene, p53 and DPC4 tumor suppressor genes, and the p16 cell cycle regulatory protein. The clinical symptoms of pancreatic cancer include jaundice, abdominal pain, and weight loss. There is often a delay in diagnosis that contributes to the high rate of mortality resulting from the disease. Newer diagnostic and staging modalities involve the use of tumor markers, helical computed tomography scanning, magnetic resonance imaging, endoscopic ultrasound, and laparoscopy. If the tumor is localized to the pancreas, surgical resection offers the only chance of long-term cure. Adjuvant chemoradiation strategies can improve survival and decrease local recurrence. In advanced disease, palliation of obstructive jaundice, gastric outlet obstruction, and pain is important.

INTRODUCTION

In the United States, pancreatic cancer (ductal adenocarcinoma) accounts for approximately 30,000 deaths per year. The majority of patients present in the late stages of the disease with locally advanced or metastatic tumors. Only 10–20% of patients are candidates for resection and hence have any potential for cure. The signs and symptoms of pancreatic cancer vary from vague nonspecific abdominal complaints to severe jaundice and often the diagnosis can be difficult, especially in the early stages. Until the past decade or so, the traditional approach was surgical exploration for tissue diagnosis, staging, and assessment of resectability. More recently, sophisticated tests, including thin-cut helical computed tomography (CT) scan, magnetic resonance imaging (MRI), endoscopic ultrasound (EUS), biochemical tumor markers, fine-needle aspiration (FNA) cytology, and laparoscopy, have added a new dimension to the diagnosis and staging of pancreatic carcinoma. The treatment of pancreatic cancer is surgical resection, when possible. Adjuvant chemoradiation has been shown by several, but not all, studies to improve survival. The overall prognosis for these patients depends on pathologic variables of the tumor. Future strategies for earlier diagnosis and treatment are focused on the evolving knowledge of the genetic mutations that characterize pancreas cancer.

EPIDEMIOLOGY AND ETIOLOGY

Cancer of the pancreas is distinctly more common in older people with most patients between the ages of 65 and 80 at diagnosis. There is a slight male predilection for the disease with the male to female ratio being 1.3 to 1.0. The strongest association is between pancreatic cancer and cigarette smoking. Current estimates suggest that 30% of pancreatic cancer cases are due to cigarette smoking. A high-protein and high-fat diet, characteristic of the Western population, has been proposed as a possible factor. Exposure to industrial carcinogens, especially betanaphthylamine and benzidine, has been documented in pancreatic cancer patients. A higher that normal incidence rate of the neoplasm has also been reported in chemists, workers in metal industries, and coal and gas plant employees.

Diabetes mellitus has been proposed as a risk factor for pancreatic cancer. However, a large cohort study examining this issue showed that the diabetes was typically of new onset, indicating that it was brought on by the tumor. Another known risk factor is longstanding chronic pancreatitis. Such patients have a 1.8 and 4.0% chance of developing pancreatic cancer 10 and 20 years, respectively, after their initial diagnosis of chronic pancreatitis. Finally, pancreatic cancer is associated with certain inherited diseases, such as the atypical mole melanoma syndrome and hereditary pancreatitis.

PATHOLOGY AND MOLECULAR BIOLOGY

Most (95%) malignant neoplasms of pancreatic origin arise from the exocrine portion of the gland, with ductal adenocarcinomas being the most common subtype. The predominant histologic feature of these tumors is a dense collagenous stroma with atrophic acini, remarkably preserved islet cell clusters, and a slight to moderate increase in the number of ducts, both normal-appearing and cancerous (Fig. 1). The diagnosis of ductal adenocarcinoma rests on the identification of mitoses, nuclear and cellular pleomorphism, discontinuity of ductal epithelium, and evidence of perineural, vascular, or lymphatic invasion. Much more infrequent are tumors arising from the islets of Langerhans (endocrine cells

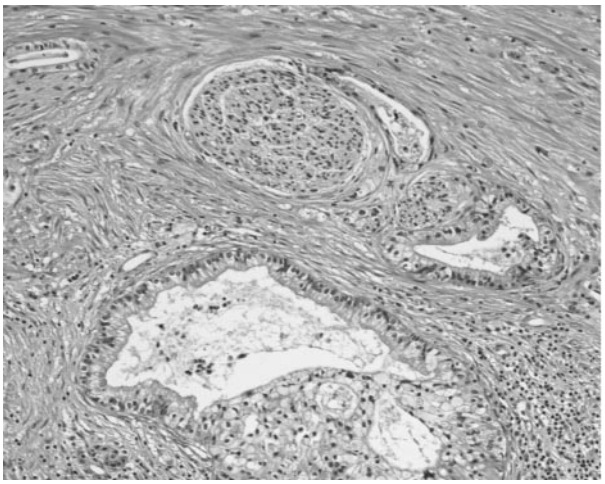

FIGURE 1 Hematoxylin and eosin section of pancreatic ductal adenocarcinoma. Note extensive fibrosis and perineural invasion.

of the pancreas). Primary nonepithelial tumors of the pancreas (e.g., lymphomas or sarcomas) are extremely rare.

Sporadic cancers of the pancreas are frequently associated with the activation of an oncogene, K-ras, and the inactivation of multiple tumor suppressor genes, including p53, *DPC4* (deleted in pancreatic carcinoma, locus 4), p16, and Rb. Up to 90% of human pancreatic cancers have ras gene mutations, most of which are K-ras mutations, and K-ras mutations seem to be an early event in pancreatic carcinogenesis. A number of studies have indicated that p53 mutations are relatively common in adenocarcinoma of the pancreas, occurring in 70% of patients. In addition, p53 mutation may be an independent prognostic factor in patients with pancreatic ductal adenocarcinoma. Mutations in the p16 gene are found in approximately 60% of pancreatic adenocarcinomas and may be associated with short patient survival. *DPC4* is inactivated in approximately half of all pancreatic cancers and, in contrast to p53 and p16, appears to be relatively specific to pancreatic cancer.

CLINICAL PRESENTATION

The clinical features of pancreatic cancer vary from vague symptoms of abdominal discomfort to anorexia, weight loss, and obstructive jaundice (Table I). The initial symptoms and signs depend on the site and extent of the pancreatic cancer. Not surprisingly, tumors of the pancreatic body and tail can grow to a very large size before obvious symptoms alert the patient or physician to the diagnosis. On the other hand, small tumors, when located in the pancreatic head, can cause obstructive jaundice or "pancreatitis," alerting the clinician to suspect pancreatic cancer.

Progressive jaundice occurs in over 75% of patients with carcinoma of the head of the pancreas and the incidence of jaundice decreases as the location of the lesion progresses to the left toward the tail of the pancreas. Occasionally, a tumor may invade and compress the third or fourth part of the duodenum without actually obstructing the common bile duct. This is often seen in cancer originating in the lower part of the uncinate process that tends to extend inferiorly into the root of the superior mesenteric vessels. Pain is extremely frequent and the classic description of painless jaundice is rarely encountered. Weight loss and anorexia are also common symptoms even in early stages. Nausea, epigastric bloating, change in bowel habits, and vomiting are occasionally present. Hematemesis and melena may sometimes occur in late cases as a result of direct invasion into the duodenal or gastric mucosa by tumor or portal vein–splenic vein compression by the tumor, leading to gastric varices. Chills and fever due to ascending cholangitis rarely occur even in longstanding biliary obstruction unless the biliary tree is contaminated by catheterization at endoscopic retrograde cholangiopancreatogram (ERCP).

Physical examination may not be pathognomonic but may aid in the diagnosis. Approximately 75% of patients with carcinoma of the head of the pancreas are jaundiced. The palpable gallbladder (Courvoisier's sign) may be present in 25% of patients with a malignant obstruction of the common bile duct. Patients with advanced disease may present with ascites, palpable supraclavicular lymphadenopathy (Virchow's node), a periumbilical mass (Sister Mary Joseph's nodule), or a palpable rectovaginal or rectovesical nodularity (Blumer's shelf). Diabetes of recent onset in elderly

patients with vague gastrointestinal symptoms should alert the physician to a possible underlying pancreatic carcinoma. Migratory thrombophlebitis (Trousseau's sign) can be present in any patient with advanced cancer, is not specifically indicative of pancreatic carcinoma, and, by itself, does not merit diagnostic laparotomy or laparoscopy.

DIAGNOSIS AND STAGING

It is clear that no clinical feature by itself is sufficiently accurate to make a definite diagnosis of, or to exclude, a pancreatic cancer. The following list should serve as a guideline to choose those patients who may warrant further investigation of the pancreas. The clinical suspicion should be increased in patients who are over 40 years of age, who are heavy cigarette smokers, and who present with any of the following symptoms: (1) obstructive jaundice; (2) unexplained recent weight loss greater than 10% of body weight; (3) unexplained upper abdominal or lumbar back pain; (4) unexplained dyspepsia; (5) sudden onset of diabetes mellitus without any predisposing factors, such as a family history of diabetes mellitus or obesity; (6) one or more attacks of "idiopathic" pancreatitis; and (7) unexplained steatorrhea. It should be remembered that the earlier the cancer, the more difficult it is to achieve a positive diagnosis, even at operation.

CA 19–9 and Other Tumor Markers

CA 19–9 was first described in 1979 as a tumor-associated antigen and later identified as a Lewis blood group-related mucin. Although initially CA 19–9 was thought to be useful in the management of patients with colorectal carcinoma, its role in pancreatic cancer became more evident. Over the past 10 years, several hundred papers have subsequently documented the utility of CA 19–9 in the diagnosis, prognosis, and monitoring of pancreatic cancer. However, as is the case with most tumor markers, the sensitivity of CA 19–9 is not perfect. Therefore, the proper role for CA 19–9 is as a diagnostic adjunct or simply as another piece of critical diagnostic information to be integrated into the diagnostic decision-making process.

When CA 19–9 reference values of >90 or >200 U/ml are used, the diagnostic accuracy for pancreatic cancer is 85 or 95%, respectively. However, there are several factors that influence CA 19–9 interpretation, most importantly the degree of jaundice. The false increase is likely because of hepatic insufficiency to degrade and excrete CA 19–9 metabolically. Additionally, CA 19–9 levels can be elevated in other tumor types, such as lung and ovarian cancers. Even in severe cases of pancreatitis, high CA 19–9 levels are noted. Interferon significantly elevates CA 19–9. Finally, patients with the Lewis blood phenotype (-a, -b) and pancreatic cancer may not have elevated levels of CA 19–9. The combined use of CT and CA 19–9 in nonicteric patients provides a positive predictive value of 99 to 100% in the diagnosis of pancreatic cancer when a reference value of 100 U/ml is used. Likewise, better results are obtained if CA 19–9 is used in conjunction with ultrasound or ERCP. A host of other tumor markers, such as CA 125, CEA, CA 494, CA 242, CA 50 SPAN-1, DU-PAN 2, and CA12−5, have been described for detection of pancreatic adenocarcinoma. Although some of these markers appear promising, most of them are not widely available and have not been tested to same degree as CA 19–9.

Ultrasonography

Real-time ultrasonography is an excellent modality for the initial evaluation of upper abdominal pain or obstructive jaundice. It does not entail exposure to ionizing radiation and is less costly and time consuming than CT scan. However, 15 to 20% of ultrasound examinations are technically suboptimal, as a result of bowel gas interference, obesity, or previous operations. Furthermore, visualization of the body, tail, and uncinate process is often marginal. Bile duct dilation defined as greater than 7 mm is commonly seen with carcinoma of the pancreatic head. However, bile duct dilation is not specific for carcinoma and may be indicative of advancing age, prior cholecystectomy, common duct stones, ampullary stenosis, and pancreatitis. Pancreatic ductal dilation, defined as ductal diameter exceeding 2 to 3 mm, is one of the most frequent secondary signs, seen in 20 to 60% of cases of pancreatic cancer. Most pancreatic cancers are hypoechoic relative to the normal parenchyma, whereas an increase in echogenicity may be found in focal pancreatitis. Ultrasonography is also useful in the detection of ascites and liver metastases. The yield of ultrasonography depends mostly on the skill of the ultrasonographer and thus may vary from institution to institution.

Computed Tomography Scanning

Thin-section helical CT scanning through the pancreas with an intravenous bolus injection of contrast remains the test of choice to evaluate the extent of disease in pancreatic cancer and to assess tumor resectability (Fig. 2). Typical CT findings of pancreatic cancer are those of a mass that deforms the size and contour of the gland. Most tumors have a central area of decreased attenuation (hypodense compared to

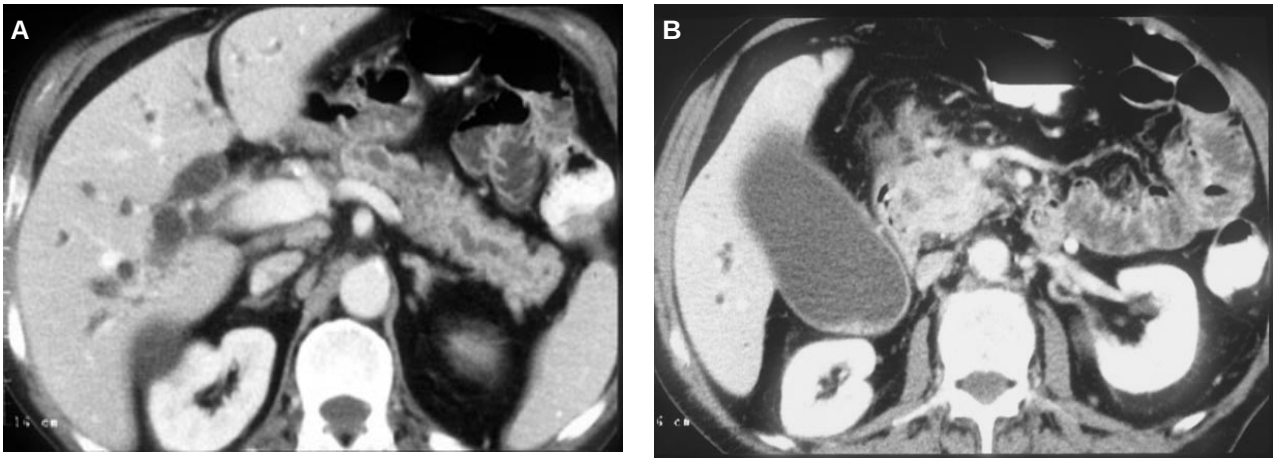

FIGURE 2 (A) CT scan showing both common bile duct and pancreatic duct dilation (double duct sign) in a patient with adenocarcinoma of the pancreatic head. (B) Note the massively enlarged, easily palpable gallbladder (Courvoisier's gallbladder).

normal pancreas). Dilation of the pancreatic duct proximal to the tumor is present in 70–80% of cases. Other common findings include pancreatic atrophy proximal to the tumor and a double duct sign if the tumor is located in the pancreatic head (Fig. 2).

The radiologic criteria for potentially resectable disease are defined as (1) the absence of extrapancreatic disease; (2) the absence of direct tumor extension to the superior mesenteric artery and celiac axis as defined by the presence of a fat plane between the low-density tumor and these arterial structures; and (3) a patent superior mesenteric–portal vein confluence (Fig. 3). In addition, CT is useful in determining the distant spread of pancreatic cancer. Liver metastases from pancreatic ductal carcinoma are hypovascular and are hypoattenuating to the liver on portal-phase scans (Fig. 3). Other common sites of metastases include the mesentery, the omentum, and the lungs. The presence of ascites usually indicates carcinomatosis and unresectability. False-negative CT scanning can be caused by small (less than 1 cm) metastasis to the liver and small peritoneal seedings.

Magnetic Resonance Imaging

Although CT scan is typically the first choice in pancreatic imaging, MRI is rapidly evolving and may play an increasing role in the evaluation of the patient

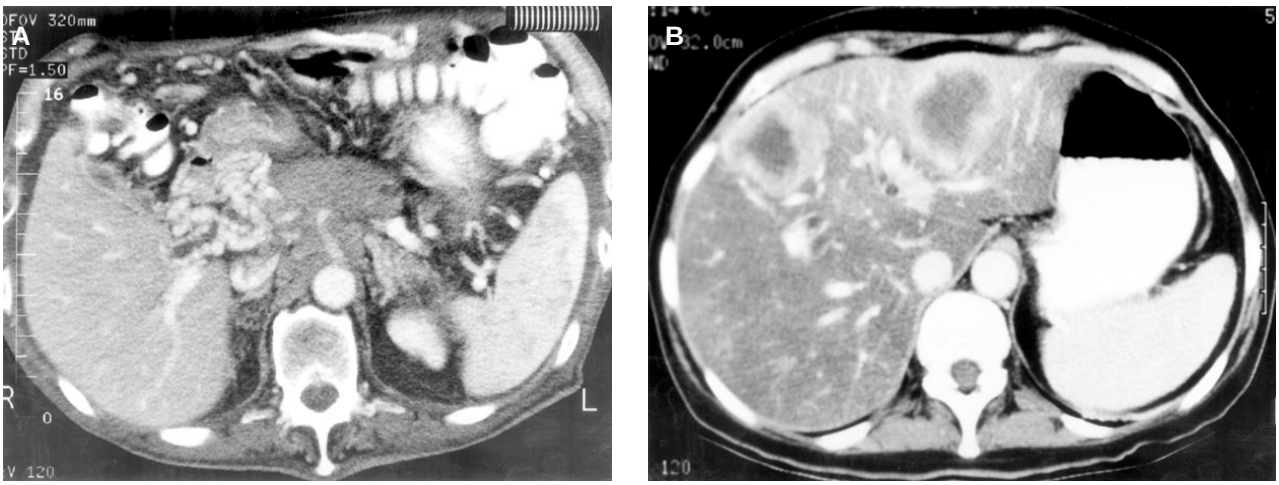

FIGURE 3 (A) CT scan of an unresectable adenocarcinoma of the pancreatic head with tumor encasement of the celiac artery. Note the extensive venous collateral secondary to occlusion of the superior mesenteric–portal vein confluence. (B) Large hypodense liver metastases in stage IV pancreatic adenocarcinoma.

with pancreatic cancer. Optimal MRI of the pancreas uses phased-array surface coils placed anteriorly on the patient's abdomen and posteriorly against the spine. Axial T1- and T2-weighted images are then obtained through the pancreas using a section thickness of 6 to 8 mm, with a 1 to 2 mm gap, respectively. On axial T1-weighted images, pancreatic abnormalities generally show decreased signal compared with the relatively high signal of the normal pancreas. Axial T2-weighted images are particularly useful in assessing the extent of inflammatory or cystic disease involving the pancreas. Duct dilation is demonstrated best on T2-weighted or magnetic resonance cholangiopancreatography (MRCP) images.

Endoscopic Retrograde Cholangiopancreatography

Until recently, ERCP played a major role in the diagnosis of pancreatic cancer. However, rapid technologic advances in newer imaging modalities, such as MRCP and endoscopic ultrasonography, are redefining the indications for ERCP. Furthermore, ERCP is an invasive test that carries a morbidity of 2 to 3%, most commonly from pancreatitis and cholangitis. Therefore, the role of ERCP in the diagnosis of pancreatic cancer is rapidly diminishing.

The utility of preoperative endoscopic stent drainage in the jaundiced patient has been controversial. Recent data suggest that preoperative biliary drainage is associated with increased morbidity and mortality rates in patients undergoing pancreaticoduodenectomy. At the Memorial Sloan Kettering Cancer Center, over half of patients undergoing a Whipple resection underwent preoperative biliary drainage (endoscopic stents, percutaneous drains/stents, or surgical drainage). Preoperative biliary drainage was determined to be the only statistically significant variable associated with infectious complications, intra-abdominal abscess, and postoperative death. These investigators concluded that stent drainage should be avoided whenever possible in patients with potentially resectable pancreatic and peripancreatic lesions.

ERCP will continue to be indicated in the patient who is not a surgical candidate. Stent drainage is widely considered a reasonable way of palliating malignant obstructive jaundice in patients who are not candidates for operative palliation. Other indications for ERCP include biliary obstruction that is not associated with a pancreatic mass. In such cases, diagnostic ERCP may reveal a nonmalignant cause of biliary obstruction such as choledocholithiasis, which can be effectively treated by sphincterotomy and stone extraction. However, diagnostic endoscopic ultrasound is emerging as the initial evaluative method, reserving ERCP for sphincterotomy and stone extraction.

Endoscopic Ultrasound

Endoscopic ultrasound produces high-frequency ultrasonographic images of the pancreas using the wall of the stomach and duodenum as an acoustical window. EUS provides an exceptional degree of anatomic detail that results in the ability to identify and stage lesions accurately. The pancreas, portal vein, celiac axis, common bile duct, gallbladder, and liver can all be visualized with EUS (Fig. 4). Although EUS itself does not provide a tissue diagnosis, the development of EUS-guided FNA makes diagnosis possible.

An abundance of data indicates that EUS is a sensitive method for the detection of pancreatic tumors. The larger series have demonstrated sensitivities of 90% or better. EUS is especially helpful for smaller lesions. In most studies, EUS is superior to transabdominal ultrasound and CT and is equivalent to ERCP for lesions that are 3 cm or smaller. Most tumors are relatively hypoechoic compared with pancreatic parenchyma, although the echo pattern becomes mixed and more variable the larger the size of the tumor. Cancers tend to have an irregular margin, sometimes with extending pseudopodia, but malignant lesions smaller than 3 cm may have a smooth margin. Unfortunately, areas of focal inflammation can also have a similar hypoechoic pattern and therefore the specificity for EUS for

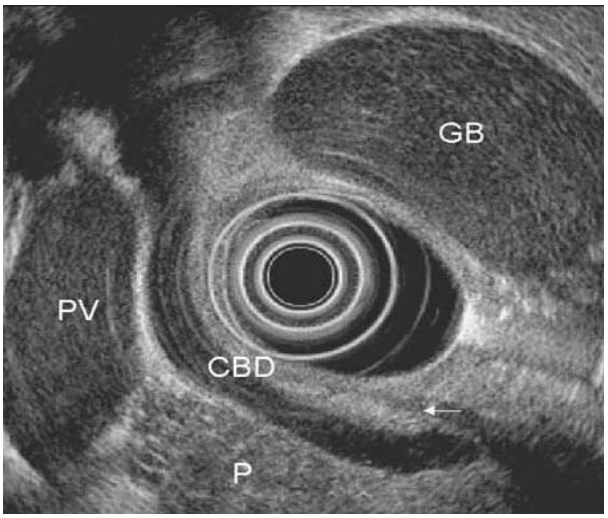

FIGURE 4 Endoscopic ultrasound of the pancreas. CBD, common bile duct; GB, gallbladder; P, pancreas; PV, portal vein.

differentiating pancreatic cancer from focal pancreatitis is approximately 70%.

Fine-Needle Aspiration Cytology

In patients with potentially resectable disease, percutaneous or endoscopic ultrasound-guided needle biopsy should be considered *only* in cases where pretreatment cytologic confirmation of the diagnosis is important, such as in patients being considered for preoperative multimodality therapy as part of a clinical trial. FNA is performed by passing a 21- to 23-gauge needle into the pancreatic mass using the appropriate imaging technique for guidance and then applying suction with a syringe. The specimen is then expressed onto a microscope slide, smeared, fixed in 95% alcohol, and stained by the Papanicolaou or other method. If an experienced cytopathologist is available, a diagnosis can generally be made within 20 minutes of obtaining the biopsy.

The typical findings of pancreatic adenocarcinoma include single or irregularly arranged clusters of cells exhibiting cellular pleomorphism, large vesicular nuclei, and prominent nucleoli. However, such cytologic appearances may sometimes fail to differentiate between an adenocarcinoma, a lymphoma, or an islet cell tumor. The main problem with fine-needle aspiration, however, is sampling error. A negative cytologic specimen does *not* exclude cancer.

FNA of the pancreas is useful for masses in the body and tail of the gland because cancers in this location are usually unresectable, especially if there is CT or EUS evidence of unresectability. It is especially valuable in the frail or elderly patient in whom one wishes to avoid a purely diagnostic laparotomy when surgical palliation is not indicated or warranted. The technique, however, should not be used for small, potentially resectable cancers because of sampling error and the theoretical possibility of seeding along the needle tract. The pancreas is a vascular organ with a rich lymphatic network. Common sense dictates that meddlesome needling can disseminate a cancer that already has a high propensity for local invasion and vascular permeation. When FNA is indicated, EUS may be the preferred approach, owing to a more direct route that does not violate the peritoneum.

Laparoscopy

Pancreatic cancer is notorious for its high predilection for liver and peritoneal metastases. Identifying small (1 to 2 mm) implants that are not definable on CT scan can now be achieved with laparoscopy. Laparoscopy is minimally invasive and can establish the diagnosis through visualization and biopsy of metastatic lesions. It can also serve as an avenue for obtaining peritoneal cytology, which can be positive in 20 to 30% of cases. With peritoneal lavage, cytologic exam of washings can be positive up to 30% of the time, indicating tumor unresectability and poor survival (median < 6 months).

The exact role of laparoscopy as a diagnostic tool and in the staging of pancreatic cancer remains to be defined. Studies by Cuschieri and Warshaw have established the value of laparoscopy in detecting liver and peritoneal metastases. However, many of their patients had locally advanced disease that was not amenable to surgical resection. When laparoscopy is limited to patients who fulfilled strict CT criteria for resectability, Fuhrman and colleagues could not confirm the diagnostic value of routine preoperative laparoscopic evaluation.

Sequence of Diagnostic Tests

The goal of preoperative diagnostic staging in pancreatic cancer is to differentiate the small group of patients who have a potentially resectable localized cancer from those with locally advanced disease and/or disseminated metastases. Figure 5 is an algorithm for the diagnosis and staging of pancreatic tumors. Patients with a clinical suspicion of pancreatic cancer should undergo physical examination and laboratory evaluation including CA 19–9 levels. Helical CT scan is the initial modality used to image the pancreas. MRI offers an alternative or adjunct to CT imaging of the pancreas. If the CT scan is equivocal, endoscopic ultrasound has been found to be useful, especially in the detection of small ampullary or periampullary neoplasms. If EUS reveals findings of unresectablity, such as superior mesenteric or celiac artery encasement, portal vein occlusion, or liver metastases, a tissue diagnosis can be established in the same session by EUS-guided FNA.

If the patient appears to have localized, surgically resectable disease by CT and EUS, it is appropriate to prepare the patient for an operation. Laparoscopy may be used as a preliminary test to detect small peritoneal or liver metastases that were not seen on initial imaging studies. The authors do not advocate routine biopsy of the mass or peripancreatic lymph nodes at surgery because these are excised *en bloc* with the specimen. On the other hand, if the tumor is found to be unresectable at operation, every attempt must be made to establish a tissue diagnosis by biopsy and frozen section histology prior to leaving the operating room. This removes any doubt about the exact diagnosis and the patient can be referred for palliative treatment.

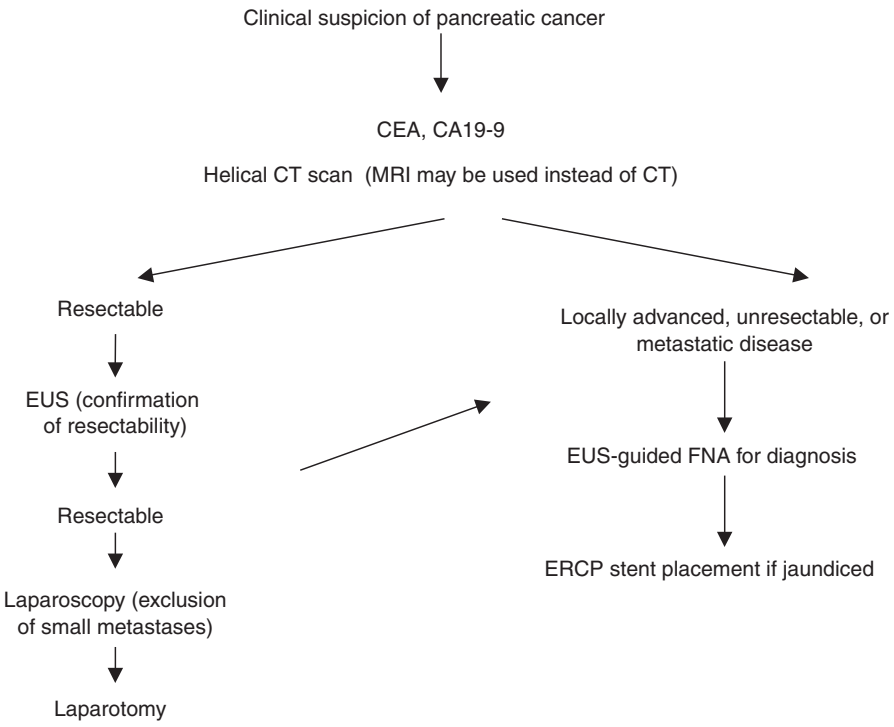

FIGURE 5 Algorithm for diagnosis and staging of pancreatic tumors.

CURRENT TREATMENT STRATEGIES AND PROGNOSIS

Emphasis must be placed on preoperative evaluation and adequate preparation of patient with pancreatic cancer. As mentioned earlier, CT scan, cytology, and EUS provide the surgeon with valuable preoperative information and obviate the need for time-consuming maneuvers on the operating table. It cannot be overemphasized that pancreatic exploration with a view to resection should not be performed by the occasional surgeon or resident in training or at institutions where there is not sufficient back-up expertise (endoscopy, radiology, cytology, and critical care) that is necessary for the care and management of these difficult problems.

Surgery

Pancreaticoduodenectomy (Whipple operation) is most commonly employed for tumors of the head of the pancreas (Fig. 6). The operation is optimal for malignant tumors that are confined to the duodenum, ampulla of Vater, or lower common bile duct. The neck of the gland is divided to the left of the superior mesenteric vein and the body and tail of the pancreas and spleen are left undisturbed. *En bloc* excision of the regional lymph nodes from the porta hepatis, aortocaval, and superior mesenteric regions again forms part of the operation. With the Whipple operation, endocrine function can be preserved. Although there is the possibility of an anastomotic leak from the pancreaticojejunostomy, this complication occurs in less than 10–15% of patients at centers experienced with pancreatic surgery. Also, more effective management of pancreatic anastomotic leakage with hyperalimentation, percutaneous drainage, and a somatostatin analogue has reduced the magnitude of this problem. Total pancreatectomy should be reserved for situations when there is tumor at the pancreatic margin on serial frozen sections or if the pancreas is not suitable for an anastomosis. A pylorus-preserving Whipple operation is a reasonable alternative but may result in transient gastric stasis.

A cancer of the pancreas is considered unresectable if there are distant (liver or peritoneal) metastases, invasion of major vessels (portal vein, hepatic artery, superior mesenteric vessels, or celiac axis), or any extension beyond the area of usual total pancreatectomy specimen. The possible exception is the case of isolated portal vein invasion provided the vein is patent. In these selected cases, portal vein resection with interposition graft placement has been described. Puckering of the

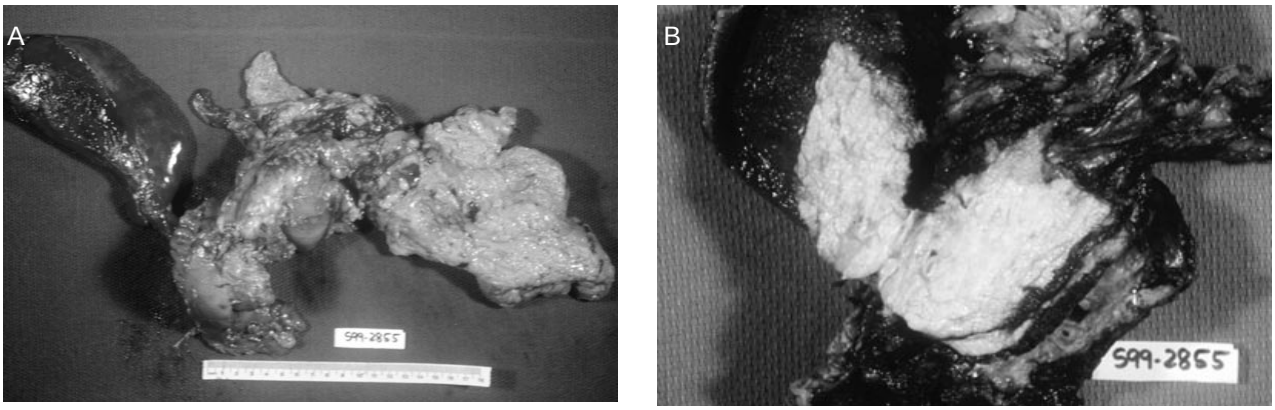

FIGURE 6 (A) Whipple specimen from a patient with pancreatic cancer. (B) The tumor is sectioned.

transverse mesocolon per se does not always indicate unresectability since the transverse mesocolon and, if necessary, the transverse colon can be excised in a total pancreatectomy specimen if there are no contraindications to a resection.

The mortality for major pancreatic resection is between 0 and 5% at specialized centers. Death as a result of operative complications usually occurs within the first 2 months of operation. After 2 months and up to 2 years later, death is usually due to metastatic pancreatic cancer although a few individuals can present as late as the end of the third year with metastatic disease. If the patient has survived 3 years, the cause of death is usually unrelated to pancreatic cancer. The estimated 5-year survival rate in patients with localized adenocarcinoma of the pancreas who undergo surgical resection of the primary tumor ranges from 6 to 24%. Survival after potentially curative resection for periampullary neoplasms including pancreatic cancer depends primarily on pathologic factors. Factors shown to influence survival include tumor size, lymph node metastases, tumor differentiation, margin status, and vascular and perineural invasion. In addition, tumors of the ampulla of Vater, distal common bile duct, and duodenum have a more favorable prognosis than that of pancreatic ductal carcinoma.

Chemotherapy and Radiation

Data from several randomized trials have shown a significant survival benefit in patients treated with infusional 5-fluorouracil (5-FU) and external beam radiation following pancreatectomy. Therefore, in patients who are well enough to tolerate it, adjuvant chemoradiation is recommended. Newer agents, such as gemcitabine, are currently being studied in combination with radiation as alternatives to 5-FU.

If diagnostic studies indicate that the patient has locally advanced, unresectable disease or metastatic disease, nonoperative palliation of jaundice can usually be achieved by endoscopically placed biliary stents. If the patient survives for more than a few months, recurrent cholangitis associated with stent blockage is a problem that necessitates regular endoscopic removal and replacement of the stent. Newer self-expandible metallic devices, such as the Wall stent, may provide improved patency rates compared to plastic stents. Percutaneous transhepatic placement of an internal expandable metal stent is being tried by interventional radiologists and offers yet another option for palliation of the jaundiced patient with malignant biliary obstruction.

If these nonoperative techniques are unsuccessful, biliary tract decompression can be performed either by cholecystojejunostomy or by hepaticojejunostomy (each with a diverting enterostomy), depending on whether the cystic duct is widely patent and is in full communication with the biliary tree proximal to obstructing cancer. When there is evidence of gastric outlet obstruction from tumor compression of the duodenum, gastrojejunostomy can be performed. Chemoradiation with 5-FU and external beam irradiation for locally advanced, unresectable tumors is indicated. If liver metastasis or carcinomatosis is found at laparotomy, single-agent chemotherapy with gemcitabine may provide palliation and improve the patient's quality of life.

CONCLUSION

Pancreatic cancer is a common cause of cancer-related mortality. Although the exact etiology for pancreatic cancer is unknown, the molecular events that take place involve mutations in oncogenes and tumor

suppressor genes. The diagnosis of pancreatic cancer continues to evolve with new technological advances in imaging, endoscopy, and biochemical tumor markers. The goal of such new diagnostic testing remains earlier tumor detection, thus providing the patient with the best chance for cure. The primary treatment for localized disease is surgical resection. Adjuvant chemoradiation has been shown by most, but not all, studies to improve local control and survival. In patients with advanced disease, palliation of jaundice, pain, and gastric outlet obstruction can be achieved by the use of stents and/or surgical bypass. Newer agents, such as gemcitabine, have been shown to improve the quality of life for patients with advanced pancreatic cancer.

Pancreatic Enzyme Secretion (Physiology)

CRAIG D. LOGSDON
University of Michigan, Ann Arbor

acetylcholine The major neurotransmitter of the parasympathetic nervous system.
cholecystokinin A gastrointestinal peptide hormone with multiple functions regulating pancreatic secretion and gastrointestinal function.
cholecystokinin-releasing peptide A trypsin-sensitive peptide whose presence in the lumen of the intestine leads to the release of cholecystokinin from intestinal enteroendocrine cells.
chyme The mixture of ingested foodstuffs with gastric secretions.
dorsal motor nucleus of the vagus A region of the brainstem that contains nuclei for vagal efferent neurons.
enteroendocrine cells Endocrine cells found throughout the epithelium of the gastrointestinal tract.
G-proteins Guanine nucleotide-binding proteins.
protein kinases Enzymes that add phosphate groups to proteins and thereby regulate their functions.
secretin A gastrointestinal peptide hormone that stimulates bicarbonate and fluid secretion from pancreatic ducts.
vagus nerve The 10th cranial nerve, which innervates much of the digestive system, including the pancreas.
zymogen granule The membrane-bound granules within pancreatic acinar cells that store digestive enzymes.

Pancreatic secretion occurs in various "phases" corresponding to the demand for pancreatic juice. The major phases are the (1) interdigestive, (2) cephalic, (3) gastric, (4) intestinal, and (5) humoral phases. The interdigestive phase is that period between meals when there is little need for pancreatic juice. The cephalic phase occurs when there is anticipation of food, perhaps due to smell, taste, or habitual behavior associated with feeding. The gastric phase begins with the ingestion of food and corresponds to that period of time when the food resides within the stomach, before entering the small intestine. The intestinal phase is the time during which the food resides within the intestine; this phase corresponds to the period when there is peak demand for pancreatic juice. The humoral phase describes the time after significant digestion has taken place and nutrient absorption has occurred, but while active digestive processes are still present. Specific regulatory mechanisms are responsible for regulating pancreatic secretion during these different phases and these regulatory mechanisms are the primary focus of this article.

INTRODUCTION

The exocrine pancreas produces a bicarbonate-rich secretion termed "pancreatic juice" that contains abundant digestive enzymes, proteins specialized for the molecular disassembly of complex organic constituents. Pancreatic juice is necessary for the proper digestion of ingested foodstuffs. Relative to its weight, the pancreas secretes more protein than any other organ. Without proper digestion, food cannot be absorbed and hence insufficient pancreatic secretion can lead to malnutrition. Furthermore, undigested food that reaches the colon promotes bloating, gas, and diarrhea. Thus, it is important that pancreatic secretion matches food intake.

Pancreatic juice originates from the exocrine pancreas, which is composed of numerous acini, cluster-like groups of acinar cells, and associated ducts. The acinar cells are responsible for the synthesis, storage within zymogen granules, and regulated release of the digestive enzymes and may also contribute to the fluid component of pancreatic juice. The duct cells provide a conduit for passage of pancreatic juice out of the pancreas and are also the primary site of pancreatic bicarbonate and fluid secretion. Because the major constituents of pancreatic juice, digestive enzymes and bicarbonate-rich fluid, originate in two different cell types, it is possible experimentally to separate the factors that influence each component. However, physiologically these components are not separated but occur in a coordinated manner with greater or lesser proportions of each being secreted depending on the demand. In addition to these two basic cell types that produce pancreatic juice, there are other important influences on pancreatic secretion. One such influence is the sphincter of Oddi. This sphincter, located at the entrance of the common bile/pancreatic duct into the intestine, regulates the flow of juice from the pancreas into the intestine and is influenced by nervous and hormonal inputs. Another influence on pancreatic secretion is pancreatic blood flow. Secretion is an energy-consuming process such that increased blood flow, supplying oxygen to the tissue, is required during

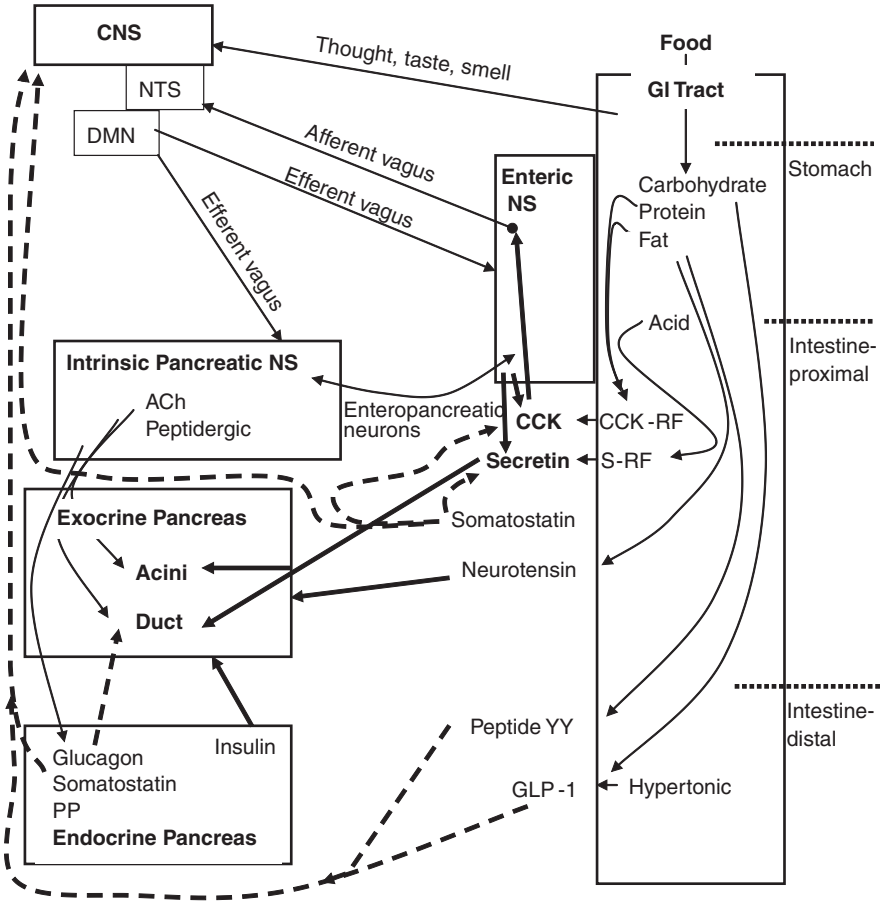

FIGURE 1 Regulation of exocrine pancreatic secretion. Pancreatic secretion of protein from acinar cells and of fluid and bicarbonate from duct cells is regulated by cholinergic (ACh) and peptidergic neurons within the intrinsic pancreatic neural network. Activity of the intrapancreatic nerves is modulated by extrinsic innervation through the vagus nerve originating in the brainstem. Vagal signals are influenced by information arising from sensory input both within the vagus and from other central nervous system (CNS) centers that are coordinated in the nucleus of the solitary tract (NTS). Pancreatic secretion is also modulated both positively (solid arrows) and negatively (dashed arrows) by hormones. Hormones arise both from the endocrine pancreas and from enteroendocrine cells within the epithelium of the intestine. Hormones can have direct effects or influence the nervous system. CCK and secretin are the major hormonal regulators of pancreatic secretion. CCK influences pancreatic secretion in humans by activating afferent neurons within the enteric nervous system. Secretin acts directly on pancreatic duct cells and synergizes with the effects of ACh on acinar cells. Somatostatin is an inhibitory substance that appears to act as a hormone on the CNS and also as a paracrine inhibitor of CCK and secretin release. Hormone-secreting cells and nerves within the gastrointestinal (GI) tract respond to the presence of specific components of chyme within specific compartments of the GI tract. The release of CCK and secretin appears to be regulated by releasing factors originating from cells within the GI tract. Signals from proximal portions of the GI tract tend to be stimulatory, whereas those from distal portions tend to be inhibitory.

active secretion and factors that diminish pancreatic blood flow reduce pancreatic secretion.

GENERAL ISSUES CONCERNING THE INTEGRATIVE PHYSIOLOGIC REGULATION OF PANCREATIC ENZYME SECRETION

Pancreatic secretion is influenced by many types of regulators, including hormones, neurotransmitters, and paracrine effectors. Figure 1 summarizes the roles of several of the major regulatory factors that will be discussed in this article. As noted in Fig. 1, the effects of regulatory substances on pancreatic secretion can occur either directly, by effects on acinar or duct cells, or indirectly, by effects on afferent neurons, the central nervous system (CNS), or enteroendocrine cells. Regulatory substances can also have interactions with one another that can be antagonistic, additive, or synergistic.

Many factors are able to influence pancreatic secretion experimentally. However, not all factors that are able to affect secretion do so in a normal physiological setting. Thus, it becomes important to distinguish between those that normally regulate pancreatic secretion, generally termed "physiological," and those that influence secretion only under experimental conditions, often termed "pharmacological." In order for a regulatory substance to be considered physiological, it must meet certain criteria. First, the concentration of the substance must increase in the physiologically relevant compartment during the appropriate phase of digestion. For a hormone, that means that plasma levels, which are relatively easy to monitor, must be elevated. For neurotransmitters or paracrine regulators, the relevant compartment is much less accessible and determination of relevant concentrations can be difficult. Second, concentrations of the candidate regulator that occur naturally must be able to influence pancreatic secretion. Again, many substances can affect pancreatic secretion at high concentrations that do not influence pancreatic secretion in normal circumstances. This criterion requires knowledge of the physiologic concentration, which is again easier for hormones than for neurotransmitters or paracrine substances. Furthermore, some regulators have important synergistic interactions with other regulators. In this case, administration of one without the other may not be sufficient to elicit a response. The third criterion is that inhibition of the regulator should influence pancreatic secretion during a normal meal. Experimental strategies to test this may include pharmacological, immunological, and genetic approaches. Each of these experimental approaches has its caveats. However, when several approaches verify the same role, then strong conclusions can be made. Similarly, it may not be possible to fulfill all three of these criteria for a specific molecule, but the more criteria that can be fulfilled, the stronger the argument for a physiologic role.

INTEGRATIVE REGULATORS OF PANCREATIC SECRETION

Neural Mechanisms

Intrinsic Pancreatic Neurons and the Enteropancreatic Neural Reflex

Intrapancreatic postganglionic cholinergic and noncholinergic neurons directly influence acinar and duct cell secretory activity. These neurons are activated by the central nervous system via the vagus nerve. Important vagovagal reflexes occur during gastric and intestinal phases of pancreatic secretion in which both afferent and efferent nerves are carried by the vagus. The vagal afferent nerve terminals in the stomach and duodenum are responsive to cholecystokinin (CCK), leptin, serotonin, interleukin-1B, and mechanical stimuli and communicate with the central nervous system. Direct neural connections have also been recently described between neurons in ganglia of the myenteric plexi of the stomach and duodenum and the intrapancreatic plexus. These enteropancreatic neural pathways have cholinergic and serotonergic components.

The Central Nervous System Controls Pancreatic Secretion through the Autonomic Nervous System

During the cephalic phase of pancreatic secretion, information from olfactory, visual and other inputs is integrated at the level of the nucleus of the solitary tract (NTS), which is located in the medulla or brainstem. Similarly, during later phases of pancreatic secretion, information arriving from vagal afferent neurons is processed in the NTS. The NTS projects to the efferent vagal neurons in the dorsal motor nucleus of the vagus. Central stimulants of vagally mediated pancreatic secretion remain to be clearly identified. However, central administration of orexin-A and thyrotropin-releasing hormone stimulates pancreatic juice flow. Central inhibitors of vagal efferent neurons include pancreastatin and pancreatic polypeptide.

The parasympathetic nervous system is the major controller of pancreatic secretion, with the vagus nerve being the primary source of parasympathetic

innervation. Activation of parasympathetic activity stimulates pancreatic fluid and enzyme secretion. In contrast, the sympathetic nervous system primarily plays an inhibitory role in regulating pancreatic secretion. Sympathetic innervation occurs chiefly through the splanchnic nerves. Splanchnic neural activation appears to inhibit pancreatic secretion largely through its vasoconstrictive effects on pancreatic blood flow.

Neurotransmitters Regulating Pancreatic Secretion

The most important stimulant of pancreatic secretion is acetylcholine released from the nerve termini of intrapancreatic neurons, which acts directly on both acinar and duct cells through the occupation of muscarinic cholinergic receptors (m3 receptors). Activation of these receptors leads to increased cellular signaling events, which result in the exocytotic release of digestive enzymes from the pancreatic acinar cell and increased bicarbonate and fluid secretion from the duct cells. Thus, inhibition of cholinergic nervous transmission, for example, by administration of atropine, inhibits both fluid and enzyme secretion.

There are also direct actions of noncholinergic, peptidergic neurotransmitters released from intrapancreatic neurons. Gastrin-releasing peptide, vasoactive intestinal peptide (VIP), and pituitary adenylate cyclase-activating polypeptide are stored in and released from intrapancreatic neurons and can act as stimulants of pancreatic secretion. These effects are more pronounced in certain animal species. Somatostatin, peptide tyrosine tyrosylamide (PYY), and enkephalins are examples of peptides that act as inhibitors of pancreatic secretion. Few of these, however, act directly on acinar cells and most inhibit the CNS or act at the level of intrapancreatic ganglia. The specific roles of these peptidergic neurotransmitters has been difficult to determine because of significant interactions between regulators and species differences in the activity of the regulators.

Hormonal Mechanisms

Pancreatic secretion is also regulated by the actions of a number of gastrointestinal hormones that originate from endocrine cells within the mucosa of the gastrointestinal tract and are therefore referred to as "enteroendocrine" cells. These hormones are released into the blood on ingestion of a meal. Individual hormones are regulated by specific components of the chyme, including both ingested foodstuffs and components secreted into the gut by mucosal cells and accessory organs. Hormones travel through the blood and can have direct effects on pancreatic acinar or duct cells via high-affinity receptors for the hormones or they may interact with afferent neurons to regulate local neural mechanisms or act on central neural sites.

Cholecystokinin

CCK is the major peptide hormone that regulates pancreatic protein secretion. CCK also influences the flow of secretions into the small intestine by relaxing the sphincter of Oddi and contracting the gallbladder. In addition, CCK reduces gastric emptying. Taken together, these actions of CCK regulate the movement of both food and digestive secretions into the small intestine. CCK also supports pancreatic secretion through its tropic effects on the pancreas. It stimulates the synthesis of new digestive enzymes and maintains the growth of the pancreas. In various species, the pancreas atrophies in the absence of intralumenal nutrients and will grow under conditions in which plasma CCK is chronically elevated, as occurs following administration of trypsin inhibitor.

CCK is produced and secreted by a specific class of intestinal enteroendocrine cells (I cells). It is released by hydrolytic products of digestion including amino acids and fatty acids. The mechanism by which these nutrients induce CCK release is not fully understood. The presence of active trypsin in the intestinal lumen inhibits CCK release in many species and ingestion of trypsin inhibitors causes high and sustained levels of plasma CCK. Diversion of the pancreatic juice from the duodenum also increases CCK plasma levels. Taken together, these observations suggest that feedback inhibition of CCK release occurs. The "feedback hypothesis" suggests that proteins bind or inhibit intralumenal endopeptidases, which would otherwise inactivate a CCK-releasing peptide. Several candidate molecules that have the ability to increase CCK release when infused into the small intestine have been identified. However, the physiological significance of these CCK-releasing peptides remains to be elucidated.

CCK plays a central role in the stimulation of pancreatic secretion during a meal. Under fasting conditions, the plasma CCK levels are very low ($\sim$1 pmol/liter in humans). After ingestion of a typical meal, the concentration increases to 6–8 pmol/liter within 10 to 30 min, followed by a gradual decline to basal levels over $\sim$3 h. Infusion of similar doses of CCK produces the same levels of pancreatic enzyme secretion. Furthermore, administration of CCK antagonists produces a 50–60% reduction of meal-stimulated pancreatic secretion.

The mechanism of CCK stimulation of pancreatic secretion appears to be somewhat determined by the species. In rodents, receptors exist on pancreatic acinar cells that can respond directly to CCK within physiologic concentrations. However, in humans, these receptors are not expressed on pancreatic acinar cells. Therefore, it appears that the major mechanism of CCK stimulation of pancreatic secretion is via an indirect mechanism that involves activation of receptors on vagal afferent neurons that are present within the enteric nervous plexus in the intestinal mucosa. These neurons communicate with the central nervous system and a stimulatory signal is conveyed back to the pancreas via vagal efferents to mediate secretion that is dependent on cholinergic signaling. The major evidence in support of this model is that the cholinergic antagonist atropine blocks pancreatic secretion in response to infusion of physiological doses of CCK. There may also be effects of CCK on enteropancreatic neurons that do not require an intact vagus nerve, as CCK can stimulate pancreatic secretion in patients after vagotomy. However, this remains unproven.

Secretin

Secretin is the intestinal peptide hormone that is the major regulator of pancreatic fluid and bicarbonate secretion. Secretin is released from intestinal enteroendocrine cells (S cells) in response to a reduction in duodenal pH. Acidic chyme entering from the stomach leads to secretin release and subsequent pancreatic bicarbonate secretion, which neutralizes gastric acid. The mechanisms responsible for secretin release remain under active investigation, but there is some evidence for a secretin-releasing factor that may be released by low-pH conditions. Nonacid factors may also play a role in secretin release. Bile, as well as fatty acids and other digestive products of fat, can increase plasma secretin levels. However, the physiologic importance of these nonacid factors is questionable, as plasma secretin does not increase in subjects in whom meal-induced acid secretion is neutralized.

Infusion of secretin at concentrations similar to those observed after a meal leads to the stimulation of pancreatic fluid and bicarbonate secretion, and neutralization of secretin, using antiserum, greatly reduces pancreatic bicarbonate release. Secretin activates specific receptors expressed on pancreatic duct and acinar cells. Thus, secretin appears to directly mediate its effects on pancreatic secretion. Secretin appears to act in synergy with CCK, as the combination of these hormones leads to much greater levels of pancreatic secretion than either one alone.

Other Stimulatory Hormones

A variety of other hormones have been reported to have stimulatory effects on pancreatic secretion. Insulin potentiates the secretory response to CCK and secretin, an observation that may explain why enzyme secretion is frequently reduced in human diabetics who otherwise do not exhibit overt pancreatic disease. The influences of insulin on exocrine secretion may also help to explain the location of the insulin-secreting cells that are within the islets of Langerhans, which are dispersed throughout the exocrine pancreas. Insulin is also critical for maintaining rates of acinar cell protein synthesis and adequate stores of digestive enzymes.

Other hormones that may be stimulatory for pancreatic secretion include gastrin, neurotensin, and motilin. Gastrin, which is structurally related to CCK, can also stimulate pancreatic secretion when infused at relatively high concentrations. However, it is unclear whether or not the serum levels of gastrin obtained after a meal are sufficient for pancreatic stimulation. Neurotensin is released from enteroendocrine cells by intestinal fatty acids and infusion of neurotensin can stimulate pancreatic secretion. However, the concentrations of neurotensin required to stimulate pancreatic secretion are higher than those normally observed after a meal. Therefore, it is unclear whether or not neurotensin is a physiological stimulant of pancreatic secretion. Motilin is a hormone that is known to regulate the cyclic interdigestive migrating motor complex that influences intestinal motility. Bolus injection of motilin also results in a transient increase in pancreatic secretion. Thus, it has been suggested that motilin may regulate the cyclic secretion of pancreatic juice during the interdigestive state.

Inhibitory Hormones

After a meal, pancreatic secretory levels decline and return to a low basal level. Much of this reduction in pancreatic secretion is due to a decrease in the levels of stimulatory signals. However, there is also evidence for inhibitory control. For example, infusion of glucose or amino acids to raise serum concentrations inhibits pancreatic secretory responses to a test meal. The release of inhibitory hormones from the islets of Langerhans, distal small intestine, and colon has been postulated to account for this observation. The most well-established inhibitory hormones include glucagon and its related peptides, as well as somatostatin, and PYY.

Glucagon and the glucagon-related molecules oxyntomodulin and glucagon-like peptide-1 (GLP-1) inhibit pancreatic secretion stimulated by secretin and CCK or by ingestion of a test meal. The inhibitory effect

includes a reduction of fluid and bicarbonate as well as enzyme secretion. Glucagon is released from pancreatic islets of Langerhans by the hyperaminoacidemia observed after a high-protein meal. Oxyntomodulin is a 37-amino-acid glucagon-containing peptide that is 10 times more potent than pancreatic glucagon in terms of its ability to reduce pancreatic secretion. Oxyntomodulin originates in enteroendocrine cells located in the distal intestine and its release is stimulated by hypertonic solutions. GLP-1 is another GI hormone derived from the glucagon precursor whose cells of origin (K cells) are located within the epithelium of the more distal small intestine. GLP-1 appears to be secreted in response to carbohydrates within the gut lumen. Glucagon, oxyntomodulin, and GLP-1 appear to inhibit pancreatic secretion via action on a central vagal site.

Somatostatin is another candidate as a physiological inhibitor of pancreatic secretion. Somatostatin is produced and secreted by both delta cells of the islets of Langerhans and enteric endocrine cells. Infusion of somatostatin inhibits CCK-stimulated pancreatic enzyme secretion. However, the concentrations required for this effect are higher than those observed in the serum under physiologic conditions. Furthermore, the mechanisms involved in the inhibitory effects of somatostatin remain uncertain. Somatostatin does not seem to exert effects on vagal afferent or efferent pathways but instead has effects on a central vagal site where it can reduce the effects of CCK. Somatostatin also has been reported to reduce the release of secretin and CCK from enteroendocrine cells and it is therefore likely that somatostatin also has a paracrine effect on CCK and secretin release.

PYY and pancreatic polypeptide are also inhibitory hormones. PYY is a 36-amino-acid peptide that is present in the distal small intestine, colon, and rectum and is released by fat and protein in the distal gut. Pancreatic polypeptide (PP) is closely related to PYY, but PP is localized in the islets of Langerhans. The only apparent physiologic actions of PP are the inhibition of pancreatic and biliary secretion. PP secretion is regulated by a cholinergic mechanism. Infusion of either PYY or PP inhibits meal-stimulated pancreatic secretions. These effects appear to be mediated by an influence on central vagal regulation of pancreatic secretion.

CELLULAR MECHANISMS REGULATING PANCREATIC SECRETION

Receptors

As described above, hormones and neurotransmitters that stimulate pancreatic secretion may do so by directly regulating acinar and duct cells or by regulating these cells indirectly through nerves or blood vessels. Determination of the physiologic regulatory pathways can be aided by analysis of effects on isolated acinar and duct cells and localization of receptors for each regulator on its target cell. For pancreatic acinar cells, the ability to stimulate amylase secretion *in vitro* is useful for determining the direct effects of agonists and antagonists. The presence of specific receptors has also been confirmed by binding studies with radiolabeled analogues and antagonists. Receptors can also be localized using electron microscopic autoradiography and confocal fluorescence microscopy. Preparations of isolated duct segments or cultured monolayers of duct cells that can be utilized to investigate direct interactions with regulatory molecules have also been developed.

Acinar cells have been found to bear receptors for CCK, bombesin, acetylcholine (m3 muscarinic), VIP, and secretin. However, important differences exist between species. For example, rodents, but not humans, express CCK_1 receptors. CCK interacts with both CCK_1 (previously CCK_A) receptors, which are highly specific for CCK, and CCK_2 (gastrin, previously CCK_B) receptors, which respond to both CCK and gastrin. Much is known about CCK_1 and m3 receptors and their signaling, because of their presence on rodent acinar cells. CCK receptors on afferent nerves appear to be of the CCK_1 type and have properties similar to those on acinar cells. It is more difficult to study the receptors regulating the pancreatic duct cells because of the relatively small number of these cells and the difficulty in studying their physiologic functions (e.g., ion transport) *in vitro*. However, studies have indicated the presence of receptors for secretin, ATP, CCK, VIP, and acetylcholine on these cells.

Transmembrane Signaling

All major secretagogue receptors are members of the seven hydrophobic transmembrane domain family of receptors that interact with guanine nucleotide-binding proteins (G-proteins) to activate intracellular signaling. The secretagogue receptors couple to the activation of heterotrimeric G-proteins that are composed of three subunits (α, β, and γ) and are usually defined on the basis of their α-subunit. The G-proteins primarily responsible for the stimulation of pancreatic acinar cell secretion are members of the G_q family, which includes G_q and G_{11}. These G-proteins regulate secretion through interactions with a phosphoinositide specific phospholipase C, leading to increases in diacylglycerol and inositol trisphosphate and ultimately protein kinase C and Ca^{2+}. Other secretagogues, such as secretin, activate G_s proteins. G_s is coupled to the activation of adenylate

cyclase and increases intracellular cyclic AMP (cAMP) and protein kinase A activity. G_s-coupled receptors are weak stimulators of acinar cell secretion but have synergistic effects when combined with receptors that activate the G_q/Ca^{2+} pathways.

It should also be noted that secretagogue receptors may have other important actions on pancreatic acinar cells, such as tropic effects or influences on enzyme gene expression, and these effects may involve other signaling pathways. CCK has been reported to activate a wide variety of effector proteins including phospholipase C, phospholipase A2, phospholipase D, protein kinase A, protein kinase C, phosphatidylinositol 3-kinase, focal adhesion kinase, tyrosine kinases, several mitogen-activated protein kinases, and stress-activated protein (SAP) kinase and the nuclear oncogenes c-fos, c-myc, and c-jun.

Mechanism of Action of Intracellular Messengers

The mechanisms by which increases in intracellular messengers act to induce protein and fluid secretion are not completely understood. It is generally held that second messengers exert their effects by changes in the phosphorylation of regulatory proteins. In addition to protein kinase C and protein kinase A (PKA), which were previously mentioned, several Ca^{2+}-activated kinases have been identified in pancreatic acinar cells including Ca^{2+}/calmodulin-activated type II and type III kinase and myosin light chain kinase. Pancreatic acinar cells also contain the major classes of serine/threonine phosphatases (i.e., PP1, PP2A, and PP2B), which may also be important for the regulation of pancreatic secretion. One of these, PP2B or calcineurin, is activated by the Ca^{2+}/calmodulin complex.

The role of intracellular messengers and effectors in pancreatic enzyme secretion is summarized in Fig. 2. Simulation of secretion normally involves synergistic interactions among intracellular messengers. In the case of acetylcholine and CCK, this includes interactions between Ca^{2+} and diacylglycerol-activated pathways. Agents such as VIP and secretin, which increase cAMP, add a further interaction at the intracellular effector level. Proteins localized on the granule and lumenal plasma membrane and several soluble and cytoskeletal proteins may be involved in exocytosis. In pancreatic duct cells, the same intracellular messengers and kinases regulate ion pumps, carriers, and channels involved in fluid and electrolyte secretion. In this case, the primary intracellular messenger is cAMP, which activates PKA, which phosphorylates cystic fibrosis transmembrane regulator, the ion channel involved in anion egress from duct cells.

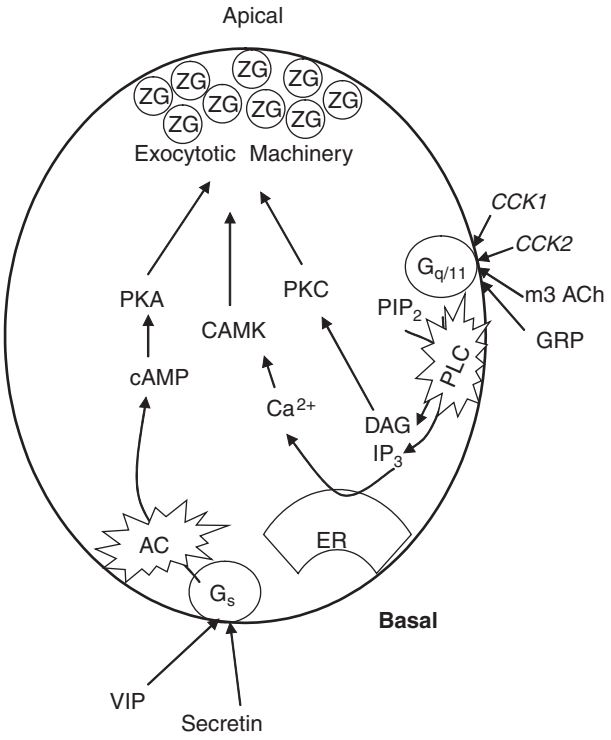

FIGURE 2 Pancreatic acinar cell stimulus–secretion coupling. The pancreatic acinar cell expresses receptors for a variety of molecules that stimulate secretion. Specific high-affinity receptors including muscarinic cholinergic (m3 ACh) and gastrin-related peptide (GRP) receptors, as well as in some species either CCK1 or CCK2 receptors or both, activate G-proteins of the G_q/G_{11} type to activate a phospholipase C (PLC), which converts phosphotidylinositide 1,4-bisphosphate (PIP_2) into diacyglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). IP_3 subsequently activates specific receptors on the endoplasmic reticulum (ER) intracellular Ca^{2+} stores, causing an increase in cytoplasmic Ca^{2+}. Increased Ca^{2+} activates Ca^{2+}-dependent kinases including calmodulin kinase (CAMK). DAG activates protein kinase C (PKC). Other stimulatory molecules, such as the neurotransmitter vasoactive intestinal peptide (VIP) and the hormone secretin, activate specific receptors that are coupled to G-proteins of the G_s type. Activation of G_s stimulates adenylate cyclase (AC) production of cyclic AMP (cAMP). Increased cAMP levels activate protein kinase A (PKA). Increased activity of the various kinases leads to activation of the exocytotic machinery, which includes membrane fusion-related molecules including Rab and soluble *N*-ethylmaleimide-sensitive attachment protein receptor (SNARE) proteins existing on zymogen granule (ZG) membranes and the apical plasma membrane, as well as cytoskeletal components including actin and microtubule networks.

Zymogen Granule Exocytosis

The terminal steps in protein secretion involve exocytotic release of enzymes from zymogen granules. This involves a membrane fusion event between zymogen granules and the apical plasma membrane. Membrane

fusion involves a number of specific membrane-associated proteins of the soluble *N*-ethylmaleimide-sensitive attachment protein receptor (SNARE) family and Rab families. The actin cytoskeleton is also involved in exocytosis, serving alternately as a barrier, preventing premature secretion, and as a potential motile element. Microtubules are also involved in the movement of zymogen granules to the apical portion of the cell, where they can interact with the exocytotic machinery.

SUMMARY

In summary, pancreatic exocrine secretion is regulated by a complex interplay of nervous, hormonal, and paracrine regulation that matches fluid, bicarbonate, and enzyme levels to meet physiologic demands. Complex interactions occur between multiple regulatory molecules and signaling pathways. The relative contribution of various components to the overall secretory function varies with the phase of secretion. Significant species differences occur with regard to receptor localization and the importance of different arms of the regulatory mechanisms.

Pancreatic Function Tests

MATTHEW J. DIMAGNO
University of Michigan Medical School, Ann Arbor

bentiromide test Tubeless pancreatic function test that indirectly measures pancreatic chymotrypsin output using bentiromide as a substrate.
cholecystokinin Gastrointestinal hormone that stimulates secretion of digestive enzymes by pancreatic acinar cells.
chronic pancreatitis Clinical diagnosis reflecting permanent or progressive deterioration in pancreatic function or structure or both.
fecal pancreatic elastase I Tubeless pancreatic function test that directly measures fecal pancreatic elastase I in stool.
malabsorption Impaired intestinal absorption of micronutrients due to either intestinal disease or maldigestion.
maldigestion Impaired digestion of macronutrients (i.e., fat), as in pancreatic insufficiency.
secretin Gastrointestinal hormone that stimulates secretion of bicarbonate and water by pancreatic ductal cells.

The exocrine function of the human pancreas is to secrete digestive enzymes that aid in absorption of dietary nutrients. Tests to measure pancreatic secretions can be invasive, requiring insertion of tubes to collect pancreatic fluids, or noninvasive, requiring oral administration of compounds and subsequent assays of stool, blood, urine, or breath components.

INTRODUCTION

Pancreatic function tests are used to measure pancreatic secretion in humans. The tests are clinically useful to discriminate between pancreatic and nonpancreatic causes of malabsorption. Pancreatic malabsorption occurs when residual pancreatic enzyme secretion is only 5–10% of normal levels, as occurs in severe chronic pancreatitis, when tests of pancreatic function are frequently abnormal. Both invasive and noninvasive tests exist. The most sensitive and specific tests, the secretin and cholecystokinin (CCK) stimulation tests, are invasive in that they require placement of a gastroduodenal tube; they are also time-consuming (2–3 hours) and are performed in only a few medical centers. "Tubeless" tests are more efficient, but, unfortunately, their clinical use is limited by their relative insensitivity to detecting mild impairments in pancreatic function, as in early chronic pancreatitis, when the secretin or CCK test may be abnormal.

TESTS REQUIRING A GASTRODUODENAL TUBE

Secretin and cholecystokinin are gastrointestinal hormones that may be given alone or together to stimulate and measure pancreatic secretion directly. This protocol, which is primarily used in research, requires placement of a double-lumen tube (Dreiling tube), which is anatomically positioned using fluoroscopy. The gastric aspiration port is positioned in the distal stomach for removal of contaminating gastric juice, while the duodenal aspiration port is positioned in the first, second, and third segments of the duodenum for removal of pancreatic juice under continuous suction. Juice removed from the duodenal port is used for analysis of pancreatic secretion, including measurements of pancreatic juice volume and bicarbonate concentration for the secretin test and trypsin and lipase output for the CCK test. For example, either in response to meals (the Lundh test) or to intravenous secretin administration, both pancreatic juice flow and juice bicarbonate concentration increase. A peak bicarbonate fluid concentration of less than 80 mEq/liter of bicarbonate indicates impaired pancreatic secretory function, suggestive of chronic pancreatitis. However, a positive test (and impaired pancreatic secretion) may occur in the absence of clinical or radiologic features of chronic pancreatitis, in conditions such as diabetes mellitus, protein-calorie malabsorption, gastric surgery, truncal vagotomy, celiac sprue, and hepatic cirrhosis.

TUBELESS TESTS

Noninvasive tubeless pancreatic function tests indirectly measure pancreatic function by relying on two bioassay principles. Patients with chronic pancreatitis may produce insufficient pancreatic digestive enzymes (e.g., lipase, chymotrypsin, amylase, elastase, and trypsin), causing maldigestion and poor absorption of foods (e.g., fat, protein, and carbohydrates), which may be measured in the stool. Alternatively, oral administration of a synthetic compound that is acted on by a specific pancreatic digestive enzyme will generate a product that may be measured in stool, blood, breath, or urine.

 Copyright 2004, Elsevier (USA). All rights reserved.

Diminished recovery of the product suggests impaired pancreatic enzymatic activity. Insensitivity and failure to detect mild disease is a problem common to all tubeless tests; bioassays in these protocols are able to distinguish reliably only among patients with moderate and severe pancreatic insufficiency. In addition, these tests are not always specific to pancreatic function; patients with normal pancreatic secretion may have a positive test result if they have hepatobiliary disease or small bowel diseases causing malabsorption (i.e., celiac sprue, Crohn's disease, or Whipple's disease) or have had prior gastric surgery.

As illustration of a tubeless test, the bentiromide test indirectly measures pancreatic chymotrypsin output. Endogenous chymotrypsin, a pancreatic digestive enzyme, cleaves orally administered bentiromide (*N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid), liberating *para*-aminobenzoic acid (PABA), which is absorbed, hepatically metabolized, and excreted in urine. Decreased recovery occurs in patients with inadequate pancreatic function, as in chronic pancreatitis. Many medications interfere with urinary measurements of free PABA and its metabolites and should be discontinued 3 days prior to the test. Because renal dysfunction lowers urinary recovery of PABA, measurement of PABA in serum rather than in urine has been developed with similar test sensitivity. An alternative but similar tubeless test is the fluorescein dilaurate (pancreolauryl) test, which measures nonspecific lipase (cholesterol esterase) activity and is slightly more sensitive than the bentiromide test.

Measurement of fecal pancreatic elastase I is the most commonly used tubeless test in the United States and Europe but is nonetheless controversial, because it has not been shown to be consistently sensitive or specific for mild or moderately impaired pancreatic secretion. The test is simple, relatively inexpensive, and involves measuring human fecal pancreatic elastase by enzyme-linked immunosorbent assay (ELISA). Unlike other pancreatic digestive enzymes, fecal pancreatic elastase levels do not change during intestinal transit, are stable in stool samples for up to 1 week, and are unaffected by concurrent use of oral pancreatic enzyme replacement therapy.

SUMMARY

Tubeless pancreatic function tests are useful for diagnosis of chronic pancreatitis in the setting of malabsorption, when the pancreas is severely damaged. In the setting of mild to moderate disease (when malabsorption is not present), the clinical utility of these tests is less well defined due to poor test sensitivity. In this situation, when a diagnosis is necessary to achieve patient management, the invasive secretin and CCK stimulation tests are preferred, if available.

Pancreatic Polypeptide Family

PETER J. MANNON
National Institute of Allergy and Infectious Diseases, Bethesda, Maryland

enteroendocrine cell A specialized epithelial cell diffusely distributed throughout the gut epithelieum that releases a hormone after exposure to luminal contents and other stimuli.
enterogastrone Intestine-derived factor released in response to intestinal fat; inhibits gastric acid secretion when administered at physiologic levels.
interdigestive motility complex A cyclic, periodic pattern of gastric and intestinal contraction during the fasting state characterized by four phases: no activity (Phase 1), uncoordinated activity (Phase 2), a brief period of sweeping peristaltic contractions (Phase 3), and a period of uncoordinated activity preceeding Phase 1 (Phase 4).
prepro hormone The precursor peptide containing all the hormone gene-encoded amino acids (including the signal peptide) before processing to the mature peptide.

The pancreatic polypeptide family of peptides consists of pancreatic polypeptide, peptide YY, and neuropeptide Y. These peptides share significant features of gene organization, amino acid sequence, three-dimensional structure, and receptor binding specificity. However, pancreatic polypeptide and peptide YY are restricted to endocrine cells of the pancreas and distal gut epithelium and are released in response to meals. Neuropeptide Y is restricted to neural tissue and is released by nerve stimulation in the manner of a neurotransmitter. Pancreatic polypeptide and peptide YY generally exert inhibitory effects on gut function, such as gastric acid secretion and gastrointestinal motility, in order to regulate the postprandial state. Neuropeptide Y is better known for its effects on the cardiovascular, endocrine, and central nervous systems, but it also exerts inhibitory effects on gut secretion and motility.

INTRODUCTION

The pancreatic polypeptide family of peptides includes pancreatic polypeptide (PP), peptide YY (PYY), and neuropeptide Y (NPY). These peptides are related by a high degree of sequence homology among their 36 amino acids as well as by a shared hairpin-like tertiary structure. These similarities are thought to reflect origins from common ancestral genes, gene duplications resulting in new peptides, and peptide sequence conservation related to evolutionary pressures. However, there has been significant divergence of distribution, production, and actions of these peptides, with PP and PYY produced by endocrine cells of the pancreas and the gut epithelium, respectively, and NPY produced by neurons in the peripheral and central nervous systems.

Family Discovery

Pancreatic polypeptide was the first family member to be purified and identified by amino acid sequence following its recognition as a persistent contaminant of insulin preparations. In contrast, peptide YY and neuropeptide Y were both discovered using a strategy to isolate novel peptides that have been amidated at their C terminus, a biochemical modification often indicating innate bioactivity in peptides. Peptide YY and neuropeptide Y were isolated from extracts of porcine intestine and brain, respectively. The purification and amino acid sequence of all of these peptides were completed in advance of establishing their biological effects.

Peptide Structure

The three-dimensional structures of the peptides in this family, deduced from crystallography and molecular modeling, have helped to explain the stability of these molecules and the specificity of interaction with receptor proteins. The structure is best described as two helices running antiparallel to each other; there is a polyproline type II helix (amino acids 1–8) connected to an α helix (amino acids 14–32) connected by a type II β turn and stabilized by hydrophobic interactions between the helices. The C-terminal hexapeptide is flexible, projecting from the base of the molecule. Much of the receptor binding specificity is found in the close approximation of amino acid residues from the two ends of the molecule, as well as the terminal hexapeptide composition.

PANCREATIC POLYPEPTIDE

Tissue Distribution

Pancreatic polypeptide expression is restricted to endocrine cells found predominantly in the pancreas, where they can exist as part of the endocrine islets or as single or groups of cells in the exocrine pancreatic tissue, and less often in the epithelium of pancreatic ducts. The density of PP-containing cells is highest in the pancreatic head, and the tissue concentration of PP is five to eight times higher in the pancreatic head compared to the tail. The PP-immunoreactive cells have also been reported in the gastric mucosa of some adult mammals (dog, cat, opossum) and in the human colon.

Gene Organization

The human gene for pancreatic polypeptide is made up of four exons and three introns that encode the 95-amino-acid pancreatic polypeptide prepro hormone. Exon 1 encodes the 5′ untranslated region, exon 2 encodes a 29-amino-acid signal peptide and PP, exon 3 encodes a 23-amino-acid extension, and exon 4 encodes a further 7-amino-acid extension and the 3′ untranslated region. Posttranslational processing produces the 36-amino-acid peptide with an amidated C-terminal tyrosine residue.

Mechanisms of Pancreatic Polypeptide Release

Pancreatic polypeptide is primarily released following nutrient ingestion and requires an intact vagus nerve for full response. PP release occurs with all phases of feeding, including the cephalic, gastric, and intestinal phases. The cephalic phase, induced by sham feeding in animals or spit-and-chew techniques in humans, stimulates between 10 and 20% of the total meal-stimulated PP response. The cephalic-phase release of PP enhances further PP release during the gastric and intestinal phases that follow. The early phases of meal-stimulated PP release depend on vagal input. The cephalic-phase PP release is blocked by anticholinergic drugs and truncal vagotomy. Similarly, gastric distension resulting in PP release is blocked by anticholinergic drugs and vagotomy. Vagal activity, whether by direct electrical vagal stimulation or stimulation by insulin hypoglycemia, can increase PP serum levels.

In contrast, the intestinal phase of the feeding response, simulated by administering nutrients directly into the duodenum, does not depend on the neural reflexes mediating the cephalic phase and gastric distension responses. Although intestinal-phase PP release is optimized by intact vagal inputs, it still occurs after vagotomy, likely through remaining local enteric–pancreatic neural reflexes. Moreover, it is thought that intestinal-phase feeding also involves other nutrient-stimulated hormones—cholecystokinin (CCK), for instance—that contribute to the later increases in meal-induced PP release. The hormonal regulation of PP release during intestinal digestion is complex and not well defined.

Serum pancreatic polypeptide levels in the fasting state vary rhythmically with the hormonal and motility events that characterize the interdigestive motility complex. Basal PP levels peak through phases 1 to 3 and then return to low levels during phase 4. These basal PP level fluctuations are abolished by local ganglionic blockade and anesthetic use, supporting a role for neural reflexes in this response. Finally, average basal (fasting) pancreatic polypeptide levels increase with age.

Pancreatic Polypeptide Receptors

The Y4 receptor, the high-affinity receptor for pancreatic polypeptide, has been cloned and sequenced from many mammalian species, including rodents, pigs, and humans. The Y4 receptor is a member of the G protein-coupled receptor superfamily, and Y4 receptors have dissociation constants in the range of 20–40 p*M* for same-species cognate ligands (human PP for the human PP receptor, for instance). However, Y4 receptors are only PP preferring and not PP specific, allowing binding of PYY and NPY peptides at 100-fold lower affinities. In certain species, PP binds to the Y5 receptor (human and bovine PP have high binding affinity, and rat PP has low binding affinity, for the rat PP Y5 receptor), although with lower affinity than NPY or PYY. Last, lower vertebrates possess a PP receptor that also recognizes PYY.

Pancreatic polypeptide receptors have been reported in the gut, pancreas, brain (hypothalamus, hippocampus, and vagal nuclei of the brain stem), and kidney of various species.

Pancreatic Polypeptide Biological Actions

There is limited understanding of the physiologic role of pancreatic polypeptide. Two biologic effects that pancreatic polypeptide exerts in a number of species are inhibition of exocrine pancreatic secretion and inducing relaxation of the gallbladder. When PP is administered to produce serum levels attainable after meals, stimulated pancreatic enzyme secretion in dogs and humans is inhibited. Reduced bilirubin secretion into the duodenum after PP infusion is also noted in humans, and decreases in intraluminal gallbladder pressure (pigs) and increased gallbladder filling are seen in animal models. Because these effects occur at

nonpharmacologic serum levels, they are interpreted as being possibly physiologic responses. The effect on the pancreas could act as a negative feedback signal to turn off meal-stimulated pancreatic secretion and the gallbladder effect could preserve extrahepatic bile excretion between meals.

Other effects attributed to PP include inhibition of gastric secretion (at high doses in dogs; no effect at lower doses in humans), modulation of gastric emptying, and modest inhibition of feeding when administered peripherally (accompanied by decreased gastric emptying) and stimulation of feeding when given centrally (accompanied by increased gastric emptying). However, hypersecretion of PP in humans due to PP-producing tumors produces no symptoms, and elevated PP levels in rats transgenic for the PP gene are associated with only modest inhibition in food intake and gastric emptying. On the other hand, patients with Prader–Willi syndrome (congenital obesity, hyperphagia, hyperglycemia, and hyperinsulinemia) have abnormally low basal and meal-stimulated levels of PP; PP administration can diminish their hyperphagia through an unknown mechanism.

PEPTIDE YY

Tissue Distribution

Peptide YY is predominantly expressed in endocrine cells but is also produced by neurons in certain species. The primary source of serum PYY released into the bloodstream is enteroendocrine cells in the distal gut epithelium; PYY-immunoreactive cells can be found in the upper small intestine of many mammals, but the concentration of these cells increases in an aboral direction, whereby the colon and rectum have the highest density of PYY-producing cells. The PYY-containing cells have a flasklike appearance characteristic of open-type endocrine cells, with a wide base containing the secretory granules and a thin apical arm extending to the gut lumen. A large proportion of the PYY-containing granules also contain proglucagon-derived peptides such as glicentin and glucagon-like peptides 1 and 2.

PYY is also contained in endocrine cells in the gastric mucosa of a few adult animal species, but these are a minor proportion of total PYY-containing cells. PYY can colocalize with glucagon (rats and mice) and PP (dogs and pigs) in pancreatic endocrine cells and in specialized epithelium of alveolar ducts (Syrian golden hamsters). Peptide YY has been found in neural structures of the enteric nervous system, including myenteric ganglia and serosal ganglia. Central nervous system localization of PYY has also been made in the hypothalamus, brain stem, and spinal cord of the rat.

Gene Organization

The human gene for peptide YY is also made up of four exons and three introns that span approximately 1.2 kb and encode a 97-amino-acid prepro hormone. Exon 1 encodes the 5′ untranslated region, exon 2 encodes a 28-amino-acid signal peptide and most of PYY, exon 3 encodes the C-terminal PYY tyrosine and a 26-amino-acid extension, and exon 4 encodes a further 7-amino-acid extension and the 3′ untranslated region. Posttranslational processing produces the 36-amino-acid peptide with an amidated C-terminal tyrosine residue. The structure of this gene is so similar to that of the human PP gene that it is thought to be the result of a gene duplication event.

Peptide YY has also been discovered to exist as a 34-amino-acid peptide, PYY 3–36, in some species, including humans. This shortened form is likely due to proline dipeptidyl peptidase IV digestion of the full-length peptide. PYY 3–36 can account for up to 50% of total PYY activity in postprandial human serum, and has affinity for Y receptors that bind C-terminal fragments of PYY and NPY. Last, the prostate- and testis-restricted 33-amino-acid human seminal plasmin peptide (so-called PYY2) is homologous to the 12 amino-terminal residues of human PYY, but does not appear to have binding activity at Y receptors.

Mechanisms of Peptide YY Release

Peptide YY is released in response to ingested food, presumably to coordinate postprandial gastrointestinal reflexes. In humans, PYY serum levels begin to increase within 30 minutes of a meal and reach a plateau after 1–2 hours. The maximum level is maintained for up to 4 hours and then returns slowly to baseline. It is hypothesized that the early increase is due to signals from the duodenum because ingested nutrients have not had time to reach the distal gut for direct stimulation of PYY-containing cells. There are data to support a neurohumoral mechanism regulating PYY release from the distal gut by upper intestinal stimuli, but this is only found in certain species.

There is evidence that gastrin and CCK may be involved in the early postprandial PYY release. Gastric acid secretion stimulated by meals (in dogs) contributes to gastric-phase PYY release because early PYY release can be blocked by histamine receptor blockade and proton pump inhibitors. Gastrin has been found to inhibit PYY release from intestinal endocrine L cells, so the inhibition of gastrin release accompanying gastric acid secretion may remove this inhibitory input on PYY secretion. In rats treated with proton pump inhibitors, the resulting increases in gastrin levels are thought to

be responsible for the decrease in PYY content and mRNA levels in the colon because this effect is blocked by a gastrin/CCK-B receptor antagonist. Furthermore, in dogs, CCK infusion increases PYY levels, and this effect can be blocked by CCK-A receptor antagonists. It is not clear if CCK acts directly on PYY-secreting cells or via intermediate neural pathways.

Neural factors play a role in physiologic PYY release. For instance, there may be a baseline inhibitory effect of intact gut innervation on PYY release because truncal vagotomy, general anesthesia, and jejunoileal denervation enhance meal-stimulated PYY release in dogs. On the other hand, a PYY-releasing signal from the duodenum to the distal gut can be interrupted by atropine (in dogs, not rats), hexamethonium (dogs and rats), truncal vagotomy (rats), and CCK receptor antagonists (dogs, not rats). In addition, adrenergic, cholinergic, and certain peptidergic (bombesin, gastrin-releasing peptide) stimuli have been shown to stimulate PYY release, but the physiologic relevance of this is unknown.

The majority of postprandial PYY release is related to exposure of the distal small bowel and colon to the luminal remnants of a meal. In humans, peptide YY is released in proportion to the calorie content (higher levels with more calories) and nutrient composition of a meal (fat meals stimulate significantly more PYY release compared to isocaloric protein or carbohydrate meals). This is consistent with the effect on PYY release following direct instillation of specific nutrients into the distal gut. Administration of oleic acid to distal intestinal epithelium can result in PYY release (seen in dog, cat, rat, and human models). However, the most consistent effect is seen with combinations of oleic acid and bile salts, specifically taurocholate and deoxycholate; oleic acid by itself may have no effect on PYY release (in humans, for instance). Although bile salts enhance the effect of fatty acids on PYY release via direct epithelial contact, they can also have similar stimulatory effects on their own. Glucose and protein or amino acids can also stimulate PYY release after instillation into the distal gut, but whether this is of physiologic importance is not known. Last, adenylyl cyclase-coupled stimuli increasing intracellular cyclic AMP levels appear to be the predominant signals for directing PYY release.

Peptide YY Receptors

Peptide YY is a high-affinity cognate ligand for several Y receptor subtypes, including the Y1, Y2, and Y5 receptors. Y1 receptors have high affinity for PYY, neuropeptide Y, and specific substituted forms of these peptides, [Pro^{34}]PYY and [Pro^{34}]NPY, and low affinity for C-terminal fragments of these peptides as well as intact PP. In addition to widespread distribution in the central nervous system, Y1 receptors are also found in veins and arteries as well as in colonic epithelial cells and nerve fibers and ganglia of the enteric nervous system in humans. Y2 receptors display high affinity for PYY, NPY, and various of their C-terminal fragments; compared to the Y1 receptor, there is low-affinity binding of [Pro^{34}]-PYY and [Pro^{34}]NPY and no binding of PP. Y2 receptors occur in the brain, but also in the colonic epithelium of rats, in blood vessels (dog saphenous vein), and in nerve fibers of the autonomic nervous system. The Y5 receptor is described as "Y1-like" because not only do PYY and NPY bind with high affinity, but so do the Y1 analogues ([Pro^{34}]PYY and [Pro^{34}]NPY) in addition to long C-terminal fragments such as NPY 2–36 and PYY 3–36; however the C-terminal fragment NPY 13–36 binds with much lower affinity (PP binding affinity for the rat and human Y5 receptor was low for rat PP but high for human and bovine PP). The Y5 receptor subtype is found primarily in the brain.

Other reported receptors for PYY include the Y6 receptor and a PYY-preferring receptor. The Y6 receptor was originally found in rat brain and subsequently rabbit, monkey, and human homologues were described. The rat Y6 receptor has been variably shown to possess a high affinity for PYY with a Y1-like binding profile or a high affinity for PP and lower affinity for PYY. The Y6 receptor has not been shown to be a physiologically relevant receptor in humans. A PYY-preferring receptor has been suggested to exist because of a three to five times greater potency compared to NPY for some biological effects, but this purported receptor has not been characterized molecularly and remains theoretical at present.

Peptide YY Biological Actions

Peptide YY has been characterized as a candidate enterogastrone but additionally has been shown to inhibit intestinal motility, gut epithelial secretion, and pancreatic secretion. There are several aspects of interpretation of the large body of data pertaining to the biological effects of PYY that must be kept in mind; although similar effects for PYY are seen in many animal models, the ultimate effect of PYY is very dependent on (1) the species studied, (2) whether resting or stimulated conditions are tested for PYY inhibitory effects (and the type of stimulation used), and (3) what doses of PYY are required for effects (whether effects of PYY are observed at postprandial serum concentrations or only at higher, so-called pharmacologic, doses).

Whether PYY acts as a classic enterogastrone is not clear. On the one hand, it has been shown that

intravenous administration of PYY at doses reproducing higher postprandial levels and supraphysiologic levels can inhibit gastric acid production in humans, rats, and dogs. On the other hand, the inhibition of gastric acid production and emptying induced by introducing fat into the upper small intestine is not due to the accompanying PYY elevations (in humans and dogs) but is due to other factors, such as CCK. On its own, PYY is most potent at inhibiting cephalic-phase gastric acid production (nearly 90% inhibition in sham-fed dogs), and this requires vagal innervation. PYY can also inhibit gastric acid production by additive effects with glucagon-like peptide-1, secretin, and somatostatin or by directly blocking gastrin-stimulated histamine release from enterochromaffin-like (ECL) cells (in rats).

PYY can also act in the central nervous system (CNS) to modulate gastric acid secretion. However, the route of access of PYY to the CNS results in different effects on gastric acid production. It has been shown that intravenous PYY can cross the blood–brain barrier to bind specifically to regions of the dorsal vagal complex (DVC) [the nucleus tractus solitarii, the dorsal motor nucleus (DMN) of the vagus, and the area postrema (AP)], where Y receptor subtypes Y1, Y2, and Y4 have been found. The inhibitory activity of PYY on centrally stimulated gastric acid secretion (cephalic phase, for instance) may occur within the CNS because intracisternal injection of neutralizing antibodies against PYY can block its inhibitory effects. On the other hand, when PYY is directly microinjected into the DVC of rat brain stem, there is a dose-dependent increase in gastric acid secretion (that is dependent on an intact vagus nerve). These observations suggest that PYY has a complex role in gastric acid regulation that varies with the phase of gastric acid production.

One of the most consistently observed effects of PYY is the inhibition of intestinal motility. This effect is thought to enhance intraluminal nutrient digestion and absorption, earning PYY the rubric "the ileal brake." Delays in orocecal transit time are induced by PYY infusions that reproduce normal postprandial PYY levels. The decrease in intestinal motility following fat exposure in the lower small bowel can be blocked by neutralizing serum PYY with specific antisera. This effect on intestinal motility may be beneficial in conditions resulting in delivery of unabsorbed nutrients to the distal bowel and colon, such as pancreatic insufficiency, Crohn's disease, and acute diarrhea, which are associated with high basal and postprandial PYY levels.

In the pancreas, supraphysiologic levels of PYY can inhibit secretin-stimulated secretion in the anesthetized cat. Similarly, high doses of intravenous PYY inhibit meal- and secretin-stimulated pancreatic secretion in the dog, but porcine PYY has no effect on secretin- or CCK-stimulated pancreatic secretion in humans.

Other PYY biological effects in the gut include inhibition of stimulated apical chloride secretion in gut epithelium and an increase in intestinal absorption in intact animals. PYY has been shown to stimulate proliferation in gut epithelium (Y receptors are expressed by the gut epithelium of humans, rabbits, and rats) and may be involved in gut epithelial differentiation signals. PYY effects on feeding behavior are included in the discussion of neuropeptide Y.

NEUROPEPTIDE Y

Tissue Distribution

The majority of neuropeptide Y is found in the central and peripheral nervous systems (also seen in chromaffin cells of the adrenal medulla and pheochromocytomas), so that its distribution in the gut is within nerve cells and fibers. The NPY-immunoreactive (NPY-IR) nerves in the gut may be intrinsic or extrinsic to the gut. The intrinsic NPY-IR nerves are part of the nonadrenergic enteric nervous system, where NPY may colocalize with other neuropeptides, such as vasoactive intestinal peptide (VIP) and peptide histidine isoleucine. The extrinsic NPY-IR nerves generally are adrenergic fibers where NPY colocalizes with norepinephrine, and they innervate vascular structures. NPY is found in ganglia cell bodies, with higher frequency in submucosal plexi but also occurring in the myenteric plexi and extrinsically in the celiac ganglion. NPY-IR nerve fibers are found extending from plexi to the muscle layers of the muscularis propria, as well as within the muscularis mucosa, and into the mucosa, where they may closely invest the crypts. Perivascular NPY-IR fibers are largely of extrinsic adrenergic origin.

NPY Gene Expression and Receptors

The human gene for neuropeptide Y is also made up of four exons and three introns that span approximately 8 kb and encode 97-amino-acid residues of the NPY prepro hormone. Exon 1 encodes the 5′ untranslated region, exon 2 encodes residues 1–28 of the signal peptide and most of NPY, exon 3 encodes the C-terminal tyrosine, the 3-amino-acid cleavage site, and a 23-amino-acid extension, and exon 4 encodes a further 7-amino-acid extension and the 3′ untranslated region. Posttranslational processing produces the 36-amino-acid peptide with an amidated C-terminal tyrosine residue.

The full-length amidated 36-amino-acid peptide is the major form of NPY found in the bloodstream after

release from nerve endings following sympathetic stimulation or feeding. NPY binds to several Y receptor subtypes as previously discussed. An NPY-specific receptor subtype, Y3, that does not bind PYY has been described pharmacologically but has yet to be cloned. Given the extensive representation of NPY in nerves in the gut, it is important to note that Y receptors are found on ganglion cells and nerve fibers (in humans) and on epithelial cells (in rabbits, humans, rats, and mice), where NPY released from nerve endings (and possibly PYY released from enteroendocrine cells) could exert an effect.

NPY Biological Actions

Neuropeptide Y has a wide variety of activities, including vasoconstriction and regulation of cardiac function, stimulation of feeding, modulation of pituitary release of hormones, and effects on circadian rhythm and anxiety state. In the gut, administration of NPY potently inhibits mucosal fluid and electrolyte secretion stimulated by prostaglandin E2, VIP, and cholera toxin. NPY has effects on gut motility as well, mediating contraction and relaxation of the lower esophageal sphincter (cat), contraction of longitudinal muscle and inhibition of peristalsis and circular muscle reflex contraction (guinea pig), and contraction of longitudinal muscle (rat, dog). NPY appears to mediate its effects on motility not by direct actions on muscle but rather by inhibition of excitatory neurons of the enteric nervous system.

Neuropeptide Y has emerged as one of the key neuropeptides active in stimulating feeding behavior and coordinating peripheral signals involved in body weight regulation. Studies in rodents show that NPY injected into the brain (cerebral ventricles and hypothalamus) induces feeding, prolongs feeding, and causes feeding to resume in fed animals. Increases in endogenous NPY occur in the paraventricular nucleus of the hypothalamus prior to nocturnal feeding, during fasting, and accompanying the hyperphagia of drug-induced diabetes and genetically obese animals such as fatty Zucker rats and *ob/ob* mice. These latter observations suggest that NPY plays a physiologic role in feeding behavior. Current models of NPY-induced feeding show that the NPY released from fibers originating in the hypothalamic arcuate nucleus is responsible for stimulating feeding. The stimulation of feeding appears to be mediated through Y1 or Y5 receptor subtypes, likely located in other hypothalamic areas such as the paraventricular nucleus. Though rises in NPY levels in the hypothalamus precede feeding, it is not yet clear what the exact proximate mechanisms are that control and coordinate this increase.

Neuropeptide Y-stimulated feeding may also be part of a larger regulatory mechanism that is influenced by signals from outside the central nervous system. It has been shown that activation of Y2 receptor subtypes in the rat hypothalamus can decrease the release of NPY. In support of this activity, a Y2-preferring ligand PYY 3–36 can inhibit nocturnal onset feeding in rats (injected intraperitoneally) and decrease calorie intake in humans following intravenous infusions that mimic postprandial blood levels. This suggests that peripheral postprandial PYY release (recall the PYY 3–36 fragment can account for up to 50% of total PYY activity in postprandial human serum) may contribute to a satiety effect by attenuating the NPY effect in the hypothalamus. Whether this inhibitory effect is accomplished by direct effects on the hypothalamus or indirectly via other neural mechanisms has yet to be established.

Leptin is another peripheral signal related to regulation of body weight that can influence hypothalamic NPY activity. Leptin can decrease the production of NPY in the arcuate nucleus of the hypothalamus (mice); subpopulations of NPY-containing neurons in the rat hypothalamus involved in reactions to fasting also express the leptin receptor, supporting a role for leptin regulation of NPY in feeding response. It is thought that fluctuations in leptin levels related to body fat stores may contribute to enhanced NPY-induced feeding during low-body-fat conditions (low leptin levels) and blunted NPY-induced feeding during high-body-fat states (high leptin levels).

These data suggest that NPY has an important role in central control of feeding behavior and that peripheral signals, including postprandial PYY release and leptin levels related to body fat stores, modulate the feeding response to establish satiety and energy homeostasis.

Pancreatic Pseudocysts

THEODORE R. LIN AND MICHAEL W. MULHOLLAND
University of Michigan Medical Center, Ann Arbor

computerized tomography A radiographic technique allowing visualization of a plane or section through the body.
endoscopic retrograde cholangiopancreatography A procedure whereby pancreatic and biliary ducts are visualized by endoscopic injection of contrast medium.
pseudocyst A non-epithelial-lined collection of pancreatic secretions.

Pancreatic pseudocysts are non-epithelial-lined fluid collections that arise as a consequence of acute pancreatitis, trauma, or chronic pancreatitis. They are believed to result from disruption of the pancreatic duct with subsequent leakage of pancreatic exocrine secretions into surrounding peripancreatic tissue. The incidence of pancreatic pseudocysts varies widely, especially with the increased use of axial imaging in patients with pancreatitis and abdominal pain. Most pseudocysts are asymptomatic; the development of symptoms may herald significant complications, including perforation, obstruction, hemorrhage, and infection. Most pseudocysts are single, unilocular lesions. One-third of pseudocysts are located in the pancreatic head and the remainder are found in the body and tail regions. The fluid filling the pseudocyst cavity is usually watery in nature and rich in pancreatic enzymes, including amylase, lipase, and trypsin. Some endoscopic retrograde cholangiopancreatogram studies have shown that in 80% of cases, the pancreatic duct communicates with the pseudocyst.

PRESENTATION AND DIAGNOSIS

A lingering course of acute pancreatitis, persistent abdominal pain, or an epigastric mass may be potential indicators of pseudocyst development. Additional signs and symptoms may signify complications. Infection manifests with fever and abdominal pain. Patients with ruptured pseudocysts present with severe acute abdominal pain, peritoneal irritation, and shock. Gastrointestinal bleeding and vomiting occur when pseudocysts erode into the surrounding viscera and vascular structures.

The diagnosis of pseudocysts has been greatly facilitated by the use of axial imaging. Computerized tomography (CT) is the standard for diagnosis and detects small pseudocysts even less than 1 cm in diameter. Moreover, CT is helpful in delineating the features of pseudocysts, including anatomic location, fibrosis of the wall, presence of blood or infectious material, and viability of the surrounding pancreatic parenchyma (Fig. 1).

An assessment of the likelihood of spontaneous resolution and the risk of developing complications guides clinical decision-making. Management may consist of observation and surveillance or intervention. Pancreatic pseudocysts resolve spontaneously through absorption, rupture into neighboring viscus, or drainage through the pancreatic duct, with spontaneous resolution in 50% of cases. Factors that affect the likelihood of spontaneous resolution include size, chronicity, and multiplicity. Most pseudocysts will resolve without intervention within 6 weeks. Lesions that are less than 6 cm in size are more likely to heal than those that are larger than 6 cm. Those attributed to chronic pancreatitis are less likely to heal than pseudocysts secondary to acute pancreatitis. Multilocular lesions

are also less likely to heal spontaneously than unilocular lesions.

THERAPEUTIC APPROACHES

Endoscopic, percutaneous, and surgical approaches may be employed to treat complicated or symptomatic pancreatic pseudocysts. Endoscopy may be used to create a communication between the pseudocyst and either the stomach or small bowel. A broadly adherent, opposing wall of stomach or small bowel is absolutely required for this approach to be considered; preprocedural axial scanning is required to document this circumstance. A stent or catheter is then deployed, creating a conduit for internal drainage of the pseudocyst. Radiographically guided percutaneous placement of an indwelling catheter into the pseudocyst is another means of treating unresolving or complicated cases of pancreatic pseudocyst. External catheter drainage of the pseudocyst may be complicated by secondary infection of the pseudocyst, catheter obstruction from particulate debris, and the development of enterocutaneous or pancreaticocutaneous fistulas. Surgical approaches to complicated pancreatic pseudocysts are based on creating an internal drainage communication between the pseudocyst and either the stomach or small intestine (Fig. 2). As in the endoscopic approach, a broadly adherent pseudocyst wall is essential to the success of the drainage procedure. Moreover, an adequately mature and fibrous wall is required to ensure a stable anastamosis. Pseudocysts located in the tail of the pancreas may be amenable to resection by distal pancreatectomy. In these cases, splenectomy is warranted if the lesion is in close proximity to the splenic hilum.

Pancreatic Transplantation

ROBERT M. MERION
University of Michigan, Ann Arbor

allograft A graft transplanted between genetically nonidentical individuals of the same species.
diabetes mellitus A chronic metabolic disorder in which utilization of carbohydrate is impaired and that of lipid and protein is enhanced; it is caused by an absolute or relative deficiency of insulin and is characterized, in more severe cases, by chronic hyperglycemia, glycosuria, water and electrolyte loss, ketoacidosis, and coma.
diabetic neuropathy A generic term for any diabetes mellitus-related disorder of the peripheral nervous system, autonomic nervous system, and some cranial nerves.
immunosuppression Prevention or interference with the development of an immunologic response; it may reflect natural immunologic unresponsiveness (tolerance), may be artificially induced by chemical, biological, or physical agents, or may be caused by disease.
pancreatic islet Cellular masses varying from a few cells to hundreds of cells lying in the interstitial tissue of the pancreas that constitute the endocrine portion of the pancreas and are the source of insulin and glucagon.
renal failure Loss of kidney function, either acute or chronic, that results in azotemia and syndrome of uremia.
retinopathy Retinal changes occurring in diabetes mellitus, marked by microaneurysms, exudates, and hemorrhages, and sometimes by neovascularization.

Pancreatic transplantation is a surgical treatment for severe diabetes mellitus and its complications. Most commonly, the entire gland is transplanted heterotopically in cases of longstanding type 1 diabetes. In a number of scattered reports, isolated pancreatic islets have been transplanted, with mainly unsatisfactory results. The two primary objectives of pancreatic transplantation are to restore normal glucose homeostasis and to prevent, delay, or reverse the end-organ complications associated with the underlying disease.

INTRODUCTION

Pancreatic transplantation has been performed since 1966. Results were poor during the first two decades for three main reasons. First, inability to successfully preserve pancreatic allografts during the required period of time between removal from the donor and implantation into the recipient led to early allograft failure in a significant proportion of cases. Second, fragility of the organ and injury related to ischemia and reperfusion resulted in a high incidence of allograft thrombosis. Third, immunosuppression was inadequate to prevent rejection and the treatment of pancreas transplant rejection was unsatisfactory.

Since the 1980s, results of pancreatic transplantation have steadily improved. Improved procurement techniques and more reliable preservation solutions have reduced the early failure rate and, combined with surgical innovations, have lessened the incidence of early allograft thrombosis. Immunosuppressive drug developments have significantly reduced the incidence, severity, and consequences of allograft rejection and now result in excellent long-term insulin-independent survival.

INDICATIONS AND CONTRAINDICATIONS

Patients with longstanding type 1 diabetes mellitus are candidates for pancreatic transplantation. A demonstrated absence of C peptide confirms the failure of endogenous insulin production. The development of end-organ complications such as diabetic proliferative retinopathy, peripheral and autonomic neuropathy, gastrointestinal dysmotility, and diabetic nephropathy signals advanced stages of the disease and warrants consideration for transplantation.

Three forms of pancreatic transplantation are offered to suitable patients depending upon the degree of renal impairment. These comprise pancreas transplant alone (PTA), simultaneous pancreas–kidney transplantation (SPK), and sequential pancreas after kidney transplant (PAK).

In patients without marked renal impairment, control of blood glucose via conventional means such as intermittent subcutaneous insulin injections or insulin pump is almost always successful in preventing life-threatening hypoglycemic episodes. However, a small number of patients have severe hypoglycemic

 Copyright 2004, Elsevier (USA). All rights reserved.

unawareness, multiple hospitalizations for diabetic coma or seizures, and inability to control blood sugar despite adequate compliance with an aggressive regimen. These patients may be candidates for PTA, provided that an adequate renal reserve is present.

Individuals who have already developed renal failure are also candidates for pancreatic transplantation and require renal replacement therapy as well, in the form of a kidney transplant. Two modalities are available for such patients and the choice between them depends on the availability of a kidney donor. In the first case, if a living donor is available, the kidney transplant is performed first and the patient may receive a subsequent cadaveric pancreas transplant (PAK), provided that the kidney transplant is functioning adequately. If a living donor transplant is not feasible, the patient may receive both organs from a single cadaveric donor (SPK).

RECIPIENT EVALUATION

Candidates up to 45 years of age are routinely considered, but older patients require more careful scrutiny due to demonstrated inferior patient and graft survival outcomes. The duration of diabetes mellitus should be assessed and absence of C-peptide secretion confirmed. Systematic assessment of end-organ complications is important. Diabetic retinopathy requiring laser photocoagulation, vitrectomy, or other measures should be assessed. Blindness is not an absolute contraindication to pancreatic transplantation, but its presence may suggest more advanced systemic disease. Peripheral neuropathy and associated musculoskeletal manifestations such as Charcot joints may be present. Autonomic neuropathy with symptomatic orthostatic hypotension and gastrointestinal dysmotility syndromes are common in this patient population. Meticulous investigation of correctable coronary artery disease is mandatory in light of the high incidence of both overt and asymptomatic lesions. The presence of severe peripheral vascular disease is a marker for systemic atherosclerosis and, particularly if associated with major amputation, is considered a relative contraindication. The need for immunosuppressive therapy, with its attendant risks of neoplasia and infection, means that preexisting malignancies (other than nonmelanoma skin cancers) and active or ongoing infections are also contraindications to pancreatic transplantation.

Unlike most surgical procedures, solid organ transplantation requires lifelong immunosuppression and cooperation with a complex medical regimen. Accordingly, patients must be capable of understanding the risks and benefits of the procedure and have a requisite system of social support.

DONOR CONSIDERATIONS

Virtually all pancreatic transplants are procured from brain-dead cadaveric donors. Donor assessment is a critical step as the pancreas is more susceptible to preprocurement ischemic injury than other solid organs. Donors over the age of 45 years and those whose cause of death was cerebrovascular accident are risk factors for allograft failure. High levels of vasopressor drugs and the use of antidiuretic drugs (vasopressin, desmopressin) to treat diabetes insipidus in the donor may also be associated with a higher risk of failure.

Most cadaveric pancreata are procured from multiorgan donors from whom kidneys, liver, heart, and lungs are also being retrieved. Coordination between several donor operative teams may therefore be necessary, although these procedures are now fairly standardized. The entire pancreas along with the associated donor duodenum is procured. The vascular anatomy of the liver and pancreas must be shared, since the portal vein is the venous outflow for the pancreatic allograft and is also required for the liver. Similarly, the arterial blood supply to the pancreas and liver arises from the celiac axis and arterial anomalies, which may be found in upward of 20% of donors, must be assiduously searched for and preserved.

RECIPIENT OPERATION

Technical details of the recipient pancreas transplant have evolved significantly. Placement of the organ into the iliac fossa within the peritoneal cavity (as opposed to the retroperitoneum) is preferred. Arterial blood supply to the pancreas, arising from branches of the celiac axis and from the superior mesenteric artery, dictate *ex vivo* reconstruction prior to implantation. A Y-graft of bifurcated donor iliac artery is generally used to enable a single arterial anastomosis to the common or external iliac artery in the recipient. The donor portal vein is anastomosed to the external iliac vein of the recipient.

The more common systemic drainage results in chronic hyperinsulinemia, although no specific adverse consequences have emerged and glucose homeostasis is excellent. Some groups have advocated portal venous drainage of the pancreas as a more physiological setup. First passage of pancreatic venous blood through the liver is associated with normal levels of circulating

insulin and a glucose tolerance that more closely approximates a normal pattern.

Exocrine secretion of the pancreas is the Achilles heel of pancreatic transplantation. The two major choices are to create an anastomosis between the donor duodenum and the recipient bladder or to create an anastomosis between the donor duodenum and the recipient small bowel. The former was used for many years, as it was perceived to be safer in the event of a postoperative leak. However, dehydration and acidosis from urinary losses of alkaline pancreatic secretions have led to a return to enteric drainage of the donor pancreas in over one-half of cases.

The pancreas allograft is placed contralateral to a kidney transplant. Most groups prefer to place the pancreas graft on the right side if possible. Since the left iliac vein passes under the iliac artery on that side, placement of the pancreas on the left may result in venous hypertension in the graft and a higher risk of allograft thrombosis.

IMMUNOSUPPRESSION

The majority of transplant centers use anti-lymphocyte preparations as part of an induction immunosuppression regimen following pancreatic transplantation. The agents available include polyclonal (equine and rabbit) and murine monoclonal antibodies to the T-cell CD3 receptor or the receptor for interleukin-2. Maintenance immunosuppression usually consists of a three-drug cocktail using a calcineurin inhibitor (cyclosporine or tacrolimus), an anti-metabolite (usually mycophenolate mofetil), and corticosteroids.

Rejection occurs in up to one-half of recipients. It must be diagnosed early and treated aggressively to avoid graft failure. The diagnosis increasingly relies on a tissue biopsy obtained percutaneously, laparoscopically, or via laparotomy. Pancreas allograft rejection is most commonly treated with a full course of anti-lymphocyte globulin or monoclonal anti-T-cell antibody.

OUTCOME

The success of pancreatic transplantation can be measured in terms of patient and graft survival as well as by the effects of the transplant on end-organ complications. Patient survival for all modalities of the procedure (PTA, SPK, PAK) exceeds 94% at 1 year and 83% at 5 years. Pancreas graft survival rates are dependent on several factors, the most important of which is the modality of therapy (Table I). SPK recipients have the highest pancreas graft survival rates, closely followed by recipients of PAK transplants. Rejection is easiest to diagnose in SPK recipients, where the kidney transplanted from the same cadaveric donor acts as a barometer for the immunologic response to the grafts. Those who receive a PTA have the poorest results, presumably because the diagnosis of rejection is more difficult.

TABLE I 1- and 3-Year Pancreas Transplant Graft Survival Rates by Modality of Transplantation

Pancreas transplant modality	1-year graft survival (%)	3-year graft survival (%)
Simultaneous pancreas–kidney transplant	84	77
Pancreas after kidney transplant	70	56
Pancreas transplant alone	64	50

Diabetic retinopathy may paradoxically worsen transiently after pancreatic transplantation, but by 2 years post-SPK transplantation a higher proportion of patients have stable eyes when compared to comparable diabetic patients treated with kidney transplant alone. Peripheral neuropathy may have multifactorial etiology, particularly in patients with established renal failure. Nevertheless, pancreas transplant recipients have been shown to have less severe and more slowly progressive neuropathy than their nontransplanted counterparts. A successful pancreatic transplant protects the transplanted kidney (or the native kidney in the case of a PTA) from the development or progression of diabetic nephropathy.

Quality of life is dramatically improved for recipients of pancreatic transplantation. Freedom from decades of dietary restrictions and abolition of the fear of hypoglycemic coma or seizures are obvious benefits. Objective measures of health status and quality of life have been repeatedly demonstrated to be greatly improved among pancreatic transplant recipients.

STATUS OF ISLET TRANSPLANTATION

Since the primary objective of pancreatic transplantation is the restoration of glucose homeostasis, the concept of isolated pancreatic islet transplantation has been attractive for many years. Unfortunately, despite several decades of research and modest numbers of human clinical investigations, long-term insulin independence has been achieved in fewer than 10% of cases. A recent effort using a corticosteroid-free immunosuppressive regimen in a small number of patients has provided promising results. Improved methods for large-scale islet isolation and more effective immunosuppressive drugs are

credited with these successes. However, long-term follow-up will be required before any conclusions can be drawn regarding the efficacy of this approach.

Pancreatic Triglyceride Lipase

MARK E. LOWE

Washington University School of Medicine, St. Louis, Missouri

dietary fats Predominantly triglycerides, which consist of acyl chains or fatty acids linked to glycerol through ester bonds.

lipase Enzyme that catalyzes the hydrolysis of ester bonds in dietary fats to release fatty acids.

pancreatic triglyceride lipase Specific enzyme produced and secreted by pancreatic acinar cells; primarily responsible for intestinal digestion of triglycerides.

Pancreatic triglyceride lipase is the major pancreatic lipase synthesized and secreted by pancreatic acinar cells. It accounts for most of the luminal digestion of triglycerides in the small intestine. This function is critical for the utilization of dietary triglycerides, because intestinal enterocytes cannot absorb long-chain triglycerides unless lipases convert them to fatty acids and monoacylglycerols.

INTRODUCTION

The digestion of dietary fats in humans begins in the stomach, where gastric lipase (a distinct protein) releases about 15% of the fatty acids from triglycerides. Lipases secreted by the pancreas complete dietary fat digestion in the small intestine. Of these lipases, pancreatic triglyceride lipase (PTL) predominates, as evidenced by patients with congenital deficiency of PTL who malabsorb 50–60% of dietary fats. Cholesterol esterase, another nonspecific lipase, mediates the hydrolysis of other dietary lipids. Other more distantly related lipases, such as lipoprotein lipase and hormone-sensitive lipase, mediate the uptake and release of fatty acids from various tissues.

PHYSIOLOGY

Only the pancreas synthesizes significant amounts of PTL, and this occurs in the acinar cells of the pancreas. In addition to this tissue-specific expression, mRNA encoding PTL shows temporal and cell-specific regulation. The fetal pancreas of humans and rodents does not express mRNA for PTL. After birth, the pancreas of suckling mouse or rat pups does not express PTL mRNA until the suckling–weanling transition.

In addition to this tissue-specific expression, mRNA encoding PTL shows temporal and cell-specific regulation. The fetal pancreas of humans and rodents does not express mRNA for PTL. After birth, the pancreas of suckling mouse or rat pups does not express PTL mRNA until the suckling–weanling transition.

Copyright 2004, Elsevier (USA). All rights reserved.

Human newborns have decreased lipase activity in pancreatic secretions and may also have decreased expression of PTL. Once expressed, mRNA encoding PTL appears in the pancreatic acinar cells and not in other cell types in the pancreas. Pancreatic acinar cells synthesize and secrete PTL into the pancreatic duct through both basal and regulated pathways. In the common duct, PTL mixes with biliary lipids and bile salts before entering the duodenum, where lipolysis occurs. PTL is active at the neutral pH normally present in the intestinal lumen. It can be inactivated by low pH, as occurs with gastric hypersecretion.

LIPOLYSIS

PTL is a carboxyl esterase that prefers acylglycerides to other dietary lipids, such as phospholipids, cholesterol esters, and galactolipids. PTL efficiently hydrolyzes a broad range of acyl chains of varying length and saturation from the 1 and 3 positions of tri- and diglycerides, producing fatty acids and 2-monoacylglycerides. *In vitro*, PTL cleaves acyl chains from C_{14} to C_{22} carbon chains with only a sixfold difference in rates between the best and worst substrates.

Several properties of PTL distinguish it from other enzymes. Like all lipases, PTL has low activity against water-soluble substrates and has much higher activity against water-insoluble substrates at oil–water interfaces, such as those presented by emulsions of dietary lipids. Paradoxically, many of the usual constituents of the duodenum, such as bile salts, phospholipids, proteins, and polysaccharides, inhibit PTL. Another pancreatic protein, colipase, restores activity to PTL under these conditions by anchoring it at the lipid–water interface.

PROTEIN STRUCTURE

The primary structures of PTL and of colipase from multiple species have been solved by chemical methods or predicted from their cDNA sequence. Both proteins are synthesized with 17-amino-acid signal peptides. Mature human PTL contains 449 amino acids (molecular mass, 49,558 Da) and human colipase contains 95 amino acids (molecular mass, 10,104 Da). In contrast to many other pancreatic exocrine proteins, PTL is not synthesized as an inactive proform or zymogen. Colipase is secreted as a proform, called procolipase, that contains a five-amino-acid propiece, which is cleaved to produce colipase. Unlike the exocrine proenzymes, procolipase does function and can restore activity to bile-salt-inhibited PTL.

The three-dimensional structure of PTL without colipase and two structures of the PTL–colipase complex have greatly increased our understanding of PTL function. PTL consists of two distinct domains, an N-terminal α/β hydrolase fold and a C-terminal β-sheet structure with homology to the C2 domains that are found in a wide range of proteins. Colipase binds to the C-terminal domain of PTL. The active site of PTL resides in the N-terminal domain and contains a glutamic acid–histidine–serine catalytic site. In the PTL structure and in one of the PTL–colipase structures, a surface loop covers the active site and prevents substrate from entering the active site. In the other PTL–colipase structure, the "lid" has moved into a position that opens and configures the active site and, together with colipase, presents a large hydrophobic surface that serves as the lipid binding site.

University of California, San Diego

pancreatic cystic neoplasms Pancreatic tumors that arise from parenchymal cells and often form cystic shapes seen in imaging studies.

pseudocyst A non-epithelial-lined collection of pancreatic secretions.

The vast majority of pancreatic tumors are adenocarcinomas arising from the ductal epithelium. Pancreatic tumors other than ductal adenocarcinoma are rare and can be broadly classified as cystic versus solid lesions. The primary cystic neoplasms of the pancreas represent the majority of these tumors; other rare solid tumors are occasionally seen.

INTRODUCTION AND CLASSIFICATION

Lesions arising from within the pancreas can generally be classified as either cystic or solid and as benign or malignant. However, the distinction between benign and malignant neoplasms can be difficult to make and several tumors represent a spectrum of disease with an indistinct transition point from benign to malignant. The most commonly encountered masses in the pancreas are not tumors or cysts but collections of fluid with a fibrous wall, termed pseudocysts. Pancreatic adenocarcinoma represents the most common neoplasm of the pancreas, accounting for perhaps 90–95% of tumors. The other tumors are all considered rare and can be classified based on appearance as cystic or solid (see Table I). The solid tumors include nonendocrine tumors, metastatic cancers, and endocrine tumors. This article will focus on the primary cystic neoplasms of the pancreas with a brief discussion of the assortment of other solid nonendocrine tumors.

TABLE I Classification of Pancreatic Tumors

A. Cystic
- a. Mucinous cystic neoplasms
  - i. Mucinous cystadenoma
  - ii. Mucinous cystic tumor with moderate dysplasia
  - iii. Mucinous cystadenocarcinoma
- b. Serous cystadenoma
- c. Serous cystadenocarcinoma (case reports)
- d. Intraductal papillary mucinous tumor
- e. Acinar cell cystadenocarcinoma
- f. Cystic choriocarcinoma
- g. Cystic teratoma
- h. Cystic islet cell tumor
- i. Cytic necrosis of adenocarcinoma/lymphoma
- j. Papillary cystic epithelial neoplasm
- k. Angimatous neoplasms
  - i. Angioma
  - ii. Lymphangioma
  - iii. Hemangioendothelioma

B. Solid
- a. Ductal adenocarcinoma
- b. Pancreatic lymphoma (primary vs systemic)
- c. Adenosquamous carcinoma
- d. Giant cell carcinoma (sarcomatoid or osteoclast-like carcinoma)
- e. Acinar cell carcinoma
- f. Pancreaticoblastoma

Cystic Tumors of the Pancreas

The cystic neoplasms were first recognized in 1824 but their classification has continued to evolve for the past 180 years. Initially, cystic tumors were recognized according to the sizes of the cysts, being either microcystic or macrocystic. In 1978, the distinction between two major types of cystic neoplasms was made according to the nature of the cyst contents: serous versus mucinous. A few years later in 1982, the third major tumor in this class was discovered. However, the terminology varied considerably and not until the late 1990s was the term intraductal papillary mucinous tumor (IPMT) widely accepted.

The list of cystic tumors within the pancreas is large but more than 90% of these tumors are composed of mucinous cystic neoplasms, serous cystadenomas, and IPMTs. The remainder are exceedingly rare and limited information is available regarding their nature. These tumors have many similar features in age of onset, clinical presentation, and treatment; however, prognosis varies considerably. The most important differential diagnosis to consider with all cystic tumors is the vastly more common pseudocyst for which detailed historical

 Copyright 2004, Elsevier (USA). All rights reserved.

information regarding pancreatitis or abdominal trauma is paramount. Other findings to suggest pseudocyst rather than cystic tumor include lack of septations, loculations, solid components, or calcifications on computed tomography (CT) or any communication between the cyst and ductal system on endoscopic retrograde cholangiopancreatography (ERCP). Perhaps the best distinguishing feature is the amylase content of the aspirated fluid, generally greater than 5000 IU/liter.

Mucinous Cystic Neoplasms

These tumors represent a spectrum of disease ranging from presumably benign to clearly malignant with local invasion and distant metastases occasionally seen. Previously classified as mucinous cystadenoma with variable degrees of dysplasia versus cystadenocarcinoma, the currently favored term is mucinous cystic neoplasms (MCNs) due to the difficulty in accurately diagnosing these lesions as benign versus malignant.

The MCNs are the most frequently encountered form of cystic neoplasm in the pancreas, representing 45–50% of these tumors. Women are more commonly affected, perhaps as high as 4 : 1, and the median age at diagnosis is 50–55 years. MCNs are usually composed of multiple cysts and range in size from 1 to 26 cm. Benign tumors tend to be smaller (5 to 6 cm), whereas malignant tumors average 8 to 11 cm. The mucinous tumors tend to be "macrocystic" in appearance, with fewer cysts and each cyst greater than 2 cm in size. Solid components and calcifications are occasionally found and usually connote a malignant change. The majority of MCNs are found in the body and tail of the pancreas and rarely connect with the ductal system (5%).

The majority of patients diagnosed with MCNs are symptomatic. Common presenting symptoms include vague abdominal pain, bloating or abdominal fullness, and early satiety. A few patients are able to feel an abdominal mass. Jaundice, pancreatitis, and weight loss are less common to rare. An increasing percentage of patients are asymptomatic and found to have incidental pancreatic masses after abdominal imaging for unrelated conditions. Diagnosis is then made after abdominal imaging is obtained, with ultrasound (US), CT, or magnetic resonance imaging. Although MCNs can be suspected based upon radiologic findings, a definitive diagnosis requires either aspiration of cyst fluid or surgical resection. Large tumors can be percutaneously aspirated safely; however, smaller tumors are increasingly being sampled via endoscopic US (EUS). Characteristic and diagnostic features of MCN fluid include high viscosity, positive mucin staining, low amylase, positive cytology (in 50%), and moderately elevated carcinoembryonic antigen (CEA) >200 ng/ml.

The lining of MCNs is composed of a mucin-producing tall columnar epithelium with a ductal origin. Up to 75% of cysts have been found to have regions of cyst wall denuded of epithelium, involving on average 40% of the wall. In addition, multiple reports of benign, dysplastic, and malignant epithelium coexisting within the same tumor have been described. For these reasons, once an MCN is suspected, surgical resection is strongly advised. This should entail either a distal pancreatectomy with splenectomy or a pancreaticoduodenectomy or Whipple procedure. Limited enucleation is not recommended. Long-term survival is good for patients with resectable disease, ranging from 50 to 75% at 5 years. Studies of adjuvant therapy including chemotherapy and radiation are ongoing and thus their effectiveness is not fully known.

Serous Cystadenoma

As opposed to its mucinous counterpart, the serous cystic tumor represents a more homogenous and predictable entity. Almost universally benign, only six case reports of malignant serous cystadenocarcinomas have been reported.

The serous cystadenomas are probably the second most common cystic tumor of the pancreas, representing 16 to 27% of cystic tumors in most series. Similar to MCNs, women are predominantly affected, again approaching 4:1 in incidence, and age at diagnosis is typically the sixth or seventh decade. These tumors can also be a component in 15% of patients with Von Hippel-Lindau syndrome. Concomitant renal, retinal, or cerebellar vascular tumors are usually found. The overall size of the serous tumors is similar to MCNs at 1 to 26 cm with an average of 6 to 10 cm, but the individual cysts tend to be much smaller, ranging from micrometers to 2 cm in diameter in a honeycomb fashion. The previously descriptive classification of "microcystic" adenoma is no longer used. Unlike the MCNs, serous tumors often have characteristic findings on radiologic imaging. The vascular, fibrous, calcified connective tissue of the tumor creates a central stellate scar with a characteristic "sunburst" pattern on plain films, CT, or angiography. Unfortunately, this pathognomonic finding is present in only 10 to 30% of tumors. Some authors believe that if it is present, further diagnostic testing, such as cyst aspiration, is unnecessary. Although found throughout the gland, these tumors tend to occur in the head of the pancreas more commonly than MCNs.

As with MCNs, the majority of patients diagnosed with serous tumors are symptomatic at presentation.

Symptoms are generally related to mass effect and include abdominal pain, fullness, and the feeling of a mass in up to 33% of patients. Biliary or pancreatic obstruction resulting in jaundice, cholangitis, or pancreatitis is unusual. Weight loss may be present, probably related to early satiety rather than to anorexia as is commonly found with malignancy. The proportion of patients who are asymptomatic at diagnosis will likely continue to increase with the rising use of abdominal imaging modalities for various complaints. As with MCNs, definitive diagnosis of serous cystadenomas usually requires additional testing after initial radiographic studies reveal a cystic mass. Aspiration of cyst fluid is helpful but may be more difficult due to smaller sizes of the individual cysts. The fluid can usually be distinguished from MCNs or pseudocysts by finding low viscosity, negative mucin staining, low CEA < 5 ng/ml, low amylase, and a unique characteristic of positive PAS (periodic acid-Schiff)-staining cells on cytologic analysis due to the abundant glycogen. PAS-positive cells are reported in approximately half of cases and if present, strongly support the diagnosis.

The epithelium of serous cystadenomas is composed of glycogen-rich low cuboidal cells. No mucin is produced. Unlike the MCNs, the progenitor cell is believed to be the centroacinar cell as opposed to ductal epithelial cells. The problem of frequently coexisting benign and dysplastic cells has not been reported for serous tumors. Due to the more benign nature of these tumors, patient management includes more options. Patients who are elderly or otherwise poor surgical candidates and asymptomatic patients may be safely followed with surveillance imaging. If the lesion continues to grow or symptoms develop or worsen, then surgical referral can be reconsidered. Most authors agree that young patients or symptomatic patients should undergo complete resection with either a distal pancreatectomy or a Whipple procedure to eliminate the chance of malignant degeneration as well as potential complications, such as hemorrhage or obstruction. Long-term survival is excellent.

Intraductal Papillary Mucinous Tumor

In the early 1980s, a new subset of the mucinous cystic tumor was noted that tended to involve the ductal system causing ductal dilation as well as acute and chronic pancreatitis. Various names were given to describe this subset of tumors, such as mucinous ductal ectasia, mucin-hypersecreting tumor, mucinous villous adenomatosis, and ductectatic mucinous cystadenoma, to name a few. By the mid-1990s, the consensus was for intraductal papillary mucinous tumor (IPMT). Similar to MCNs, IPMTs encompass a spectrum of disease from entirely benign to frankly malignant with many intermediates in between. Approximately 40% of tumors are malignant at time of presentation.

IPMTs are less common than MCNs, but are similar in incidence to serous tumors, representing the third most common cystic tumor of the pancreas (some authorities list IPMT as the second most common type). The incidence has risen over the past decade, likely due to increasing recognition of this distinct tumor type as well as improved radiographic techniques. Unlike both MCNs and serous tumors, males are more commonly affected with IPMTs. Age of onset is usually over 60 years. The gross and histologic findings are distinct from the other cystic tumors in that there is a papillary growth of tumor within the main or secondary pancreatic ducts, giving rise to main duct or branch duct types. The ducts then become obstructed and subsequently dilated, giving the appearance of a cystic tumor. "Mucin lakes" have been described in the surrounding pancreas and one series reported 20% to have concomitant lesions similar to MCNs, typically in the head of the pancreas. These likely represent the branch duct type with cystic dilations. The other characteristic finding, usually seen at ERCP, is protrusion of the major and/or minor papillae into the duodenum with extrusion of copious amounts of mucin.

As with the other cystic tumors of the pancreas, the majority of patients with IPMT are symptomatic at diagnosis. Unlike other cystic tumors, patients with IPMT frequently suffer from recurrent acute pancreatitis or chronic pancreatitis with episodic or chronic abdominal pain and symptoms related to obstruction of the bile ducts, pancreatic ducts, or small bowel. Weight loss, steatorrhea, and diabetes are not uncommon. Elevations of amylase or lipase are found in up to half of patients at presentation. The tumor markers CEA and CA19-9 are elevated in approximately 10 to 15% but are not felt to be useful in diagnosis due to the low specificity. Diagnosis usually requires advanced endoscopic techniques such as ERCP and EUS with fine-needle aspiration. Characteristic findings include a patulous ampulla with mucus emanating from a dilated orifice, cystic dilation of the main and secondary ducts, filling defects within the ducts, and pancreatic parenchymal atrophy. Strictures are notably absent. ERCP also allows for collection of ductal secretions and forceps biopsy for pathology and cytology. EUS is particularly helpful in distinguishing this tumor from chronic pancreatitis, which can have a similar appearance. These procedures are important for outlining the extent of disease to plan for surgical resection.

The epithelium of the IPMTs is composed of tall columnar mucin-producing cells, similar to MCNs.

These cells tend to form papillary projections, which can also be seen in MCNs. The epithelium frequently undergoes hyperplastic, dysplastic, and carcinomatous changes. Local invasion is not uncommon. The disease typically begins in the head of the pancreas with slow spread throughout the gland. Due to the high likelihood of finding malignant disease at diagnosis or on follow-up, complete resection is strongly recommended for all surgical candidates without evidence of local or metastatic spread. This typically requires a pancreaticoduodenectomy, distal pancreatectomy with splenectomy, or total pancreatectomy. The use of intraoperative frozen sections to outline the extent of malignancy is essential for curative resections. The survival for patients with curative resections is good, with estimates of 60 to 80% at 5 years. Patients with unresectable disease have outcomes similar to those for pancreatic adenocarcinoma.

Other Cystic Lesions

The vast majority of cyst-like lesions within the pancreas are not true cysts or tumors but actually pseudocysts. These are collections of pancreatic secretions related to ductal disruption after acute pancreatitis or pancreatic trauma.

Other cysts within the pancreas are exceedingly rare. These can be classified as congenital/inherited, infectious, and neoplastic. The congenital/inherited lesions include simple cysts, polycystic disease (with or without kidney involvement), Von Hippel-Lindau disease, dermoid cysts, and macrocysts secondary to cystic fibrosis. Infections with parasites such as *Echinococcus granulosis* and *Taenia solium* can also produce cystic lesions within the pancreas. Other neoplastic cystic lesions in addition to the three most common ones described above include acinar cell cystadenocarcinoma, cystic choriocarcinoma, cystic teratoma, cystic islet cell tumors/acinar cell cystadenocarcinoma (usually nonfunctioning), cystic necrosis of adenocarcinoma or lymphoma, papillary cystic epithelial neoplasms, and angiomatous lesions, such as angiomas, lymphangiomas, and hemangioendotheliomas. These tumors are described in the literature with case reports, and only minimal details regarding their clinical behavior are known.

Solid Tumors of the Pancreas

Though the overwhelming majority of solid tumors in the pancreas are adenocarcinomas, a few other types of tumors are known to occur and will be described here.

Lymphomas can involve the pancreas in up to one-third of patients. However, primary lymphoma of the pancreas is a rare tumor, accounting for less than 1% of all extranodal non-Hodgkin's lymphomas and only 0.3% of pancreatic tumors. Abdominal pain and weight loss are common complaints at presentation. Lactate dehydrogenase may be elevated. Due to the large size attained by these tumors, a palpable mass can be felt in over half of patients. Jaundice may be found in one-third. Pancreatitis is uncommon. These tumors are frequently misdiagnosed as adenocarcinoma prior to surgery. A clue to the diagnosis may be an unusually large solid tumor. Therapy consists of combination chemotherapy and radiation but survival is poor.

Two variants of ductal adenocarcinoma include adenosquamous carcinoma and giant cell carcinoma of the pancreas. Both arise from the ductal cell. Adenosquamous cancers have a transition point to squamous epithelium. They tend to be hypervascular. The giant cell carcinoma is also known as sarcomatoid and several subtypes have been described. Of note, these tumors tend to spread hematogenously and generate distant metastases unlike adenocarcinoma. Overall, the clinical presentation, response to therapy, and prognosis are very similar to those for adenocarcinomas.

Acinar cell carcinomas have also been described. These malignant tumors arising from the endocrine portion of the pancreas can present as cystic or solid tumors. Most are nonfunctioning and are discovered incidentally or due to mass effect. Serum lipase levels may be elevated and peripheral fat necrosis may be noted.

Pancreaticoblastoma is a rare tumor usually found in children at a mean age of 4 years. Girls are affected more often than boys. Rare cases can present in adulthood. The tumors tend to be large at the time of presentation and symptoms of pain or fullness are related to mass effect. Distant metastases can develop. Treatment involves wide excision.

Pancreatitis is an inflammatory disease of the pancreas. In clinical terms, acute pancreatitis usually develops rapidly and without a prior history of repeated pancreatitis attacks. In contrast, chronic pancreatitis may be characterized by symptoms that slowly develop and a history of multiple previous pancreatitis attacks. Pathologically, acute pancreatitis is defined as pancreatitis that occurs in a previously healthy gland and that, after the acute attack resolves, leaves a pancreas that may be both morphologically and functionally normal. In contrast, the gland is usually abnormal before an attack of chronic pancreatitis becomes clinically apparent. That preexisting abnormality usually involves diffuse fibrosis of the gland with loss of both exocrine and endocrine elements, and those changes persist even after the attack of chronic pancreatitis has resolved.

PATHOLOGY

An attack of acute pancreatitis may be either mild or severe. Pathological changes of mild acute pancreatitis include edema, peripancreatic fat necrosis, and a mild intrapancreatic inflammatory reaction. In contrast, severe pancreatitis is pathologically characterized by varying degrees of parenchymal necrosis along with a severe intrapancreatic inflammatory reaction. Intrapancreatic hemorrhage as well as both intrapancreatic and peripancreatic fluid collections can be seen in severe pancreatitis along with extensive peripancreatic fat necrosis.

ETIOLOGY

Acute pancreatitis typically occurs as a consequence of some other process; collectively, those processes are referred to as the "etiologies" of acute pancreatitis. In developed countries, roughly 80% of patients with acute pancreatitis develop their disease as a result of either biliary tract stone disease or as a result of prolonged and excessive abuse of ethanol. In any particular population, the distribution between these two causes is related to the incidence of those inciting events in that population—i.e., in inner city populations, ethanol abuse is the most common cause, whereas in more affluent suburban groups, biliary tract stones account for most cases of pancreatitis. A number of drugs can also cause pancreatitis (see Table I). Duodenal or pancreatic tumors as well as other lesions causing pancreatic duct

Pentamidine		
Estrogens		
Dideoxyinosine		
Thiazides		

obstruction (e.g., duodenal Crohn's disease, duodenal ulcers, or periampullary diverticulitis) can also precipitate an attack of acute pancreatitis. Some patients have acute pancreatitis on a hereditary basis. Recent studies have identified a number of genetic mutations that are associated with pancreatitis in those individuals. In some people, the mutation results in an abnormal cationic trypsinogen that, once activated, may be resistant to inactivation by trypsin inhibitors in the pancreas. In other individuals, hereditary pancreatitis may be due to genetic defects that result in production of ineffective trypsin inhibitors in the pancreas. Pancreatitis can also be triggered by a number of miscellaneous events, including hyperlipidemia, shock, hypothermia, trauma, scorpion bites, and endoscopic retrograde cholangiopancreatography (ERCP). The anatomic variant pancreas divisum has also been associated with episodes of pancreatitis, but whether it should be considered a cause of acute pancreatitis is a controversial issue. Roughly 15% of patients develop pancreatitis for no identifiable reason. In those cases, the pancreatitis is considered to be "idiopathic." Recent reports have suggested that many of those patients with idiopathic pancreatitis actually have pancreatitis as a result of overlooked biliary tract disease (microlithiasis), an autoimmune process, or cystic fibrosis.

The mechanisms by which a biliary tract stone might trigger acute pancreatitis have been the subject of considerable study and speculation. Opie suggested in 1901 that a stone might migrate into or through the terminal biliopancreatic ductal system, causing obstruction and creating, behind that obstruction, a common bile–pancreatic channel that would permit bile to reflux, retrogradely, into the pancreatic duct. More recent studies, however, have indicated that stone-induced obstruction of the pancreatic duct, rather than reflux of bile into the pancreatic duct, is the event that probably triggers acute pancreatitis. Presumably, the stone, or inflammation caused by passage of a stone, causes obstruction of the distal duct, and continued secretion above that obstruction leads to pancreatic ductal hypertension. By mechanisms that have not been defined, pancreatic ductal hypertension then causes changes within pancreatic acinar cells that result in acinar cell injury and pancreatitis (see below).

The mechanisms by which ethanol abuse might cause acute pancreatitis are not known with certainty, but it is generally believed that ethanol or one of its metabolites triggers pancreatitis by exerting a direct toxic effect on the pancreas, much like a drug. Experimental evidence to support this hypothesis is, however, limited. The chronic pancreatitis that is associated with prolonged and excessive ethanol abuse may reflect changes resulting from repeated subclinical episodes of acute ethanol-induced pancreatitis.

PATHOPHYSIOLOGY

The earliest changes of acute pancreatitis appear to occur within pancreatic acinar cells, and perhaps the earliest of those changes involves intraacinar cell activation of digestive enzyme zymogens. The pancreatic acinar cell synthesizes and secretes a large number and amount of digestive enzymes, and those enzymes play a critical role in digestion. Under normal conditions, the potentially harmful digestive enzymes are synthesized and secreted as inactive proenzymes or zymogens, which become activated only after they traverse the pancreatic ductal system and enter the duodenum. There, the brush border enzyme enterokinase (enteropeptidase) catalyzes the activation of trypsinogen and trypsin activates the other zymogens, including chymotrypsinogen, proelastase, and the procarboxypeptidases. During the earliest stages of pancreatitis, activation of digestive enzyme zymogens, including trypsinogen, occurs within acinar cells. The mechanisms responsible for that intraacinar cell activation of trypsinogen are not entirely clear, but one widely accepted hypothesis suggests that it is catalyzed by lysosomal hydrolases such as cathepsin B and that the activation occurs because lysosomal hydrolases and digestive enzymes become colocalized within membrane-bounded intracellular organelles during the very early stages of pancreatitis. Presumably, intraacinar cell zymogen activation leads to acinar cell injury and that injury then leads to pancreatitis.

CLINICAL PRESENTATION

Symptoms

The classical symptoms of acute pancreatitis are abdominal pain, nausea, and vomiting. The pain is usually experienced in the upper abdomen and usually radiates straight through to the back. It is usually constant and gradually increases in severity. It may be relieved by sitting upright and/or leaning forward. Nausea and vomiting usually follow the onset of pain but the pain is not relieved even by repeated episodes of vomiting. Fever is common but rigors, when they occur, should suggest that biliary obstruction and cholangitis are also present. Clinical jaundice can be present either as a result of biliary tract obstruction or as a result of cholestasis caused by pancreatitis.

Physical Examination

Acute pancreatitis is usually associated with diffuse abdominal tenderness, and both voluntary and involuntary guarding are typically noted on physical examination. An abdominal mass, particularly in the upper abdomen, can sometimes be felt. The patient is frequently described as "writhing about" on the stretcher in search of a position of comfort. Physical changes indicative of severe dehydration may be present either as the result of repeated vomiting or because of loss of fluid into the extravascular spaces. Tachycardia, fever, tachypnea, and hypotension are commonly seen when pancreatitis is severe. When retroperitoneal hemorrhage has occurred, ecchymoses in the flank (Grey–Turner sign) or periumbilically (Cullen's sign) may be observed. Jaundice is not uncommon, but during the early stages of pancreatitis, the jaundice is usually mild.

Blood Tests

Routine blood tests usually reveal an elevated white blood cell count and a so-called shift to the left manifested by an increase primarily in neutrophils. The hematocrit is usually elevated as a result of fluid loss, either externally as the result of vomiting or internally as a result of fluid shifts to the extravascular compartment. Measurement of serum electrolytes in the former case usually reveals changes indicative of a hypochloremic alkalosis whereas serum electrolytes may be normal in spite of severe dehydration if most of the fluid has been lost into the extravascular space. In either case, hypoalbuminemia is common. The bilirubin and transaminases may be elevated, and the alkaline phosphatase may be elevated with these changes due either to extrahepatic biliary obstruction or to the cholestasis of severe illness. Patients with hyperlipidemia-induced pancreatitis typically have very high serum triglycerides during an attack and, not infrequently, lactescent serum can be seen. The classical change in blood chemistry associated with acute pancreatitis is a rise in the serum amylase, lipase, or both. The magnitude of these rises does not indicate the severity of the attack and a substantial fraction of patients may be examined in the hospital setting after these changes have resolved and their amylase or lipase levels have returned to normal. It is important to recognize that an elevated amylase can be noted in a variety of disease states other than pancreatitis (see Table II) and that a rise in serum amylase is therefore not necessarily diagnostic of pancreatitis. Similarly, a normal or near-normal serum amylase value does not exclude the diagnosis of acute pancreatitis.

A number of other tests have been proposed for the diagnosis of acute pancreatitis. These include measurement of trypsinogen activation peptide (TAP) in blood or serum, measurement of serum immunoreactive trypsin, measurement of urine amylase levels, and measurement of the clearance ratio of amylase to creatinine. Unfortunately, none of these tests is without false positives or false negatives and, at present, they would appear to have little to offer for the diagnosis of acute pancreatitis. Recent studies have suggested that a

TABLE II Causes of Elevated Serum Amylase Activity

Pancreatic causes	Intraabdominal nonpancreatic causes	Extraabdominal causes
Acute pancreatitis	Perforated hollow viscus	Salivary gland pathology
Pancreatic ascites	Cholangitis	Burns
Pancreatic trauma	Renal failure	Lung tumors
Chronic pancreatitis	Mesenteric ischemia/infarction	Diabetic ketoacidosis
Pancreatic cancer	Cholecystitis	Pneumonia
Endoscopic retrograde cholangiopancreatography	Ruptured ectopic pregnancy	
	Bowel obstruction	
Pseudocysts	Ovarian cyst	
Duct obstruction		

number of blood tests can be used to predict the severity of pancreatitis. These include measurement of serum interleukins (IL-1 and IL-6), tumor necrosis factor α (TNFα), and C-reactive protein. Changes in the levels of these elements are not specific to pancreatitis and these tests should therefore not be used for the diagnosis of pancreatitis.

Imaging Studies

Plain films of the abdomen usually reveal an ileus pattern. Occasionally, a prominent loop of air-filled jejunum (sentinel loop) near the pancreas is seen in the left upper quadrant of the abdomen, but this is not uniformly the case. On chest X-ray, pleural effusions and lower lobe atelectasis are common. Occasionally, ultrasound examination of the abdomen may be helpful in the diagnosis by revealing pancreatic swelling and the presence of gallbladder and/or bile duct stones. However, ultrasound examination is often incomplete because the dilated, gas-filled bowel loops that are present as the result of pancreatitis-induced ileus may preclude a comprehensive ultrasound exam.

Perhaps the most useful imaging study for acute pancreatitis is the computed tomography (CT) scan, particularly when it is combined with intravenous bolus administration of contrast material. This exam usually detects all but the mildest changes of pancreatitis, including pancreatic swelling, peripancreatic inflammation, the presence of acute peripancreatic fluid collections, and the development of pancreatic necrosis. The latter change is manifested by areas of non-contrast-perfused pancreatic tissue. The contrast-enhanced CT scan can be particularly useful by excluding other causes of severe abdominal pain and peritonitis, including perforated viscus and ischemic bowel. The finding of a normal pancreas on contrast-enhanced CT examination in the presence of clinical changes suggestive of severe pancreatitis should alert the clinician to the high likelihood that the patient does not, indeed, have pancreatitis.

Prognosis

Several scoring systems have been used in an attempt to determine, early in the course of pancreatitis, whether the attack is mild or severe. These include the Ranson system (see Table III), the Glasgow system, the CT scoring system, and the Acute Physiology and Chronic Health Evaluation (APACHE) scoring system. Obesity has also been identified as an independent risk factor. It is also likely that an experienced clinician using simple "good judgment" can also discriminate between mild and severe pancreatitis with similar accuracy. Patients with severe pancreatitis, for the most part, experience a complex disease with secondary failure of other organs (lungs, kidney, etc.), which often requires prolonged intensive care, may necessitate repeated operations and may be associated with mortality rates of 20–40%. On the other hand, mild pancreatitis is truly a mild disease with recovery in several days, little morbidity, and negligible mortality.

TREATMENT

Initial Treatment

The initial treatment of acute pancreatitis includes the firm establishment of a diagnosis. A number of other serious problems, including perforated viscus, ischemic or infarcted bowel, and bowel obstruction, can masquerade as pancreatitis, and making the firm diagnosis of acute pancreatitis may not be a trivial matter. Usually, patients present with classical symptoms, physical findings, and laboratory changes, including hyperamylasemia. An early CT scan can be used to confirm the diagnosis. However, when doubt persists, a diagnostic laparotomy, to exclude other causes of abdominal pain, may be required.

Once the diagnosis of acute pancreatitis is established, attention should be directed at relieving pain and providing fluid resuscitation. The pain of pancreatitis may be severe and difficult to control. It is generally

TABLE III Ranson's Signs for the Prognosis of Acute Pancreatitis[a]

On admission	During initial 48 hours
Age Over 70 Years	Hematocrit decrease over 10% with rehydration
White blood cell count over 18,000/mm^3	Blood urea nitrogen rise greater than 2 mg/dl
Blood glucose over 20 mg/dl	Serum calcium below 8 mg/dl
Lactate dehydrogenase over 400 IU/liter	Arterial oxygen below 60 mmHg
Glutamic aspartate aminotransferase above 250 U/liter	Base deficit over 5 mEq/liter
	Fluid sequestration over 4 liters

[a]Adapted from Ranson (1979). The total number of positive items correlates with morbidity and mortality.

believed that meperidine, rather than morphine, is the opiate of choice for pain control in pancreatitis. Fluid requirements, particularly in severe pancreatitis, can be enormous, and, in many ways, resemble those of a severe burn. The hematocrit elevation can be used to estimate the intravascular fluid deficit, and that deficit should be replaced with an isotonic solution containing albumin. Usually, the standard serum electrolytes are normal and fluid replacement can be achieved with either lactated Ringer's solution or normal saline. Hypocalcemia can be present and, if ionized serum calcium levels are depressed, calcium administration may be indicated. Hypomagnesemia, particularly in patients with a history of ethanol abuse, may also be present and require treatment.

Adequate fluid resuscitation is perhaps the single most important element in the early treatment of severe pancreatitis, and there is evidence that inadequate fluid repletion can markedly worsen the severity of a pancreatitis attack. Proper administration of fluid in this setting may require placement of a central venous or pulmonary artery pressure monitor. This is especially true in patients with comorbidities such as cardiac disease and in those with adult respiratory distress syndrome (ARDS), because overhydration in these patients may also create serious problems.

Prophylactic antibiotics may be helpful in the early treatment of patients with severe acute pancreatitis. Several reports have indicated that early administration of broad-spectrum antibiotics that penetrate the pancreas may decrease either the mortality or the morbidity of severe pancreatitis by reducing the incidence of later septic complications. This is a controversial issue, however, because the administration of prophylactic antibiotics may favor the emergence of resistant organisms, particularly fungi, in the inflamed pancreas, actually worsening the clinical course.

Patients with severe pancreatitis may suffer from a prolonged illness, and provision of adequate nutrition is therefore essential. The early institution of total parenteral nutrition in these patients has gained wide acceptance, although, at present, there is considerable interest in providing nutrition via an enteral route. Early enteral nutrition, provided via a nasoenteric or nasogastric tube, may also be beneficial in preventing bacterial translocation from the bowel to the pancreatic bed, thus, in this manner, reducing the incidence of pancreatic infection. Randomized studies to evaluate this possibility are currently underway.

A number of other therapies for pancreatitis have been proposed, frequently on the basis of preclinical animal experiments, but none of these interventions has been shown to be of benefit. Included among these unproved therapies are peritoneal lavage, plasma ultrafiltration, nasogastric suction, and administration of variety of agents, including atropine, glucagon, calcitonin, somatostatin, steroids, protease inhibitors, heparin, and platelet-activating factor antagonists. There is currently great interest in the possibility that agents that modify the inflammatory response by interfering with cytokine/chemokine action may be useful in the early treatment of pancreatitis, and it is likely that prospective trials of such agents will be forthcoming. However, at present, no agents directed at altering the inflammatory response have been of proved benefit in the treatment of severe acute pancreatitis.

The role of early (i.e., within 48–72 hours of the onset of an attack) endoscopic biliary stone clearance, achieved by ERCP, with or without endoscopic sphincterotomy, has been the subject of several prospective randomized trials. Each of those studies has shown that early stone clearance is of no benefit in mild pancreatitis. On the other hand, in severe pancreatitis, early stone clearance has been shown to be of benefit in two studies but of no benefit in a third study. Thus, at present, the role of early stone clearance by ERCP and endoscopic sphincterotomy is controversial.

Late Treatment of Complications

Acute pancreatitis may be complicated by the late development of pancreatic infection or by the evolution of a pancreatic pseudocyst. Pancreatic infection, when it involves infection of either necrotic pancreatic tissue or necrotic peripancreatic tissue, usually requires surgical debridement. For the most part, this is accomplished by repeated operations, during which the infected necrotic tissue is removed and drains are placed. Recently, attempts to accomplish this by percutaneous or even endoscopic methods have also been described, but the role of those methods remains to be established.

Pancreatic pseudocysts are collections of fluid that are contained within the boundaries created by adjacent structures. Most communicate with the pancreatic ductal system and contain fluid with high concentrations of pancreatic digestive enzymes. They may be colonized by bacteria, but clinical infection, with signs of sepsis, is usually absent. When clinical infection is present, a pancreatic abscess (i.e., infected pseudocyst) should be suspected. Pancreatic pseudocysts that are asymptomatic and of stable size do not require treatment. When infected, they should be drained, usually by percutaneous methods externally. It is generally believed that, in the absence of infection, pseudocysts that are symptomatic and/or enlarging after 6 weeks of observation should be

treated, but there is no agreement as to the ideal method of treating such pseudocysts. Successful treatment has been reported using percutaneous drainage (i.e., with CT or ultrasound guidance), endoscopic internal drainage (i.e., with endoscopic ultrasound guidance), or by surgical internal drainage (i.e., by cyst gastrostomy or cyst Roux-en-Y jejunostomy). In practice, the approach is usually determined by the local expertise available at the treating institution.

Pancreatitis, Chronic

CHRIS E. FORSMARK
University of Florida, Gainesville

cholecystokinin A gastrointestinal hormone that stimulates pancreatic secretion of digestive enzymes as well as gallbladder contraction.

endoscopic retrograde cholangiopancreatography A procedure utilizing an endoscope to inject radiographic contrast into the pancreatic and bile ducts. Treatment of certain problems including ductal strictures and removal of ductal stones is possible with this technique.

endoscopic ultrasonography A procedure utilizing an endoscope with an ultrasound probe mounted on the tip, which allows highly detailed examination of the pancreas and surrounding structures.

neurolysis Destruction of nerves to produce pain relief

pseudoaneurysm Aneurysmal dilation of a peripancreatic artery produced by the local injurious effects of a pseudocyst.

pseudocyst A collection of fluid produced by leakage of pancreatic juice and surrounded by a capsule of fibrous and granulation tissue.

secretin A gastrointestinal hormone that stimulates pancreatic secretion of fluid and bicarbonate.

steatorrhea The presence of significant undigested fat in the stool. A marker of inadequate or incomplete digestion of fat.

trypsinogen A pancreatic digestive enzyme that, once activated, has the capacity to activate all the other pancreatic digestive enzymes.

trypsin inhibitor protein (also known as SPINK-1) A pancreatic secretory protein that inhibits the action of activate trypsin and functions as a protective mechanism to prevent inadvertent activation of digestive enzymes within the pancreas.

Chronic pancreatitis is characterized by inflammation, fibrosis, and eventually destruction of both exocrine and endocrine tissue. By definition, the damage is permanent and irreversible. This histological definition, although still widely accepted, is difficult to apply in practice, as pancreatic tissue is rarely available for evaluation. Over a number of years, a series of international panels have attempted to draw up definitions for chronic pancreatitis but these have also been based on histology. More recent attempts to define and categorize chronic pancreatitis have focused on the results of diagnostic tests or on etiology, bypassing the difficult issue of defining the disease. For many clinicians, the definition has been based on abnormalities of the pancreas visible on imaging studies such as computed tomography, ultrasound, or endoscopic retrograde cholangiopancreatography. Unfortunately, these abnormalities (such as diffuse pancreatic calcifications or a dilated pancreatic duct) may take years to develop and may not even develop in some patients. Defining the disease based on imaging studies will therefore miss many patients with the disease. More recent attempts to categorize chronic pancreatitis have focused more on etiology, but no single, widely accepted method for defining and categorizing chronic pancreatitis exists.

DEMOGRAPHIC FINDINGS

Estimates of the incidence and prevalence of chronic pancreatitis vary widely. Autopsy studies suggest a prevalence of 0.04–5%. Autopsy studies may overestimate true prevalence as histologic changes of chronic pancreatitis can be found in certain subgroups (e.g., longstanding alcohol use, very elderly) in whom no symptoms of chronic pancreatitis were present in life. Incidence studies range from less than 1 to more than 10 new cases per 100,000 population. The single prospective study that was performed found a prevalence of 27.4 cases per 100,000 population and an incidence of 8.2 new cases per 100,000 population. In the United States, this accounts for more than 60,000 hospital admissions yearly in which chronic pancreatitis is one of the discharge diagnoses.

Most of these demographic data are based on patients with alcohol-induced chronic pancreatitis, as these are the easiest to diagnose using routinely available imaging studies. Patients with other forms of pancreatitis (e.g., idiopathic chronic pancreatitis) and those with less advanced cases of alcoholic chronic pancreatitis may lack these easily identifiable abnormalities and so may not be included in epidemiological studies. The true incidence and prevalence are therefore probably higher than the available estimates.

Chronic pancreatitis produces significant morbidity, mortality, and health care costs. A recent analysis of both acute and chronic pancreatitis estimated total

 Copyright 2004, Elsevier (USA). All rights reserved.

costs at 2.5 billion dollars yearly. Morbidity and mortality occur as a consequence of the disease itself, the therapy used to treat it (e.g., surgery), or ongoing alcohol abuse (in those with alcohol-induced chronic pancreatitis). Abdominal pain, maldigestion with weight loss, diabetes mellitus, secondary cancers, and continued alcohol abuse are the major negative influences on quality and length of life. Overall, 10-year mortality is approximately 30% and 20-year mortality is approximately 50% or greater. Death is often not due to chronic pancreatitis but rather to other medical conditions (cirrhosis, malignancy, and vascular disease), continued alcohol abuse, or postoperative complications.

ETIOLOGY AND PATHOPHYSIOLOGY

Despite intense effort, no clear unifying pathophysiologic mechanisms have been identified. Although all etiologies of chronic pancreatitis may produce similar histologic damage, the pathophysiologic mechanism may vary from etiology to etiology. The ultimate effect is damage to the pancreatic acini, ducts, nerves, and islet cells and the development of the cardinal manifestations of abdominal pain, maldigestion, and diabetes mellitus. The etiologies of chronic pancreatitis are listed in Table I and are discussed below.

Alcohol Consumption

Alcohol consumption is the major cause of chronic pancreatitis. Although there is no "safe" level of intake below which chronic pancreatitis does not occur, prolonged alcohol intake is usually required (e.g., 4 pints of beer or 800 ml of wine per day for 6–12 years). Only a minority of alcoholics (approximately 15%) drinking this much will actually develop chronic pancreatitis, suggesting that an important cofactor (such as diet or genetics) exists. In Westernized societies, 70% of cases of chronic pancreatitis are due to alcohol consumption, with the remaining 30% due to other causes or idiopathic disease. The mechanism by which alcohol produces pancreatic injury and chronic pancreatitis is unknown.

By the time the first clinical attack of alcoholic pancreatitis occurs, most patients have already developed histologic changes of chronic pancreatitis. Continued alcohol abuse leads to ongoing pancreatic damage although damage may continue even with complete abstinence, albeit at a slower rate. The prognosis of alcoholic chronic pancreatitis is poor, with the frequent development of exocrine or endocrine insufficiency and increased mortality due to the consequence of continued alcohol abuse.

TABLE I Causes of Chronic Pancreatitis

Alcohol abuse
Tropical pancreatitis
Obstruction of pancreatic duct
Trauma to pancreatic duct
Benign or malignant ductal stricture
Consequences of pancreatic duct stent
Pancreas divisum
Genetic causes
Hereditary pancreatitis (trypsinogen gene mutations and others)
Cystic fibrosis
Autoimmune chronic pancreatitis
Recurrent or severe acute pancreatitis
Idiopathic pancreatitis
Early-onset
Late-onset

Tropical Pancreatitis

Tropical pancreatitis is the most common form of chronic pancreatitis in certain areas of Indonesia, India, and Africa. The most classic form includes abdominal pain beginning in childhood, with subsequent diabetes, malnutrition, and diffuse pancreatic calcifications. Less severe forms also seem to exist. Most people ultimately die from complications of the disease. Malnutrition is felt to be important in the development of tropical chronic pancreatitis, perhaps due to deficiencies in trace elements or antioxidants. Toxic products contained in the diet (e.g., cassava or sorghum) or the environment or genetics may also play a role in pancreatic injury.

Pancreatic Duct Obstruction

Any condition that chronically obstructs the main pancreatic duct can lead to chronic pancreatitis in the gland "upstream" from the obstruction. Obstruction may be due to benign strictures, ampullary stenosis or neoplasms, pancreatic tumors or pseudocysts, congenital variants, or endoscopically placed pancreatic duct stents. Long-standing obstruction leads to irreversible chronic pancreatitis, but both functional and structural improvement can be seen if the obstruction is discovered and relieved.

One form of pancreatic duct obstruction deserves specific mention. Pancreas divisum, a congenital failure of fusion of the dorsal and ventral pancreatic ducts, may lead to obstruction of the pancreatic duct and chronic pancreatitis. The small ventral pancreas drains through the larger major papilla and the larger dorsal pancreas drains through the smaller accessory papilla. Pancreas

divisum occurs in up to 7% of the population. Although the vast majority of patients with this congenital abnormality have no symptoms, a small subset of patients will develop acute or chronic pancreatitis.

Genetic Forms of Chronic Pancreatitis

Hereditary Pancreatitis

Several kindreds from around the world with acute and chronic pancreatitis have been described. The pattern of inheritance is autosomal dominant with incomplete penetrance and the typical clinical features are recurrent acute pancreatitis beginning at an early age, culminating in advanced chronic pancreatitis. Pancreatic cancer is a common complication, occurring in up to 40% of these patients. There are a number of genetic defects that have been identified in these kindreds with hereditary pancreatitis. Functional genomic studies initially identified a single point mutation in the cationic trypsinogen gene. Trypsinogen is a proenzyme that, once activated, has the ability to activate not only itself but other digestive enzymes as well. In the normal state, trypsinogen is activated only within the duodenum, safely away from the pancreas. Trypsinogen may, however, undergo a very slow autoactivation within the pancreas. A number of mechanisms exist to prevent this activated trypsin from activating other digestive enzymes within the pancreas and causing pancreatitis. Based on molecular modeling, the mutation was thought to convey a gain-of-function mutation, in which the mutated trypsinogen was resistant to inactivation once activated. Trypsin, the activated form of trypsinogen, could then activate all of the other pancreatic digestive enzymes within the pancreas. This continual low-grade activation of digestive enzymes within the pancreas is believed to produce ongoing damage, which ultimately produces severe chronic pancreatitis. Since this initial discovery, several other gene mutations have been identified in the cationic trypsinogen gene as well as within an enzyme meant to inactivate trypsin, the trypsin inhibitor protein (serine protease inhibitor kazal type 1 or SPINK-1). Studies have not yet identified these gene mutations as being important in patients with other forms of chronic pancreatitis (idiopathic and alcoholic chronic pancreatitis).

Cystic Fibrosis

In children, cystic fibrosis is the most common cause of pancreatic insufficiency. Precipitation of protein plugs and inspissated mucus occur in the pancreatic duct, much as in the bronchioles, leading to damage to the gland due to chronic obstruction. Recent studies have noted cystic fibrosis gene mutations in patients with acute and chronic pancreatitis who have no pulmonary or sinus conditions commonly associated with cystic fibrosis. In some studies, at least half of patients initially diagnosed with "idiopathic" chronic pancreatitis have at least one cystic fibrosis allelic mutation. Many of these mutations are not measured on commercially available screens and complete genetic analysis is required to identify the mutations.

Rare Forms of Chronic Pancreatitis

Autoimmune Chronic Pancreatitis

Chronic pancreatitis may rarely be seen in association with autoantibodies, elevated levels of immunoglobulins, and dense lymphocytic infiltrate within the pancreas (if histology is available). In over half of these cases, other autoimmune diseases coexist including primary sclerosing cholangitis, primary biliary cirrhosis, autoimmune hepatitis, and Sjogren's syndrome.

Recurrent or Severe Acute Pancreatitis

A very severe attack of acute pancreatitis or multiple less severe attacks may produce enough damage to the gland to result in chronic pancreatitis. Most commonly, this occurs after the development of a stricture in the pancreatic duct that produces continuing damage to the gland upstream of the stricture.

Hypertriglyceridemia

Triglyceride levels above 1000 mg/dl can initiate acute pancreatitis. Recurrent attacks of hyperlipidemic pancreatitis may ultimately produce chronic pancreatitis. This occurs most commonly as a result of familial hyperlipidemias (types IV and V) exacerbated by estrogen use or poorly controlled diabetes. This cause of both acute and chronic pancreatitis should not be forgotten, as effective therapy is available.

Idiopathic Chronic Pancreatitis

Between 10 and 30% of patients will not have an easily definable cause of chronic pancreatitis. Idiopathic chronic pancreatitis is the second most common cause of chronic pancreatitis in adults, behind alcohol abuse. Some of these patients may actually be alcoholics and may be missed if this history cannot be elucidated. Some may have cystic fibrosis gene mutations, as noted above. Two different forms of idiopathic chronic pancreatitis have been described, a late-onset form and an early-onset form. The late-onset form occurs at a mean age of 56 years, commonly presenting with steatorrhea or diabetes and less commonly with abdominal pain. The early-onset form begins at approximately age 20 and is

characterized by severe pain in essentially all patients but very infrequently by steatorrhea or diabetes. Many of these patients with early-onset idiopathic chronic pancreatitis do not have easily identifiable abnormalities of the pancreas on imaging studies [computed tomography (CT), ultrasound (US), or endoscopic retrograde cholangiopancreatography (ERCP)] and are commonly misdiagnosed.

CLINICAL FEATURES

Abdominal Pain

Abdominal pain is the predominant symptom of chronic pancreatitis and the one that most adversely affects quality of life. The most frequent type of pain is dull, located in the epigastrium with associated back pain, and made worse by eating or lying in the supine position. Food may be avoided, leading to weight loss and malnutrition. Pain may be episodic (lasting from hours to weeks) or more constant or continuous. The pain is generally moderate to severe and narcotic analgesics are required in many patients. Pain is not universal, however. Pain never develops in up to 15% of patients with alcoholic chronic pancreatitis and up to 25% (or more) of patients with late-onset idiopathic chronic pancreatitis. In some patients, the pain may "burn out" after many years of chronic pancreatitis, although this is unpredictable.

There are many potential sources of pain. The most common contributing factors are considered to be inflammation and damage to pancreatic and peripancreatic visceral afferent nerves, pancreatic tissue ischemia, hyperstimulation of the pancreas due to interruption of normal feedback control, and complications of chronic pancreatitis (pseudocyst, common bile duct or duodenal obstruction, superimposed pancreatic carcinoma).

Maldigestion

Exocrine insufficiency (steatorrhea) due to chronic pancreatitis does not occur until the capacity of the pancreas to secrete lipase and colipase is reduced to less than 10% of normal. Maldigestion is thus a marker of far-advanced chronic pancreatitis. Fat maldigestion is more common and more clinically important than protein or carbohydrate maldigestion. Maldigestion is due to diminished secretion of pancreatic enzymes as well as reduced secretion of bicarbonate from the pancreatic ductal system; with reduced bicarbonate, the lower duodenal pH inactivates many pancreatic digestive enzymes. Weight loss is not invariable with maldigestion as intake may be increased, but can occur if food is avoided due to pain or if intake is inadequate due to chronic alcoholism. Folate deficiency may be seen, particularly in chronic alcoholics. Osteopenia and osteoporosis may also develop as a consequence of vitamin D deficiency.

Diabetes Mellitus

Endocrine insufficiency (diabetes mellitus) develops when enough pancreatic islet cells have been destroyed to significantly impair insulin production. The islet cells are more resistant to damage than the acinar and ductal cells, so diabetes is also a marker of far-advanced chronic pancreatitis. This form of diabetes is rarely associated with ketoacidosis but frequent treatment-associated episodes of hypoglycemia can occur (due to inadequate glucagon reserves). Microvascular complications of diabetes (retinopathy or neuropathy) occur as frequently as in other diabetics, if corrected for the duration of disease.

DIAGNOSIS

Clinical features such as abdominal pain, steatorrhea, or diabetes usually suggest the possibility of chronic pancreatitis, and this is confirmed by one of a wide variety of diagnostic tests. The true gold standard diagnostic test, pancreatic histology, is rarely available and alternative tests serve as imperfect substitutes. Most of the diagnostic tests currently in use are imaging studies that detect structural abnormalities within the pancreas. These can include such features as a dilated or irregular pancreatic duct, pancreatic gland atrophy, or diffuse pancreatic calcifications. Chronic pancreatitis can be a slowly progressive disease and these changes may take years to develop. Similarly, functional problems such as exocrine or endocrine insufficiency may not develop for years. In advanced and long-standing disease, easily visible structural and functional abnormalities may be seen and this makes the diagnosis straightforward. In less advanced disease or disease of shorter duration, however, these structural and functional changes may not be present and the diagnosis can be challenging. This has led to a general clinical differentiation: "big-duct disease" and "small-duct disease." Big-duct disease is the presence of significant structural abnormalities of the pancreas (dilation of the main pancreatic duct, diffuse calcifications) and is often associated with exocrine or endocrine insufficiency. Small-duct disease implies the absence of these advanced structural abnormalities and usually the absence of exocrine or endocrine insufficiency. This differentiation is clinically useful; those with big-duct disease have advanced or long-standing disease, are easiest to diagnose, are usually alcoholic,

TABLE II Diagnostic Tests and Studies for Chronic Pancreatitis (Listed in Order of Decreasing Sensitivity)

Tests of function	Procedures examining structure
Secretin or secretin–cholecystokinin test	EUS[a]
Fecal elastase or chymotrypsin	ERCP
Serum trypsin	MRI/MRCP[a]
Fecal fat	CT
Blood glucose	Ultrasound
	Plain abdominal radiograph

[a] Estimated. The sensitivity of EUS may be better than that of ERCP, MRI, and CT. The specificity of EUS is, however, suboptimal and limits its overall accuracy. The sensitivity of MRI/MRCP is not known but is still probably less than that of ERCP using current image technology.

and are most suitable for endoscopic or surgical therapy. Those with small-duct disease are much more difficult to diagnose, are more likely idiopathic, and are most suitable for medical therapy.

Very few diagnostic tests measure abnormalities of pancreatic function. With the exception of direct hormonal stimulation testing, these tests of function are abnormal only in far-advanced disease when exocrine insufficiency has already developed. Diagnostic tests used for chronic pancreatitis are listed in Table II and are discussed below.

Tests of Pancreatic Structure

Plain Abdominal X Rays

The finding of diffuse pancreatic calcification on a plain abdominal radiograph is specific for chronic pancreatitis but is seen only in far-advanced disease. Focal pancreatic calcification may be due to other conditions such as trauma, islet-cell tumors, or hypercalcemia.

Abdominal Ultrasonography and Computed Tomography

A transabdominal ultrasound may note pancreatic parenchymal calcifications, pancreatic atrophy, or a dilated pancreatic duct. Overlying bowel gas can interfere with visualization of the pancreas, making the sensitivity of ultrasound greater than that of plain X rays but less than that of CT. CT findings of chronic pancreatitis include atrophy of the gland, irregular contour of the pancreas, dilation or irregularity of the pancreatic duct, and calcified pancreatic calculi (Fig. 1). CT is also useful in looking for complications of chronic pancreatitis (e.g., pancreatic carcinoma or pancreatic pseudocyst).

Magnetic Resonance Imaging and Magnetic Resonance Cholangiopancreatography

The quality of standard magnetic resonance imaging (MRI) images of the pancreas continues to improve but has not yet reached the overall quality of CT. Magnetic resonance cholangiopancreatography (MRCP) utilizes an anatomic reconstruction of the biliary and pancreatic ductal systems. MRCP is most accurate in advanced chronic pancreatitis but the accuracy with less-advanced chronic pancreatitis is substantially reduced.

Endoscopic Ultrasonography

The endoscopic ultrasonography (EUS) instrument is a high-frequency ultrasound probe mounted on an endoscope. High-resolution images can be acquired of the pancreatic duct, parenchyma, and surrounding structures. EUS is highly accurate in advanced chronic pancreatitis (Fig. 2). The sensitivity and especially the specificity of the test in patients without these advanced abnormalities are not yet known.

Endoscopic Retrograde Cholangiopancreatography

ERCP is one of the most commonly used imaging techniques in the evaluation of patients with presumed chronic pancreatitis. The procedure involves injection of the pancreatic duct with radiographic contrast. The diagnosis of chronic pancreatitis by ERCP is based on changes in the main pancreatic duct and the duct side branches. These changes include duct dilation, stricture formation, irregular duct contour, associated filling of

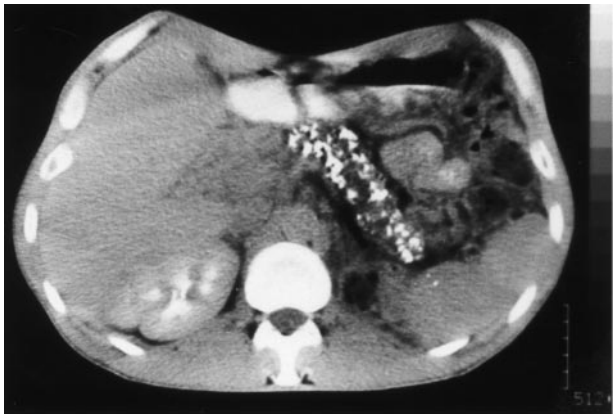

FIGURE 1 An abdominal CT scan demonstrates diffuse and dense calcification within the pancreas of a patient with long-standing alcohol-induced chronic pancreatitis.

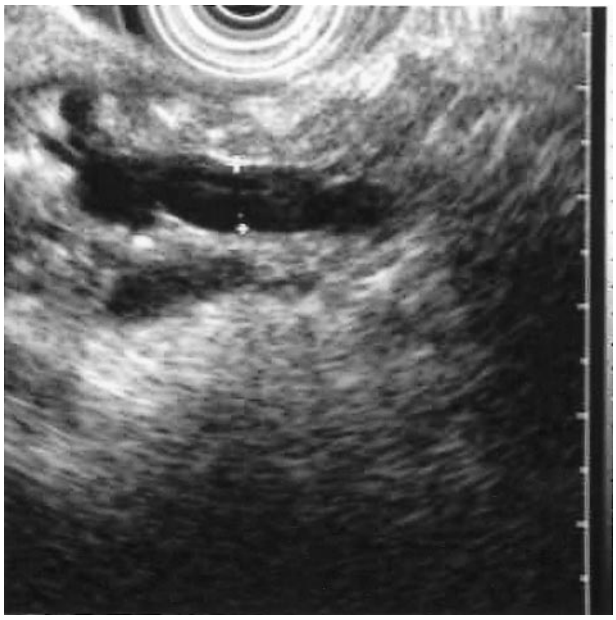

FIGURE 2 An EUS image of chronic pancreatitis. The instrument is seen at the top of the image. The dilated pancreatic duct (measurement markers) is seen at the bottom. The parenchyma of the gland between the scope and dilated duct has irregular echotexture, also consistent with chronic pancreatitis.

cavities or pseudocysts, and filling defects (i.e., pancreatic ductal calculi). ERCP is highly accurate in advanced disease and reasonably accurate in less severe disease (Fig. 3). Some patients, however, can have chronic pancreatitis with a normal ERCP. ERCP is also limited by a number of clinical considerations. In up to one-third of procedures, the ERCP image obtained is of inadequate quality to allow a definitive conclusion. Other conditions can mimic the ERCP changes seen in chronic pancreatitis (pancreatic carcinoma, acute pancreatitis, pancreatic duct stenting, and aging). The procedure is expensive and requires substantial experience and skill and procedure-related complications can occur in up to 10% of patients. Given these factors, ERCP is usually a late step in the evaluation of patients with suspected chronic pancreatitis. ERCP does have one advantage in that therapy can also be accomplished in some patients. This therapeutic, rather than diagnostic, role of ERCP is discussed below.

Test of Pancreatic Function

Laboratory Tests

Serum amylase or lipase levels are often normal and also not of diagnostic importance. Serum trypsin (another pancreatic enzyme) is more useful as a diagnostic test. Levels below 20 mg/dl are seen in advanced chronic pancreatitis (i.e., steatorrhea is present). Pancreatic enzymes may also be measured in stool. Since these enzymes are not reabsorbed, diminished levels in stool are an indirect measure of output of pancreatic enzymes. Both fecal elastase and fecal chymotrypsin have been measured, but only fecal elastase is commercially available. Overall, the sensitivity approaches 90% in advanced disease but is only approximately 50–60% in less advanced disease. This is equivalent to the accuracy of serum trypsin. Measurement of serum glucose or 72 h fecal fat output can document endocrine or exocrine insufficiency but are not useful for diagnostic purposes.

Indirect Tests of Pancreatic Function

There are a number of methods to indirectly measure pancreatic function. Usually, a substrate that requires the presence of pancreatic digestive enzymes within the gut lumen for metabolism is given. Metabolic products are then measured; their relative production rate indirectly reflects pancreatic enzyme secretion. Maldigestion of these substrates does not occur until overall exocrine insufficiency has developed; hence, these tests will be accurate in advanced or end-stage disease but inaccurate in earlier disease. Many variations of this type of test have been developed using a

FIGURE 3 An ERCP of a patient with chronic pancreatitis. The scope can be seen, along with a pancreatic duct filled with radiographic contrast. The pancreatic duct is dilated and the side branches of the duct are also dilated and irregular. The findings are consistent with chronic pancreatitis and demonstrate big-duct disease (see text for explanation).

variety of substrates (bentiromide test, pancrealauryl test, Lundh test meal, amino acid consumption test, and dual-label Schilling test). None of these tests is available for routine clinical use.

Direct Tests of Pancreatic Function

These tests measure the actual output from the pancreas after stimulation with a secretagogue. The secretagogues used are secretin, cholecystokinin, or both. Pancreatic secretions are collected with a tube placed in the duodenum. The sensitivity of these tests, like all diagnostic tests, depends on the severity of the disease. The overall sensitivity (74–90%) and specificity (80–90%) are however, superior to those of any other currently available diagnostic test. There are substantial data indicating that direct hormonal stimulation tests can also diagnose chronic pancreatitis at a somewhat earlier stage than any other available test. Unfortunately, these tests are available at only a few referral centers and are unavailable to many clinicians.

Diagnostic Strategy

The ideal test would have high sensitivity (in both small-duct and big-duct disease) and specificity and be inexpensive, safe, and widely available. No ideal diagnostic test exists. The appropriate use of the variety of available tests requires an understanding of their sensitivity, cost, and risk. Initially, tests that are safe, simple, and inexpensive are used. These tests generally are able to identify only patients with advanced or big-duct chronic pancreatitis. Such tests could include serum trypsin, fecal elastase, and US. When these first-echelon tests are not diagnostic, more invasive, risky, or costly tests would be considered. Second-echelon tests include hormonal stimulation tests, CT scan, MRI/MRCP, or EUS. The most invasive and risky test, ERCP, is most commonly used when the diagnosis remains unclear or when therapy, rather than diagnosis, is required.

TREATMENT

Treatment of Exocrine and Endocrine Insufficiency

Steatorrhea

Steatorrhea occurs only when 90% of pancreatic output has been lost, due to inadequate delivery of both lipase and bicarbonate. The acidic environment further inactivates what lipase may be present and precipitates bile salts, worsening fat absorption. The replacement of endogenous digestive enzymes with exogenous enzymes is the goal of therapy. The use of appropriate dosages of these enzymes leads to resolution of diarrhea and weight loss, although steatorrhea is rarely completely corrected.

The various commercially available preparations and their lipase content are listed in Table III. At least 30,000 IU of lipase needs to be delivered to the duodenum during each meal. Patients using the lower-potency preparations must therefore take three to four pills with each meal. Fewer pills must be taken with the more potent formulations. The enteric-coated preparations are protected from gastric acid. The non-enteric-coated preparations will be destroyed by gastric acid and so must be used in conjunction with an agent to reduce gastric acid output (histamine-2 receptor antagonists or proton pump inhibitors). The most common reason for failure of these enzymes to correct steatorrhea is inadequate dose, usually due to the patient's unwillingness to take the number of pills required. Another common reason is inactivation of lipase by gastric acid in those receiving non-enteric-coated preparations. Dietary manipulations may be needed in the management of malabsorption and malnutrition. The diet should usually contain a moderate percentage of fat (30%), a high percentage of protein (30%), and a low percentage of carbohydrates (40%) and should be supplemented with a high-quality multivitamin, calcium, and vitamin D.

TABLE III Commercially Available Pancreatic Enzymes for the Treatment of Steatorrhea[a] or Pain[b]

Brand name	Units of lipase per pill
Non-enteric-coated enzyme preparations	
Viokase, Viokase 16	8,000; 16,000
Ku-Zyme HP	8,000
Generic pancrealipase	8,000
Enteric-coated enzyme preparations	
Creon 5, 10, 20	5,000; 10,000; 20,000
Pancrease MT 4, 10, 16, 20	4,000; 10,000; 16,000; 20,000
Ultrase 6, 12, 18, 20	6,000; 12,000; 18,000; 20,000

[a] For the treatment of steatorrhea, both non-enteric-coated and enteric-coated preparations can be used. The dosage depends on the lipase content; 30,000 units of lipase should be delivered with each meal. Non-enteric-coated enzymes require cotreatment with agents to suppress gastric acid.

[b] For the treatment of pain, only non-enteric-coated enzyme preparations are used: four to eight pills (depending on potency) before meals and at night. As above, an adjuvant agent to reduce gastric acid is required.

Diabetes Mellitus

Diabetes is late complication of chronic pancreatitis. Microangiopathic complications occur with regularity, including retinopathy, nephropathy, neuropathy, and more rapid atherosclerosis. Another common complication is treatment-induced hypoglycemia. These patients can have inadequate glucagon as well as insulin reserves and cannot respond to hypoglycemia with a glucagon surge and subsequent increase in blood glucose levels. Overly vigorous attempts to control blood sugar can be associated with disastrous complications of treatment-induced hypoglycemia.

Some patients will respond to oral hypoglycemics, but many require insulin. The goal of insulin therapy is usually to control urinary losses of glucose rather than attempt tight control of blood sugar. Tight control of blood sugar is usually indicated in only one subgroup, those with hyperlipidemic pancreatitis, where tight control of blood sugar is needed to allow control of triglyceride levels.

Pain

Medical Treatment

There are many causes of pain and no single treatment is effective in all patients. Abstinence from alcohol reduces the risk of other alcohol-related complications such as cirrhosis, prolongs life, slows the rate of progression of chronic pancreatitis, and may reduce pain. Analgesics are routinely required. Nonnarcotic analgesics should be used first and if narcotics are required, the least potent formulation should be tried first (e.g., propopxyphene with acetaminophen, tramadol). More potent narcotics are required in many patients and addiction occurs in up to 20% of these patients. In patients who require narcotics, the addition of an antidepressant (tricyclic antidepressants or selective serotonin reuptake inhibitors) can be helpful as these can potentiate the effect of narcotics.

Several small studies have suggested that non-enteric-coated pancreatic enzymes can reduce abdominal pain in some patients with chronic pancreatitis. The theoretical basis of their effect is to reduce pancreatic stimulation (or hyperstimulation) by cholecystokinin. This effect, of reestablishing normal negative feedback control of pancreatic secretion, is operative only in the duodenum. Enteric-coated preparations typically release their enzymes in the jejunum; hence, non-enteric-coated preparations are selected if the intent is to treat pain. The response in these trials is mixed. Patients who seemed to respond best to the use of conventional enzymes are those with mild to moderate chronic pancreatitis (without steatorrhea or small-duct disease). Patients with advanced disease (steatorrhea or big-duct disease) did not seem to respond. If tried, this therapy should be considered only in select patients (small-duct disease, no steatorrhea) and should use the correct enzyme and the correct dose (non-enteric-coated preparations at high dosage, coupled with an agent to reduce gastric acid).

A few small studies of octreotide (Sandostatin) have suggested that the use of this agent may reduce the pain of chronic pancreatitis, perhaps by reducing pancreatic stimulation or perhaps by a direct anti-nociceptive effect. A few small studies have also suggested that the use of antioxidants (mixtures of vitamins E and C, selenium, methionine, and β-carotene) may reduce pain. Neither treatment is currently recommended outside clinical trials.

Neurolysis

Interruption of nociceptive visceral afferents from the pancreas can be accomplished by ablation of the celiac nerve plexus. This has been tried by both CT-guided and EUS-guided methods, using injection of anesthetics, steroids, or alcohol. The therapy seems most effective for the pain of pancreatic cancer but is usually too short-lived for patients with chronic pancreatitis. EUS-guided techniques appear to work better and for somewhat longer periods of time than CT-guided techniques. Destruction of visceral afferents by destruction of the splanchnic nerves (thoracoscopic splanchnicectomy) is also being investigated but the efficacy remains to be established.

Endoscopic Therapy

Available endoscopic therapies include pancreatic duct sphincterotomy, pancreatic duct stenting, dilation of ductal strictures, removal of pancreatic stones, and treatment of complications such as pseudocyst or biliary obstruction. The primary goal of endoscopic therapy is to remove or bypass any obstruction within the pancreatic duct. Careful selection of patients for this therapy is critical. Appropriate candidates are those with a significant pancreatic ductal stricture in the head of the pancreas or those with a few obstructing stones in the head of the gland. Approximately one-third to one-half of patients with big-duct disease satisfy these criteria. In these carefully selected groups, up to three-fourths of patients will experience pain relief after endoscopic therapy. Complications of endoscopic treatment of chronic pancreatitis occur in 15–20% of patients (pancreatitis, bleeding, perforation, and sepsis). Pancreatic stents, used for therapy in these patients, can in and of themselves also injure the pancreatic duct and

parenchyma in up to half of patients treated, and these changes may not resolve. Endoscopic therapy is a reasonable alternative in appropriately selected patients at centers with appropriate expertise.

Surgical Treatment

Surgical therapy is considered for pain and for complications of chronic pancreatitis (pseudocyst, bile duct obstruction, and duodenal obstruction). The most commonly performed operation for pain is the lateral pancreaticojejunostomy (modified Puestow procedure). The dilated pancreatic duct is longitudinally incised along its length and overlaid with a defunctionalized Roux limb. The procedure carries low rates of complications (5%) and mortality (2%). The pancreatic duct must usually be dilated to greater than 5 mm; hence, this type of surgery is considered in those with big-duct disease. After a Puestow procedure, immediate pain relief occurs in 70–90% of patients. Pain is controlled in only 50% after 1–3 years of follow-up. In some centers, resection of all or part of the head of the pancreas is combined with a ductal drainage procedure. Morbidity and mortality from these operations is higher than that seen with a Puestow procedure, but long-term pain relief is also higher. Subtotal or total pancreatic resections are rarely indicated and are currently associated with unacceptable postoperative complications, particularly brittle diabetes mellitus.

Treatment for Pain

No single therapy is effective in all patients and the choice of a treatment depends on a variety of factors. The most important include pancreatic ductal anatomy, presence of complications, and local expertise. The first step is to make sure the diagnosis is correct. It is inappropriate to consider therapies with potential side effects or complications unless the diagnosis is secure. Second, it is worthwhile to look for specific complications that have specific therapy, such as pancreatic pseudocyst, duodenal obstruction, common bile duct obstruction, peptic ulcer disease, or pancreatic carcinoma (these are discussed below). Medical therapy is appropriate in all patients. This should include encouragement of abstinence from alcohol (if applicable), a low-fat diet, and analgesics. The choice of subsequent therapy depends in large part whether the patient has small-duct or big-duct disease. In those with small-duct disease, a trial of high-dose non-enteric-coated enzymes coupled with acid suppression is appropriate. Treatment options for those with big-duct disease are largely mechanical, with either endoscopic or surgical attempts to decompress the enlarged pancreatic duct. Patients who fail the above therapies may be considered for more experimental therapies such as celiac plexus block, splanchnicectomy, or octreotide. Significant pancreatic resections are considered an option of last resort in both groups of patients.

COMPLICATIONS

Pancreatic Pseudocyst

Approximately one-quarter of patients with chronic pancreatitis develop a pseudocyst. Many pseudocysts remain asymptomatic. Symptomatic pseudocysts may obstruct a surrounding hollow viscus (duodenum producing nausea and vomiting or common bile duct producing jaundice), may cause pain, may bleed (internally or into the gut lumen), or may rupture (into the peritoneal cavity producing pancreatic ascites or into the pleural space producing a pancreatic pleural effusion). Overall, these complications occur in approximately one-third of patients. The diagnosis is best made with CT. The diagnosis is usually suspected due to a worsening pattern of pain, persistent elevations in amylase or lipase, or symptoms pointing toward one of the above complications.

Not all pseudocysts require treatment. Those that are less than 6 cm in diameter, that are causing no symptoms, and that occur in a reliable patient can be safely observed. Symptomatic pseudocysts can be managed with percutaneous, endoscopic, or surgical decompression, depending on location and local expertise.

Two complications deserve specific mention. Bleeding is rare but can be life-threatening. Bleeding can occur from a pseudoaneurysm associated with a pseudocyst. Evidence of gastrointestinal bleeding in a patient with a pseudocyst is usually treated as an emergency. If initial evaluations do not reveal a source, an emergent CT is performed to look for a pseudoaneurysm. Confirmation of the pseudoaneurysm with CT should be followed with emergent angiography and embolization. Rupture of a pseudocyst or leak from the pancreatic duct can produce pancreatic ascites of a pancreatic pleural effusion. These should be suspected when a very high level of amylase (typically >4000 IU/liter) is found in ascites or a pleural effusion. Endoscopic treatment at ERCP, with sphincterotomy and stenting, is usually curative. Surgical therapy is reserved for failure of endoscopic therapy.

Pseudocysts should not be mistaken for cystic neoplasms. These neoplasms usually have a thick wall or internal nodules along the wall, often with internal sepatations. They most frequently occur in middle-aged women without previous pancreatitis and without risk factors for pancreatitis. These neoplasms are

frequently misdiagnosed; the therapy is resection, not drainage.

Gastrointestinal Bleeding

Bleeding may occur not only as a consequence of a pseudoaneurysm (as noted above) but also from thrombosis of the splenic vein as it travels behind the pancreas. This produces a "left-sided" portal hypertension with gastric varices out of proportion to esophageal varices. Splenectomy is curative.

Pancreatic Carcinoma

Chronic pancreatitis is a risk factor for pancreatic adenocarcinoma and the two may coexist. The overall risk is approximately 4% lifetime, although this may increase to 40% for those with hereditary pancreatitis. There is no currently effective screening method, but superimposed carcinoma is usually suspected due to weight loss or a worsening in a previously stable pain pattern.

Duodenal or Common Bile Duct Obstruction

Obstruction of the duodenum or intrapancreatic common bile duct may occur due to fibrosis and inflammation within the head of the pancreas or due to an associated pseudocyst. Duodenal obstruction produces nausea, vomiting, and early satiety and is best confirmed by a barium upper gastrointestinal series. Common bile duct obstruction can produce jaundice, biliary pain, cholangitis, or asymptomatic elevations in liver chemistries. These patients may also have intrinsic liver disease, so a liver biopsy is usually indicated before deciding on treatment for asymptomatic elevations in liver chemistries. All other symptomatic presentations require therapy. Endoscopic biliary stenting is an appropriate temporizing measure but these patients generally require surgical biliary bypass.

Others

Small bowel bacterial overgrowth and gastroparesis may complicate chronic pancreatitis. Both can interfere with effective treatment of steatorrhea and gastroparesis may cause pain of its own accord.

Pancreatitis, Experimental Models

ASHOK K. SALUJA AND LAKSHMI BHAGAT
University of Massachusetts Medical School

acute pancreatitis Acute inflammatory disease of the pancreas.
caerulein An analogue of cholecystokinin that, because it is more stable, is used for secretagogue-induced pancreatitis.
CDE diet Choline-deficient diet supplemented with ethionine; this diet induces pancreatitis in female mice.
sodium taurocholate A bile salt that induces pancreatitis when injected retrograde into the pancreatic duct.
trypsin The pancreatic digestive enzyme whose premature activation within the pancreas is a common feature of various models of pancreatitis.

Acute pancreatitis is an inflammatory disease of the pancreas that is associated with little or no fibrosis. It can be initiated by several factors including gallstones, alcohol, trauma, and infections and in some cases it may be hereditary. Very often, the patients develop additional complications, such as sepsis, shock, and respiratory and renal failure, resulting in considerable morbidity and mortality. Approximately 300,000 cases occur in the United States each year; some 20% of cases are severe. Despite considerable work being carried out in this area, the pathophysiological mechanisms associated with this disease still remain incompletely understood. This can be attributed in part to the relative inaccessibility of clinical material for experimental studies and has therefore led to the development of several models of experimental pancreatitis to explore its etiology, pathophysiology, and treatment regimens. This article will focus on the experimental models used to study acute pancreatitis. For the sake of simplicity, these models have been divided into two broad categories depending on the approach used to induce pancreatitis, namely, noninvasive and invasive models.

NONINVASIVE MODELS OF PANCREATITIS

Secretagogue-Induced Pancreatitis

More than a century ago, Mouret observed that excessive neural stimulation results in injury of the exocrine pancreas. Subsequent studies have not only confirmed these findings but also have shown that in addition to stimulation with the cholinergic agonists (carbamylcholine), excessive stimulation with cholecystokinin (CCK) and its analogue, caerulein, also results in acute pancreatitis. In fact, the caerulein-induced model has become the most widely used model with which to study acute pancreatitis in rodents.

CCK receptors present on the pancreatic acinar cells exist in two affinity states—high and low. Occupancy of high-affinity receptors by low concentrations of CCK (or caerulein) results in stimulation of digestive enzyme secretion, whereas interaction of CCK with low-affinity receptors results in inhibition of digestive enzyme secretion. Acute pancreatitis is induced by occupancy of these low-affinity receptors by caerulein and it can be prevented by administration of CCK-receptor antagonists (e.g., L-364-718 or CCK-JMV-180, an antagonist of low-affinity CCK receptors in rats).

Administration of caerulein to rodents at doses that are 10- to 100-fold higher than those that evoke maximal secretion of digestive enzymes from pancreatic acinar cells results in a rapid development of pancreatitis. Stimulation with supramaximal concentrations of CCK and carbamylcholine can also induce pancreatitis; however, caerulein is used most frequently. Caerulein can be given intravenously at doses sufficient to deliver 5–10 μg/kg/h in a continuous infusion. Alternatively and perhaps more conveniently, pancreatitis can also be induced by hourly intraperitoneal or subcutaneous injections, although this approach is usually not as reliable as intravenous infusions. Pancreatic injury in rats develops rapidly, increases with the duration of infusion, and is maximal within 12 h. This relatively mild form of pancreatitis is characterized by massive pancreatic edema (which can be visualized macroscopically), increased serum levels of pancreatic enzymes (such as amylase and lipase), cytoskeletal (actin) reorganization, acinar cell vacuolization, necrosis, and inflammation. Strikingly, intra-acinar cell activation of trypsinogen can be observed within minutes of initiation of caerulein infusion.

The caerulein-induced model has become the model of choice for studying pancreatitis in mice, particularly in genetically altered strains. For these studies,

 Copyright 2004, Elsevier (USA). All rights reserved.

pancreatitis is usually induced by administration of 8 to 12 hourly intraperitoneal injections of caerulein (50 μg/kg). The resulting pancreatitis is more severe in mice than in rats and after 12 injections of caerulein, the pancreas develops extensive necrosis and inflammation. This noninvasive model has also proved to be a good model with which to study pancreatitis-associated lung injury.

Due to its ease of use and reproducibility, the caerulein-induced model has been extensively used to study the pathophysiological mechanisms involved in pancreatitis. Several recent studies using this model have shown that one of the earliest events in the onset of pancreatitis is the colocalization of digestive enzyme zymogens and lysosomal hydrolases in large vacuoles observed during pancreatitis. This colocalization could result in premature intra-acinar activation of trypsinogen and perhaps other digestive zymogens, leading to acinar cell injury. This model has also been extensively used to elucidate the role of heat shock proteins and inflammatory mediators in pancreatitis and associated lung injury.

Overall, the caerulein-induced model is probably the most popular experimental model of pancreatitis because it offers several advantages: it is very easy and inexpensive to use, is noninvasive, develops rapidly and reproducibly in mice and rats, which are easy to handle and in addition, the severity of the resulting disease can be regulated and manipulated. However, the main drawback of this model is its questionable clinical relevance.

Diet-Induced Pancreatitis

Administration of ethionine, the ethyl analogue of methionine, was initially shown to induce mild edematous, nonlethal pancreatitis in rats, cats, dogs, and monkeys. Subsequently, Lombardi and co-workers in 1975 developed a model of acute necrotizing hemorrhagic pancreatitis by feeding a choline-deficient ethionine-supplemented (CDE) diet to young female mice. However, this disease is lethal and all the mice die within 5 days if they are fed the CDE diet *ad libitum*. Later, this protocol was modified to reduce the mortality rate to 50 to 70% by limiting diet consumption and feeding the CDE diet for only 24 h. The mice are fasted for 24 h before and after being given the CDE diet. Estrogen and a reduced capacity to neutralize acute pancreatitis enzymes probably mediate the sex difference in response to the dietary regimen.

Like the secretagogue model, this model has also been shown to be associated with a defect in stimulus–secretion coupling and the digestive enzyme zymogens have been shown to be colocalized with the lysosomal enzymes within 1 day of the start of the CDE diet. This model shares many histological and biochemical features with clinical pancreatitis in humans and is also associated with acute lung injury.

Arginine-Induced Pancreatitis

This infrequently used model, originally described by Tani and co-workers in 1990, involves administration of a single large intraperitoneal injection of L-arginine to rats and results in necrotizing pancreatitis that is less severe than the CDE diet-induced pancreatitis. The disease evolves over a period of 72 h with the initial appearance of small intracellular vesicles within 6 h, a significant elevation in serum amylase and lipase and acinar cell necrosis within 24 h, and a marked inhibition of protein synthesis within 72 h after administration of the injection. Changes in the actin cytoskeleton are an early component in this model of pancreatitis. It is also accompanied by a stress response with a large increase in heat shock proteins 27 and 70. The pancreas starts recovering by 7 days and regains its normal function by 14 days. The mechanism by which L-arginine induces pancreatitis is not well understood although it is likely that it acts by inducing an intracellular stress response.

Immune-Induced Pancreatitis

Immune-induced pancreatitis can be initiated by a Schwartzmann or an Arthus type of reaction, by injection of foreign serum intraperitoneally or into the pancreatic duct, and by the intraductal injection of anti-pancreatic basement membrane antibodies.

INVASIVE MODELS OF PANCREATITIS

Observations made as early as 1856 by Claude Bernard and in 1901 by Opie laid the foundation for the development of invasive models of acute pancreatitis. Opie proposed the "common channel" theory on the basis of the autopsy results of two patients who died from acute necrotizing pancreatitis and were found to have gallstones impacted in the ampulla of Vater. According to this theory, the stones obstructed the terminal common channel of the bile and pancreatic ducts so that the bile could now reflux into the pancreatic ductal system and initiate pancreatitis. Although several objections have been raised and alternative hypotheses suggested, this hypothesis is still accepted by many as a valid explanation for the triggering event in gallstone pancreatitis. Alternatively, a stone on passage into the duodenum stretches the sphincter of Oddi, thus permitting reflux of duodenal contents into the pancreatic duct.

Yet another widely accepted theory is based on the premise that obstruction of the pancreatic duct leads to retention of the pancreatic juice within the pancreatic ductal system and that rupture of the intrapancreatic ducts because of the increased ductal pressure leads to spilling of the pancreatic juice containing the digestive enzymes into the gland itself, thereby initiating a cascade of events resulting in pancreatitis.

For the most part, these experimental models have been designed to test the validity of the aforementioned theories and thus include perfusion or retrograde injection of bile and other agents into the pancreatic duct, construction of a closed duodenal loop to facilitate reflux of duodenal contents into the pancreatic ductal system, and temporary obstruction/ligation of the pancreatic or biliopancreatic ductal system.

Closed Duodenal Loop

This model, one of the first experimental models of acute pancreatitis when it was described by Pfeffer *et al*. in 1957, has undergone a series of modifications over the years and is used mainly to establish the etiology of pancreatitis. In their initial studies, Pfeffer and coworkers, using fasted mongrel dogs, isolated 10 cm of the duodenum just beyond the pylorus and ligated the bile duct so that the closed duodenal segment communicated with the pancreatic ductal system. Gastric outflow was reestablished by construction of a gastrojejunostomy. Under these conditions, edematous changes were noted after 4 h and parenchymal necrosis developed between 9 and 11 h after the surgery. However, fat necrosis and inflammation occurred infrequently. The possible mechanisms of pancreatitis induced using this approach include pancreatic ischemia, overdistension of the duodenal loop, and reflux of the duodenal contents into the pancreatic ductal system since pancreatic duct ligation or pancreatic duct cannulation ameliorates the changes associated with pancreatitis in this model.

The model has undergone several changes including placement of an intralumenal tube in the ligated area to maintain intestinal continuity, performing a gastrojejunostomy and insertion of a bypass cannula (Herrera fistula), and injection of infected bile or bile salt–trypsin mixture into the closed loop.

Since the severity of pancreatitis associated with this model is highly variable and is associated with little or no fat necrosis and inflammation, it is not universally accepted as a model of acute pancreatitis. Furthermore, its clinical relevance still remains to be established.

Retrograde Ductal Injection and Prograde Perfusion

Acute pancreatitis can be induced in relatively large animals (dogs, cats, pigs, rats) by cannulating the pancreatic duct and retrogradely injecting agents such as activated digestive enzymes (trypsin, elastase, lipase, phospholipase A), bile, bile plus trypsin or the purified bile salt, sodium taurocholate alone or with trypsin, and fatty acids. The critical features of this model are the pressure that is used for injecting these agents and the finding that the severity of pancreatitis is directly correlated with the pressure and the volume of the injected material.

Perhaps the earliest model of acute pancreatitis was developed in 1856 by Claude Bernard, who injected olive oil and bile retrogradely into the pancreatic duct of the dog and observed the subsequent development of pancreatitis. This model is suitable to study the late but not the early events associated with severe pancreatitis. In an attempt to study the early events and to reduce the severity of pancreatitis, Aho and co-workers modified the protocol by injecting small volumes of sodium taurocholate (3 to 5%) over a period of 1 min in rats. The pancreatitis induced in this case evolves slowly over a period of 72 h and the severity of pancreatitis correlates directly with the injected concentration of sodium taurocholate.

Pancreatitis of severity ranging from mild edematous to necrotizing can also be initiated in large animals such as cats, pigs, dogs, and primates by cannulating the pancreatic duct and prograde perfusing it with a permeability-increasing agent at low pressure followed by infusion of infected bile, hydrochloric acid, aspirin, bile salts, or even activated digestive enzymes. Perfusion of the last agent in combination with prostaglandin E2 has been shown to induce necrotizing pancreatitis.

Duct Ligation/Obstruction Models

Pancreatic duct ligation or obstruction models were designed to recapitulate the events that occur during gallstone pancreatitis in humans. Ligation or temporary obstruction of the pancreatic duct in most animals results in pancreatic edema, mild inflammation, and acinar cell apoptosis, ultimately leading to atrophy of the gland. However, the severity of the pancreatitis can be enhanced by combining duct ligation with stimulation of secretion and pancreatic ischemia. Most of these studies have been performed on rabbits and rats.

On the other hand, ligation of the pancreatic duct or of the common biliopancreatic duct of the American opossum results in severe hemorrhagic pancreatitis, which is associated with acute lung injury and a

14-day mortality rate of 100%. The opossum is a very useful animal for studies mimicking gallstone pancreatitis because its biliopancreatic anatomy closely resembles that of humans. However, unlike in humans where necrotizing pancreatitis is focal and restricted, in the opossum it is diffuse and uniformly distributed throughout the gland. In the opossum, pancreatic duct obstruction appears to be the sole cause of pancreatitis and neither biliary duct obstruction nor bile reflux is essential for triggering or worsening the severity of pancreatitis.

IN VITRO MODEL OF PANCREATITIS

Although pancreatitis is an inflammatory disease, many of the early changes take place in pancreatic acinar cells. For example, in all models of pancreatitis, intra-acinar cell activation of trypsinogen is one of the earliest events that precede overt pancreatitis. In order to study the mechanisms of pathobiological events initiated in pancreatic acinar cells, an *in vitro* model has been developed and has been extensively used in the past few years. In this model, stimulation of rat pancreatic acini with supramaximal concentrations of caerulein results in intra-acinar cell activation of trypsinogen.

For these studies, dispersed pancreatic acini are prepared from freshly harvested pancreas by collagenase digestion and gentle shearing. Acini thus prepared are more than 95% viable and remain healthy for up to 24 h. These acini can be incubated with high concentrations of caerulein and the resulting acinar cell changes can be monitored. Such an *in vitro* reductionist approach has been useful in studies designed to elucidate the mechanisms involved in the activation of trypsinogen and the ensuing acinar cell injury that is observed during pancreatitis. Furthermore, studies using this *in vitro* model have shown that a sustained rise in intracellular calcium is required for activation of trypsinogen and that inhibition of cathepsin B activity prevents this activation.

CONCLUSIONS

Although a number of models, both invasive and noninvasive, have been developed to study the different aspects of acute pancreatitis, there is still no "perfect model" that recapitulates the events occurring during clinical acute pancreatitis in their entirety. Notwithstanding the shortcomings associated with the models described above, these experimental approaches have helped greatly in unraveling the signaling events and the complex interaction of acinar, nonacinar, and inflammatory cells during the initiation and progression of this disease.

Pancreatitis, Hereditary

DAVID C. WHITCOMB
University of Pittsburgh

cationic trypsinogen Precursor form of trypsin defined by its cationic (net positive) charge.
hereditary pancreatitis Form of the disease that appears to be acquired via an inherited gene.
pancreatitis Inflammation of the pancreas.

Hereditary pancreatitis refers specifically to otherwise unexplained acute or chronic pancreatitis in an individual from a family in which pancreatitis appears to be passed down from generation to generation through an inherited gene. Familial pancreatitis is a broader term that refers to pancreatitis of any cause in an individual from a family whose members develop pancreatitis at a higher rate than would be expected by chance alone. Familial pancreatitis may or may not be caused by a genetic mutation. Hereditary pancreatitis therefore defines a narrow, specific term whereas familial pancreatitis is a broad, general term that also encompasses inherited types of pancreatitis.

CLINICAL FEATURES

Pancreatitis is inflammation of the pancreas. Acute pancreatitis occurs when normal pancreatic tissue suddenly becomes inflamed. Inflammation is occasionally caused by a bacterial or viral infection or by direct trauma to the abdomen. However, in most cases, acute pancreatitis develops when the inactive pancreatic digestive enzymes become active inside the pancreas rather than inside the intestine. In this case, the pancreas literally begins to digest itself, leading to severe inflammation. Chronic pancreatitis describes the effects of prolonged inflammation in which the normal pancreatic tissue is partially or completely destroyed and replaced with scar tissue.

A typical description of hereditary pancreatitis includes a family history in which the older generations describe lifelong histories of attacks of abdominal pain beginning in childhood. The pain often becomes continuous by adulthood or disappears. In more severe cases, chronic pancreatitis or diabetes mellitus develops, and pancreatic cancer (or an adenocarcinoma of unknown origin) may be seen after age 50 years. In the younger generations, the childhood attacks would be diagnosed as acute pancreatitis. However, only about half of the offspring in each generation develops the typical symptoms, and the other half of the family tree never has symptoms. In some cases, the symptoms skip a generation, demonstrating that about one out of five people with the pancreatitis-causing gene mutation are silent carriers. This pattern of inheritance is typical of autosomal dominant genetic disorders that are passed from generation to generation through a single defective gene.

The average person inheriting a gene mutation causing hereditary pancreatitis has several symptoms. At about age 10 years they begin developing attacks of severe abdominal pain caused by acute pancreatitis. The exact age of first attack in an individual can vary from about 1 year old to adulthood, but usually occurs in childhood. The pain is centered in the epigastrium, which is about a third of the way from the rib cage to the navel. The pain often increases, beginning as a poorly described ache with nausea and becoming a very severe, steady pain with nausea and vomiting. The pain may extend to the back, to the sides (usually left), or to the entire abdomen. It is unusual to have fever or diarrhea, and during the attack the person usually tries to lie in a curled up position and to remain motionless. The attacks may last for 2–3 days (this is also variable), with attacks usually occurring a couple of times a year.

Later in life, about 5–10 years after the first attack of acute pancreatitis, up to half of the individuals with hereditary pancreatitis will develop chronic pancreatitis. The symptoms of chronic pancreatitis include continuous abdominal pain, difficulty digesting food, bulky stools or diarrhea-like symptoms, and (later) diabetes mellitus. Patients with chronic pancreatitis for several decades are also susceptible to pancreatic cancer, especially if they smoke cigarettes.

CAUSES

The first mutation causing hereditary pancreatitis was discovered in 1996 on chromosome 7 within the *cationic trypsinogen* gene, or *PRSS1*. Trypsinogen is the inactive form of the protein-digesting enzyme trypsin, which

 Copyright 2004, Elsevier (USA). All rights reserved.

cuts protein chains at arginine or lysine amino acids. Trypsinogen normally becomes activated to trypsin after passing into the intestine, and trypsin activates the other inactive digestive enzymes inside the intestine, where ingested food is digested. The hereditary pancreatitis mutation changes the DNA code for a key arginine amino acid (symbol R) at position 122 of the trypsin molecule to code for the amino acid histidine (symbol H), resulting in a "R122H" mutation. Arginine 122 acts an emergency "fail-safe" self-destruction site on the back side of the trypsin molecule, allowing this digestive enzyme to be eliminated by a second trypsin molecule if the trypsinogen becomes active trypsin inside the pancreas. This site is regulated by calcium, and in low calcium concentrations the trypsin will destroy itself (e.g., within the acinar cell). When this site is mutated to histidine, the pancreatic acinar cells cannot eliminate prematurely activated trypsin, which then activates other digestive enzymes. The prematurely active digestive enzymes begin digesting the pancreas, leading to acute pancreatitis. Repeated episodes of acute pancreatitis lead to severe scarring of the pancreas, or chronic pancreatitis. About two-thirds of the families with hereditary pancreatitis have one of several known cationic trypsin mutations, and the other third has unknown mutations.

DIAGNOSIS AND TREATMENT

The diagnosis of hereditary pancreatitis is currently made by diagnosing pancreatitis in two or more members of a family in two generations in which other causes have been excluded (for example, pancreatitis from gallstones). In addition, hereditary pancreatitis can be diagnosed in individuals with pancreatitis through genetic testing. The two common mutations for which testing is recommended are the cationic trypsinogen R122H and N21I mutations. Mutations in the trypsin inhibitor gene (*SPINK1*) and some mutations in the cystic fibrosis gene (*CFTR*) are also seen in pancreatitis, but usually not in families with hereditary pancreatitis. Mutations in these genes are common, and a single mutation does not cause the pancreatitis seen in hereditary pancreatitis.

Currently, there are no specific, proved therapies to prevent or treat hereditary pancreatitis. Smaller meals, diets low in fat and protein, and vitamin and antioxidant supplements have been recommended by some experts, and are usually not discouraged. Smoking cigarettes and alcohol consumption are strongly discouraged because these factors promote pancreatitis and contribute to pancreatic cancer. Medications to reduce stomach acid, supplements containing pancreatic enzymes, and even insulin injections may be necessary if chronic pancreatitis develops. Surgery may be necessary to treat some complications.

acute pancreatitis An acute inflammatory condition of the pancreas associated with a broad variety of etiologies in children.

chronic pancreatitis An inflammatory condition of the pancreas with evidence of permanent and progressive morphological damage.

hereditary pancreatitis An autosomal dominant disease that accounts for 1% of cases of both chronic and recurrent pancreatitis; genetic mutations have been identified in cationic trypsinogen for many patients.

metabolic pancreatitis Pancreatic disorder related to abnormalities such as hyperlipidemia or hypercalcemia, which can cause acute or recurrent pancreatitis but which is extremely rare in pediatrics.

pseudocyst A complication of pancreatitis with a cystic structure not lined with epithelium, which distinguishes it from a true cyst. Most commonly, the walls of the cyst are formed in part by the stomach, spleen, and pancreas.

sphincterotomy Incision of the sphincter of Oddi (with reference to pancreatitis).

Pancreatic disorders in childhood include congenital anatomic and genetic disorders as well as acquired disorders. Most of these disorders are rare. This article will focus on the various types of pancreatitis and briefly describe their clinical characteristics.

ACUTE PANCREATITIS

Acute pancreatitis is an acute inflammatory condition of the pancreas. It is associated with a broad variety of causes in childhood, in contrast to the two main causes of gallstones and alcohol in adults (Table I). Nearly 20% of pediatric cases of pancreatitis are associated with trauma, approximately 10% are associated with gallstones or congenital structural abnormalities of the pancreatico-biliary ductular system, and less than 5% are associated with medications; only rarely are cases associated with metabolic abnormalities and between 15 and 20% have no explanation even after exhaustive evaluation (idiopathic). Over half of all children with pancreatitis have an associated systemic illness. Of those with multisystem disease, between one-quarter and one-third present with sepsis or shock, approximately 5% have an associated viral illness, and over half have a systemic illness, such as a collagen vascular disease or heart disease. In children under 4

years of age, the final diagnosis is rarely idiopathic, and in children under 3 years of age, all patients will have an associated systemic illness, such as sepsis or shock.

The incidence of pancreatitis in childhood has been difficult to determine. Acute pancreatitis has been an uncommon diagnosis at most pediatric institutions. However, a recent single institution review suggested that there may be an increasing incidence with between 70 and 100 new cases of pancreatitis now identified each year. The symptoms at presentation are similar to those in adults. Typically, children present with abdominal pain and/or vomiting. The combination of elevated serum lipase and amylase levels is reliable for the diagnosis of pancreatitis in children. Pancreatitis appears to be less severe in children with a low mortality compared to adults (no prospective studies available). However, severe metabolic and physical complications, such as hypoalbuminemia, hypocalcemia, pseudocysts, necrosis, pleural effusions, and hypoxia, can result.

Hemorrhagic pancreatitis is said to occur in approximately 13% of cases, but in recent experience it appears to be less frequent. Use of Ranson's or the Glasgow criteria to assess severity has not been validated for the pediatric population, but these criteria appear to be useful in providing evidence of complications.

Pseudocysts are reported to occur in approximately 15% of children with pancreatitis but limited information about this complication is available. Usually, the amylase and lipase levels are elevated and associated with abdominal pain, emesis, and/or fever.

The mainstay of treatment is symptomatic and similar to that in adults.

CHRONIC PANCREATITIS

Chronic pancreatitis is an inflammatory condition of the pancreas with evidence of permanent and progressive morphological damage observed on biopsy, autopsy, or radiological studies. Clinically, it is characterized by recurrent or persistent abdominal pain (80% of patients). Steatorrhea and weight loss may also be present. The incidence and prevalence of this condition in children are uncertain but chronic pancreatitis is uncommon. However, estimates in adults suggest that the prevalence is between 1 and 5% with an incidence of close to 8 cases per 100,000 population.

In children, chronic pancreatitis appears to result in two primary forms: (1) a calcifying form that can be associated with hereditary pancreatitis, hypercalcemia, hyperlipidemia, cystic fibrosis (with pancreatic sufficiency), juvenile tropical pancreatitis, and idiopathic pancreatitis and (2) an obstructive form (unusual in children) that is more commonly associated with trauma, sclerosing cholangitis, sphincter of Oddi dysfunction, congenital anomalies, idiopathic fibrosing pancreatitis, and chronic renal failure. Autoimmune pancreatitis resulting in chronic pancreatitis has been described in adults but, as of this writing, it has not been recognized in children.

Genetic susceptibility to chronic pancreatitis appears to be related to mutations in the cationic trypsinogen gene (PRSS1; see Hereditary Pancreatitis below), cystic fibrosis transmembrane conductance regulator (CFTR), and polymorphisms in the serine protease inhibitor, Kazal type 1 (SPINK1). These mutations do not account for all cases of chronic pancreatitis.

Treatment is symptomatic and similar to that used in adults.

HEREDITARY PANCREATITIS

Hereditary pancreatitis is an autosomal dominant disease that accounts for 1% of cases of both chronic and recurrent pancreatitis. The disease has been associated with mutations in the cationic trypsinogen gene. In addition, polymorphisms in SPINK 1 appear to increase the risk for the development of both familial (hereditary) and chronic pancreatitis but not primarily cause it. Clinically, there is incomplete penetrance with variability in the age at presentation and the severity of symptoms. Symptoms can begin as early as the first decade and are present in up to 80% of affected individuals by 20 years of age (range between 11 months and old age). Initial attacks resemble those of acute pancreatitis. Over time, patients develop signs and symptoms more typical of chronic pancreatitis although some patients will have calcification and some evidence of atrophy at the time of first presentation.

If hereditary pancreatitis evolves to chronic pancreatitis, some patients will develop complications more typical of this chronic disorder, including fibrosis, ductal abnormalities, calcifications, diabetes mellitus (reported in 10–25% of cases), steatorrhea and malabsorption (reported in 5 to 45% of cases), pseudocysts, and portal and splenic vein thrombosis. A more serious complication is that of pancreatic cancer, which may have a greater than 50-fold increased incidence in patients with hereditary pancreatitis.

Therapeutic interventions remain symptomatic. Thus, the approaches used are the same as those for other forms of pancreatic inflammation. Additionally, antioxidant cocktails are commonly prescribed. There are limited data supporting their effectiveness in this condition, although they are reported to be effective in recurrent pancreatitis.

METABOLIC PANCREATITIS

Hyperlipidemia

Hyperlipidemia is a reported cause of pancreatitis but appears to be exceedingly rare in pediatrics. The reported incidence of pancreatitis for each type of hyperlipidemia is as follows: type 1, 35%; type IV, 15%; and type V, 30–40%. The pancreatitis appears to be acute and recurrent. Use of an antioxidant cocktail has been reported to stop recurrent episodes of pancreatitis related to hyperlipidemia. If triglycerides are elevated during an episode of acute pancreatitis, they should be reevaluated after resolution of the pancreatitis to determine whether an underlying error in lipid metabolism is present.

Hypercalcemia

Hypercalcemia is a rare cause of pancreatitis. It can result from a variety of disorders, including total parenteral nutrition, vitamin D poisoning, sarcoidosis, metastatic bone disease, and the infusion (iatrogenic) of high doses of calcium. The role of primary hyperparathyroidism in either acute or chronic pancreatitis is unclear but certainly is a rare cause. It appears to occur in 7–15% of all patients with hyperparathyroidism and accounts for less than 1% of all cases of pancreatitis in adults or children.

Paraneoplastic Syndrome

ROBERTO DE GIORGIO*, MONICA BOVARA*, GIOVANNI BARBARA*, VINCENZO STANGHELLINI*, STEFANIA GUERRINI*, FABRIZIO DE PONTI*, MARCELLO TONINI†, AND ROBERTO CORINALDESI*

University of Bologna and †University of Pavia, Italy

chronic intestinal pseudo-obstruction A syndrome due to a failure of intestinal propulsion and characterized by a clinical picture resembling mechanical obstruction in the absence of any lesion occluding the lumen of the gut.

enteric nervous system The collection of neurons embedded in the wall of the gastrointestinal tract, organized in two major ganglionated (i.e., the myenteric or Auerbach's and submucosal or Meissner's) plexuses and able to control all digestive functions, including motility, absorption/secretion, sensitivity, and microcirculation.

onco-neural antigens Antigens shared by tumor cells and neural tissues that are likely capable of triggering the immune response involved in the neuropathophysiology of paraneoplastic syndrome.

Paraneoplastic syndromes encompass a wide array of clinical manifestations that may affect virtually all organs of the human body as a result of a systemic response evoked by a remote tumor. The gastrointestinal tract may be the target of a paraneoplastic syndrome evoked most commonly by small-cell lung carcinoma, thymoma, and gynecological and breast tumors. Symptoms arising in this context include diarrhea, constipation, nausea, vomiting, and abdominal pain. These symptoms may precede the diagnosis of the underlying neoplastic disease; thus, the differential diagnosis of gastrointestinal manifestations may also take into account the occurrence of a remote cancer. Symptoms are the result of altered gastrointestinal secretory motor function related to an impairment of the intrinsic innervation supplying the gastrointestinal tract (i.e., the enteric nervous system).

INTRODUCTION AND GENERAL FEATURES

Certain types of tumors express molecules, namely, onco-neural antigens, against which the immune system reacts as part of the immune-mediated anti-neoplastic response. This humoral and cell-mediated immune response cross-reacts with onco-neural antigens physiologically expressed by the enteric nervous system, thus leading to dysfunction and structural damage. As a result, a severe perturbation of gastrointestinal motility, ranging from achalasia, gastroparesis, and megacolon to chronic intestinal pseudo-obstruction, occurs. The histopathological hallmark of these motor disorders is an inflammatory lympho-plasmacellular infiltrate within the ganglionated plexuses of the enteric nervous system, mainly in the myenteric plexus (or Auerbach's plexus). This histopathological picture, referred to as myenteric ganglionitis, is associated with degeneration and loss of neurons, likely reflecting the immune-mediated injury within the myenteric plexus, throughout the gastrointestinal tract.

TYPES OF ANTI-NEURONAL ANTIBODIES IN PARANEOPLASTIC SYNDROME

In addition to a cellular immune response, several distinctive anti-neuronal antibodies can be found in the serum of patients with paraneoplastic dysmotility. Depending on their molecular target, they are referred to as anti-Hu (also known as type 1 anti-neuronal nuclear antibodies), anti-Yo (anti-Purkinje cell cytoplasmic antibodies), P/Q- and N-type Ca^{2+} channel antibodies, and ganglionic-type nicotinic acetylcholine receptor antibodies. Although the pathogenetic role played by anti-neuronal antibodies in enteric neuronal damage is still under investigation, their detection is of great importance in the diagnosis of an underlying, often occult, tumor.

Anti-Hu antibodies, usually found in the serum of patients with paraneoplastic encephalomyelitis/subacute sensory neuropathy, can be also detected in paraneoplastic gastrointestinal dysmotility. The Hu antigens are four nervous system-specific RNA-binding proteins, with a crucial role in neuronal development and survival. It is plausible that binding of autoantibodies to the enteric neuronal Hu proteins may play a role in the neuronal dysfunction underlying gastrointestinal paraneoplastic syndrome. Another class of anti-neuronal antibodies includes the anti-voltage-gated

 Copyright 2004, Elsevier (USA). All rights reserved.

Ca^{2+} channels, which are often identified in the serum of patients with Lambert-Eaton myasthenic syndrome associated with small-cell lung carcinoma. These autoantibodies, including the P/Q- and N-type Ca^{2+} channels (which control acetylcholine release), may also be involved in central as well as autonomic nervous system dysfunction related to paraneoplastic syndromes. Together with anti-Hu antibodies, the N-type anti-voltage-gated Ca^{2+} channel antibodies are the most common autoantibodies described in patients with paraneoplastic dysmotility.

Anti-Yo antibodies, found in the serum of patients with paraneoplastic cerebellar degeneration as a manifestation of gynecologic or breast cancer, are also detected in rare cases of paraneoplastic gastrointestinal dysmotility related to ovarian carcinoma. These antibodies target the Yo (recently redefined as cerebellar degeneration-related) antigens, which exert a functional inhibition of c-*myc* transcriptional activity, likely inducing neuronal damage through the activation of apoptosis.

In severe gastrointestinal dysmotility, the suspicion of a paraneoplastic syndrome should be always taken into account. Testing for neuronal autoantibodies is helpful for accurate diagnosis of patients with paraneoplastic syndrome. Further research is needed to better clarify the mechanisms underlying paraneoplastic-related enteric neuropathy.

Parasitic Diseases, Overview

RODNEY D. ADAM
University of Arizona College of Medicine, Tucson

cyst An environmentally stable form of the life cycle of a protozoan that reproduces asexually. The cyst has a hard outer wall and is involved in the transmission of the organism from one host to another.

definitive host The host in which a parasite achieves sexual maturity.

intermediate host For a parasite with sexual reproduction, this is an additional host(s) in which a parasite develops to some extent, but not to sexual maturity.

oocyst Cystic stage of the Apicomplexa, resulting from sporogony (e.g., *Plasmodium*, *Cryptosporidium*, *Toxoplasma*, *Cyclospora*).

parasite An organism that is physiologically dependent on another organism and extracts its nutrients from this host. More specifically, when the term is used for organisms colonizing humans, it frequently refers to protozoans and helminths and sometimes ectoparasites (e.g., ticks, lice).

trophozoite The vegetative or growing form of an organism, used to describe an asexual stage of a protozoan organism.

All the noncommensal (and perhaps commensal) bacteria, fungi, protozoa (or protists), and helminths are parasitic organisms when they colonize their human hosts. However, this article will be limited to the more commonly used, narrow definition that includes only the protozoa and helminths. The parasitic diseases are major causes of morbidity and mortality throughout the world, but strike the populations of the tropical and developing regions disproportionately. *Plasmodium falciparum,* the species that causes most cases of fatal malaria, along with *Mycobacterium tuberculosis*, is one of the two organisms most likely to cause fatal infection. Substantial disease burden also results from numerous other protozoan and helminthic organisms. This article will focus primarily on those parasitic organisms that cause diseases with significant gastrointestinal manifestations.

INTRODUCTION

In addition to the readily apparent differences in biology and size of the protozoa in comparison to the helminths, there are a number of important generalizations that can be made in regard to the differences in human infections and clinical manifestations. All of the protozoa that are pathogenic for humans are microscopic unicellular organisms that have the ability to reproduce asexually within the human host and thus have the potential to cause a very high disease burden from a single inoculating organism. In contrast, the pathogenic helminths are multicellular organisms that replicate sexually in the definitive host and many require at least one intermediate host to complete their life cycles. Therefore, they do not multiply within the human host, so the disease manifestations are determined by the initial inoculum size, the chronicity, and the host response to the infection. Most of the helminths do not live in the human host for more than several years, so late clinical manifestations are generally the residual of earlier infection and inflammatory response rather than ongoing infection. A corollary of this principle is that acquired immunodeficiency syndrome (AIDS) and other forms of immunocompromise do not result in the markedly increased disease burden that can be seen with protozoa, fungi, or bacteria. The major exception to this general rule is *Strongyloides stercoralis*, which has an autoinfection cycle and is able to replicate to very high numbers in immunocompromised human hosts, especially those receiving high doses of corticosteroids.

Blood eosinophilia is common with invasive helminth infections, frequently reaching very high levels (e.g., 30 to 50% of cases). The degree of eosinophilia is relatively mild in helminths that reside in the gut lumen. Protozoan pathogens typically do not evoke significant blood eosinophilia, but *Entamoeba histolytica* infections do frequently cause tissue eosinophilia. The most common (and not so common) medically important protozoa are listed in Table I and the helminths are listed in Table II. The subsequent portion of this article will give a brief description of the parasites with significant gastrointestinal manifestations. Even for those organisms without significant gastrointestinal manifestations, the diagnosis may be established by identification of the organism or its eggs in intestinal or fecal samples. The organisms for which the diagnosis may be made by gastrointestinal samples are listed in Table III.

TABLE I Protozoa Pathogenic for Humans

Organism	Classification	Geographic distribution	Means of human acquisition	Other mammalian hosts	Tissue tropism	Method of diagnosis	Clinical manifestations
Plasmodium sp.	Apicocomplexa (Sporozoa)	Tropical and subtropical regions	Anopheline mosquito bite	None (for human *Plasmodium* species)	Erythrocytes	Microscopic examination of blood smear	Febrile illness
Babesia spp.	Apicocomplexa	Worldwide	Tick bite	Rodent (*B. microti*); cattle (*B. bovis* and *B. divergens*)	Erythrocytes	Microscopic examination of blood smear	Febrile illess
Toxoplasma gondii	Apicocomplexa	Worldwide	Ingestion of pseudocysts in contaminated meat; ingestion of oocysts in material contaminated by cat fees; vertical transmission	Cat is definitive host; numerous mammals are incidental hosts	Nucleated cells, especially in heart and brain	Histology; serology	Multiple
Cryptosporidium parvum	Apicocomplexa	Worldwide	Ingestion of oocysts, especially in contaminated water	Cattle and other mammals	Small intestinal epithelial cells	Stool microscopy; intestinal histology	Diarrhea; rare extraintestinal disease
Cyclospora cayetanensis	Apicocomplexa	Worldwide	Ingestion of oocysts in contaminated food or water	None known	Small intestine	Stool microscopy	Diarrhea
Sarcocystis sp.	Apicocomplexa	Worldwide, especially Southeast Asia	Ingestion of sporocysts from feces or meat (human is definitive host); ingestion of fecal oocysts (human is intermediate host)	Carnivore is definitive host; herbivore is intermediate host	Muscle cells	Histology (muscle)	Usually asympto-matic; myositis; diarrhea
Isospora belli	Apicocomplexa	Tropical and subtropical regions	Ingestion of oocyst	None known	Small intestine	Stool microscopy	Diarrhea
Leishmania sp.	Kinetoplastid flagellate	Different locales for different species in tropical and subtropical regions	Bite of sandfly	Numerous	Histology; serology (for visceral)	Visceral infection; mucocutaneous; cutaneous	
Trypanosoma cruzi	Kinetoplastid flagellate	South and Central America	Bite of Reduviid bug	Numerous	Muscle, especially cardiac and GI	Serology	Acute (meningitis or carditis); chronic (cardiomyopathy, mega-GI disease)
Trypanosoma brucei sp.	Kinetoplastid flagellate	Equatorial Africa	Bite of Tsetse fly	Game animals (East African); none (West African)	Lymphatics, blood; CNS	Microscopy of blood or CSF Histology	Febrile illness with lymphadenopathy; meningo-encephalitis

(*continues*)

TABLE I Protozoa Pathogenic for Humans (*continued*)

Organism	Classification	Geographic distribution	Means of human acquisition	Other mammalian hosts	Tissue tropism	Method of diagnosis	Clinical manifestations
Giardia lamblia	Diplomonad flagellate	Worldwide	Ingestion, most commonly through contaminated water	Numerous	Small intestine	Stool microscopy; stool antigen detection	Diarrhea; malabsorption
Entamoeba histolytica	Rhizopod (ameba)	Developing regions	Ingestion, most commonly through contaminted food	None	Stool microscopy; serology	Colitis; hepatitic "abscesses"	
Dientamoeba fragilis	Trichomonad	Worldwide	Water; fecal–oral		Intestine	Stool microscopy	Usually asymp-tomatic; diarrhea
Balantidium coli	Ciliate	Worldwide	Ingestion of cysts	Numerous, especially pigs	Colon	Stool microscopy; intestinal histology	Usually asymptomatic; colitis
Blastocystis hominis	Unknown	Worldwide, especially developing regions	Probably fecal–oral	Unknown	Intestine	Stool microscopy	Usually asymptomatic; may cause diarrhea
Naegleria fowleri	Rhizopod (ameba)	Warm climate; freshwater	Nasal invasion from swimming in warm freshwater	Free-living	CNS	Microscopy of CSF	Meningitis
Acanthamoeba spp.	Rhizopod (ameba)	Worldwide	Eye (direct contact)	Free-living	CNS; cornea	CNS (brain histology); eye (histology or culture)	Meningoencephalitis; keratitis
Trichomonas vaginalis	Trichomonad	Worldwide	Sexual	None	Vaginal epithelium	Microscopy of vaginal fluid	Vaginitis
Enterocytozoon bieneusi	Microsporidia	Worldwide	Ingestion of contaminated water	Numerous	Gastrointestinal tract	Stool microscopy	Diarrhea (chronic in AIDS)

TABLE II Helminths Pathogenic for Humans

Organism	Geographic distribution	Means of human acquisition	Definitive host	Intermediate host(s)	Tissue tropism	Method of diagnosis
Nematodes						
Ascaris lumbricoides	Worldwide, especially tropics	Egg ingestion	Human, possibly other mammals	None	Small intestine	Identify ova in stool
Ancylostoma duodenale (Old World hookworm)	Eastern hemisphere	Penetration of skin by larvae	Human	None	Small intestine	Identify ova in stool
Necator americanus (New World hookworm)	Americas	Penetration of skin by larvae	Human	None	Small intestine	Identify ova in stool
Enterobius vermicularis	Worldwide	Egg ingestion	Human	None	Cecum	Identify worms in perianal area
Trichuris trichiura	Worldwide, especially developing regions	Egg ingestion	Human, other mammals	None	Large intestine	Identify ova in stool
Trichinella spiralis	Worldwide	Ingestion of larvae from muscle	Numerous carnivores	Same as definitive	Small intestine, muscle	Serology, identify larvae in muscle
Wuchereria bancrofti	Tropics and subtropics	Larvae injected by mosquito	Human	Mosquito	Blood, lymphatics	Identify microfilariae in blood, serology
Brugia malayi	South and Southeast Asia	Larvae injected by mosquito	Human	Mosquito	Blood, lymphatics	Identify microfilariae in blood, serology
Onchocerca volvulus	Africa, Central and South America	Larvae injected by blackfly	Human	Blackfly	Eye, skin	Identify microfilariae in skin, serology
Strongyloides stercoralis	Worldwide, especially tropics and subtropics	Penetration of skin by larvae; Penetration of colon by larvae (autoinfective cycle)	Human (also free-living)	None	Small intestine	Identify larvae in concentrated fecal samples, serology
Trematodes						
Schistosoma mansoni	Africa, South America	Penetration of skin by cercariae	Human	Snail	Inferior mesenteric veins	Identify eggs in stool, serology
Schistosoma hematobium	Africa, Middle East	Penetration of skin by cercariae	Human	Snail	Vesical plexus	Identify eggs in urine
Schistosoma japonicum	Southeast Asia	Penetration of skin by cercariae	Human	Snail	Superior mesenteric veins	Identify eggs in stool, serology
Paragonimus westermani	Asia, Africa, South America	Ingestion of metacercariae	Human	Snail, crab	Lungs	Identify eggs in stool
Clonorchis sinensis	Southeast Asia	Ingestion of metacercariae	Human	Snail, fish	Biliary system	Identify eggs in concentrated stool
Fasciola hepatica	Sheep-raising areas	Ingestion of metacercariae	Human	Snail, watercress	Biliary system	Identify eggs in stool
Cestodes						
Taenia solium	Scattered worldwide	Ingestion of cysticerci in meat (to be definitive host); ingestion of eggs (to be intermediate host)	Human	Pigs (occasionally humans)	Intestine (muscle and brain as intermediate host)	Identify eggs or proglottids in stool, serology
Taenia saginata	Cattle-raising areas	Ingestion of cysticerci in meat	Human	Cattle	Intestine	Identify eggs or proglottids in stool
Echinococcus spp.	Scattered worldwide	Egg ingestion	Canines	Numerous mammals	Liver, other organs	Serology, identify cysts in lesions
Diphyllobothrium latum	Scattered worldwide	Cyst ingestion from uncooked fish	Human, other mammals	Freshwater fish	Intestine	Identify eggs or proglottids in stool

TABLE III Important Parasitic Infections Diagnosed from Gastrointestinal Samples

Organism	Type of sample
Protozoa	
Entamoeba histolytica	Identification of cysts or trophozoites in feces or colon biopsy specimens (also do serology)
Giardia lamblia	Identification of cysts or trophozoites in feces
Cryptosporidium parvum	Identification of oocysts in feces or merozoites in intestinal biopsies
Cyclospora cayetanensis	Identification of oocysts in feces
Isospora belli	Identification of oocysts in feces
Enterocytozoon bieneusi	Identification of organism in intestinal biopsy or fecal sample
Helminths	
Trichuris trichiura	Identification of ova in microscopic examination of stool
Enterobius vermicularis	Identification of pinworms in perianal region
Ascaris lumbricoides	Identification of ova in microscopic examination of stool
Strongyloides stercoralis	Identification of larvae in feces or duodenal contents; poor sensitivity, so serologic studies should also be performed
Hookworm (*N. americanus* and *A. duodenale*)	Identification of ova in microscopic examination of stool
Schistosoma mansoni	Identification of ova in feces or rectal biopsy; serologic studies are helpful
Clonorchis sinensis	Identification of ova in feces using concentration techniques
Fasciola hepatica	Identification of ova or adult worms in feces
Paragonimus westermani	Identification of ova in microscopic examination of stool
Taenia solium	Identification of parasite proglottids or ova in feces (ova appear identical to *T. saginata* ova)
Taenia saginata	Identification of parasite proglottids or ova in feces (ova appear identical to *T. solium* ova)
Diphyllobothrium latum	Identification of parasite proglottids or ova in feces

PROTOZOA

The protozoa have generally been classified according to morphologic criteria into four major groups, the Sporozoa, the flagellates, the amebas, and the ciliates. The Sporozoa form a diverse group of organisms in terms of their hosts, transmission cycles, tissue tropism, and clinical manifestations, but clearly fall into one clade or genetic group. In contrast, the flagellates form several genetic groupings: the kinetoplasts (*Trypanosoma* spp., *Leishmania* spp.), the diplomonads (*Giardia lamblia*), and the trichomonads (*Trichomonas vaginalis*). *En. histolytica* is the most important pathogen of the amebas. *Balantidium coli* is rarely a pathogen, but is frequently listed since it is the only medically important ciliate. In addition to these four groups, the microsporidia have emerged as important pathogens, especially as complications of human immunodeficiency virus (HIV) infection. The microsporidia may actually be fungi, but will be addressed here since they are commonly considered to be protozoa. In addition to the pathogenic organisms, a number of protozoa are frequently identified in fecal specimens, but are seldom or never associated with disease. *Blastocystis hominis* may occasionally be pathogenic, although this remains controversial. *Entamoeba coli*, *Entamoeba hartmanni*, and *Endolimax nana*, as well as a number of other organisms, may be identified in fecal specimens, but are nonpathogenic.

En. histolytica is the most frequent parasitic cause of life-threatening gastrointestinal disease, resulting in an estimated 100,000 deaths per year throughout the world. Human infection is initiated by ingestion of *En. histolytica* cysts via contaminated food or water or by direct contact with infected individuals. There are no known nonhuman hosts, so zoonotic transmission does not occur. An accumulation of literature since 1978 has provided convincing evidence of pathogenic and nonpathogenic strains of *En. histolytica*, eventually resulting in the division of these organisms into two species, the pathogenic *En. histolytica* and the nonpathogenic *En. dispar*. The two organisms appear the same morphologically, so routine fecal specimens will not distinguish between the two.

After excystation in the small intestine, *En. histolytica* trophozoites replicate in the large intestine, where they ingest host immune cells and erythrocytes and cause tissue necrosis. Infected patients have locally invasive disease with abdominal pain, bloody diarrhea, and fever. Occasionally, the trophozoites disseminate beyond the large intestine, most commonly to the

liver. Patients with liver involvement have right upper quadrant abdominal pain and fever and discrete lesions that can be identified by ultrasound or computed tomography (CT) scanning. The finding of liver abscesses in a patient with a compatible clinical presentation who has anti-amebic antibodies is nearly diagnostic of amebic liver abscess, but pyogenic liver abscesses should be ruled out in patients with negative serologic tests and those who fail to respond to appropriate medical therapy (usually metronidazole).

Although the observation of *Entamoeba* cysts in fecal specimens in fecal specimens will not distinguish between *En. histolytica* and *En. dispar* infections, the discovery of trophozoites engulfing red blood cells (RBCs) is diagnostic of *En. histolytica* infection. RBCs are commonly present in stool specimens, but white blood cells are uncommon, probably because the trophozoites ingest the neutrophils. In invasive colonic disease, an antibody response is found in over 90% of patients. Although these are not protective antibodies, their measurement is very useful in the diagnosis of amebiasis. Up to 99% of patients with extraintestinal amebiasis will demonstrate an antibody response.

G. lamblia is a common cause of diarrheal disease with malnutrition and weight loss throughout the world. Human infection is initiated when the environmentally stable cysts are ingested, most commonly via contaminated water or by direct fecal–oral contact, such as may occur in a day-care center. Although there has been considerable controversy regarding the potential role of zoonotic transmission, recent molecular studies allow the conclusion that most dog and livestock *G. lamblia* isolates are genetically different from human isolates, indicating that these organisms are not major sources of human infection. In contrast, cats and beavers harbor genotypes that are the same as the human isolates, leaving open the possibility that human infection can be acquired from these animals.

Excystation occurs in the proximal small intestine, yielding the disease-causing trophozoites that replicate in the small intestine. Trophozoites adhere to the intestinal wall by mechanical suction generated by the ventral disk. The mechanism of diarrhea is unknown, since invasion does not occur and no toxins have been identified. Many people remain asymptomatic, but those with symptoms have diarrhea with loose foul-smelling stools and bloating. Weight loss is common and symptoms frequently last weeks or months in the absence of treatment. In the United States, giardiasis causes approximately the same number of hospitalizations as shigellosis. The diagnosis is usually established by the identification of cysts or trophozoites in fecal specimens or by detection of *Giardia* antigens in fecal specimens, either by indirect fluorescent antibody (IFA) or by enzyme-linked immunosorbent assay. The diagnosis can sometimes be made using a string test in which patients swallow a capsule on a string. After several hours, the capsule is examined microscopically for the presence of *Giardia* trophozoites. In patients with persistent diarrhea and malabsorption who have negative fecal examinations, upper endoscopy with small intestinal biopsy can be used to look for evidence of giardiasis or other small intestinal disease.

Cryptosporidium parvum is an apicocomplexan organism that was recognized as an important cause of diarrhea after the advent of the AIDS epidemic. Human infection results when oocysts are ingested, typically from contaminated water. The infections may be acquired from other humans or from livestock. An outbreak involving an estimated 400,000 persons in Milwaukee, Wisconsin, in 1993 may have resulted from human or livestock contamination of the water. In immunocompetent individuals, diarrhea with loose stools typically lasts approximately 1 week. However, in patients with advanced HIV infection, profuse watery diarrhea may persist for months, leading to dehydration. In addition, *C. parvum* may rarely disseminate to the gallbladder, causing symptomatic biliary disease. The asexual replication of merozoites in an intracellular, but extracytoplasmic space in small intestinal endothelial cells results in the symptoms. The diagnosis of intestinal disease is established when the oocysts are identified in fecal samples, either by routine staining or by acid-fast or fluorescence antibody staining. *Candida* spp. can be confused with *C. parvum* oocysts on routine stains, but the acid-fast stain will easily distinguish the two, since *C. parvum* oocysts are acid-fast. The diagnosis can also be established by identifying the merozoites in small intestinal endothelial cells obtained by intestinal biopsy. There is no known effective therapy for cryptosporidiosis, so treatment is supportive.

Cyclospora cayetanensis is a recently identified cause of diarrheal illness in humans. It was initially thought to be a cyanobacteria-like organism or a blue green alga, but in 1993, was described as an apicocomplexan, which is closely related to the poultry pathogens, the *Eimeria* spp. Cyclosporiasis gained prominence in the United States when it was associated with outbreaks of diarrheal disease acquired from imported raspberries in the summer of 1996 and subsequent summers. Human infections are initiated when sporulated oocysts are ingested followed by replication in the small intestine. Diarrhea with loose stools begins an average of 1 week after exposure and may last several weeks in the absence of therapy. The diagnosis is established by identifying the oocysts in fecal specimens from

infected persons after routine preparation or after acid-fast staining or by the detection of autofluorescing oocysts. To date, no nonhuman reservoirs have been identified.

Trypanosoma cruzi is a zoonotic organism that infects a variety of mammals throughout much of South and Central America and is transmitted from one host to another by the bite of a Reduviid (kissing) bug. Humans are accidental hosts and not part of the usual life cycle of the organism. Epimastigotes replicate in the Reduviid bug, followed by differentiation into metacyclic trypomastigotes. The infection results when the metacyclic trypomastigotes from the insect feces gain access through a mucous membrane surface or through compromised skin. The bite of the insect is intensely pruritic and the scratching that occurs after the bite may allow the *Tr. cruzi* epimastigotes access. The organisms then invade host cells, where they differentiate into amastigotes, replicate, and then differentiate into trypomastigotes followed by cell rupture and invasion of the next cell.

An acute illness with fever, local inflammation, and sometimes cardiac or central nervous system (CNS) manifestations may result. Most of these cases resolve spontaneously. Subsequently, whether or not symptoms are present acutely, some patients go on to a prolonged asymptomatic parasitemia (indeterminate phase). Some of those patients go on to develop chronic Chagas' disease, sometimes known as mega-gastrointestinal disease. The most common cause of morbidity and mortality is cardiomyopathy with concomitant ventricular arrhythmias. The other major cause of morbidity is hypertrophy and dilation of the gastrointestinal tract, most commonly the colon or esophagus. Patients may thus present with severe constipation or megacolon or with severe dysphagia and regurgitation. When the diagnosis is suspected in someone with an appropriate exposure history and clinical syndrome, serologic testing will usually support the clinical diagnosis. Endogenous cases in the United States have been documented rarely in Texas, but cases have been acquired through organ transplants from infected individuals and may also occur by blood transfusion. Anti-parasitic treatment is sometimes effective in acute infections, but is ineffective in chronic infections. Therefore, treatment of chronic infection is supportive.

The microsporidia are currently classified with the protozoa, but their classification is uncertain and they may belong to the fungi. They are obligate intracellular organisms and became recognized as significant human pathogens after the advent of the AIDS epidemic. Many species from multiple genera have been associated with human infection. *Enterocytozoon bieneusi* is the most common microsporidial infection in AIDS patients and infects the small intestine, biliary tract, and liver. Patients have diarrhea and malabsorption, with the severity and duration of disease depending on the level of immunosuppression. The diagnosis can be established by the identification of organisms in intestinal biopsy samples, by electron microscopy, or by routine histochemical methods. Sometimes the organisms can be detected in biliary, intestinal, or fecal fluids. Other microsporidia cause primarily disseminated or corneal disease.

HELMINTHS

The helminths that cause human infections are classified as nematodes (roundworms), cestodes (flatworms), and trematodes (flukes). The nematodes are frequently divided intestine and tissue-dwelling organisms.

Ascaris lumbricoides (roundworm) infection is initiated when the ova are ingested from an environmental source. When larvae hatch from the ova, they migrate through the lungs, sometimes resulting in cough and pulmonary infiltrates. Blood eosinophilia is common at this time. The larvae are then swallowed and return to the small intestine where they become adult worms. Most infections result in no gastrointestinal symptoms, but heavy infections can result in intestinal obstruction due to a mass of adult worms. Biliary tract invasion occurs rarely, resulting in acute abdominal pain and biliary obstruction. In roundworm infections with no overt symptoms, malabsorption is common, especially in developing areas.

Hookworm infections are established when larvae from the soil penetrate the skin and migrate through the lungs. They are then swallowed to make their way to the small intestine. The initial phase of the infection may result in pruritis at the site of larval penetration or pulmonary symptoms similar to those of roundworm infections. The majority of infections do not result in gastrointestinal symptoms, but abdominal pain, diarrhea, and malabsorption may be seen, especially with heavy infections. The most important clinical consequence of infection is iron deficiency anemia, which is proportional to the worm burden and is more severe with Old World hookworms (*Ancylostoma duodenale*) than with New World hookworms (*Necator americanus*).

Trichuris trichiura (whipworm) infections are initiated by the ingestion of ova, followed by hatching into larvae in the small intestine and migration of the larvae to the large intestine, where the adult worm lays eggs. Most infections are probably asymptomatic, but heavy

infections can result in iron deficiency anemia, dysentery, or rectal prolapse.

Trichinella spiralis infections (trichinosis) are established when meat that contains larvae from infected mammals (e.g., pigs, polar bears) is ingested. Cooking and prolonged freezing kill the larvae, so the risk is greatest from fresh raw meat. Mild gastrointestinal symptoms may ensue within a week after infection, but most patients remain asymptomatic at this stage. After approximately 2 to 6 weeks, larval migration results in fever, headache, periorbital or facial edema, conjunctivitis, and neurologic symptoms. The severity of illness generally correlates with the degree of the initial inoculum. Eosinophilia is pronounced. Death may occur from heart failure or CNS involvement. A suspected diagnosis may be supported by serologic testing and confirmed by the detection of larvae in muscle biopsy specimens. Treatment consists of corticosteroids in addition to anti-helminthic therapy.

St. stercoralis third-stage (L3) larvae in soil infect humans by direct penetration of intact skin. They pass through the lungs and mature in the intestine into parthogenetic adult worms, which lay eggs that hatch in the intestine to form L1 larvae. The L1 larvae may then complete their life cycle in the soil. However, as part of the autoinfective cycle, the larvae can mature to the L3 stage in the intestine and migrate to a location in the intestine or elsewhere. The number of larvae in the typical *Strongyloides* infection is small, but in immunocompromised hosts (especially those on high doses of corticosteroids for prolonged periods of time), large numbers of larvae are produced through the autoinfective cycle. These larvae may invade extraintestinal sites such as the lungs and CNS, carrying bacteria with them as they go. These bacteria are actually the major cause of morbidity and mortality in overwhelming strongyloidiasis.

Schistosomiasis refers to disease caused by several species of the genus, *Schistosoma*. The *Schistosoma* species that infect humans cause most of their disease when the adult worms lay eggs in the venous system for which they are tropic, causing scarring and venous obstruction. *Schistosoma hematobium* infects the bladder and its venous system, whereas the other *Schistosoma* species infect the gastrointestinal system and are tropic for parts of the mesenteric venous system. The most common cause of gastrointestinal and mesenteric infection is *Schistosoma mansoni*; the others have similar clinical manifestations, but vary in their geographic distributions. *Sc. mansoni* infection is initiated when cercariae released by the intermediate host snail, which resides in freshwater, penetrate the intact skin. Pruritis (swimmer's itch) may develop at the time of cercarial penetration, but is more commonly associated with schistosomes that do not infect humans; these latter schistosomes may be encountered in the United States. Approximately 1 to 2 months after a massive *Sc. mansoni* or *Schistosoma japonicum* infection, patients may develop a syndrome with acute fever with systemic and pulmonary symptoms, called Katayama fever. They have hepatosplenomegaly, lymphadenopathy, and eosinophilia. Most people recover spontaneously, but deaths may occur, especially with *Sc. japonicum*.

However, most of the morbidity associated with schistosome infections is due to the chronic scarring that results. The degree of scarring is generally proportional to the worm burden and egg output of the infecting organisms. The cercariae transform into schistosomulae, which first migrate to the liver and lungs and then to the inferior mesenteric plexus, where they mature into adults and lay their eggs. The scarring results in elevated splenic and portal pressures with splenomegaly and portal hypertension. The diagnosis can be established by the identification of *Sc. mansoni* eggs in fecal specimens or in rectal biopsies. In endemic areas, liver ultrasound is very effective in evaluating the extent of hepatic fibrosis resulting from the chronic infection. Screening is important in these areas, since anti-helminthic treatment may eliminate the organisms and prevent scarring, but does not reverse scarring that has already occurred.

Clonorchis senensis is a liver fluke found in eastern Asia that infects fish-eating mammals, whereas *Fasciola hepatica* is found in sheep-raising areas throughout the world. Human infections with these parasites may result in symptomatic biliary disease.

The human is the definitive host for *Taenia saginata*, the beef tapeworm, and cattle are the intermediate hosts. Human infections are generally asymptomatic, although mild abdominal pain or diarrhea may result. Infections may be diagnosed by finding the eggs or the proglottids in fecal specimens. When only the eggs are found, they cannot be distinguished morphologically from those of *Taenia solium*.

Humans are normally the definitive hosts for *Ta. solium*, the pork tapeworm. The human infection results when inadequately cooked meat containing cysticerci (the larval form) is ingested. The tapeworm then matures in the intestine and lays eggs, which are passed in the feces to be ingested by the porcine intermediate host. This form of infection is relatively inconsequential. However, humans may develop cysticercosis when they become an accidental intermediate host by ingesting eggs either from their own infection or from another source. The larvae then migrate to muscles or brain, where they eventually calcify. The inflammatory

response and calcifications of cysterci in the brain may result in seizures or other CNS manifestations. In endemic areas, cysticercosis is the most common cause of adult-onset seizures. Cysticercosis can be diagnosed by the classic clinical findings as well as by serologic testing. Patients may have simultaneous intestinal infection, so fecal specimens should be examined in patients with a new diagnosis of cysticercosis.

Canines are the definitive hosts of the *Echinococcus* species and the intermediate hosts vary with the species. *Echinococcus granulosus* causes hydatid disease and is the most common species to infect humans. Domestic dogs are the usual definitive hosts and sheep and other livestock animals are the normal intermediate hosts, so the organism is endemic in many grazing areas. In the United States, most cases are found in sheep-grazing areas of southern Utah and northern Arizona. Human infections are initiated when people ingest eggs from canine feces, becoming accidental intermediate hosts. The eggs hatch to form oncospheres, which migrate to their final destination to form larval cysts. The most common location is the liver, but the lungs or other organs may also be involved. Symptoms usually result from the space-occupying effect of the cysts, but an abrupt onset of fever with hypotension or even anaphylaxis can result from accidental rupture of a cyst. Imaging with ultrasound or CT scanning yields characteristic results and the suspected diagnosis can be confirmed by serologic testing. Therapy may consist of medical (albendazole) and/or surgical therapy and should be individualized. When needle aspiration or surgical excision of a possible echinococcal lesion is performed, care must be taken to avoid spilling the contents into the peritoneum, which could lead to life-threatening anaphylaxis or spreading of the infection. *Echinococcus multilocularis* causes a more aggressive disease (alveolar hydatid disease), since the cysts produce buds that metastasize throughout the body. Although liver lesions are the most common lesions, life-threatening cerebral lesions may also result. The usual definitive hosts of *Ec. multilocularis* are northern foxes and the intermediate hosts are the rodents on which the foxes feed; therefore, the organism is endemic to parts of the Arctic and sub-Arctic regions.

Parasympathetic Innervation

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

dorsal vagal complex The parasympathetic center in the brainstem (medulla oblongata) where sensory signals from the gut and motor outflow to the gut are integrated.

efferent neuron A neuron that transmits signals from the brain or spinal cord to the gut.

Three divisions of the autonomic nervous system innervate the digestive tract. One is the parasympathetic division; the other two are the sympathetic and enteric divisions. The parasympathetic division is subdivided anatomically into the cranial and sacral divisions due to the neuroanatomic organization in which neurons that send fibers to the gut are located both in the brainstem and in the sacral region of the spinal cord. Projections to the digestive tract from these regions of the central nervous system are termed preganglionic efferents.

PARASYMPATHETIC NEURONS

Neuronal cell bodies of the parasympathetic cranial division reside in the medulla oblongata and project out of the brain in the vagus nerves (see Fig. 1). Cell bodies of the sacral division are located in the sacral region of the spinal cord and project in the pelvic nerves to the large intestine. Efferent fibers in the pelvic nerves make synaptic contact with neurons in ganglia located on the serosal surface of the colon and in ganglia of the enteric nervous system deeper within the large intestinal wall. Efferent vagal fibers form synaptic connections with neurons of the enteric nervous system in the esophagus, stomach, small intestine, and colon, as well as in the gallbladder and pancreas.

DORSAL VAGAL COMPLEX

Cell bodies of efferent vagal neurons are in the dorsal motor nucleus of the medulla oblongata. They are part of the dorsal vagal complex, which consists of the dorsal motor nucleus of the vagus, nucleus tractus solitarius, area postrema, and nucleus ambiguous. The nucleus tractus solitarius handles the sensory information entering the brain from the gut. The area postrema is a chemical sensor that signals the presence of agents in the blood and the nucleus ambiguous consists of motor neurons, some of which project to innervate the esophagus.

The dorsal vagal complex is the central integrative center for the outflow of signals from the brain to the gut. This center in the brain is more directly involved in the control of the specialized digestive functions of the esophagus, the stomach, and the functional cluster of the duodenum, gallbladder, and pancreas than in the distal small bowel and large intestine. The circuits in the dorsal vagal complex and their interactions with higher centers are responsible for the rapid and more precise control required for adjustments to rapidly changing conditions in the upper digestive tract during anticipation, ingestion, and digestion of meals of varied composition.

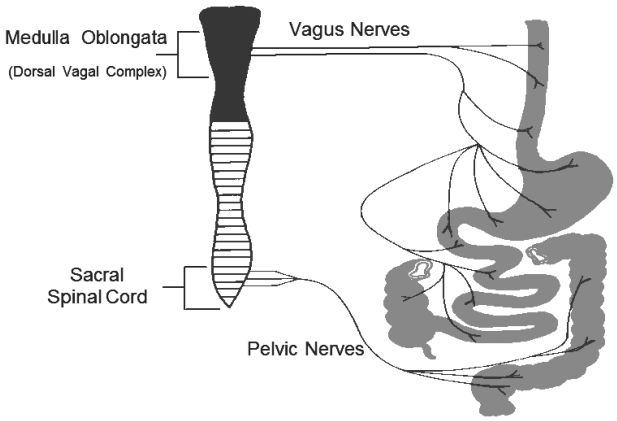

FIGURE 1 The parasympathetic division of the autonomic nervous system has cranial and sacral divisions. The cranial division consists of nerve cell bodies located in the medulla oblongata and the projections of the vagus nerves to the digestive tract. Cell bodies of neurons of the sacral division are positioned in the sacral region of the spinal cord. They project from the pelvic nerves to the large intestine.

FUNCTION

Efferent nerves of the cranial parasympathetic division transmit signals to the enteric innervation of the gastrointestinal musculature to control digestive processes both in anticipation of food intake and following the meal. This involves both stimulation and inhibition of contractile behavior in the stomach, stimulation of gastric acid secretion, stimulation of pancreatic secretion, and contraction of the gallbladder. Stimulation of inhibition or contraction results from activation of the enteric circuits that excite inhibitory or excitatory motor neurons, respectively.

Parasympathetic sacral efferents to the small and large intestinal musculature are predominantly stimulatory due to their input to the enteric microcircuits that control the activity of excitatory motor neurons. Signals transmitted by the sacral efferents are involved mainly in the initiation of defecation.

enteral Gastrointestinal feedings, either by mouth or through a tube placed in the stomach or intestinal tract.

parenteral nutrition The infusion of all essential nutrients by the intravenous route, bypassing the gastrointestinal tract. Also referred to as PN, total parenteral nutrition, artificial nutrition, intravenous feedings, or hyperalimentation.

tonicity A measure of the number of osmotic particles within a fluid. Isotonic refers to a similar number of particles in an intravenous solution and in the blood plasma. A hypertonic solution has a higher concentration of a solute than is found in blood.

Parenteral nutrition is a method of feeding patients by infusing a mixture of all necessary nutrients into the circulatory system, thus bypassing the gastrointestinal tract. This approach is also referred to as intravenous nutrition, total parenteral nutrition, artificial nutrition, and hyperalimentation. This method of nutritional support is utilized in patients who cannot eat or take nutrients into the intestinal tract by tube feedings. In other situations, this method of feeding is indicated in patients who cannot absorb adequate nutrients due to gastrointestinal disease, injury, or loss of the intestinal tract and therefore can receive nutrients into the body only by intravenous infusion.

BACKGROUND

Intravenous fluids administered to hospitalized patients usually contain only sugar (glucose, also referred to as dextrose) and some minerals (usually only salt, sodium chloride). These solutions are similar in concentration (tonicity) to blood plasma and therefore this infusate does not injure the lining of the veins in the arms through which they are infused (this injury to veins is a process called phlebitis). Additionally, the isotonic solutions do not damage the circulating red blood cells. This means, however, that the

solutions can contain only 50 g of glucose per liter of solution. Because the usual adult patient requires only 2–3 liters of solution per day to maintain normal hydration, only 100–150 g of glucose will be delivered daily, providing approximately 400–600 cal/day. This amount of energy is inadequate to meet the daily energy requirements of the usual adult, which usually range from 1500 to 2500 kcal/day, and these needs may be further increased due to disease and weight loss.

The breakthrough in the development of parenteral nutrition came on two fronts. First, dietary fat (soybean oil) was emulsified and provided as lipid particles, which were safe and well tolerated when administered intravenously. Next, all other essential nutrients (glucose, amino acids, electrolytes, vitamins, and minerals) were mixed together to make a highly concentrated solution. This nutrient mix was combined with the fat emulsion and infused slowly into the superior vena cava (the large vein that drains blood from the head, upper chest, and arms into the heart) via a central venous infusion catheter. The concentrated solution was rapidly diluted by the high level of blood flow through the heart and the nutrients were delivered by the bloodstream to all organs of the body. Infusion of this concentrated solution into an arm vein causes severe chemical phlebitis, resulting in extensive local inflammation and clotting at the infusion site. Infusion through the central venous catheter, however, allowed adequate nutrients to be delivered in a reasonable volume of fluid without this complication occurring.

Approximately 35 years ago, researchers demonstrated the efficacy of this approach by feeding beagle puppies for up to 1 year entirely by the intravenous route. Normal growth and development were observed. Next, the mixture was infused into an infant who was born with only a short length of small intestine, inadequate to maintain sufficient absorption. The child was sustained by intravenous feedings for up to 2 years while surgical correction of the bowel was undertaken. During this time, the baby also demonstrated normal growth and development. These were the first demonstrations that by infusing all necessary nutrients by the intravenous route and bypassing the gastrointestinal tract of an organism normal growth and development could be achieved.

INDICATIONS

In adults, the general indications for parenteral feedings include hospitalized patients who cannot take food or tube feeding formulas by the enteral route (e.g., via the intestinal tract). In well-nourished individuals, 7–10 days of conventional intravenous support (using 5% dextrose solutions) is generally provided, but if the period of partial starvation is to extend beyond this time, parenteral nutrition is indicated to prevent the potential complications associated with malnutrition. If the duration of illness is known to extend beyond 10 days, such as occurs in patients with severe pancreatitis, major trauma, or burn injuries, and enteral feedings are impossible, parenteral nutrition is initiated at an earlier stage in the hospital course. If the patient is malnourished as indicated by weight loss, the feedings will also be started as soon as the patient has stabilized. Preoperative patients with weight loss (greater than 15% normal body weight) who cannot take enteral feedings may also benefit from a course of parenteral nutrition for 7–10 days before surgery.

Individuals who have undergone massive intestinal resection may also require parenteral nutrition as a form of long-term nutritional support. Others with inflammatory bowel disease, severe malabsorption, and motility and obstructive disorders also frequently require such intravenous support.

Premature infants have minimal body stores of adipose and lean tissue and often require several weeks of intravenous feedings before full enteral feeding is possible. Therefore, parenteral nutrition is often utilized in these infants and those requiring surgical correction of major gastrointestinal anomalies.

NUTRITIONAL REQUIREMENTS

In order to provide adequate nutrients to an individual patient, the specific nutritional requirements of the individual must be determined. These needs may differ from requirements that were present during health; malnutrition is associated with deficits that need repair and many diseases are associated with infection and inflammation that impose increased requirements for many nutrients.

Energy

Basal energy requirements are a function of the individual's weight, age, gender, and activity level and the disease process. In general, hospitalized adults require approximately 25–30 kcal/kg/day but these requirements may be greater in patients with injury or infection (see Table I).

Protein

Protein (or amino acids, the building blocks of proteins) is the functional and structural component of the

TABLE I Energy Requirements

Patient condition	Basal metabolic rate	Approximate energy requirement (kcal/kg/day)
No postoperative complications, gastrointestinal fistula without infection	Normal	25–30
Mild peritonitis, long-bone fracture or mild to moderate injury	25% above normal	30–35
Severe injury or infection	50% above normal	35–45
Burn 40–100% of total body surface	Up to 100% above normal	35–60

body. With disease, poor food intake, and inactivity, body protein is lost and individuals become weak and waste muscle mass. Protein requirements for most healthy individuals are 0.8 g/kg/day (approximately 40–70 g of protein/day). Critically ill patients may need 1.5–2.0 g protein/kg/day (approximately 60–150 g/day) depending on the disease process, but this amount is often reduced in patients with kidney or liver disease.

Vitamins and Minerals

These requirements are usually met when standard volumes of a nutrient mix are provided. Increased amounts of vitamins are usually provided to severely ill patients (Table II) and blood levels are periodically determined to adjust the infusion levels of minerals such as sodium, potassium, chloride, phosphorous, magnesium, and zinc. Trace elements are usually added daily (Table III).

APPLICATION

The Solution

The patient is assessed and the nutritional requirements are determined by a physician, dietician, or other skilled provider. A prescription is submitted to the pharmacy or nutrition-mixing service for a mixture of parenteral nutrients to be composed for the specific patient. The nutrients are usually placed in 2- to 3-liter plastic bags and the contents are infused daily (Table IV). Alternatively, premixed solutions can be taken off the shelf and utilized but the fixed nutrient concentration limits the versatility of this approach in a heterogeneous patient population.

The Central Venous Catheter

To administer the highly concentrated nutrient solutions, a catheter must be placed into the central venous system with its tip in the superior vena cava.

TABLE II Vitamin Requirements

Vitamin	Units	Recommended dietary allowance (RDA) for daily oral intake	Daily requirement of the moderately injured	Daily amount provided by standard intervenous preparations
Vitamin A (retinol)	IU	1760 (females)–3300 (males)	5000	3300
Vitamin D (ergocalciferol)	IU	200	400	200
Vitamin E (tocopherol)	mg	8–10	Unknown	10
Vitamin K (phylloquinone)	μg	20–40	20	0
Vitamin C (ascorbic acid)	mg	60	75	100
Thiamine (vitamin B_1)	mg	1.0–1.5	2	3
Riboflavin (vitamin B_2)	mg	1.2–1.7	2	3.6
Niacin	mg	13–19	20	40
Pyridoxine (vitamin B_6)	mg	2.0–2.2	2	4
Pantothenic acid	mg	4–7	18	15
Folic acid	mg	0.4	1.5	0.4
Vitamin B_{12}	μg	3.0	2	5
Biotin	μg	100–200	Unknown	60

TABLE III Trace Mineral Requirements

Mineral	Recommended dietary allowance (RDA) for daily oral intake (mg)	Suggested daily intravenous intake (mg)
Zinc	15	2.5–5.0
Copper	2–3	0.5–1.5
Manganese	2.5–5.0	0.15–0.8
Chromium	0.05–0.2	0.01–0.015
Iron	10 (males)–18 (females)	3

Such a catheter can be placed via the subclavian vein, through a neck vein (the jugular vein approach is less desirable because of the high rate of associated infection), or by using a long catheter placed in an arm vein and then threaded into the central venous system (a peripherally inserted central catheter line) (Fig. 1). Once the correct position of the catheter has been established (usually by X ray), the infusion can begin.

Administration

To ensure that the solution is administered at a continuous rate, an infusion pump is utilized to administer the solution. In hospitalized patients, infusion usually occurs over 22–24 h/day. In ambulatory home patients, administration usually occurs overnight (12–16 h).

Monitoring

With solution infusion, a variety of determinations are made to ensure that the individual is responding appropriately to the infusate. This step involves primarily the measurement of glucose in the blood or urine (using techniques similar to those utilized by diabetic patients when monitoring sugar levels) but monitoring may be much more frequent and complex in critically ill patients. Urine output is measured over each 24 h period. In hospitalized patients, these measurements are usually performed by a highly trained nurse.

TABLE IV The Composition of a Standard Liter of Adult Parenteral Nutrient Solution

Glucose	150 g
Amino acids	42 g
Sodium	50 mEq
Chloride	60 mEq
Potassium	40 mEq
Phosphorous	15 mg
Acetate	75 mEq
Magnesium	12 mEq
Sulfate	12 mEq
Calcium	5 mEq
Gluconate	5 mEq

Variations Due to Age and Disease

Fluid volume and nutrient concentration must vary in pediatric patients depending on their age and weight. In adults with abnormal fluid loss, renal or liver failure, or other metabolic disorders, special mixtures are compounded to meet specialized fluid and nutrient requirements.

PERIPHERAL VEIN NUTRITION

Slightly hypertonic nutrition solutions can be prepared from commercially available amino acid mixtures (5%) dextrose solutions (10%), and fat emulsions (20%). These nutrient mixtures have a low caloric density (approximately 0.3 to 0.6 kcal/ml) and thus provide only 1200 to 2300 kcal/day in 2000 to 3500 ml of solution. The advantage to using these dilute nutrient mixtures is that they can be infused through a plastic cannula placed in a large-bore arm vein, thus avoiding the central catheter. This approach may be useful in the short term or, combined with minimal feedings administered via the gastrointestinal tract, the two methods of nutrient administration together may provide adequate nutrient requirements to a critically ill patient. These solutions tend to cause phlebitis (inflammation) of the arm veins and the infusion site must be inspected frequently and the infusion site changed every 48–72 h. Thus, this approach is acceptable only as a short-term solution to delivery of the parenteral nutrients.

COMPLICATIONS AND MONITORING

Catheter Care and Catheter Sepsis

Although it is not the most common problem related to intravenous feedings, catheter infection is probably the most common, serious problem related to this technique. The catheter is a plastic or Silastic tube that passes through a skin puncture site and then enters

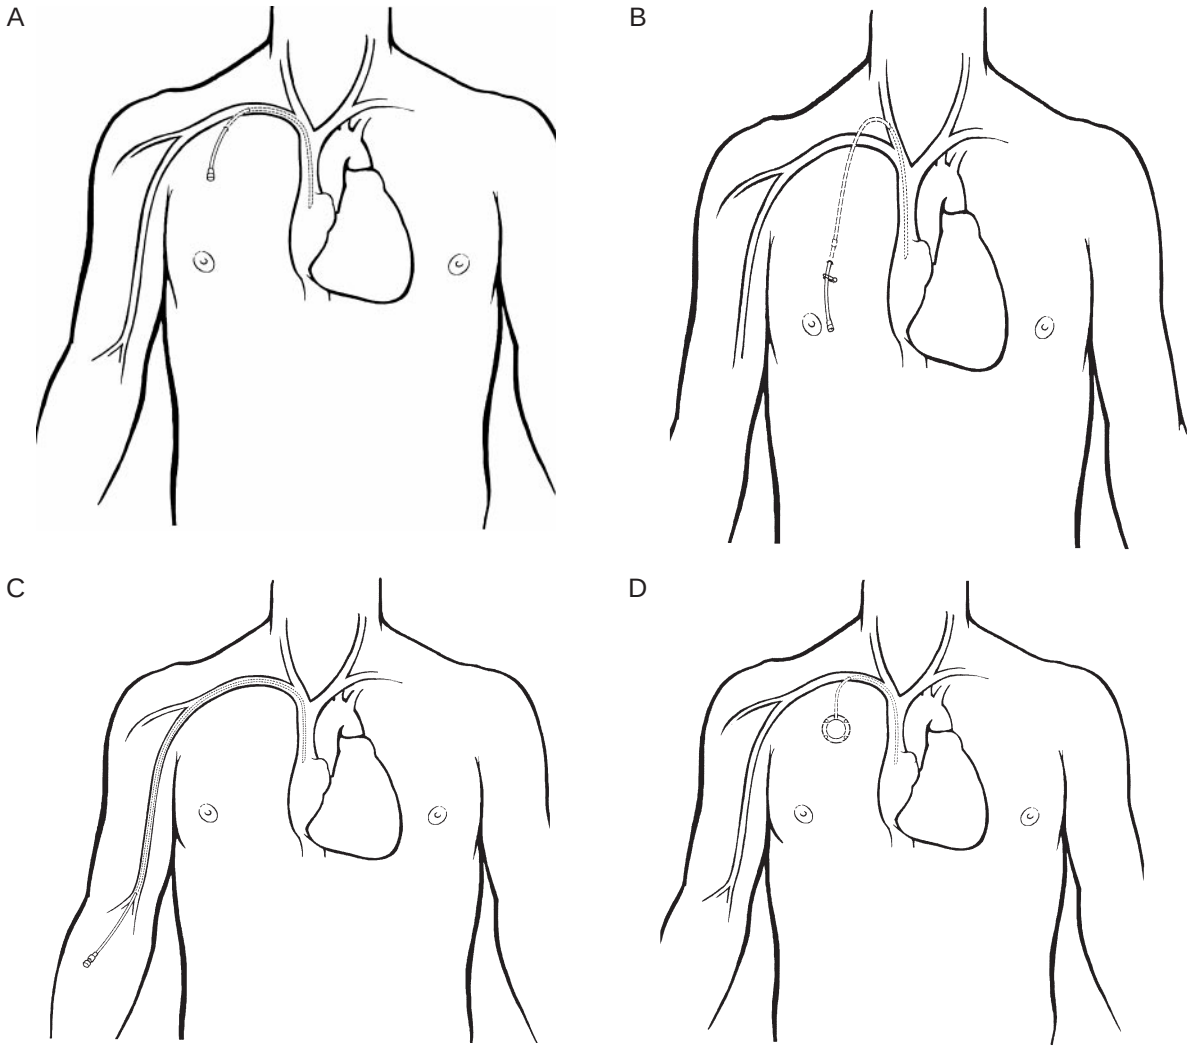

FIGURE 1 (A) This is a central venous catheter placed in the subclavian vein with its tip in the superior vena cava. (B) In the operating room, a catheter is inserted into the jugular vein in the neck and is directed into the superior vena cava. The distal portion of the catheter is tunneled under the skin to provide a subcutaneous tract that will resist infections. This device, which is inserted in patients requiring long-term (home) therapy, is often referred to as a Hickman catheter. (C) This fine plastic catheter is placed in an arm vein and is directed into the superior vena cava. This procedure is performed at the bedside, usually by a highly trained nurse. This approach is commonly referred to as a PICC (peripherally inserted central catheter) line. (D) This catheter is buried entirely below the skin and has a circular port covered by a rubber diaphragm, which is placed just below the skin. The patient intermittently pierces the skin and underlying diaphragm with the infusion needle in preparation for the nutrient infusion. The needle is removed at the termination of the therapy, so that no external catheter is visible.

the circulatory (venous) system. Thus, the catheter entrance site may serve as a portal for the entry of bacteria and other microorganisms into the body. In addition, many individuals requiring this therapy have inadequate mechanisms to fight infection, making these malnourished or critically ill patients all the more vulnerable to this completion of catheter sepsis (infection).

Catheter sepsis is characterized by the classic signs of infection: chills, fever, and, on occasion, drainage around the catheter entrance site. The white blood cell count is usually elevated and frequently

microorganisms are cultured from the bloodstream or the catheter tip. Fortunately, with removal of the infusion catheter, the symptoms usually abate in most patients. A short course of antibiotics is then usually adequate to clear the infection. However, many critically ill patients have fever from other sources (pneumonia or wound infections, for example) and the presence of this symptom complex associated with fever in a seriously ill patient often makes accurate diagnosis of catheter infection very difficult.

To prevent this complication, a rigorous program of catheter care is followed. Only intravenous nutrition solutions are administered through the catheter and no blood may be withdrawn from the catheter. Two to three times weekly, the dressing around the catheter is removed and, using sterile technique, the skin around the entrance site is scrubbed to reduce the number of microorganisms on the skin, thus decreasing the chance of catheter infection. The entrance site is inspected for signs of inflammation and drainage and if present, cultures are usually taken or the catheter is removed. Sterile technique is also utilized while attaching a new bag of nutrient solutions to the catheter for infusion. Catheter care and administration of the nutrient solution are generally carried out by a specially trained member of the nursing staff or a nurse with expertise in this field assigned to the nutritional support service.

Metabolic Complications

Although there is wide potential for problems (Table V) because of the variability in the patient's clinical status, metabolic complications are generally minimized by the adherence to a strict monitoring protocol (Table VI).

The major concern is the occurrence of hyperglycemia (an elevated blood sugar), which is associated with the infusion of excess glucose in the feeding solution or the diabetic-like state in the patient associated with many critical illnesses. Hyperglycemia can result in an osmotic diuresis (abnormal loss of fluid via the kidney), dehydration, and hyperosmotic coma. A diagnosis is made by the presence of elevated blood glucose levels and the detection of sugar in the urine. When this complication occurs, the infusion solution may be reformulated to decrease the amount of infused

TABLE V Some Metabolic Complications of Parenteral Nutrition

Problems	Possible causes	Solution
Glucose		
Hyperglycemia, glycosuria, osmotic diuresis, hyperosmola nonketotic dehydration, and coma	Excess quantity of glucose infused; inadequate endogenous insulin; increased glucocorticoids; sepsis	Reduce quanity of glucose infused
Ketaocidosis in diabetes mellitus	Inadequate endogenous insulin response; inadequate exogenous insulin therapy	Administer exogenous insulin; reduce glucose
Fat		
Altered coagulation	Hyperlipidemia	Decrease administration rate
Hypertriglyceridemia	Rapid infusion; decreased clearance	Decrease administration rate
Impaired liver function	May be caused by fat emulsion or by an underlying disease process	Consider infusions for only 16–18 h/day
Essential fatty acid deficiency	Inadequate essential fatty acid administration	Administer fat emulsion
Amino acids		
Serum amino acid imbalance	Unphysiologic amino acid profile of the nutrient solution; ?? amino acid utilization with various disorders	Change type of amino acid mixture administered
Hyperammonemia	Excessive ammonia in protein hydrolysate solutions; deficiency of specific amino acids; primary hepatic disorder	
Prerenal asotemia	Excessive amino acid infusion with inadequate calorie administration; inadequate free water intake; dehydration	Reduce amino acid intake
Elevated or subnormal blood levels of electrolytes and minerals	Inadequate or excess administration	Adjust administration rate; evaluate underlying pathophysiology

TABLE VI Monitoring Patients Receiving Parenteral Nutrition

Variables	Suggested monitoring frequency	
	First week	Later
Energy balance	**Daily**	**Daily**
Weight		
Metabolic variables		
Blood measurements	Daily	1–2 × weekly
Plasma electrolytes (Na^+, K^+, Cl^-)	3 × weekly	2 × weekly
Blood urea nitrogen	3 × weekly	2 × weekly
Plasma total calcium and inorganic phosphorus	Daily	3 × weekly
Blood glucose	3 × weekly	2 × weekly
Plasma transaminases	2 × weekly	Weekly
Plasma total protein and fractions	As indicated	As indicated
Blood acid–base status	Weekly	Weekly
Hemoglobin	2 × weekly	Weekly
Magnesium	Weekly	Weekly
Triglycerides		
Urine measurements	Daily	Daily
Glucose	Daily	Daily
Specific gravity or osmolarity		
General measurements	Daily	Daily
Volume of infusate	Daily	Daily
Oral intake (if any)	Daily	Daily
Urinary output		
Prevention and detection of infection		
Clinical observations (activity, temperature, symptoms)	Daily	Daily
WBC and differential counts	As indicated	As indicated
Cultures	As indicated	As indicated

glucose (usually the glucose infused should not exceed 4 mg/kg/min). Alternatively, insulin can be administered (either administered by subcutaneous injection or placed in the infusion bag).

The patient may also accumulate triglycerides in the bloodstream with infusion of the fat emulsion. Infusion of both glucose and fat emulsion in excess may result in pulmonary insufficiency. With excess glucose infusion, excess carbon dioxide (CO_2) production occurs as CO_2 accumulates in the bloodstream, a result of glucose metabolism. With lipid infusion, the lipid particles may accumulate in the lungs and reduce the diffusion capacity of respiratory gases.

In addition to these metabolic problems, the concentrations of a variety of electrolytes and minerals may vary and these levels are monitored by frequently determining concentrations in the bloodstream. Adjustments in the concentrations of the nutrients in the infusates are then made.

Mechanical Complications

As with any device, catheters and tubing may become clotted or twist and obstruct. Pumps may also fail or operate improperly. Of more concern is the infrequent complication of superior vena cava thrombosis, which is related to the catheter being placed in this large vein. This complication is associated with clotting of this large vessel draining the upper body and results in swelling of the arms and face. This occurs more commonly in children than adults but usually prevents further intravenous support and thus poses a serious life-threatening problem to many patients when this complication occurs.

HOME PARENTERAL NUTRITION

Patients who are unable to eat and absorb adequate nutrients for maintenance over the long term may be candidates for home parenteral nutrition. Many such individuals suffer from short-bowel syndrome caused by loss of the intestinal tract due to (1) extensive Crohn's disease, (2) mesenteric infarction, or (3) severe abdominal trauma. Pseudo-obstruction, radiation eneteritis, carcinomatosis, necrotizing enterocolitis, and intestinal fistulas are other reasons for poor bowel function and indications for home nutritional support.

To be eligible for this home parenteral nutritional therapy, patients must be able to master the techniques associated with this support system, be motivated, and have adequate social support in the home. Patients receive extensive evaluation, teaching, and training during a period of hospitalization that covers basic principles of parenteral nutrition and provides guidelines for catheter care, the maintenance of asepsis, and the use of infusion pumps.

A patient who is judged to be a candidate for home parenteral nutrition requires an indwelling Silastic catheter designed for long-term permanent use (see Fig. 1).

The nutrient solutions are prepared weekly and delivered to the patient's home. The patient sets up the infusion system and attaches the catheter to the delivery tubing in the evening for infusion over the next 12–16 h. The intravenous nutrition is terminated by the patient the next morning. Home care nurses see the patient at regular intervals and monitor infusion techniques, evaluate the patient's response to therapy, and continue the educational process for both the patient and family.

Home nutrition evolved because patients required this type of nutritional support for months or years, but costs of hospitalization made such therapy impossible in the hospital setting. This resulted in the development of private home care companies who have a support staff (including home nurses), mix and provide the solutions, maintain an inventory of supplies, respond to emergencies, and facilitate billing and collection for these services from insurers.

EFFICACY

Though the need for nutrition support in critically ill patients may seem obvious, this method of care has only recently became subject to critical review and to the objective assessment of outcome and cost benefit. A summary of these findings follows.

In one report, a total of 13 prospective randomized trials that evaluated the use of preoperative parenteral nutrition in surgical patients were identified. The patients were considered by their physicians to be moderately malnourished. A pooled analysis of the data showed that patients who received preoperative TPN had 10% fewer postoperative complications than the control group. The analysis found no significant difference in mortality between the parenterally fed groups and the controls.

Use of parenteral nutrition in the immediate postoperative period was also evaluated. In contrast to the analysis of the preoperative data, this study of postoperative feeding concluded that patients who received TPN after an operation had an approximately 10% higher risk of ensuing complications, with no associated benefit.

Trials addressing perioperative nutritional support have also been conducted in patients undergoing surgery in the upper abdomen for gastroenterological malignancies. In one such study, patients undergoing major pancreatic resection were randomly assigned either to a group that received TPN on postoperative day 1 or to a non-TPN group. No significant benefit from the use of adjuvant TPN could be demonstrated and the incidence of complications (primarily those associated with infection) was significantly greater in the TPN group.

Finally, a large meta-analysis evaluated the effects of providing parenteral nutrition versus no feeding in 2211 critically ill patients. The use of intravenous feedings did not influence mortality but may have reduced the complication rate, especially in malnourished patients. The authors concluded that further studies were necessary to firmly establish the latter conclusion.

All of these studies indicate the need to identify specific targeted patient groups who will benefit from this complex and expensive technique. Broad-scale use of this nutritional support technique is not indicated.

THE FUTURE

Because of costs, complications, and the ability to provide nutritional support by enteral tube feedings, the use of parenteral nutrition is decreasing in the United States. However, in specific patient groups it remains cost-effective and life-saving.

Several new components or products have become available to improve the type of substrate administered. New fat emulsions that include omega-3 fatty acids (fish oil) have been developed and these compounds are believed to be able to enhance the immune system in critically ill patients. In addition, some amino acids have not been included in the parenteral mixtures because of solubility problems or instability related to sterilization or prolonged shelf-life. However, these compounds have recently been combined with other amino acids to form stable dipeptides, which are now being included in the parenteral amino acid solutions. One such substance that is now available is the amino acid glutamine, which is thought to enhance immunological and bowel function in selected populations. This may translate into a method of nutritional support that improves recovery following major surgery and chemotherapy and improves resistance to infection in individuals with other life-threatening illnesses.

secretagogue A substance, such as a hormone or paracrine signal, that stimulates secretion.

Parietal cells are located within glands in the gastric mucosa. They have the unique ability to secrete a massive amount of hydrochloric acid (HCl), which sustains the highly acidic environment within the lumen of the stomach. The unusual morphology of the parietal cell has fascinated researchers for over 100 years. When parietal cells are stimulated by the appropriate secretagogues, they also undergo spectacular morphological transformations that are correlated with the activation of the enzyme H^+,K^+-ATPase. HCl is generated by the H^+,K^+-ATPase, acting in concert with ion channels and other ion transporters. The H^+,K^+-ATPase is composed of a catalytically active α-subunit and a β-subunit that targets the enzyme to the appropriate membrane compartment. The three major secretagogues, histamine, acetylcholine, and gastrin, stimulate HCl secretion by activating different signaling pathways that interact at the level of the parietal cell. Because of the common occurrence of peptic ulcer disease, the acid secretory function of the parietal cell has been studied extensively. However, the parietal cell has other functions. In human, monkey, cat, dog, sheep, rabbit, and guinea pig, parietal cells secrete intrinsic factor, which is essential for the efficient absorption of vitamin B12 or cyanocobalamin in the distal ileum. Parietal cells may also secrete prostaglandins as well as growth factors including transforming growth factor-α, amphiregulin, and heparin-binding epidermal growth factor. Prostaglandins exert a cytoprotective effect on the gastric mucosa and the local release of growth factors appears to play an important role in regulating the growth and differentiation of epithelial cells within the gland units.

glands. They originate from immature progenitor cells in the gland isthmus and then migrate upward toward the pit region and downward toward the base of the gland. Parietal cells near the base of glands are smaller and frequently have dense accumulations of F-actin within their intracellular canaliculi. In contrast, parietal cells in the upper region of the gland have a more rounded appearance and contain more well-defined intracellular canaliculi. The designation "parietal" arose from the location of this cell within the gastric gland (bulging out along the wall; parietal being defined as relating to the walls of any hollow part of a plant or animal). Parietal cells are also referred to as oxyntic cells, based on the Greek word *oxyntos* (to generate an acidic substance). The "typical" parietal cell is usually depicted in a triangular shape with the apical region of the cell forming the apex of the triangle, which borders the lumen of the gastric gland. In stimulated parietal cells, the canaliculi are stylistically represented as simple bifurcations of microvillar membrane that extend partway into the cell. In reality, however, the intracellular canaliculi are complex, interconnected tubular systems that extend from the lumenally facing side of the cell to the basolateral membrane region (Fig. 1). The extensive array of intracellular membranes immediately beneath the intracellular canaliculi has historically been referred to as "tubulovesicles." This term was a compromise, because it was not possible to determine whether the membrane-rich structures detected with standard electron microscopy (EM) techniques were elongated tubules or round vesicles. Recent work, based on rapid freeze fixation and scanning EM as well as 3D reconstructions of transmission EM-based serial thin sections, suggests that the tubulovesicular system contains tightly packed cisternae that bear some resemblance to classical Golgi stacks.

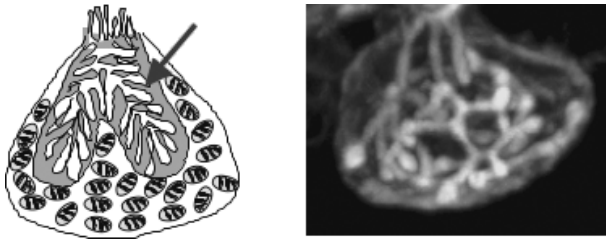

FIGURE 1 The complexity of the intracellular canaliculus is not conveyed in simple drawings. (Left) Typical depiction of an actively secreting parietal cell with a simple canaliculus containing elongated microvilli (arrow). (Right) 3D reconstruction of confocal microscopic images of a parietal cell within a gastric gland. The gland was fixed and stained with fluorescently tagged phalloidin, which specifically labels F-actin. Reprinted from Chew, C. S., Parente, J. A., Jr., Chen, X., and Chaponnier, C. (2000). The LIM and SH3 domain-containing protein, lasp-1, may link the cAMP signaling pathway with dynamic membrane restructuring activities in ion transporting epithelia. *J. Cell Sci.* **113**, 2035–2045, with permission.

MORPHOLOGICAL CHANGES AND ION TRANSPORT ACTIVITIES ASSOCIATED WITH HYDROCHLORIC ACID SECRETION

In addition to complex internal membrane structures, parietal cells are unusually rich in F-actin and possess a large number of energy-generating mitochondria. When parietal cells are stimulated to secrete hydrochloric acid (HCl), the canalicular membrane compartment expands at the expense of the intracellular tubulocisternal membrane compartment and this expansion is correlated with the appearance of numerous elongated microvilli. The mechanism driving these changes is controversial. One view is that the two compartments are continuous. The other, which forms the basis of the membrane recruitment hypothesis originally proposed by John Forte and colleagues in 1977, is that the canalicular and tubulocisternal membranes are distinct intracellular compartments. The membrane recruitment hypothesis proposes that the activation of the acid secretory response induces an exocytotic-like insertion of tubulocisternal membrane containing the H^+,K^+-ATPase into the canalicular membrane. Removal of the stimulus results in an endocytotic retrieval of membrane plus the H^+,K^+-ATPase back into the tubulocisternal compartment. Currently, this latter hypothesis is favored and is supported by the localization of a number of proteins associated with vesicle recycling within the parietal cell, as well as by observations that the H^+,K^+-ATPase translocates to a biochemically distinct compartment following stimulation.

Parietal cell proteins associated with vesicular trafficking include SNAP-25 (25 kDa synaptosomal-associated protein), syntaxin 3, and VAMP-2 (vesicle-associated membrane 2), which form a ternary complex that is implicated in the docking and fusion of vesicles. Proteins associated with endocytosis that have been localized in the parietal cell include clathrin, clathrin adapters, and dynamin-2. Also present are SNAREs, which are also implicated in vesicle fusion; SCAMPs, which are transmembrane proteins found in vesicles involved in membrane recycling; myosin 5b; and several rab proteins including rab11a, rab11b, and rab25. Evidence from other cellular systems suggests a role for rab proteins in regulating vesicular trafficking

between membrane compartments. The expression of a dominant negative form of rab11a in gastric parietal cells also inhibits the recruitment of the H^+,K^+-ATPase to the canalicular membrane.

Although the relationship between changes in F-actin polymerization and microvillar elongation has not yet been established, changes in the plasticity of the actin cytoskeleton are implicated in this process. At least two different actin-binding proteins, ezrin and lasp-1, are highly expressed in the parietal cell and are regulated by the cyclic AMP (cAMP) signaling pathway. Parietal cells also contain two different pools of actin: γ-actin, which is present at the cortical cell membrane, and β-actin, which is present mainly within the canalicular region.

The precise biochemical steps associated with the generation of HCl are unknown. Protons are thought to be derived from H_2O by the reaction, $HOH \rightarrow H^+ + OH^-$. Once generated, protons are actively extruded into the apically directed intracellular canaliculus by the H^+,K^+-ATPase in a neutral exchange for K^+. The activity of the H^+,K^+-ATPase is balanced by (1) the movement of Cl^- through a Cl^- channel and (2) the reuptake, or recycling, of K^+ through a K^+ channel. Although there are currently several candidates, the identity of these channels remains to be determined. The hydroxyl (OH^-) ions produced during the generation of protons combine with CO_2 in a reaction catalyzed by carbonic anhydrase to form bicarbonate (HCO_3^-), which is extruded from the cell by the action of Cl^-/HCO_3^- exchangers (AE2 isoforms) on the basolateral membrane. When this bicarbonate enters the general circulation, the pH of the venous blood exiting the stomach rises above that of the arterial blood entering the stomach, a phenomenon that has been labeled the "alkaline tide."

In addition to Cl^-/HCO_3^- exchangers, a $Na^+/K^+/2Cl^-$ cotransporter (NKCCl) resides on the basolateral membrane. Recent evidence suggests that there is a reciprocal relationship between the expression of the $Na^+/K^+/2Cl^-$ cotransporter and AE2. In rats, parietal cells above the neck of the glands express AE2 at high levels, whereas NKCCl expression is not detectable. This distribution is reversed in the neck and the base of the glands. The differences in the distribution of these transporters suggest that there are at least two different populations of parietal cells with different Cl^- entry mechanisms.

Na^+/H^+ exchangers (NHE2 isoforms) are also present on the basolateral membrane of the parietal cell. Although not directly coupled with AE2, these exchangers may act in concert with this Cl^-/HCO_3^- exchanger in a pH-dependent manner, thereby indirectly mediating the transport of NaCl into the cell. The activities of NHE2 and AE2, coupled with the basolateral Na^+,K^+-ATPase, or sodium pump, and a basolateral K^+ conductance, may facilitate the uptake of Cl^- into the cell against its electrochemical gradient. Based on targeted gene disruption studies, however, it appears that neither NHE2 nor NKCC1 is required for the acute acid secretory response.

SIGNALING PATHWAYS INVOLVED IN THE REGULATION OF HYDROCHLORIC ACID SECRETION

Parietal cells possess receptors for histamine (H2-receptor subtype), acetylcholine (muscarinic M3 receptor subtype), and gastrin [cholecystokinin B (CCK-B) or CCK_2 receptor subtype] (Fig. 2). When histamine binds to H2 receptors, the enzyme adenylyl cyclase is activated through a stimulatory heterotrimeric G-protein, G_s, catalyzing the generation of cAMP from ATP. Once elevated, cAMP activates a cAMP-dependent protein kinase(s) that phosphorylates two F-actin-associated proteins, ezrin and lasp-1. The functions of these proteins in the activation of the acid secretory response have not yet been defined; however, their localization within F-actin-rich compartments supports a role in the regulation of changes in the actin cytoskeleton that accompany active secretion. The response to acetylcholine and gastrin involves the elevation of intracellular calcium concentrations ($[Ca^{2+}]_i$), presumably by coupling of the receptors with another heterotrimeric G-protein, G_q, which activates phospholipase Cβ. Once activated, this phospholipase catalyzes the breakdown of phosphatidylinositol 4,5-bisphosphate to form diacylglycerol (DAG), which activates protein kinase C, and inositol 1,4,5-trisphosphate (IP_3). IP_3 activates an intracellular calcium channel, the IP_3 receptor, allowing for calcium release from intracellular stores. Intracellular calcium release is coordinated with the influx of extracellular calcium through unidentified storage-operated calcium channels in the plasma membrane (Fig. 2). In isolated parietal cells, histamine weakly elevates $[Ca^{2+}]_i$ in a subpopulation of parietal cells, but this response is not coupled to the activation of HCl secretion. In contrast, the presence of extracellular calcium has been shown to be essential for cholinergic activation of secretion.

Although the intracellular signaling pathways that are activated by acetylcholine and gastrin are similar with respect to calcium, only acetylcholine elicits a significant acid secretory response in the absence of a histamine background. The reason for the divergence in

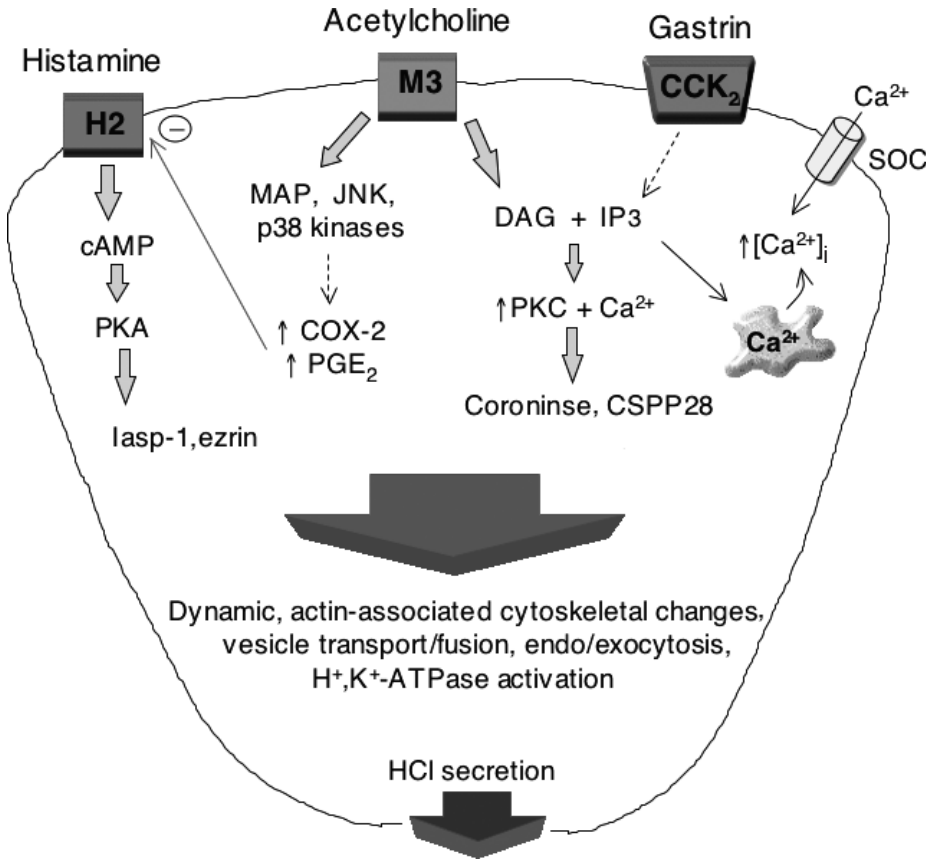

FIGURE 2 Overview of the intracellular signaling pathways involved in the activation of parietal cell HCl secretion. When histamine binds to H2-type receptors, the enzyme adenylyl cyclase is activated and catalyzes the breakdown of ATP to form cAMP, leading to the activation of a cAMP-dependent protein kinase(s). These kinases phosphorylate lasp-1 and ezrin, which are F-actin-associated proteins. Acetylcholine and gastrin activate a calcium-dependent signaling pathway(s) by binding to muscarinic M3 and CCK2 receptors, respectively. Gastrin is a weak agonist at the level of the parietal cell and little is known about its actions beyond elevation of $[Ca^{2+}]_i$. It is also unknown how elevated cAMP levels potentiate the responses to acetylcholine and gastrin. Acetylcholine and gastrin induce the formation of IP_3 and DAG, presumably by activating phospholipase Cβ. IP_3 induces the release of $[Ca^{2+}]_i$ from intracellular stores. Calcium also enters the cell through an unidentified storage-operated calcium channel(s) (SOC) in the plasma membrane. Protein kinase C (PKC) and calcium-dependent protein kinase(s) are subsequently activated, leading to increases in phosphorylation of coroninse and CSPP28. Acetylcholine also activates ERK/JNK/p38 kinases and may increase the production of PGE2. This latter response could serve as a delayed autocrine negative feedback loop to regulate histamine-stimulated HCl secretion. The link between changes in protein phosphorylation and agonist-induced changes in the actin-based cytoskeletal has not yet been defined. However, recent evidence suggests that protein phosphorylation may be involved in regulating dynamic cytoskeletal changes and vesicle transport events involved in the insertion and retrieval of the H^+,K^+-ATPase from the canalicular membrane. Dashed lines indicate less established pathways.

the secretory response to acetylcholine and gastrin is unclear, but may be associated with differences in their signaling response patterns. Acetylcholine induces a greater rise in $[Ca^{2+}]_i$ than does gastrin. In addition, acetylcholine elicits a uniform response from parietal cells in isolation, whereas gastrin stimulates only ~30% of the same cells. Moreover, although both agonists appear to activate protein kinase C, they do not appear to increase the phosphorylation of the same downstream proteins. Acetylcholine also activates the mitogen-activated protein kinases [extracellular signal-related kinase variants 1 and 2 (ERKs 1 and 2)], JUN

N-terminal kinase (JNK), and possibly the p38 kinase signaling pathway. Recent evidence suggests that the activation of these latter pathways increases cyclooxygenase 2 (COX-2) gene expression and prostaglandin E2 (PGE2) production by the parietal cell. Increased PGE2 production may serve as a delayed negative feedback control pathway to regulate histamine-stimulated HCl secretion (see below).

As with histamine, the intracellular signaling events that that are modulated by cholinergic stimulation have just begun to be defined. Thus far, two proteins have been found to undergo increased phosphoryation in parietal cells stimulated with acetylcholine: coroninse and CSPP28. Coroninse is an actin-binding protein that has been implicated in the regulation of endocytosis. CSPP28 is phosphorylated by a calcium-dependent mechanism and is enriched in light membrane fractions. Thus, like coroninse, CSPP28 may be involved in controlling vesicle movement and/or fusion.

In most, but probably not all species, histamine and cAMP are the most powerful stimulators of the acid secretory response at the level of the parietal cell. There is an acute potentiating interaction between the cAMP and calcium signaling pathways such that a low dose of acetylcholine administered along with a submaximal dose of histamine induces a greater than additive response. There is a similar potentiating interaction between histamine and gastrin. The mechanisms responsible for these potentiating interactions are not yet established.

Several factors have been found to suppress the acute acid secretory response to histamine in isolated parietal cells, including prostaglandins of the E series, somatostatin, epidermal growth factor (EGF), and transforming growth factor-α (TGF-α). All of these factors appear to couple with an inhibitory heterotrimeric G-protein, G_i. Longer exposure of parietal cells in primary culture to EGF/TGFα enhances the acid secretory response. This long-term response may be initiated by activation of the serine/threonine protein kinase, Akt, and the induction of H^+,K^+-ATPase gene expression.

Pathologic and Paralytic Ileus

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

ileus Absence of propulsive motility in the gastrointestinal tract.
laparotomy Surgical incision through the abdominal wall.
physiologic ileus Normal absence of gastrointestinal contractile activity.

The term "ileus" is derived from the Greek word *eileos*, which is translated as "to block or to twist." Ileus is generally defined as absence of propulsive motility in the small or large intestine. Absence of propulsive motility implies stasis of the luminal contents. The presence of ileus can reflect normal intestinal physiology or it can be pathologic.

INTRODUCTION

Physiologic ileus refers to the absence of motility that normally occurs for short periods of time during specialized motility patterns, such as the inactivity found during the interdigestive state in the small intestine. Pathologic ileus refers to the prolonged absence of propulsive motility that is associated with clinical symptoms of an intestinal obstruction. Various names have been applied to this form of obstruction. It may be known as adynamic ileus, inhibitory ileus, or paralytic ileus. The latter term is not strictly accurate in a pathophysiologic sense because the intestinal musculature is not paralyzed in the same sense as in skeletal muscle paralysis.

CLINICAL SYMPTOMS

Pathologic ileus can result from a variety of diverse conditions that include disease changes in the intestine and disease activity in the peritoneal cavity. Pathologic ileus may also be induced as a neurally mediated reflex response to conditions outside the peritoneum and may be associated with conditions such as general infections, spinal cord injury, and irritation of the kidneys. This form of obstructive intestinal inactivity is most commonly seen during and for prolonged periods following laparotomy. Exposure and handing of the bowel is a strong stimulus for the production of ileus. Nevertheless, the most clinically important cause of pathologic ileus is peritonitis.

The entire intestine in pathologic ileus becomes dilated with large collections of both fluid and gas. The gaseous composition is mostly air. Unlike mechanical obstruction whereby the intestine above the point of occlusion becomes distended gradually, dilatation of the entire bowel occurs quickly, with thinning of the wall as the radius increases. This underlies the extreme degree of abdominal distension that is one of the primary signs of the condition.

The clinical features of pathologic ileus do not parallel those found in mechanical obstruction. Pain is usually not a complaint, or, if present, is a dull continuous ache rather than the intermittent sharp cramping pain that occurs in structural blockage. Nausea and vomiting can be prominent and fluids given by mouth are regurgitated. Defecation and the passage of gas usually stop completely with the onset of the ileus.

PATHOPHYSIOLOGY

Paralytic ileus is not entirely applicable as a synonym for pathologic ileus, because the intestinal musculature is not paralyzed. The ability of the smooth muscle to generate maximal force of contraction is unchanged in pathologic ileus. Neural influences actively inhibit the intestinal musculature and account for the prolonged absence of muscle contraction and motility seen in pathologic ileus. The way it starts and the prolonged nature of pathologic ileus are reminiscent of skeletal muscle reflex paralysis that is acutely associated with spinal cord injury and ensuing spinal shock. In spinal shock, the neural circuits of the spinal cord that normally mediate motor reflexes become nonfunctional for a transient period of time. In the case of pathologic ileus, the neural circuits of the enteric nervous system that normally initiate and organize propulsive motor behavior in the intestine become nonfunctional for a transient period. Although neural mechanisms are involved in both cases, the details of the neurophysiologic changes cannot be explained fully for either case.

 Copyright 2004, Elsevier (USA). All rights reserved.

Activation of sympathetic innervation is implicated in the initiation of pathologic ileus. Virtually all of the sympathetic nerve fibers, which enter the intestine outside of the sphincters, end in the ganglia of the enteric nervous system. Norepinephrine released from the sympathetic nerves acts to suppress the release of acetylcholine at the millions of nicotinic synapses that are part of the integrative neural networks of the enteric nervous system. This inactivates the neural circuits and thereby prevents them from activating propulsive motility. Subpopulations of enteric inhibitory motor neurons remain active in this circumstance and act to continuously suppress contraction of the inherently myogenic musculature.

Although sympathetic activation and the release and action of norepinephrine in the enteric nervous system are an attractive explanation for pathologic ileus, some observations do not support the hypothesis. For example, pretreatment with drugs that block the receptors for norepinephrine or that suppress its release from sympathetic nerves is ineffective for prevention of the ileus associated with laparotomy. Infiltration of the splanchnic innervation with a local anesthetic to block sympathetic nerve traffic to the intestine does not reverse the ileus seen during laparotomy in dogs. On the other hand, injection of a local anesthetic into the blood entering the intestine immediately evokes rigorous contractile activity. Two conclusions emerge from these observations. One is that activation of sympathetic reflexes may release substances other than norepinephrine that initially "lock" the integrated microcircuits of the intestinal enteric nervous system in a state of prolonged paralysis; this ensues for prolonged periods of time without further sympathetic input. The second conclusion is that ongoing activity of enteric inhibitory motor neurons accounts for the absence of contractile behavior. Blockade of the inhibitory neuronal activity by injection of a local anesthetic releases the muscle from the inhibition. Uncoordinated contractile activity appears after neural blockade due to the autogenic properties of the musculature.

Pepsin

JEAN-PIERRE RAUFMAN
University of Maryland School of Medicine, Baltimore

pepsin Aspartic proteinase (36 kDa), derived from pepsinogen under acidic conditions; assists the digestion of dietary protein.

pepsinogen Proenzyme (40 kDa) synthesized and stored in zymogen granules and secreted by chief cells of the stomach.

Pepsin, a protease present in the gastric lumen, is secreted by the chief cells of the gastric mucosa as an inactive precursor, pepsinogen; pepsinogen is activated by acid present in the gastric lumen, which initiates digestion of protein. Multiple genes code for immunologically distinct forms (isoenzymes) of pepsin, but all forms appear to have functional similarity. Peptic ulcers and acid-peptic disease derive their names from pepsin.

HISTORICAL OVERVIEW

In groundbreaking experiments using human gastric juice, the American physician/physiologist William Beaumont (1785–1853) hypothesized that, in addition to acid, an unknown factor contributed to protein digestion. The German physiologist Theodor Schwann (1810–1882) identified this factor from its ability to digest egg white and designated it "pepsin" (derived from the Greek word *pepsis*, for digestion). In England, using amphibian peptic cells as a model, the Cambridge physiologist John Langley (1852–1925) elucidated the formation of pepsinogen in chief cells, its storage in cytoplasmic zymogen granules, and, after secretion, its conversion to the active acid protease, pepsin. In 1930, John Northrop crystallized pepsin. Recent advances in structural biology have revealed how the three-dimensional structure of these molecules explains their activation and actions.

STRUCTURE AND ACTIVATION OF PEPSIN

Like other aspartic proteinases (EC 3.4.23.X), pepsin (approximate molecular mass, 36 kDa) is synthesized as a proenzyme, pepsinogen (approximate molecular mass, 40 kDa), which is stable at neutral and alkaline pH (>6) and is converted to active pepsin at acid pH by proteolytic cleavage of an N-terminal prosegment (inhibitory piece). Studies of the crystal structure of pepsinogen indicate that the inhibitory piece shields the substrate-binding portion of the active protease, with six basic amino acids in the prosegment forming electrostatic interactions with acidic amino acids in pepsin. Thus, at neutral pH, the inhibitory piece maintains the enzyme in its inactive form by sterically blocking access to the active site and neutralizing negative charges in pepsin, thereby stabilizing the conformation of the proenzyme.

Exposure to acid results in protonation of carboxylate groups and repulsion of the net positive charges that disrupt the electrostatic interactions, unblocking the active site and activating the enzyme. Moreover, pepsinogen is subject to the proteolytic action of activated pepsin (autocatalysis). By these mechanisms, exposure to pH <6 (as expected in the gastric lumen) activates a rapid (2 sec at pH 5–6; 5 msec as the pH approaches 2) cascade of pepsin activation. Returning ambient pH to neutrality can arrest or reverse these conformational changes. Increasing the pH to >7.2 (as expected in the normal small intestine) or the temperature to $>65°C$ irreversibly denatures pepsin, whereas pepsinogen is stable to pH 10 and 100°C.

The molecular structure of human pepsin (Fig. 1) is very similar to that of other members of the aspartic proteinase family. The central hydrophobic core of pepsin (catalytic aspartic acid residues at position 32 and 215) comprises the active site of the enzyme. This site can accommodate an approximately 8-amino-acid portion of protein substrate.

MEASUREMENT OF PEPTIC ACTIVITY

Measurement of peptic activity was first standardized by Anson and Mirsky in 1932; they defined 1 peptic unit as the activity of pepsin (pH 2, 37°C) that results in the release over 10 minutes of 0.1 μmol of tyrosine from 5 ml of 2% hemoglobin. To increase sensitivity and facilitate the analysis of multiple samples, investigators have modified this assay by using radiolabeled substrate (hemoglobin and albumin) and automated assays.

FIGURE 1 Schematic structure of human pepsin (EC 3.4.23.1), drawn according to coordinates deposited in the Protein Data Bank (identification number 1PSN). Light gray indicates β sheets; dark gray indicates α helices. The aspartic acid residues at positions 32 and 215 delineate the active site of the enzyme (in a ball-and-stick configuration).

Rather than using a defined absolute unit of peptic activity, many investigators express results as a percentage of peptic activity in experimental samples compared to control or, in secretory studies, as a percentage of total peptic activity in the sample.

ACTIONS IN NORMAL PHYSIOLOGY AND DISEASE

The major function of pepsin is to initiate digestion of ingested proteins. The greater activity of pepsin for meat proteins, such as collagen, indicates that the enzyme is less important for hydrolysis of vegetable proteins. In addition, in neonates, pepsin may assist in milk clotting. The pH optimum for peptic hydrolysis of proteins depends on the substrate (pH 1.5–2.5 for hemoglobin, pH 3 for albumin, and pH 5.5 for milk clotting).

Peptic activity releases free amino acids and small peptides that can be absorbed by enterocytes lining the small intestine. Relatively large peptides resulting from incomplete pepsin digestion also enter the duodenum and are further degraded by pancreatic proteinases. Some products of peptic digestion also serve a signaling function because they stimulate the release from the distal stomach (gastrin) and duodenum of hormones (cholecystokinin-releasing peptide and others) that play additional roles in regulating digestion.

Pepsin appears to play a crucial, if not necessary, role in ulceration of the stomach and duodenum. In the absence of pepsin, gastric acid does not cause ulceration. Hence, major benefits of antacid therapy in the treatment of ulcer disease may be inhibition of the conversion of pepsinogen to pepsin and the maintenance of a gastric luminal pH greater than the optimum for the enzyme. Changes in the level or distribution of pepsinogen in blood and urine that are observed in peptic ulcer disease and gastric cancer have not proved clinically useful.

Percutaneous Drainage

DAVID B. LAUTZ AND RODNEY CHAN
Brigham and Women's Hospital and Harvard Medical School

abscess Collection of pus formed by tissue destruction in an inflamed area of a localized infection.
Seldinger technique Used for the insertion of a guidewire into a vessel.
tandem-trocar technique Used to cannulate into a vessel.

Even though there has never been a debate about whether abscesses should be drained; the available options for drainage have changed. Traditionally, an operation has been required, whether a thoracotomy for empyema, or a laparotomy for diverticular abscess. The modern technique of image-guided percutaneous drainage has now become the first choice for many clinicians and patients. Surgery is increasingly reserved only for difficult-to-reach locations, for cases in which percutaneous drainage fails, or for cases in which urgent surgical exploration is needed in view of impending sepsis.

INDICATIONS, APPROACHES, AND GUIDANCE

Patients harboring intraabdominal abscesses usually present with signs of systemic inflammation, including fever, leukocytosis, and pain. Postoperative fluid collections represent the most common cause of intraabdominal abscess and are often localized to the dependent pelvis. Other common causes of pelvic abscesses include appendicitis, diverticulitis, and pelvic inflammatory diseases. Although most abscesses are drained transabdominally when possible, the pelvis represents a challenge due to obscuring bowel loops from ileus and the abundance of vascular structures. Alternative approaches of transrectal and transvaginal drainage guided by ultrasound as well as transgluteal drainage guided by computed tomography (CT) are employed routinely.

Liver abscesses are common and they can be either single or multiple. Single pyogenic abscesses are frequently located in the right lobe, whereas multiple abscesses occupy both lobes. Drainage of single abscesses can often be guided by ultrasound alone, but multiple abscesses typically require multiple drains and are CT guided. Subdiaphragmatic abscesses represent a challenging location and require a combination of imaging procedures for guidance.

Pancreatic fluid collections occur following episodes of acute pancreatitis. They can present early as pancreatic necrosis or late as symptomatic pseudocysts. CT is the usual method of drainage in these cases. Aspiration without catheter placement is not appropriate as the chance of recurrence approaches 70%.

PROCEDURES

Before starting the procedure, it is important to ensure that drainage is clinically indicated, coagulopathy is corrected, and the imaging modality and the approach are chosen. Broad-spectrum antibiotics are usually given 1 hour preprocedure. The procedure is usually performed with a combination of intravenous conscious sedation (fentanyl, versed) and local anesthesia. A diagnostic scan is typically obtained with a radio-opaque skin marker.

Diagnostic aspiration with a 22-gauge needle will confirm the depth of the cavity as well as the path for catheter placement. The aspirate should be examined by gram stain and culture, although organisms may not be found if patients have been receiving antibiotics. White cells can be absent if patients are immunocompromised. In addition, the presence of creatinine suggests a urinoma, bilirubin suggests biloma, fat globules suggest lymphocele, and amylase suggests pseudocysts. Care is taken not to decompress the abscess cavity completely. The exchange of the aspiration needle for the catheter is done using the Seldinger technique or the tandem-trocar technique and a large catheter of 12- to 14-gauge lumen is left for drainage. There are many types of catheters. Pigtails are the most common types, and the drainage site is left in the dependent position if possible. After catheterization, the cavity is irrigated many times and, most importantly, the drain is secured externally. Finally, an additional scan is completed to ensure that there are no undrained collections.

Daily drain care and inspection are paramount. The usual recommendation for flushing is 5 ml, three or four times a day, to prevent clogging. When the catheter

 Copyright 2004, Elsevier (USA). All rights reserved.

drains less than 10 ml for a 24-hour period, it is usually reasonable to remove it, but it is important to confirm that the decrease in drainage is not secondary to blockage. Sudden decrease in drainage can be secondary to catheter obstruction. Imaging with either CT or a sinogram is important to demonstrate complete drainage.

CLINICAL TRIALS

There is a lack of randomized clinical trials comparing surgical drainage to percutaneous drainage of abscesses. In a retrospective review of 32 patients with Crohn's disease who underwent percutaneous drainage from 1985 to 1999, there was a 95% success rate, with 50% of patients avoiding surgery in the short term (< 60 days). There was not any significant increase in need for surgery long term among those patients treated by drainage. The abscess recurrence rate of 22% was comparable to surgical drainage.

Although most retrospective studies of percutaneous drainage have shown promising results, one review of 160 unselected patients who underwent drainage of pancreatic pseudocysts revealed lower success (88 vs. 42%), higher mortality (16 vs. 0%), more complications (64 vs. 27%), and longer hospital stay (45 vs. 18 days) in the percutaneous drainage group.

CATHETER COMPLICATIONS

In an older retrospective study on the use of percutaneous drainage in 118 patients from 1979 to 1984, there was a reported 4.2% major complication rate, which includes septic shock, hemorrhage, subphrenic abscess, and formation of an arteriovenous fistula, and a mortality rate of 2.5%. Other complications include the formation of an enteric fistula, which presents as a change in character and volume of the drainage.

CONCLUSION

There is still some debate among authorities on surgical approaches and percutaneous drainage of abscesses, but the majority of patients who develop intraabdominal abscesses are now treated noninvasively. This approach has radically changed the surgical management of many patients and has allowed them to avoid an open surgical approach, which may increase their chances for other postoperative complications. The increasing use of and demand for guided percutaneous drainage will revolutionize the treatment of many surgical disorders as well as offer clinicians and their patients another less invasive option for drainage.

Percutaneous Endoscopic Gastrostomy (PEG)

JEREMY SPECTOR
Duke University Medical Center

enteral By way of the gastrointestinal tract.
fluoroscopy Examination of the tissues using an X-ray fluoroscope.
gastrostomy An opening into the stomach.
ligament of Treitz Suspensory muscle of the duodenum that anatomically divides the duodenum from the jejunum.
parenteral By means other than the gastrointestinal tract, such as via intravenous injection.
volvulus Twisting of the intestine, resulting in obstruction.

The placement of a percutaneous endoscopic gastrostomy tube is a widely used method of delivering enteral nutrition to those unable to eat. The process involves inserting a thin tube through the wall of the abdomen into the stomach; the tube allows nutrient augmentation, fluid administration, or medication delivery. In properly selected patients, the procedure is safe, well tolerated, and successful in over 90% of individuals.

INTRODUCTION

As the population ages and life-sustaining technologies are advanced, many circumstances arise in which patients are unable to eat or tolerate oral intake. In this setting, additional means exist to provide nutrition, fluids, and medications, either by enteral or parenteral methods. When possible, enteral feeding is the preferred route to provide nutrition to patients with a functioning gastrointestinal (GI) system. By maintaining even a minimal exposure of nutrients to the enteral GI tract, there are significant benefits for the patient, including preserving the function of the enteral immune system, preventing mucosal atrophy, maintaining the normal gut flora, and reducing the incidence of sepsis. In addition, enteral nutrition is generally safer and less costly than parenteral nutrition. For short-term needs, nasoenteric feeding tubes are safe, effective, and easy to place and subsequently to remove. However, when oral intake will be compromised for an extended period of time, percutaneous endoscopic gastrostomy (PEG) tubes have become the delivery systems of choice. Introduced in the early 1980s, PEG tubes have several advantages over surgical gastrostomies. PEG tubes can be placed using only mild sedation and topical anesthesia and require less time compared to surgical gastrostomies, which are generally performed under general anesthesia. In addition, PEG tubes are less expensive and have fewer complications compared to surgical gastrostomies.

INDICATIONS AND CONTRAINDICATIONS

In the adult population, the most common conditions that lead to PEG placement are neurologic disorders such as strokes, amyotrophic lateral sclerosis, neurologic trauma, and dementia. Other illnesses include head and neck cancers, facial trauma, and the short bowel syndrome. PEG tubes are most often placed for the purpose of providing long-term enteral nutrition. Other goals may include decreasing the risk of aspiration, improving survival, decreasing the risk of infection, and healing pressure ulcers. At times, PEG tubes are also placed to allow decompression of the stomach, such as in the setting of malignant intestinal obstruction or gastric outlet obstruction, often referred to as a "venting" PEG. Less common indications include treatment of gastric volvulus via fixation of the stomach to the anterior abdominal wall, and to allow access to the stomach for transgastric surgical instrumentation.

Absolute contraindications to PEG placement are the inability to advance the gastroscope, a limited life expectancy, or the inability to bring the gastric wall and anterior abdominal wall in apposition (which is required for proper healing and tract formation). The inability to transilluminate the anterior abdominal wall is considered by many to also be a contraindication to placement. However, there are data to suggest that with definite localization, with external palpation, and in the absence of air aspiration prior to needle visualization (see below), the technique can be performed safely. There are relative contraindications as well, including compromised wound healing, morbid obesity, massive ascites, coagulopathy, gastric varices, history of subtotal gastrectomy, peritoneal dialysis, portal hypertension, large hiatal hernia, hepatomegaly, and neoplastic or infiltrative disease involving the gastric wall.

 Copyright 2004, Elsevier (USA). All rights reserved.

PEG INSERTION

The following description is a standard technique for placing PEG tubes. Prior to the procedure, intravenous antibiotics are typically administered to minimize infectious complications. An endoscope is passed through the mouth and esophagus and into the stomach. The stomach is insufflated with air to fully distend it. The room lights are lowered and through the use of external palpation of the anterior abdominal wall, combined with internal transillumination through the gastric wall, the site for PEG tube insertion is identified. This site is marked and then prepared with a cleansing solution and a sterile field is created. Local anesthetic is administered to this site. A small-caliber needle is inserted along the projected tube insertion tract for confirmation. The needle is slowly advanced in the direction of the stomach lumen while continuous negative pressure is being applied to the plunger. Endoscopic visualization of the needle tip as it pierces the gastric wall must coincide with aspiration of air back into the syringe. Aspiration of air bubbles prior to endoscopic visualization of the needle suggests the penetration of an interposed hollow viscus (e.g., colon) and should prompt immediate removal of the needle. Once the direct tract of the PEG tube has been confirmed in this manner, a skin incision approximately 1 cm in length is made to allow passage of a trochar. The trochar is passed through the skin incision into the stomach and a flexible guidewire is advanced through the trochar. A snare is then passed through the endoscope into the stomach. The snare is opened and manipulated to secure the end of the guidewire. The scope, snare, and guidewire are then withdrawn through the mouth as a single unit.

At this point in the procedure either a "pull" or "push" technique can be performed. Both methods have similar success rates, and choice is based on operator preference and experience. Using the pull technique, a loop on the most proximal end of PEG tube is tied to the end of the guidewire that was withdrawn through the mouth. The tube is generously lubricated and the guidewire with the attached PEG is "pulled" back through the mouth into the stomach from the site of the skin incision. The tapered tube passes through the stomach wall and emerges through the premade skin incision. Traction is applied until gentle resistance, caused by an internal bumper attached to the distal end of the tube, is felt. Once mild resistance is met, the PEG tube is secured in place with an external bumper. Tube markings (in centimeters) indicate the distance between the internal and external bumpers. This distance, which is typically between 3 and 6 cm, is recorded. Usually, the endoscope is reinserted to visualize the internal bumper, in order to verify that there is the appropriate amount of traction on the tube, although this step is not required. A topical antibiotic ointment is applied to the skin site and the area is dressed and bandaged. The superfluous external portion of the PEG tube is trimmed to a workable length. An abdominal binder is applied to help keep the tube in place and minimize the risk of inadvertent tube removal while the tract matures. The push technique differs in that the tube has a central lumen, through which the guidewire is passed. The tube is "pushed" over the guidewire and advanced until it emerges through the skin surface. It is then secured in a manner similar to that used in the pull technique. A less commonly performed alternative to the push and pull techniques is the direct placement method, which uses a trochar with a peel-away surface that delivers the PEG tube and internal bumper into the stomach lumen, obviating the need to use a guidewire.

PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY

Clinical scenarios occur when enteral nutrition delivered directly to the small bowel is indicated, and a PEG tube will not suffice. Direct percutaneous endoscopic jejunostomy (PEJ) tubes are an available option for enteral access in these situations. Indications for PEJ tubes include patients who have undergone gastric resection or have gastric outlet obstruction, gastric dysmotility, or a nonfunctioning gastrojejunostomy, or patients at significant risk for aspiration events. PEJ tubes are placed in a manner similar to that of PEG tubes. A push enteroscope, which is longer than the standard upper endoscope, is used and passed into the jejunum beyond the ligament of Treitz. As with PEG insertion, transillumination of a loop of small bowel must be achieved followed by the insertion of a feeding tube into the jejunum, using the technique described for PEG placement. The tubes used for PEJs are those found in standard PEG kits. Fluoroscopy or a combined approach with a gastroenterologist and radiologist is often used to facilitate the placement of PEJ tubes. Although the procedure is more technically demanding, the success rate is comparable to that of PEG placements. Direct PEJ tubes should be differentiated from jejunal tubes that are placed through gastrostomy or PEG tubes (the so-called JET-PEG). These tubes are often used for indications similar to those for direct PEJ tubes, but it has been shown that the jejunal portions of these tubes tend to migrate back into the stomach, essentially rendering them a PEG tube.

COMPLICATIONS

PEG placement is generally a safe and well-tolerated procedure. The procedure has an associated mortality rate of approximately 1%, with major complications occurring in 2.5–3% of cases. Complications can be divided into major and minor categories. Major complications include perforation, peritonitis, aspiration, gastrocolocutaneous fistula, necrotizing fasciitis, and premature device dislodgment. Minor complications include peristomal wound infection, which is the most common complication. Antibiotic prophylaxis with 1 g of cephazolin 30 minutes prior to the procedure is recommended to reduce the incidence of this complication. Additional minor complications include tube malfunction or clogging, leakage around the tube site, and migration of the tube. Less common complications also include implantation or seeding of tumor cells at the PEG tube site, aortogastric fistula, and gastric volvulus.

ETHICAL CONSIDERATIONS

It is unfortunate that most patients in need of a PEG tube are severely debilitated and often near the end of life. Because of this, PEG use has often been the subject of charged ethical debate. In a difficult and emotional setting such as this, it is essential that the goals of the intervention are clear, and the risks and benefits thoroughly considered. Although there are many currently accepted indications for PEG placement, very few data are available to directly support its use, despite being a commonly performed procedure for over 20 years. A keen example is the use of PEG tubes to reduce the risk of aspiration pneumonia. Although direct instillation of nutrients into the stomach obviates problems with swallowing food, to date, there have been no trials that conclude either PEG or PEJ tubes reduce the risk of aspiration. Enteral feeding tubes will not eliminate aspiration of oropharyngeal secretions, a common and recurrent cause of aspiration. Further, it has been suggested that PEG tubes can actually increase the amount of gastroesophageal reflux, a risk factor for aspiration, by altering the gastroesophageal angle. Similar to the case for aspiration, there are few data to support PEG use to decrease mortality, improve wound healing, or improve markers of nutrition. These areas deserve further study.

When the benefit of a procedure is in question, the risks of the procedure must be carefully examined. PEG, although generally accepted as a safe procedure, does carry risks of morbidity and even mortality, as previously described. In several large studies, the 1-year mortality rate after PEG placement was greater than 50%. In this severely ill population, alternative noninvasive approaches should always be presented. Postprocedural ethical issues also need to be considered. These include the fact that often physical and chemical restraints need to be used in order to prevent confused or agitated patients from pulling out the tube, with the attendant complications. Additionally, when PEG feedings are to be used on a trial basis, the end points for discontinuing PEG use, such as duration and improvement in clinical parameters, should be clearly set prior to placement. All patients or their surrogates should be fully informed of the potential benefits, risks, and alternatives to PEG placement.

CONCLUSION

Since its description as an alternative to open gastrostomy, PEG tube placement has become a common endoscopic procedure. A pragmatic understanding of the realized benefits of PEG placement and enteral feeding, as well as the risks, by both the health care team and patient, is an essential first step in the process. In the future, technological advances, combined with responsible patient selection, will optimize the use of the PEG procedure for optimizing delivery of enteral feeding in various clinical settings.

Percutaneous Transhepatic Cholangiography (PTC)

PAUL V. SUHOCKI
Duke University Medical Center

choledochocele Cystic biliary dilatation within the wall of the duodenum.

choledochoenterostomy Anastomosis created between bile duct and intestine. The most commonly performed anastomosis is between bile duct and jejunostomy (Roux-en-Y) because it eliminates biliary reflux of food material.

endoscopic retrograde cholangiopancreatography Visualization of the bile ducts and pancreatic duct, achieved by injecting iodinated contrast medium through an endoscope into the biliary and pancreatic ducts in a retrograde manner.

magnetic resonance cholangiopancreatography Visualization of the bile ducts and pancreatic duct, achieved during magnetic resonance imaging; does not require contrast medium to be injected into the ducts. The ducts are visible because of differences between the magnetic properties of the biliary/pancreatic fluid and surrounding tissues.

percutaneous transhepatic cholangiography Visualization of the intrahepatic and extrahepatic bile ducts, achieved by injecting iodinated contrast medium into the bile ducts. Injection is done by passing a needle and catheter through the abdominal wall, through the liver capsule, and into the bile ducts. Percutaneous access to the bile ducts also allows the operator to perform biliary tract interventions such as percutaneous biliary drainage.

portoenterostomy Surgical treatment (Kasai) procedure for extrahepatic biliary artesia. A Roux-en-Y limb is anastomosed to the dissected fibrous biliary plate on the undersurface of the liver.

Percutaneous transhepatic cholangiography (direct injection of iodinated contrast medium into the bile ducts under fluoroscopy) is a method of imaging the bile ducts with contrast medium. Prior to the emergence of endoscopic retrograde cholangiopancreatography (ERCP), which involves injection of contrast medium into the biliary tree endoscopically through the ampulla of Vater, percutaneous transhepatic cholangiography (PTC) was the sole means of imaging the bile ducts with contrast medium. Currently, because ERCP is less invasive than PTC for obtaining a cholangiogram, it is the method of choice in medical centers that are staffed by endoscopists who are adept at the procedure. Cholangiography obtained by injection of iodinated contrast medium into the bile ducts during ERCP or PTC is considered to be the gold standard for bile duct imaging.

INDICATIONS FOR PTC

Computed tomography (CT), ultrasound (US), and magnetic resonance cholangiopancreatography (MRCP) have emerged over the past two decades as noninvasive means of viewing the bile ducts. These modalities do not require injection of iodinated contrast into the bile ducts. However, current technical limitations make the bile duct detail obtained with these imaging methods inferior to that obtained with PTC and ERCP. This is particularly true for visualization of the subsegmental bile ducts.

PTC is indicated for the following reasons:

1. To determine the level of biliary obstruction and to attempt to categorize the lesion as benign or malignant.
2. For preoperative delineation of bile duct anatomy. In this case, it is important to demonstrate the amount of normal bile duct above an obstruction for planning a choledochoenterostomy and also for excluding the presence of variant biliary anatomy.
3. To determine if a biliary stricture is present in the patient with normal-caliber bile ducts on cross-sectional imaging and to assess clinical and laboratory evidence of biliary obstruction. This scenario is most often encountered in the postoperative patient (biliary bypass, partial liver resection, orthotopic liver transplant) who has undergone choledochoenterostomy.
4. To provide a percutaneous transhepatic tract for future percutaneous interventions, such as bile duct biopsy, stone removal, balloon dilatation of a biliary stricture, or placement of a permanent metallic stent across a nonoperable malignant biliary occlusion.

PREPROCEDURE WORKUP

The patient has usually had a CT scan, abdominal magnetic resonance imaging (MRI), MRCP, or liver ultrasound prior to PTC. When obstructive cholangitis is suspected, these studies will have supplied information about the presence or absence of bile duct dilatation, obstructing mass, gallstones, biliary strictures, collections of bile, and ascites. Bile collections related to bile leak are drained percutaneously under CT or ultrasound guidance before PTC. When the presence of biliary pathology is suggested on these studies, ERCP is usually performed next to provide information about the bile ducts with an iodinated contrast cholangiogram. ERCP is associated with less risk than PTC and obviates the need for PTC if technically successful. ERCP can be unsuccessful because of: postoperative anatomy (Roux-en-Y), difficulty passing the endoscope through the duodenum because of a duodenal stricture related to pancreatitis or tumor, inability to visualize or cannulate the ampulla of Vater because of duodenal stricture or tumor, and inability to achieve an adequate level of sedation.

When PTC becomes necessary, informed consent is obtained from the patient or guardian. General anesthesia is arranged for the pediatric patient or the adult patient in whom an adequate level of conscious sedation cannot be achieved. Antibiotics are administered intravenously. Coagulation and platelet count abnormalities are corrected to as near normal as possible. Vital signs are monitored throughout the case. The patient is given corticosteroids prior to the procedure if an allergy to iodinated contrast exists.

TECHNIQUE

A radiologist performs PTC in the interventional suite of the department of radiology. A dedicated interventional radiology nurse administers conscious sedation and monitors vital signs throughout the procedure. The patient is placed prone on a fluoroscopy table in a room outfitted with a multiangle image intensifier. The abdomen is prepped and draped in sterile fashion from the level of the nipples to the umbilicus. A 22-gauge Chiba needle is passed into the liver under fluoroscopic guidance. The stylet is withdrawn and contrast is injected through the needle while the needle is retracted slowly. The operator stops retracting the needle when contrast flows into a bile duct. Several milliliters of contrast are injected into the ductal system. A 0.018-inch-diameter guidewire is advanced through the needle into the duct. The needle is replaced with a #3 French catheter with multiple side holes. The potentially infected bile is aspirated and sent to the microbiology laboratory for culture. Contrast is then injected into the ducts to obtain a diagnostic cholangiogram. Radiographic images of the opacified bile ducts are exposed from anterior–posterior, in the right-anterior oblique and left-anterior oblique directions, in order that the total extent of each duct can be evaluated.

For percutaneous access to the right hepatic biliary tree, the needle is passed into the right hepatic lobe at the junction of the lower and middle thirds of the liver. The needle is directed toward the left shoulder. For percutaneous access to the left hepatic lobe, the needle is passed into the ventral duct of the left biliary tree under sonographic guidance. Entry to the left biliary tree is usually made through a window between the left costal margin and the xiphoid process.

Unusual means of accessing the bile ducts sometimes become necessary. The gallbladder can be injected with contrast to fill the biliary tree in a retrograde fashion via the cystic duct. This method can only be used if the patient has a gallbladder and a patent cystic duct with free communication of the cystic duct with the extrahepatic and intrahepatic ducts. In patients with massive ascites and dilated bile ducts, the ductal system can be accessed by passing a needle system through the right internal jugular vein, through the right atrium, into inferior vena cava, and into the middle hepatic vein. The needle is then passed through the wall of the middle hepatic vein, through liver parenchyma, and into the biliary tree. Iodinated contrast medium is then injected through the needle system.

After diagnostic cholangiography is performed, the decision whether to intervene percutaneously is made. Interventions include bile duct biopsy, biliary drainage, balloon dilation of a benign stricture (Fig. 1), and placing an endobiliary stent (Fig. 2). This decision is often made in conjunction with the surgical and medical services.

COMPLICATIONS

Complications occurring during PTC vary with the degree of technical difficulty experienced during the procedure. Patients with obesity, coagulopathy, comorbidities, sepsis, presence of ascites, and nondilated bile ducts are at increased risk. Complications include biliary sepsis, bile ascites, hemobilia, hemorrhage, and pneumothorax.

INTERPRETATION

Biliary Obstruction

Most cases of biliary obstruction are related to calculi or neoplasm. The most common tumors are

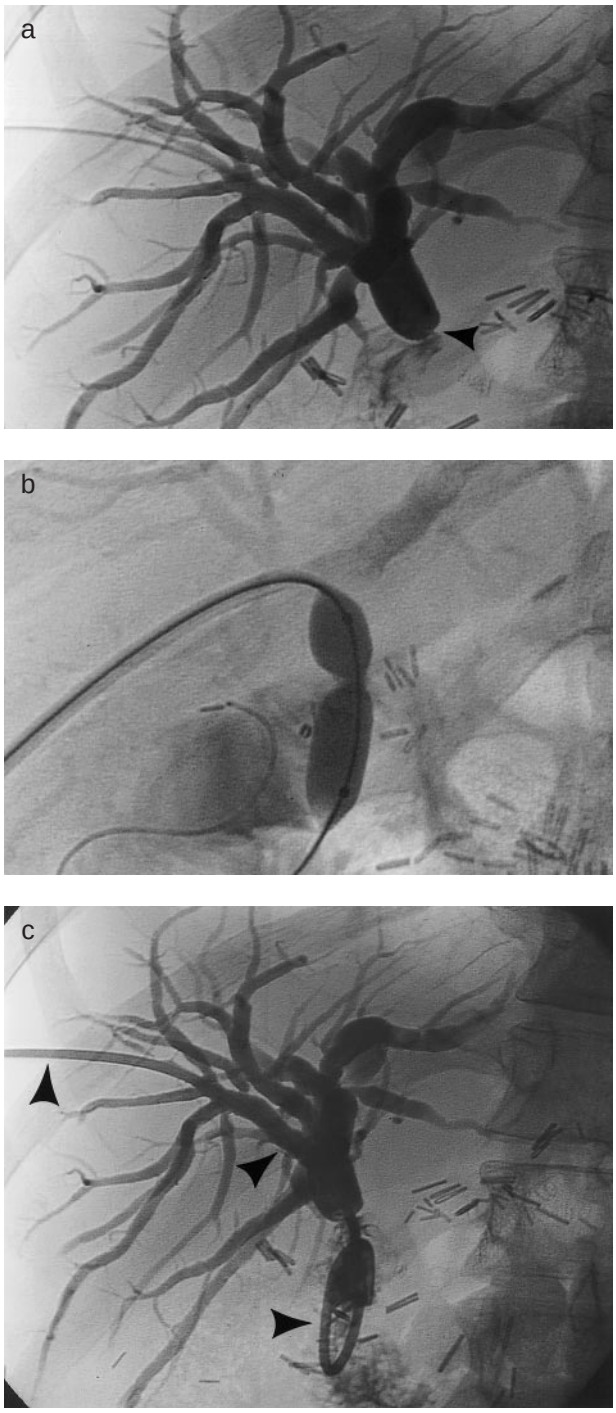

FIGURE 1 (a) Benign anastomotic stricture (arrowhead) developed 13 months following creation of an anastomosis between the common hepatic duct and the jejunum. (b) A waist can be seen while dilating the stricture percutaneously with a 10-mm-diameter balloon. (c) A biliary drainage catheter (#8 French; arrowheads) with multiple side holes is kept in place for 6 weeks postprocedure, allowing drainage of bile across the anastomosis.

pancreatic cancer (Fig. 3) and metastatic disease (Fig. 4), followed by cancer of the bile ducts (Fig. 5), ampulla, and gall bladder. Less common causes of biliary obstruction include congenital biliary obstruction, bile duct injury, pancreatitis, sclerosing cholangitis, biliary atresia, choledochal cyst, duodenal diverticulum, infection, and parasitic infestation.

Biliary atresia is the most common cause of obstructive jaundice in infancy. It can involve the intrahepatic or extrahepatic bile ducts, the latter being more commonly involved and found in 1/10,000–1/15,000 births. Hepatic biliary scintigraphy suggests the diagnosis if there is a delay of radiotracer excretion into the gastrointestinal tract. Treatment for extrahepatic biliary atresia is surgical. A portoenterostomy (Kasai procedure) is performed. Liver transplantation is considered for the patient who has a failed Kasai procedure or for whom the diagnosis of biliary atresia was made late.

Choledochal cysts are seen in 1/13,000 hospital admissions in the United States. Three-quarters of affected patients are female. Theories for the pathogenesis of choledochal cysts include (a) anomalous pancreatobiliary duct junction, (b) abnormal canalization of the bile ducts, and (c) abnormal autonomic innervation of the extrahepatic bile duct. Todani's classification of choledochal cyst disease is most widely used. Type I cysts are extrahepatic and are seen in 80–90% of all cases. These can be focal or fusiform. A type II cyst is a diverticulum of the extrahepatic duct and is seen in 3% of cases. Type III is a choledochocele, seen in 5% of cases. Type IV cysts account for 10% of cases and are subdivided into two groups; type IVA is characterized by dilatation of the intrahepatic and extrahepatic biliary tree, and type IVB cysts are multiple extrahepatic cysts. Type V cysts, known as Caroli's disease, are intrahepatic and rare. Complications of choledochal cysts include biliary obstruction, cholangitis, rupture, hepatic abscess, and cancer of the bile ducts or gallbladder. Complete excision of the cyst is recommended because of the associated risk of cancer. In patients with pancreatitis, long segment narrowing of the common bile duct (CBD) can be seen, with gentle tapering distally. The entire CBD may be involved and the ampullary segment may be normal.

Primary sclerosing cholangitis (PSC) is a progressive disease of the biliary tree characterized by inflammatory and fibrotic bile duct lesions. The etiology of the disease is unclear. Patients often present with recurrent episodes of fever, chills, weight loss, pruritus, jaundice, and mild right upper quadrant discomfort. Laboratory tests usually reveal an elevated white blood cell count and a cholestatic biochemical profile. Histologic

FIGURE 2 (a) A biliary drainage catheter (#8 French) with multiple side holes (arrowheads) traverses a long-segment malignant biliary occlusion. (b) A 10-mm-diameter stent (arrows) was positioned across the malignant occlusion to allow internal drainage of bile across the lesion. The percutaneous access was removed.

findings on liver biopsy are often nonspecific. The disease course is usually progressive, resulting in cholestatic liver disease. Cholangiography is a key component in making the diagnosis of PSC. Abnormalities of intrahepatic and extrahepatic bile ducts are seen in 75–80% of the patients. Isolated involvement of either the intrahepatic or extrahepatic ducts occurs in 10–20% of cases. Cholangiographic findings include focal narrowings, beading, pseudodiverticula, and pruning of intrahepatic duct branches. Long segment bile duct narrowing is not uncommon. However, brush cytology of dominant bile duct strictures should be performed because of the development of cholangiocarcinoma in 40% of the patients.

FIGURE 3 Abrupt termination (arrowheads) of the common bile duct is seen in a patient with pancreatic carcinoma.

Several disease processes can mimic PSC on cholangiography. These include metastatic disease to the liver, lymphoma, cholangiocarcinoma, cirrhosis, hepatic arterial chemotherapy, graft-versus-host disease, chronic allograft rejection, opportunistic infection of the bile ducts, multiple liver abscesses, systemic fungal disease, and ischemic bile duct strictures related to hepatic arterial compromise following hepatobiliary surgery or transplantation. Chronic biliary obstruction from gallstones or biliary strictures or chronic reflux of intestinal contents across biliary–enteric anastomoses can cause bacterial infection of the biliary tree, resulting in secondary cholangitis. These entities can be differentiated from PSC after careful history taking and review of hepatobiliary imaging and laboratory blood tests.

Common duct stones (Fig. 6) are seen in approximately 15% of patients with cystic duct stones. Retained stones in the biliary tree are present in 4% of patients who undergo cholecystectomy for gallbladder calculi. Bile duct calculi can also be seen in the setting of cholestasis related to intrahepatic or extrahepatic bile duct strictures (Fig. 7). Stones in the biliary tree are usually removed through an endoscopic approach. They are removed by a percutaneous transhepatic approach

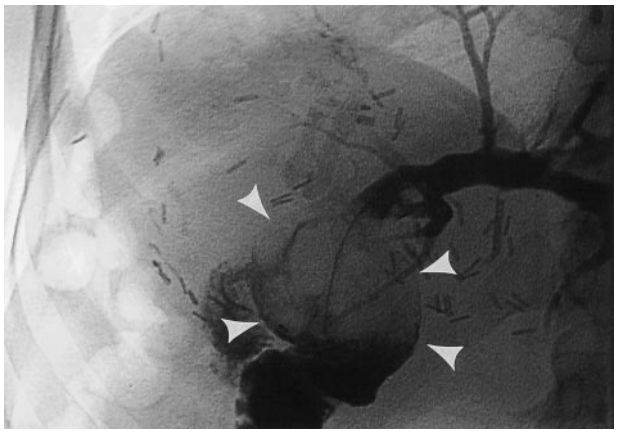

FIGURE 4 Colon carcinoma involving the portal lymph nodes creates a mass defect (arrowheads) on the common hepatic duct and the anastomosis of the common hepatic duct with the jejunum.

when the endoscopist is unable to access the biliary tree, usually in the setting of postoperative biliary anatomy. The diagnosis of biliary calculi is usually made by a noninvasive imaging method such as ultrasound or MRCP. Fifteen percent of gallstones are radio-opaque. On cholangiography, radio-opaque gallstones appear as well-defined filling defects. They are differentiated from tumors by their mobility within the ducts. Occasionally, an inflammatory reaction in the adjacent bile duct wall may cause them to be fixed, simulating a tumor. Contraction of the sphincter of Oddi can mimic the presence of a gallstone in the distal CBD. It can be difficult to differentiate gallstones from air bubbles and blood clots.

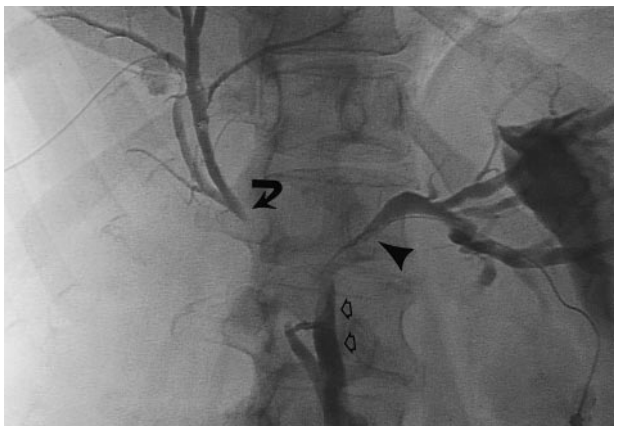

FIGURE 5 Cholangiocarcinoma (Klatskin tumor) involves the convergence of the right anterior sectoral duct (curved arrow), the left main hepatic duct (arrowhead), and the common hepatic duct (open arrows). The right posterior sectoral duct is completely occluded and does not fill with contrast.

Air bubbles coalesce, can be aspirated, and collect in anterior bile ducts. Blood clots usually clear after several days of biliary drainage.

Benign bile duct strictures are usually short. They may develop following hepatobiliary surgery, either as an iatrogenic injury to the duct or as anastomotic stricture following surgical creation of a choledochoenteric communication. When increased in length, benign biliary strictures are usually smooth and taper gradually. Cholangiographic features suggestive of cancer of the bile ducts, pancreas, or ampulla include abrupt termination of the bile duct, "apple core" concentric narrowing of the bile duct, and changes in caliber along the length of the stricture. Tumors can extend from the wall into the lumen of the bile duct in an exophytic fashion. Cross-sectional imaging often helps in making the diagnosis of malignancy. Brush biopsy of the biliary stricture or surgical exploration may be necessary to differentiate between benign and malignant lesions.

Bile Duct Leak

Bile duct injury can develop during cholecystectomy, partial liver resection, slippage of clip or ligature from the cystic duct following cholecystectomy, PTC, liver biopsy, and blunt or sharp abdominal trauma. Drainage catheters are usually placed into

FIGURE 6 Oval filling defect (arrowhead) in the distal common bile duct represents a gallstone.

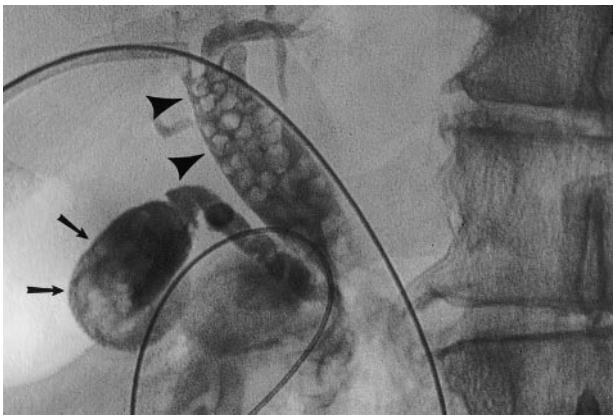

FIGURE 7 Multiple filling defects represent gallstones in the common hepatic duct (arrowheads) and gallbladder (arrows).

bile collections under CT or US. ERCP is usually successful at demonstrating a cystic duct leak or leakage from a partially or completely lacerated bile duct. PTC becomes necessary when ERCP is unrevealing or technically unsuccessful. PTC is difficult in this patient group because the decompressed bile ducts are difficult to access with a needle and subsequently to cannulate.

Aberrant extrahepatic bile ducts are at risk for injury during operation because the surgeon may not anticipate their presence. PTC may demonstrate an aberrant right hepatic duct that was torn intraoperatively and no longer communicates with the biliary tree. This torn aberrant bile duct may go unappreciated on ERCP if a vascular clip is placed on the stump of the transected bile duct that arises from the main biliary tree. In this case, the radiologist passes a catheter percutaneously into the aberrant bile duct, allowing the surgeon to identify this transected duct intraoperatively for anastomosis of the duct to jejunum.

Perforation

DAVID B. LAUTZ AND GLEN W. BARRISFORD
Brigham and Women's Hospital, Boston

angularis Angular "notch" in the stomach that demarcates the division between the body and antrum of the stomach.
diathermy Local elevation of temperature within the tissues, produced by high-frequency current, ultrasonic waves, or microwave radiation.
diverticulum Pouch or sac opening from a tubular structure or saccular organ such as the gut or bladder.
perforation Abnormal opening in a hollow organ or viscus.

Perforation is defined as an abnormal opening in a hollow organ or viscus. It is derived from the Latin *perforatus*, meaning "to bore through." Perforation is one of the most common etiologies of surgically treatable abdominal pain.

INTRODUCTION

Abdominal pain is a leading cause of hospital admission and physician visits. The severity ranges from benign self-limiting etiologies to life-threatening surgical emergencies. Subtle differences in the presentation cause this to be a very complex diagnostic dilemma. A thorough systematic evaluation is required for significant abdominal pain. Consequently, abdominal pain presents a universal challenge that transcends a wide spectrum of medical and surgical specialties.

Most abdominal pathology presents with associated abdominal pain. A complete understanding of the pathophysiology coupled with this abdominal pain is essential in the recognition of disease. Visceral, parietal, and referred pain are the commonly acknowledged divisions. The onset, quality, duration, location, and associated symptoms classify the pain. Visceral pain is perceived via autonomic nerve fibers (sympathetic/parasympathetic), which symmetrically innervate abdominal organs. As a consequence of this symmetry, the sensory perception is along the midline. Visceral pain is characterized as intermittent, deep, dull, aching, crampy pain associated with nausea and diaphoresis. Stimuli on the visceral organs include stretching/traction, compression, torsion, and chemicals. Somatic (parietal) pain is perceived via spinal nerves ipsilaterally innervating the body wall. Greater localization is achieved for this severe, persistent, sharp, stabbing pain that results from local inflammation and irritation. Referred pain typically arises from visceral organs, travels via sympathetic visceral nerve fibers, and is perceived in a location remote from the site of pathology. This double innervation is a consequence of common embryonic origin. Common examples include back pain resulting from pancreatitis, right shoulder pain from hepatobiliary disease, and left shoulder pain secondary to splenic pathology.

The initial evaluation of the acute abdomen begins with a complete history and physical, and continues with inspection, auscultation, and palpation. Nausea, vomiting, fever, chills, constipation, diarrhea, and natural history/quality/distribution of symptoms are important historical facts. Distension on inspection and decreased bowel sounds on auscultation are consistent with acute abdominal pathology. On palpation, guarding/rigidity, diffuse or point tenderness, and rebound tenderness can be observed.

Abdominal pain can arise from an array of varied etiologies presenting in a similar fashion. Subtle differences in the history, presentation, evaluation, and diagnostic workup guide the clinician. Nonsurgical pathology can mimic surgical disease. The clinician must consider nonsurgical pathology (gastroenteritis, acute hepatitis/pancreatitis, sickle cell crisis, lead toxicity, acute porphyria, or pneumonia) when considering potential surgical emergencies. Surgical disease can be further subdivided into nonperforated (acute cholecystitis) and perforated (duodenal ulcer) pathology. The commonly encountered gastroenteral perforations are presented here.

PERFORATED ESOPHAGUS

Esophageal perforation is not typically considered a cause of abdominal pain. However, in order to complete the discussion of gastroenteral perforation, esophageal perforation is briefly considered. Esophageal perforation is a surgical emergency requiring rapid diagnosis. It most commonly occurs as a result of instrumentation, trauma, spontaneous perforation, and swallowing of a foreign body. It presents with pain in the cervical area,

 Copyright 2004, Elsevier (USA). All rights reserved.

dysphagia, and odynophagia. Symptoms are notably exacerbated with swallowing or movement. A recent history of instrumentation or vomiting is usually noted. Diagnostic workup includes posteroanterior and lateral chest films with findings of mediastinal emphysema/widening, cervical emphysema, or pneumothorax. Barium esophagram in the right lateral decubitis position is the gold standard for evaluation. Computed tomography and endoscopy have a limited role in the presence of an esophagram, but may be useful in complicated cases with equivocal studies. Treatment objectives include limitation of extravasation, prevention of infection, nutritional maintenance, and restoration of structural integrity. Nonoperative treatments offer a limited role in isolated cases. Operative exploration, wide drainage, and primary closure within 24 hours (if possible) remain the treatments of choice. Outcomes are variable and are contingent on duration to diagnosis and treatment, cause and location of injury, comorbidities, and existing esophageal disease.

PERFORATED GASTRIC ULCER

Gastric ulceration often presents with acute-onset epigastric pain that radiates to the back and is exacerbated by the ingestion of food. Common risk factors include use of nonsteroidal antiinflammatory drugs (NSAIDs), cigarette smoking, and chemotherapeutic agents (5-fluorouracil, cisplatin, doxorubicin, or mitomycin C). Gastric ulcer disease presents in approximately 100,000 new cases annually and is most commonly seen in men and the elderly. Complications of gastric ulceration result in several thousand deaths and a 10% rate of gastric malignancy annually. Normal or decreased levels of acid secretion are observed with a breakdown in the gastric mucosal barrier. Ulceration is most common along the lesser curvature of the stomach at the junction between the antral and fundic mucosa. Of ulcers, 70% occur superior to the incisura angularis and 20% are distal. Gastric ulcers are classified into five categories defined by location and secretory status.

The gold standard for the evaluation of gastric ulceration is endoscopy. Treatment options include medical, endoscopic, and surgical management. Initial medical management includes antimicrobials directed at *Helicobacter pylori* (isolated in 85–90% of gastric ulcers) and antisecretory medications. Typically, a 12- to 24-week trial is undertaken. Endoscopic diathermy or vasoconstrictive injection can treat or temporize active bleeding. However, surgical management is indicated in cases complicated by nonhealing/recurrent ulcers, suspected malignancy, obstruction, hemorrhage (most common), and perforation.

Several surgical treatment options exist. Typical treatment includes excision of the lesion, a vagotomy, and a drainage procedure. The lesion should be excised if possible. Truncal or proximal gastric (highly selective) vagotomy is performed to limit acid secretion. Truncal vagotomy is undertaken at the level of the diaphragm as the vagal nerve fibers enter the abdomen. It is associated with a greater reduction in acid secretion and a lower recurrence rate compared to proximal gastric vagotomy. However, the gastric drainage mechanism and vagally supplied viscera are denervated and impaired. Thus, a gastric drainage procedure is mandatory with truncal vagotomy. However, antral nerve fibers (and gastric drainage) are preserved in cases of proximal gastric vagotomy. Unfortunately, this comes at the expense of a higher recurrence rate and greater acid secretion.

Drainage procedures include pyloroplasty and antrectomy. Several different types of pyloroplasty procedures are performed to improve drainage. However, each utilizes a longitudinal incision at the pylorus that is horizontally closed. Antrectomy is the resection of the distal stomach and removal of the pylorus. The defect can be repaired with a gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II). Complicated proximal gastric ulceration may require a subtotal gastrectomy, whereas widespread gastric disease may require a near-total gastrectomy or gastric devascularization. These latter procedures are often associated with a very high morbidity and mortality and represent less commonly employed techniques. Following gastric drainage procedures or gastric resection, postgastrectomy syndromes can emerge. Early and late dumping, afferent and blind loop obstruction, alkaline reflux, gastric atony, and nutritional disturbances are all well-described complications of gastric surgery.

PERFORATED DUODENAL ULCER

Duodenal and gastric ulcer diseases are jointly referred to as peptic ulcer disease. Although the pathophysiology and treatments are similar, duodenal ulcer disease warrants a brief independent discussion. Duodenal ulcer disease is three times as common as gastric ulcer disease (300,000 patients yearly). Malignancy is far less commonly associated with duodenal ulceration. Typically, the presentation is similar to that of gastric ulceration. However, the symptoms of duodenal ulceration are often alleviated with consumption of food. As in gastric ulceration, a better understanding of the pathophysiology has led to a decrease in operative indications. However, the operative indications/interventions are

similar. Evaluation utilizes endoscopy as the diagnostic standard.

As with gastric ulceration, treatment options may include medical, endoscopic, and surgical approaches. Surgical options are based on the same operative indications (bleeding, perforation, obstruction, and intractability). In the case of perforation, a duodenal ulcer is oversewn and a well-vascularized Graham patch is used to cover the defect. Highly selective vagotomy is preferred, but truncal vagotomy and drainage procedures are within the standard of care. Duration of symptoms, previous treatments, medication usage (NSAIDs), and comorbidity assist in operative planning. Postgastrectomy syndromes are, again, a well-documented complication.

PERFORATED APPENDICITIS

Appendicitis is the most common emergent surgical procedure performed in Western countries. Reginald Herber Fitz, a Harvard Medical School pathologist, first described the pathologic process in 1889. He illustrated an event sequence of luminal obstruction, inflammation, perforation, abscess formation, and peritonitis. Presentation involves acute or gradual onset of midline pain (usually periumbilical, but occasionally epigastric) that begins as dull cramping (visceral pain). As the inflammatory process progresses, sharp stabbing pain is localized in the right lower quadrant (somatic pain). This is often associated with nausea, anorexia, and vomiting. In the predominant number of cases, fever will be absent.

Evaluation begins with a physical examination, laboratory studies, and plain films of the chest and abdomen. On examination, peritoneal signs (rebound/guarding) and pain with any movement (Dunphy's sign), with internal rotation of the hip (obturator sign), during extension of the hip (ileopsoas sign), and initiating in the right lower quadrant during palpation of the left lower quadrant (Rosving's sign) support the diagnosis without confirmation. Laboratory studies are often unremarkable. Leukocytosis of greater than 10,000/μl is seen in approximately two-thirds of patients. In cases in which the leukocytosis exceeds 20,000/μl, suspicion for perforation greatly increases. Hematuria, proteinuria, and pyuria are commonly encountered in the absence of urologic disease. Fecaliths and free intraperitoneal air are occasionally seen on plain films. Ultrasound findings of a target lesion or a thickened incompressible appendiceal wall can be 80% sensitive and 90% specific. Computed tomography is increasingly used in establishing diagnosis. With improvement in technology, computed tomography is often more accurate than ultrasound, and more capable of identifying an abnormally positioned appendix. Additionally, a negative study rules out a variety of abdominal pathologies and diminishes the need for costly hospitalization/observation. Barium contrast studies are safe and available, but are infrequently implemented in the presence of ultrasound or computed tomography.

In general, patients who present with a clinical picture suggesting appendicitis require exploration. This can be performed laparoscopically or via laparotomy. Laparoscopic appendectomy is diagnostic and therapeutic, often resulting in a reduction of postoperative pain and length of hospitalization when compared with laparotomy. Unfortunately, laparoscopy is associated with increased operative time (expense) and postoperative emesis. However, it is often beneficial in female patients when there exists complicated differentiation from gynecologic pathology. Appendectomy via laparotomy utilizing a muscle-splitting incision remains the standard of care. In cases of perforation, the fascia is closed while the skin and subcutaneous tissues are left to close by secondary intention.

The factor associated with the greatest morbidity and mortality in cases of appendicitis is delay in diagnosis and treatment. Approximately 64% of patients present with a retrocecal appendix, which can delay the diagnosis. Diagnostic delay results in increased rates of perforation. Perforation is associated with less than 5% mortality, compared to 0.6% in nonperforated appendicitis. The perforation rate is approximately 4% in young patients and is greatly increased in the elderly. A negative appendectomy rate of approximately 25% is considered acceptable when compared with the complications associated with delay in treatment.

PERFORATED DIVERTICULITIS

The word "diverticulum" is derived from the Latin *deverticulum*, a "by-road" or "diversion" (French, *de-verto;* "to turn aside"). The diverticula arise as the colonic mucosal tissue herniates through the muscularis. Generally, two types of diverticula are seen. Right colon diverticula are usually congenital and are more commonly seen in Asian countries. Conversely, sigmoid diverticula usually occur as a consequence of a low-fiber diet (high intraluminal pressures) and are more prevalent in Western societies. Diverticulitis was initially described in the early twentieth century and has significantly increased in prevalence. It is incidentally noted in one-third of the population over 45 years of age (two-thirds over 85 years).

Diverticulitis typically presents with acute or subacute onset of left lower quadrant abdominal pain,

constipation, diarrhea, fever, and, infrequently, a palpable mass. The expression "left-sided appendicitis" has described this clinical presentation. The diagnosis is largely based on clinical findings and can be made in the absence of further imaging. However, computed tomography (CT) with intravenous contrast has been used as the initial diagnostic exam to provide objective data, assist in treatment planning, and elucidate difficult clinical scenarios. Characteristic findings on CT include thickening of the colonic wall, pericolonic fat infiltration, and pericolonic/distant abscess formation. The role of endoscopy and barium enema is limited during the acute episode due to the risk of perforation.

Diverticular disease can be categorized in two groups, asymptomatic diverticulosis and acute uncomplicated or complicated diverticulitis. Asymptomatic diverticular disease is found incidentally and can benefit from a high-fiber diet. No additional treatment may be required. Acute uncomplicated diverticulitis presents with left lower quadrant pain, fever, and leukocytosis (occasionally constipation/diarrhea, nausea/vomiting, and dysuria). It is defined as local perforation without abscess, bleeding, or free perforation. Therapy includes a high-fiber diet and broad-spectrum antibiotics. Coverage for gram-negative and anaerobic bacteria is implemented. Stable patients without diffuse abdominal findings on examination can be treated as outpatients, with close followup as judged by an experienced surgeon. In the event that these patients worsen clinically (pain/fever), admission and further evaluation/intervention are required. If no findings are noted on CT, but clinical improvement does not occur within 72–96 hours, surgical intervention can be considered. For immunocompromised patients or those unable to tolerate oral medications, admission for administration of intravenous antibiotics is preferred.

The presence of an abscess, fistula, intestinal obstruction, or free perforation classifies diverticulitis as complicated (complicated diverticulitis). The incidence of free perforation is rare, but the mortality can be as high as one-third. Traditional practice has been to resect with the initial episode. However, more conservative methods have emerged with great success. Small pericolic abscesses can be managed conservatively, whereas larger and more distant fluid collections can be successfully drained under CT guidance. In cases when drainage is inadequate, urgent surgery is required. Surgical treatment generally includes resection of the diseased sigmoid, proximal diversion, and the creation of a Hartman's pouch. Primary bowel anastomosis can be considered only under the best possible conditions and in experienced hands. Recent advent of laparoscopic resection has offered a reduction in pain and hospitalization when performed under elective circumstances.

Peristalsis

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

monosynaptic spinal reflex Neural reflex circuit in the spinal cord consisting of a sensory neuron and a motor neuron with a single synaptic connection between the two.

reflexes Motor responses to sensory stimulation; each time a "hardwired" neural circuit is activated, the responses are repeated in the same way.

Peristalsis is a term used in reference to the organized propulsion of material over variable distances within the lumen of the esophagus, the small and large intestine, and sometimes the distal stomach. The muscle layers of the intestine and esophagus behave in a stereotypical pattern to achieve peristaltic propulsion. Integrated neural circuits of the enteric nervous system control the behavior of the intestinal musculature. Peristaltic propulsion in the esophagus is controlled by signals transmitted from the brain stem to the esophagus by the vagus nerves and by the enteric nervous system.

PERISTALTIC PROPULSION

During peristalsis (Fig. 1), the longitudinally oriented muscle in the segment ahead of the advancing intraluminal contents contracts while the circumferentially oriented muscle layer relaxes in the same segment. The esophagus and intestine are tubes that behave physically like a cylinder with constant surface area. Shortening of the longitudinal axis of the cylinder is accompanied by widening of the cross-sectional diameter. Simultaneous shortening of the longitudinal axis and relaxation of the circular muscle result in expansion of the lumen. This prepares a receiving segment for the forward-moving intraluminal contents during peristalsis.

The second component of stereotypic peristaltic behavior is contraction of the circumferentially oriented muscle layer in the segment behind the advancing intraluminal contents. The longitudinally oriented muscle layer in this segment relaxes simultaneously with contraction of the circular muscle, resulting in conversion of this region to a propulsive segment that propels the luminal contents ahead, into the receiving segment. Intestinal segments ahead of the advancing front become receiving segments and then propulsive segments in succession as the complex of propulsive and receiving segments travels along the intestine.

PERISTALTIC REFLEX

Peristaltic reflex is a term sometimes applied inappropriately; it is not synonymous with the multiple patterns of coordinated propulsive motility that occur in the

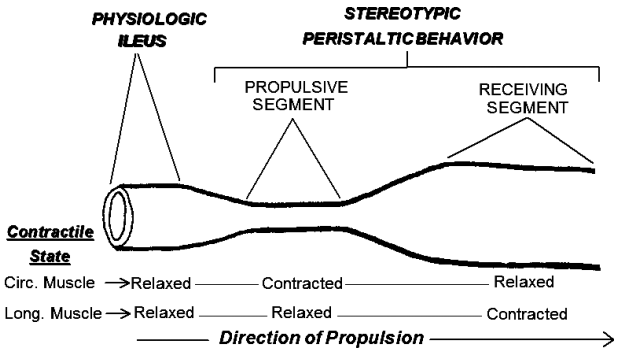

FIGURE 1 The circumferential and longitudinal muscle layers of the intestines behave in a stereotypical pattern during peristaltic propulsion. A "hardwired" reflex circuit in the enteric nervous system determines the pattern of behavior of the two muscle layers. During peristaltic propulsion, the longitudinal muscle layer in the segment ahead of the advancing intraluminal contents contracts while the circumferential muscle layer relaxes simultaneously. Simultaneous shortening of the longitudinal intestinal axis and relaxation of the circumferential muscle in the same segment result in expansion of the lumen, which becomes a receiving segment for the forward-moving contents. The second component of the reflex is contraction of the circular muscle in the segment behind the advancing intraluminal contents. The longitudinal muscle layer in the same segment relaxes simultaneously with contraction of the circular muscle, which results in conversion of this region to a propulsive segment that propels the luminal contents ahead into the receiving segment. The reflex circuits are coupled in series along the intestine, such that receiving segments convert to propulsive segments as the next segment in line becomes a receiving segment. Propulsive segments then return to their previous state of physiologic ileus. The distance over which the peristaltic reflex circuit for the formation of propulsive and receiving segments is activated in sequence down the bowel determines the length of bowel over which propulsion occurs in one or the other of the intestinal motility patterns.

small and large intestine during different digestive states. The peristaltic reflex is, rather, the intestinal analogue of spinal motor reflexes, such as the monosynaptic patellar and Achilles tendon reflexes. Monosynaptic spinal reflexes are investigator-evoked artifacts arising from connections of stretch receptors in the muscle to alpha spinal motor neurons that innervate the same muscle. They reflect the effects of sudden activation of stretch receptors (i.e., muscle spindles) in the muscle and have little relevance for understanding the complexity of neural control of movement. The peristaltic reflex is much the same in that it is a fixed response evoked by investigational stretching of the intestinal wall or stroking of the mucosa. It is like a spinal reflex in that it is a motor response to sensory stimulation, and is repeated the same way each time the "hardwired" reflex circuit is activated. The peristaltic reflex circuit is "wired" such that it evokes relaxation of the circumferentially oriented muscle layer and contraction of the longitudinal muscle below the point of stimulation, and contraction of the circumferentially oriented muscle layer above the point of stimulation.

Like the spinal reflexes, the peristaltic reflex is positioned at the lowest level of the hierarchical organization of neural control of intestinal motility, and undoubtedly underlies each of the various patterns of propulsive motility that impart functionality to the intestine during daily life. As with a spinal motor reflex, the sequencing of the pattern of behavior of the various muscle groups is hardwired into the circuitry, whereas the repetition rate of the pattern and strength of each motor component of the pattern are adjusted by sensory feedback or other commands to compensate automatically for local loads and higher functional demands on the intestine as a whole. Added factors requiring a higher order of neural control are the distance and direction in which propulsion occurs for the patterns of motility that characterize the various digestive states. Short-distance propulsion in the postprandial digestive state, propulsion over intermediate distances during interdigestive motility (i.e., migrating motor complex), long-distance power propulsion all in the orthograde direction, and retropulsion during emesis are neural control requirements unique to the enteric nervous system. Better understanding of the neural basis for intestinal motility will require moving forward from the overworked concept of the peristaltic reflex and on to investigation of microcircuits in positions at levels of organization beyond the reflex hardwiring that faithfully reproduces the muscle behavior each time the investigator stretches the intestinal wall or strokes the mucosa.

Peritoneal Disorders

BUCKMINSTER FARROW AND B. MARK EVERS
University of Texas, Galveston

peritonitis Inflammation of the peritoneal linings of the abdominal cavity; may be of infectious, chemical, or unknown origin.
peritoneal mesothelioma A rare malignant tumor arising from the peritoneal lining of the abdominal cavity.
pseudomyxoma peritonei A rare condition manifested by diffuse, gelatinous implants of the peritoneal cavity and omentum arising from mucinous neoplasms of the ovary or appendix.

Peritonitis, an inflammation of the peritoneal lining of the abdominal cavity, is the most common peritoneal disease and may be of infectious, chemical, or unknown origin. Other peritoneal disorders include peritoneal mesothelioma, a rare malignant tumor that arises from the peritoneal lining of the abdominal cavity, and pseudomyxoma peritonei, a rare condition manifested by diffuse, gelatinous implants of the peritoneal cavity and omentum that arises from mucinous neoplasms of the ovary or appendix.

PERITONITIS

The most common disorder of the peritoneum is inflammation, or peritonitis, which is usually of infectious origin. Peritonitis can be classified into two types based on etiology.

Primary Peritonitis

Primary peritonitis occurs without an identifiable source of infection, usually in patients with preexisting ascites (most commonly cirrhosis in adults or nephrotic syndrome in children). Diagnosis is made by cell count and culture of the ascitic fluid. Treatment requires antibiotic coverage appropriate for both gram-positive and gram-negative bacteria, because *Escherichia coli* and *Klebsiella pneumoniae* are increasingly common in ascitic fluid cultures.

Secondary Peritonitis

Secondary peritonitis, much more common than primary peritonitis, is caused by an intra-abdominal infection, such as perforation of the bowel, and can be further divided into acute suppurative, granulomatous, and aseptic (chemical) forms. Acute suppurative peritonitis is usually caused by spillage of intestinal contents into the peritoneal cavity as a result of primary intra-abdominal disease (e.g., perforated peptic ulcer, appendicitis, diverticulitis, perforated carcinoma), penetrating trauma, or iatrogenic perforation after instrumentation or radiologic procedures. Early signs of peritoneal inflammation include nausea, vomiting, anorexia, and vague poorly localized abdominal pain. As the infection progresses, these symptoms may worsen and the pain becomes more focal as the inflammation of the visceral peritoneum extends to the parietal peritoneal. Fever and signs of hypovolemia (tachycardia, dry mucous membranes, low urinary output) may also be present. Treatment consists of proper fluid resuscitation, antibiotic therapy, and prompt treatment of the underlying pathology usually through surgical intervention.

Granulomatous peritonitis may be from fungal, amebic, or parasitic sources, but tubercular infection is by far the most common etiology. There has been an unfortunate resurgence of tuberculous peritonitis (Fig. 1) due to an increase in the prevalence of acquired immune deficiency syndrome, although it still

FIGURE 1 Computed tomography scan demonstrates ascites (open arrow) and small bowel thickening (filled arrow) in a patient with tuberculous peritonitis. Courtesy of Charles J. Fagan, M.D. (Galveston, TX).

 Copyright 2004, Elsevier (USA). All rights reserved.

complicates less than 1% of all *Mycobacterium tuberculosis* infections. The infection usually originates outside the peritoneum from diseased bowel, from salpingitis, or through hematogenous spread of a primary pulmonary infection. Unlike suppurative peritonitis, onset of symptoms is quite insidious with 70% of patients displaying fever, malaise, anorexia, weakness, or weight loss for more than 4 months prior to diagnosis. Ascites and diffuse tenderness are usually present and should suggest the illness in high-risk or immunocompromised patients with unexplained fever and malaise. The disease usually responds rapidly to anti-tuberculosis therapy with the exception of cases involving newly emergent drug-resistant mycobacteria.

Chemical (aseptic) peritonitis results from spillage of irritant materials that are initially sterile, but with time become secondarily infected and present as suppurative peritonitis. Bile, urine, and chyle are potential endogenous causes, whereas iatrogenic etiologies include barium from radiologic studies (with a concurrent perforation) and starch powder from surgical gloves. Patients who undergo continuous ambulatory peritoneal dialysis may acquire infections of the normally sterile catheter and peritoneum, leading to bacterial peritonitis. Treatment is similar to suppurative peritonitis—fluid resuscitation, appropriate antibiotic coverage, and surgery to control the source of peritoneal contamination.

PRIMARY MESOTHELIOMA

Similar to pleural forms, primary peritoneal mesothelioma is linked to asbestos exposure, although only 20–40% of mesotheliomas occur in the peritoneum (Fig. 2). Clinical presentation includes nonspecific abdominal pain, nausea, vomiting, weight loss, and diarrhea; ascites is found in 90% of patients. Most cases are not identified until laparoscopy or laparotomy is performed. Curative treatment is rare because the disease is usually quite advanced at the time of diagnosis. Surgery serves only to confirm the diagnosis and provide palliative procedures to relieve obstruction. Chemotherapy and radiotherapy have shown minimal success although newer intraperitoneal chemotherapy and immunotherapy may improve the prognosis.

PSEUDOMYXOMA PERITONEI

Pseudomyxoma peritonei is a rare condition manifested by diffuse, gelatinous implants of the peritoneal cavity and omentum arising from mucinous neoplasms of the ovary or appendix (Fig. 3). Most cases occur in women

FIGURE 2 Computed tomography scan demonstrates diffuse mesenteric and peritoneal involvement of a soft tissue mass (arrow) causing displacement of intra-abdominal organs in a patient with peritoneal mesothelioma. Courtesy of Charles J. Fagan, M.D. (Galveston, TX).

who have disease in both organs; thus, the tissue of origin is not established. Patients may present with abdominal pain or increasing girth due to mucinous ascites, but most diagnoses are made following surgical exploration for appendicitis or ovarian tumors. Computed tomography may reveal characteristic "scalloping" of the hepatic and bowel margins. Treatment is primarily surgical, to include aggressive debulking, appendectomy, bilateral oophorectomy, and omentectomy. Recurrence rates are high (approximately 75% of patients); however, due to the low grade of this malignancy, repeat debulking procedures are indicated and may improve outcome. Chemotherapy

may produce a modest survival advantage over surgery alone; radiotherapy appears to have no role in the treatment of pseudomyxoma peritonei.

coelom Body cavity of the embryo.
mesothelium Layer of flat cells derived from the mesoderm that lines the coelom.
peritoneum Serous membrane lining the abdominopelvic walls and investing the viscera.

The peritoneum is the mesothelial lining of the peritoneal cavity and its contained viscera; it functions as a bidirectional dialysis membrane and thus plays a major role in defending against inflammatory processes of the abdomen. The peritoneum is the key organ involved in sensation of abdominal pain and is thus integral to diagnosing abdominal pathology.

EMBRYOLOGY AND DEVELOPMENT

The peritoneum and other body cavities begin to develop from the intraembryonic coelom near the end of the third week of gestation. The coelom has a parietal wall and a visceral wall, both lined by mesothelium; the parietal mesothelium is derived from somatic mesoderm whereas the visceral mesothelium is derived from splanchnic mesoderm. By the fourth week of gestation, the coelom appears as a horseshoe-shaped cavity in the cardiogenic and lateral mesoderm. The curve of the "horseshoe" represents the future pericardial cavity, and the lateral and caudal extensions represent the eventual pleural and peritoneal cavities (Fig. 1). These lateral areas communicate with the extraembryonic coelom. The development of the midgut involves a herniation through this communication into the umbilical cord, where the midgut develops into the small intestine and part of the large intestine. At this point, the intraembryonic coelom is divided into right and left halves that are divided by the ventral and dorsal mesenteries.

Toward the end of the fourth week of gestation, the lateral parts of the intraembryonic coelom move onto the ventral aspect of the embryo and the ventral mesentery degenerates, creating a large peritoneal cavity with a dorsal mesentery (Fig. 2). Until the seventh week of gestation, this peritoneal cavity communicates with the pericardial and pleural cavities through pericardioperitoneal canals; during the fifth and sixth weeks of gestation, folds form near the cranial and caudal ends of these canals. Fusion of these membranous folds with mesoderm ventral to the esophagus separates the pericardial and pleural cavities while fusion of the caudal pleuroperitoneal membranes forms the diaphragm and separates the pleural and peritoneal cavities. The peritoneal cavity then loses its connection with the extraembryonic coelom during the tenth week of gestation, when the intestines return to the abdomen from the

umbilical cord. At this point, the peritoneum lines the abdominal wall and invests the abdominal viscera.

ANATOMY AND PHYSIOLOGY

The peritoneum is made up of the visceral and parietal layers; it has a total surface area of approximately 2 m^2. The visceral peritoneum covers the intraperitoneal organs and forms the mesenteries by which they are suspended. The peritoneum and its mesentery are supplied mainly by the splanchnic blood vessels, and, to a lesser extent, by branches of the visceral and parietal peritoneum.

Differences arise in the innervations of the visceral and parietal peritoneum, leading to differing patterns of sensation of painful stimuli. The visceral peritoneum receives its innervation from the autonomic nervous system and responds primarily to traction and pressure or distension; painful stimuli are perceived as a poorly localized, dull pain. In general, pain in the epigastric region is referred from a foregut structure (e.g., stomach, duodenum, pancreas, or biliary tract); pain in the periumbilical area is the result of stimulus to a midgut structure (appendix, jejunum, or ileum) and pain in the hypogastric or suprapubic region is from a hindgut source (distal colon or rectum). In contrast, both somatic and visceral afferent nerves innervate the parietal peritoneum. Therefore, noxious stimuli are perceived as a localized, sharp pain with rebound tenderness and are referred to as "peritonitis."

Functionally, the peritoneum serves as a bidirectional dialysis membrane through which both large- and small-molecular-weight solutes pass by simple passive diffusion. Absorption can be altered by changes in intraabdominal pressure, temperature, pH, and portal pressure in addition to lymphatic blockade and peritoneal scarring. The peritoneum contains a complex defense system that protects against inflammatory processes. This system consists mainly of mechanical clearance of the peritoneal cavity, the bactericidal

mechanisms of polymorphonuclear leukocytes, and sequestration mechanisms such as fibrin trapping of bacterial activation of complement. The peritoneum is the key organ in sensation of abdominal pain and in the physical diagnosis of ongoing intraabdominal pathology.

intrinsic factor A glycoprotein that binds cobalamin specifically, attaches to a receptor (cubilin) on the apical membrane of the ileal epithelial cell, and is internalized together with its cobalamin by that cell.

Pernicious anemia (PA) is defined as cobalamin (vitamin B_{12}) deficiency caused by that vitamin's malabsorption because of the patient's failure to secrete gastric intrinsic factor. This anachronistic hematological name for what is really a gastroenterological disorder was coined originally to reflect the megaloblastic anemia that cobalamin deficiency often causes. However, many patients diagnosed with PA have little or no anemia; moreover, folate deficiency and rare metabolic disorders can cause the same anemia. PA does not refer to cobalamin deficiency produced by any other mechanisms, such as intestinal disease.

PATHOGENESIS AND DIAGNOSIS

The parietal cell synthesizes intrinsic factor (IF) and secretes it, as well as acid, into the gastric lumen. The pathogenetic basis of pernicious anemia (PA) is the inability of the parietal cell to do so. Without IF, cobalamin cannot be absorbed efficiently.

In the more common, acquired form of PA, the lack of IF results from severe atrophic gastritis with loss of parietal cells. The gastritis tends to involve the fundus while sparing the antrum and the disorder has many features of an autoimmune process. Antibody directed at the H^+,K^+-ATPase pump of the parietal cell circulates in the blood in 70–90% of patients, but it is characteristic for atrophic gastritis in general and is not specific for PA. Approximately 60–70% of patients with PA have circulating antibodies to IF, whose presence is virtually diagnostic for pernicious anemia. Serum gastrin levels are elevated in >80% of cases and often massively so. The gastritis in approximately 10% of patients with acquired PA is diffuse, does not spare the antrum, and is accompanied by fewer immune phenomena. A much rarer form of PA is an unrelated inborn error of IF synthesis in which the stomach and parietal cell function are otherwise normal.

intrinsic factor A glycoprotein that binds cobalamin specifically, attaches to a receptor (cubilin) on the apical membrane of the ileal epithelial cell, and is internalized together with its cobalamin by that cell.

Pernicious anemia (PA) is defined as cobalamin (vitamin B_{12}) deficiency caused by that vitamin's malabsorption because of the patient's failure to secrete gastric intrinsic factor. This anachronistic hematological name for what is really a gastroenterological disorder was coined originally to reflect the megaloblastic anemia that cobalamin deficiency often causes. However, many patients diagnosed with PA have little or no anemia; moreover, folate deficiency and rare metabolic disorders can cause the same anemia. PA does not refer to cobalamin deficiency produced by any other mechanisms, such as intestinal disease.

PATHOGENESIS AND DIAGNOSIS

The parietal cell synthesizes intrinsic factor (IF) and secretes it, as well as acid, into the gastric lumen. The pathogenetic basis of pernicious anemia (PA) is the inability of the parietal cell to do so. Without IF, cobalamin cannot be absorbed efficiently.

In the more common, acquired form of PA, the lack of IF results from severe atrophic gastritis with loss of parietal cells. The gastritis tends to involve the fundus while sparing the antrum and the disorder has many features of an autoimmune process. Antibody directed at the H^+,K^+-ATPase pump of the parietal cell circulates in the blood in 70–90% of patients, but it is characteristic for atrophic gastritis in general and is not specific for PA. Approximately 60–70% of patients with PA have circulating antibodies to IF, whose presence is virtually diagnostic for pernicious anemia. Serum gastrin levels are elevated in >80% of cases and often massively so. The gastritis in approximately 10% of patients with acquired PA is diffuse, does not spare the antrum, and is accompanied by fewer immune phenomena. A much rarer form of PA is an unrelated inborn error of IF synthesis in which the stomach and parietal cell function are otherwise normal.

Copyright 2004, Elsevier (USA). All rights reserved.

Whereas atrophic gastritis itself is quite common, PA is relatively uncommon. Although PA predominates in the elderly, approximately 2% of whom have unsuspected PA, it affects younger individuals too, especially among black women.

The diagnosis of PA is usually established by proving IF absence directly by assay of gastric juice or indirectly by showing abnormal absorption of radioactive cobalamin with correction when IF is given exogenously (Schilling test). A presumptive diagnosis can also be made by demonstrating antibody to IF in the blood.

DEFICIENCY OF COBALAMIN

When IF secretion fails, cobalamin absorption virtually ceases and a negative cobalamin balance gradually develops. The progression is slow because the daily turnover of cobalamin is only approximately 0.1% of the body stores. Several years usually elapse before the clinical signs of cobalamin deficiency begin to appear. Although all cells require cobalamin, the most common manifestations of cobalamin deficiency, whether due to PA or other diseases, are hematological and neurological ones. Patients can have both or just one of these two types of manifestations—or, if caught early, neither one of them.

Megaloblastic anemia is characterized by large red blood cells (a high mean corpuscular volume is often the earliest expression of cobalamin deficiency), abnormal nuclei, and eventually pancytopenia as ineffective hematopoiesis progresses. The "methylfolate trap" produced by cobalamin deficiency causes the impaired DNA synthesis of this anemia, which is indistinguishable from that in folate deficiency. The neurological problems typically involve the posterior, and occasionally lateral, columns of the spinal cord and peripheral nerves. However, all parts of the nervous system can be affected, including cerebral function. The biochemical basis for the neurological dysfunction is unknown.

COMPLICATIONS

Two types of disorders complicate PA more often than expected. One is organ-specific immune disorders such as endocrinopathy, especially hypothyroidism, which can affect 5% of patients. The other complication is gastric neoplasia. The risk of gastric carcinoma is increased several-fold in PA and gastric carcinoids may be even more common than cancer.

THERAPY AND MANAGEMENT

The cobalamin deficiency is easily treated: megaloblastic anemia is readily reversed and, if cobalamin therapy is begun early enough, so are the neurologic abnormalities. However, the gastric defect persists, making lifelong cobalamin replacement mandatory. Because cobalamin is absorbed poorly in PA, treatment is usually by injection (oral cobalamin can be used, but very large daily doses must be given). Most experts advise endoscopy for neoplasia in every patient at the time of diagnosis and thyroid function should be monitored periodically.

agonist Drug or substance that binds to a receptor on a cell to induce a response.
antagonist Drug or substance that binds to a receptor on a cell to prevent or reverse the response of an agonist.
inflammatory bowel disease A severe inflammatory disorder of the gastrointestinal tract characterized by abdominal pain, rectal bleeding, diarrhea, fever, and severe weight loss.
irritable bowel syndrome A functional disorder of the gastrointestinal (GI) tract characterized by abdominal pain and discomfort associated with altered bowel habits, occurring in the absence of structural or biochemical abnormalities within the GI tract.
neurotransmitter A chemical released by neurons in the brain or peripheral nervous system to communicate with other neurons.
peptic ulcer disease A disorder of the upper gastrointestinal tract (esophagus, stomach, and duodenum), characterized by inflammation and ulceration.
prebiotic Agents that stimulate selectively the growth of bifidobacteria and lactobacilli in the gut.
probiotic A live microbial food supplement that affects the host by improving its intestinal microbial balance.
prokinetics Agents that stimulate the movement of lumenal contents along the gastrointestinal tract.
receptor A protein structure to which neurotransmitters, hormones, and pharmaceutical bind selectively to produce a functional effect.

Disorders of the gastrointestinal (GI) tract are common, unpleasant, and complex, affecting the mucosa, musculature, and innervation from the esophagus to the colon. These disorders are manifested as ulceration, inflammation, obstruction, diarrhea, constipation, and abdominal pain. Over the past few years, although the pharmacological treatment of many GI disorders has improved significantly, the management of GI disorders still continues to pose a significant challenge to clinicians. However, as understanding of the biology of GI disorders expands, the potential for the future development of novel pharmacological agents increases. This article provides a brief pharmacological overview of the approaches to treat a series of important GI disorders.

PEPTIC ULCER AND GASTROESOPHAGEAL REFLUX DISEASE THERAPY

Under physiological conditions, cytoprotective mechanisms exist to prevent intraluminal contents from damaging the mucosal lining of the gastrointestinal (GI) tract. However, under pathophysiological conditions, there is an imbalance between defensive factors, on the one hand, and offensive factors, on the other, leading to mucosal inflammation and injury. Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay for the treatment of musculoskeletal inflammatory diseases, yet they represent one of the major causes of serious GI injury. Traditional NSAIDs are nonselective inhibitors of cyclooxygenase (COX) isoforms COX-1 and COX-2 and destroy the mucosal defense system in part through decreasing the synthesis of cytoprotective COX-1-derived anti-inflammatory prostaglandins in the upper GI tract. GI toxicity associated with NSAIDs includes dyspepsia, gastroduodenal ulcers, and severe gastric bleeding. Newer NSAIDs that act selectively to inhibit COX-2-derived pro-inflammatory prostaglandins, but not COX-1, have significantly reduced GI toxicity. Another major cause of peptic ulcer disease is *Helicobacter pylori* infection. Gastric damage also occurs in critically ill patients due to stress-related mucosal disease, thought to be caused by decreased blood flow, mucosal ischemia, and hypoperfusion–reperfusion injury.

The goals of treatment for peptic ulcer disease include relieving symptoms, increasing healing rate, preventing complications such as bleeding, perforations, and obstruction, and finally, avoiding recurrence. Pharmacological treatment for peptic ulcer disease includes the use of over-the-counter (OTC) antacids to neutralize the pH of gastric contents. Subsequently, histamine type 2 (H_2)-receptor antagonists, such as cimetidine (Tagamet), ranitidine (Zantac), nizatidine (Axid), and famotidine (Pepcid), are used to inhibit acid secretion. Proton pump inhibitors, which include omeprazole (Prilosec), lansoperazole (Prevacid),

 Copyright 2004, Elsevier (USA). All rights reserved.

rabeprazole (Aciphex), pantoperazole (Protonix), and esomeprazole (Nexium), are able to effectively suppress basal and stimulated gastric acid secretion by noncompetitive inhibition of the H^+,K^+-ATPase pump on the parietal cell. Other agents that can be employed to treat peptic ulcer disease include coating agents, such as sucralfate (Carafate), an aluminum salt of a sulfated disaccaride that coats the mucosal lining and allows healing to occur. For those patients who present with NSAID-induced peptic ulcer disease, the use of the synthetic prostaglandin analogue misoprostil (Cytotec) in combination with the NSAID has reduced the incidence of peptic ulcer disease. For patients who test positive for *H. pylori* infection, eradication of the microorganism results in ulcer healing and reduces the risk of ulcer recurrence and complications. Eradication of *H. pylori* is complex, requiring a 10- to 14-day multidrug regimen of antibiotics and acid suppression. However, newer approaches to improve the eradication of *H. pylori* will likely improve patient compliance, be devoid of the potential for antimicrobial resistance, and have a lower cost.

Another common disorder of the upper GI tract is gastroesophageal reflux disease (GERD), which is defined as the excessive backflow of gastric contents into the esophagus. Symptoms of GERD include frequent or daily heartburn, which can progress to esophageal injury. Extraesophageal injury can also occur in association with GERD, resulting in hoarseness, vocal cord granulomas, dental erosions, chronic cough, bronchitis, asthma, and unexplained chest pain. Those at risk for GERD include infants younger than 12 months, though the condition is often self-limiting. Older adults are also at risk for GERD due to prolonged acid exposure over many years. Additional risk factors for GERD include increased acid secretion, use of drugs that reduce lower esophageal sphincter (LES) pressure, abnormalities in esophageal clearance mechanisms, gastroparesis (delayed gastric emptying), hiatal hernia, obesity, spinal cord injury, thyroid disease, Zollinger-Ellison syndrome, diabetes, and connective tissue disorders. The management of GERD requires a stepwise approach, and if lifestyle modifications fail to control symptoms, pharmacological therapy can be added. Drugs used for the management of GERD include OTC antacids to neutralize the pH of gastric contents. However, acid suppression remains the cornerstone of treatment for GERD since it provides adequate symptom relief, restores the quality of life, and prevents many of the potential complications associated with the disorder. H2-receptor antagonists are able to inhibit acid secretion, provide heartburn relief, and can be purchased OTC. Proton pump inhibitors suppress acid secretion and thus provide symptomatic relief for patients with GERD and represent the preferred therapy for the long-term management of patients with erosive esophagitis. Prokinetics (see next section) can be used in patients with GERD to increase LES pressure, promote gastric emptying, and enhance gastroduodenal coordination; however, the side effects of currently available agents often limit their usefulness.

PROKINETIC AGENTS

Disorders such as gastroparesis, postoperative ileus, and pseudo-obstruction are recognized motility disorders that can affect propulsion and cause a delay in intestinal transit. Agents that accelerate GI transit are known as prokinetics and examples include cholinomimetics, such as bethanechol (Urecholine), which causes contraction of the GI musculature through stimulation of the cholinergic receptor (M_2) present on smooth muscle cells. However, the use of bethanechol is not popular since smooth muscle contractions induced by bethanechol are simultaneous rather than peristaltic. Additionally, cholinergic agonists have many side effects, including abdominal pain, diarrhea, salivation, and gastric acid secretion. Newer prokinetics came from a chemical class known as substituted benzamides, which include metoclopramide (Reglan), a dopamine D_2 receptor antagonist, and cisapride (Propulsid), which works through a serotonin receptor mechanism. Both agents enhance gastric emptying and increase intestinal transit through these different mechanisms. However, recent clinical experience has linked cisapride to life-threatening cardiac arrhythmias due to slowing of cardiac repolarization (QT prolongation), resulting in withdrawal of cisapride. This has created a gap in the prokinetic arena and appears to have resulted in the increased use of metoclopramide. Unfortunately, metoclopramide is associated with its own set of serious side effects, including gynecomastia, galactorrhea, fatigue, tremor or rigidity, and tardive dyskinesia. Motilides represent another class of prokinetic agents, so named because they stimulate the motilin receptor present on smooth muscle cells and enteric neurons. Examples include erythromycin, a macrolide antibiotic that can accelerate gastric emptying, enhance coordination between the stomach and duodenum, and stimulate the migrating motor complex. Although recent advances in the area of prokinetics have been limited, a new serotonin receptor agonist, tegaserod (Zelnorm), has been shown to stimulate intestinal transit and relieve the symptoms of constipation.

PHARMACOLOGICAL TREATMENT OF INFLAMMATORY BOWEL DISEASE

Ulcerative colitis (UC) and Crohn's disease (CD), collectively known as inflammatory bowel diseases (IBDs), are immunoregulatory disorders of the GI tract, characterized by an abnormal, intense, and sustained inflammatory response to antigen stimulation. The current hypothesis is that hyperimmune reactivity toward the antigens of enteric bacteria, in a genetically susceptible host, is the basis for disease pathogenesis. Since IBD is characterized by spontaneous "flares" and remission, therapies are directed at treating the active inflammation and maintaining remission. 5-Aminosalicylates are the accepted therapy in the treatment of acute inflammation and maintaining remission in UC. Sulfasalazine (Azulfidine) was the first agent introduced for the treatment of UC and its pharmacologically active moiety is 5-aminosalicylic acid (5-ASA). Since 5-ASA is absorbed in the small intestine, delivery systems enabling 5-ASA to reach the colon before absorption occurs have been established. Specifically, such systems include enteric coatings that dissolve at the alkaline pH present in the terminal ileum or via a prodrug, such as balsalazide (Colozol), which is metabolized by bacterial azoreductases in the colon to release the therapeutically active moiety (5-ASA) and an inert carrier molecule. Topical therapy by enemas, suppositories, or foams has been an advance in the management of distal IBD. For severe active disease, glucocorticoids have clinical importance based on their immunosuppressive capacity against humoral and cell-mediated immune responses. Glucocorticosteroids bind to specific receptors that, on activation, translocate to the nucleus and either increase or decrease the expression of responsive genes. The effects of natural (cortisol) and synthetic [prednisolone (Prelone, Pedoapred, Orapred), dexamethasone (Decadron, Dexone, Hexadrol), budesonide] glucocorticoids involve regulation of the transcription and production of pro-inflammatory cytokines and tumor necrosis factor (TNF). A major limitation in the use of glucocorticoids for chronic treatment is that therapeutic doses are much greater than the daily glucocorticoid production and thus cause significant side effects. A partial solution to this problem is the development of topical-use glucocorticoids, which have low systemic bioavailability due to poor absorption or extensive local or first-pass hepatic metabolism. Topical instillation of budesonide, beclomethasone dipropionate, or prednisolone metasulfobenzoate into the colorectal area has been shown to be effective in patients with active distal IBD. New formulations of budesonide for controlled ileal release (EntocortEC) show high topical efficacy with minimal side effects in the treatment of mild to moderate, active CD. Immunosuppressive drugs with steroid-sparing properties may be beneficial in patients who failed to respond or who develop severe side effects to glucocorticoids. Cytotoxic agents, such as azathioprine (Imuran) and 6-mercaptopurine, have been found to be helpful in patients with CD. Cyclosporine, which suppresses cellular immunity, has been shown to be effective in patients with UC. Methotrexate, a folic acid antimetabolite that is structurally related to interleukin-1 (IL-1) and can interfere with its function, is currently used in patients with refractory IBD. However, the benefits of immunosuppressants are limited by the risk of high toxicity and serious side effects. Recent therapeutic strategies for the treatment of IBD are based on the ability of monoclonal antibodies to neutralize the effect of immune molecules. Infliximab (Remicade), a chimeric monoclonal immunoglobulin G1 antibody that neutralizes TNFα, has been found to have efficacy for refractory or fistulizing CD. Additionally, a therapy based on antibodies to CD4 is under investigation. Specific inhibitors of intercellular adhesion molecules have been designed to eliminate mucosal tissue damage by reducing leukocyte infiltration. Most recently, synthetic compounds (CNI-1493) or small protein molecules (granulocyte/macrophage colony-stimulating factor, bacterial/permeability-increasing protein $rBPI_{21}$) that are normally produced by the immune system have been manufactured by recombinant gene technology and are undergoing clinical trials. Recombinant anti-inflammatory cytokines IL-10 and IL-11, as well as peptide growth factors, are also in clinical development. Despite some promising results, the clinical significance of these new mediator-targeted strategies for IBD treatment is still limited by the inconvenience and high cost imposed by the intravenous or subcutaneous routes of drug administration. Future advances in the pharmacologic approach toward IBD and optimizing the clinical management of patients with IBD will lie in identifying factors predictive of response.

TREATMENT OF DIARRHEA

Diarrhea, the frequent passage of watery/semiformed stool, is not only distressing but may be debilitating or even life-threatening. Acute uncomplicated diarrhea is often self-limiting; however, when diarrhea is chronic, it represents a major health problem and leads to significant dehydration and electrolyte imbalances. Diarrhea can be caused by infectious organisms or malabsorption and can also be drug-induced by agents such as tetracycline, specific antacids, antihypertensive

drugs such as reserpine or guanethidine, and chemotherapy. Diarrhea is also a prominent symptom of IBD. The management and pharmacological therapy of diarrhea depend on its severity. Acute uncomplicated diarrhea is often treated by OTC medications such as loperamide (Imodium), a peripherally acting opiate agent that decreases motility and limits epithelial secretion. Loperamide is efficacious and free of opiate-like and unwanted central nervous system side effects. In patients with chemotherapy-induced diarrhea, loperamide is moderately effective but for those patients refractory to loperamide, evidence suggests that octreotide, a somatostatin analogue, may be helpful in promoting intestinal absorption and relieving diarrhea. A common health problem among travelers to developing countries is diarrhea. The primary objective with pharmacotherapy for traveler's diarrhea is to reduce the symptoms and their duration with a combination of an antimicrobial agent and loperamide. Fluoroquinolones are the first drugs of choice for moderate to severe traveler's diarrhea; however, with the emergence of resistance, especially in *Campylobacter jejuni* ententis, other agents such as azithromycin and rifaximin are being investigated. For more severe forms of diarrhea, such as that seen with cholera infection, oral rehydration therapy can successfully treat the diarrhea. Future therapeutic approaches to prevent episodes of diarrhea may involve the use of prebiotics and probiotics to enhance the presence of bifidobacteria and lactobacilli in the gut to increase the body's natural defense against invading pathogens. However, future studies are needed to determine the efficacy and usefulness of these types of agents for the treatment of diarrhea.

TREATMENT OF CONSTIPATION

Constipation is one of the most common medical complaints in Western countries and is defined as difficulty in passing or straining to pass stool, with less than three bowel movements per week. Constipation often results from disordered motility, leading to a delay in intestinal propulsion and slow transit. Other patients with constipation have a disorder in defecation with normal colonic transit; however, in the majority of cases, constipation results from a diet low in fiber. Constipation can also result from diabetes, pregnancy, and structural diseases of the colon and rectum. Constipation is a very common problem affecting the elderly and often results from polypharmacy since many drugs used by the elderly are known to be associated with constipation. Usually patients with constipation have mild to moderate symptoms and can be treated with increased fluid and fiber intake accompanied by regular exercise. Laxatives are commonly used to treat constipation and most are available OTC. Laxatives exert their effects by increasing stool frequency and stool weight. They are divided into (1) dietary fiber and bulk-forming laxatives, (2) saline and osmotic laxatives, and (3) stimulant laxatives. The dietary fiber and bulk-forming laxatives, such as bran, psyllium, and methylcellulose, increase the water content and mass of the stools, thereby stimulating intestinal peristalsis and decreasing colonic transit time. Saline and osmotic laxatives cause the retention of water within the GI tract because they are poorly absorbed. Examples include magnesium salts, which are charged and thus do not readily cross cell membranes and so remain in the lumen of the GI tract. Magnesium salts have a rapid onset of action and are used for cleansing the bowel prior to radiological procedures. Nonabsorbable sugars, such as lactulose, are also examples of osmotic laxatives, as are sorbitol, glycerin, and polyethylene glycol-based solutions. Stimulant laxatives, such as bisacodyl, senna, cascara, castor oil, and colace, increase colonic peristalsis and act as powerful cathartics. Taken together, however, there is a lack of published evidence for the long-term effectiveness of laxatives for the treatment of constipation. Probiotics have been suggested to improve motility and reduce fecal enzyme activity in patients with constipation. However, large carefully controlled clinical trials are needed to determine the usefulness of probiotic therapeutic approaches for relieving constipation.

THERAPIES FOR IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a disorder of the GI tract that often begins in early adult life and may affect up to 15–20% of the population; thus, it is associated with major health and economic effects. Currently, IBS is characterized according to symptoms of abdominal pain and discomfort associated with altered bowel function occurring in the absence of structural and biochemical abnormalities. The pathophysiology of IBS is due at least in part to heightened visceral sensitivity, altered intestinal motility, and psychosocial factors, which likely are mediated via alterations in the bidirectional cross talk between the neuronal networks in the brain (central nervous system) and the gut (enteric nervous system). Because functional bowel disorders are multifaceted, drug treatment of patients with IBS is complex; however, the management of IBS in North America was recently reviewed by the American College of Gastroenterology Functional Gastrointestinal Disorders Task Force and evidence-based recommendations were made.

Traditional IBS therapeutic approaches have included the use of antispasmodic agents, such as hyoscyamine and dicyclomine, which are thought to reduce high-amplitude contractions in the GI tract. Anticholinergic side effects, such as dry mouth, blurred vision, and constipation, limit their usefulness. Moreover, there are insufficient data from clinical trials to determine the effectiveness of antispasmodic agents in patients with IBS. Antidiarrheal agents, such as loperamide, have been shown to decrease stool frequency and improve stool consistency in IBS patients; however, there is no demonstrable effect of loperamide on the relief of abdominal pain and bloating. Laxatives, such as fiber, are effective at relieving constipation but there is no demonstrable effect of bulking agents on the relief of abdominal pain and bloating in IBS. There is a limited amount of data suggesting that antidepressant therapy may provide pain relief in IBS patients. However, tricylic antidepressants, such as amitriptyline, desipramine, trimipramine, and doxepin, have not been shown to be more effective than placebo in clinical trials. The effectiveness of serotonin reuptake inhibitors for the treatment of IBS has not been carefully documented, though preliminary evidence is promising.

Recent advances in the understanding of gut physiology have led to the introduction of two novel pharmacological approaches for the treatment of IBS, both targeted toward specific receptor systems, which are likely to improve the treatment of patients with IBS. The 5-hydroxytryptamine type 3 (5-HT_3) receptor antagonist alosetron (Lotronex) has been shown to reduce the symptoms of IBS in female patients with diarrhea. Alosetron has received Food and Drug Administration (FDA) approval for the treatment of women with severe diarrhea-predominant IBS who have failed to respond to conventional IBS therapy. This cautious approach by the FDA is based on incidents of ischemic colitis that have been identified in patients taking alosetron. The efficacy of alosetron is thought to result from a delay in colonic transit and a decrease in abdominal discomfort during colonic distension. The mechanism(s) underlying the effect of alosteron remains incompletely understood; however, evidence suggests that 5-HT_3 receptors are present on afferent nerves. Thus, a reduction in symptoms may occur through a decrease in the activity of central autonomic networks. Another recent therapy designed to treat IBS is tegaserod (Zelnorm), a 5-hydroxytryptamine type 4 (5-HT_4) receptor partial agonist, which possesses promotility effects through the stimulation of intestinal and colonic transit. In preclinical studies, tegaserod reduced afferent firing rates in cats and inhibited visceral sensitivity in rodents. Tegaserod recently received FDA approval for the short-term treatment of women with IBS who have constipation. In clinical trials, tegaserod was more effective than placebo at relieving global IBS symptoms in female patients with constipation. Tegaserod also significantly improved abdominal discomfort, bloating, and constipation. Unlike cisapride, cardiac repolarization is unaffected by tegaserod and thus is not associated with potential life-threatening cardiac arrhythmias.

To improve pharmacological treatment of patients with IBS, a strong scientific rationale exists to examine the effectiveness of other agents targeted toward specific neurotransmitter systems involved in the brain–gut axis. Newer generation anticholinergics that selectively antagonize the muscarinic M_3 receptor, as well as selective antagonists of neurokinin receptors (NK_1, NK_2, and NK_3), corticotropin-releasing factor receptor type 1, somatostatin, and cholecystokinin receptor, may reduce the symptoms of IBS. Finally, as knowledge of the role of intestinal microflora grows, future approaches for the treatment of IBS to reduce pain and abdominal bloating may include dietary supplementation with prebiotics or probiotic bacteria to enhance the levels of specific, beneficial intestinal bacteria, such as *Lactobacillus plantarium 299* and *casei GG* or *Bifidobacterium infantis*. However, to date, the evidence in support of probiotic bacteria for the treatment of IBS remains controversial and requires further investigation.

FINAL COMMENTS

Substantial progress has been made in understanding the effective pharmacological approaches to the treatment of GI disorders. Future research needs to be directed at better defining GI physiology and pathophysiology so that current treatment approaches can be modified and new therapies that possess enhanced efficacy and fewer side effects can be developed.

Physiologic Ileus

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

interdigestive state Physiologic conditions in the digestive tract in the time between completion of digestion and absorption of a meal and the ingestion of the next meal.
migrating motor complex A specific pattern of small intestinal motility that begins when digestion of a meal is complete and ends with intake of the next meal. Also called interdigestive motility.
paralytic ileus/adynamic ileus A condition in which the prolonged absence of intestinal motility is pathologic.

Physiologic ileus is the term used to describe the normal absence of motility along a length of intestine. It reflects the operation of one of the neural programs in the spectrum of programs present in the enteric nervous system. Physiologic ileus is a fundamental behavioral state of the intestine in which quiescence of motor function is neurally programmed. For example, in the interdigestive state, the musculature of the small intestine is quiescent except in a limited region where the activity front of the migrating motor complex is present.

NEURAL MECHANISM

The state of physiologic ileus disappears following ablation of the enteric nervous system. In situations in which enteric neural functions are blocked by anesthetics or in patients in which pathological factors have destroyed the enteric nervous system, contractile behavior that is disorganized and nonpropulsive occurs continuously.

Physiologic ileus requires the continuous activity of subpopulations of inhibitory motor neurons that are present in the enteric nervous system. Ongoing discharge of impulses by these neurons releases inhibitory neurotransmitters at neuromuscular junctions and this maintains a state of inhibition in the muscles, which are autogenically active in the absence of neural inhibition. In the absence of ongoing neural inhibition, myogenic pacemakers (i.e., electrical slow waves) evoke contractions with each slow cycle and this results in continuous and uncontrolled contractions. Physiologic ileus refers to the normal state of motor quiescence, whereas the terms paralytic ileus and adynamic ileus refer to conditions in which the prolonged absence of intestinal motility is pathological. Pathological ileus is well known as a consequence of manipulation of the bowel and irritation of the peritoneal membranes during abdominal surgery.

Pica

EDWARD A. ROSE AND ANNE VICTORIA NEALE
Wayne State University, Detroit

geophagia Clay eating.
pagophagia Ice eating.
pica Persistent eating of nonnutritive substances for a period of at least 1 month, without an associated aversion to food.

Pica, the persistent eating of nonnutritive substances, without an associated food aversion, occurs in people of all ages and both sexes, particularly in young children and pregnant women. The term "pica" comes from the Latin word meaning magpie, presumably named after this bird's peculiar eating behaviors involving an indiscriminate preference for both foods and nonfoods. The causes of pica are uncertain, thus treatment is difficult. Although pica is not always dangerous, the underlying possible etiologies should be assessed.

HISTORY

The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) defines pica as the persistent eating of nonnutritive substances for a period of at least 1 month, without an associated aversion to food. The behavior must be developmentally inappropriate and not part of a culturally sanctioned practice, and severe enough to warrant clinical attention. Some clinicians argue that a diagnosis of pica can include the compulsive consumption of certain foods, blurring the distinction between pica and food cravings. Pica is most frequently reported in pregnant women, patients of lower socioeconomic status, and children. It is also found in some cases of iron-deficiency anemia as well as in deficiencies of other nutrients, such as zinc. In some cultures, pica is considered therapeutic and is used in treating maladies such as anemia and anxiety. Interestingly, the range of reported items of consumption has not changed much during the past four centuries. Pica of dirt and clay was known to the Greeks and the Romans and was recorded in a thirteenth century Latin work. Pica was first addressed in a medical book in 1563, in which geophagia was described in pregnant women and in children.

EVALUATION

The cause of pica behavior has eluded researchers for centuries. Researchers have described several theoretical approaches that attempt to explain the etiology from nutritional, sensory, physiologic, neuropsychiatric, cultural, or psychosocial perspectives. There have been few epidemiologic studies detailing the prevalence of pica. Estimates have varied widely within a particular population, depending on the criteria used. Studies of pregnant, otherwise healthy women have found pica in approximately 8% of respondents. Many of these patients had low serum ferritin levels, suggesting a link between pica and iron deficiency.

In the absence of complications that might signal abnormal eating patterns, diagnosis depends on self-reporting. Patients are likely to underreport pica behavior because of embarrassment or because they are not aware that such behavior might be worth reporting.

Clinical suspicion is therefore required to diagnose pica in the ambulatory setting. Iron or zinc nutrient deficiencies may be suggestive; likewise, lead or mercury poisoning may lead to the diagnosis of pica. Gastrointestinal complications such as bezoars or obstructions may also suggest pica.

TREATMENT

Given the difficulty inherent in diagnosing pica and the multitude of possible etiologies, treatment is difficult. Many studies have described diminished pica behavior in patients following iron or zinc replacement to treat low iron or zinc levels, although the empiric evidence implicating zinc deficiency in pica is less convincing than is the evidence for iron. In any case, if iron deficiency leads to pica, then pica behavior should cease once iron is replaced. Cessation of pica behavior with iron replacement may not happen, however, suggesting that continued pica behavior may constitute an addiction or a learned pattern of behavior.

Not all forms of pica are dangerous, and some cases might not require intervention. However, physicians must be prepared for cases of pica in their daily practice. Education about nutrition, along with iron therapy or transfusions, might be the first wave of intervention. Psychological counseling or behavior therapy can also be useful adjuncts. Recently, there has been some evidence that pica is a part of the obsessive–compulsive disorder (OCD) spectrum of diseases. In support of this theory, selective serotonin reuptake inhibitors (SSRIs) have shown some promise. Severe or recalcitrant cases could require referral to a mental health specialist.

Review of the literature on pica confirms just how little is known about this common but commonly missed condition. Its cause is related to many factors, and there are questions about whether pica is a cause of or an effect of metabolic or behavioral states. Accurate diagnosis is hindered by the need for self-reporting on the part of the patient and by a low index of suspicion on the part of the clinician. No specific screening tests for pica exist, but an accurate and timely diagnosis can help to avoid some of the many nutritional, gastrointestinal, and psychological complications. Finally, when pica is diagnosed, there are no proven treatments. Although selective serotonin reuptake inhibitors can be helpful in some cases, diagnosis and treatment must be individualized, and the practicing physician will most likely need to rely on help from mental health professionals.

Picture Archiving and Communication Systems (PACS)

MARC J. GOLLUB
Memorial Sloan-Kettering Cancer Center, New York

analog imaging system Plain radiograph (e.g., chest X ray, mammogram) scan devices; images are not obtained using digital computer technology.
archive Storage of data.
bit Binary unit; smallest unit of information used by a computer; 8 bits equals 1 byte.
computed radiography System using computers to capture and digitize an image rather than print it on film.
digital display protocol Preselected method of displaying a patient's new and old radiographic images.
digital fluoroscopy Capturing and transmitting fluoroscopy information to a computer rather than intensifying it and using it to expose film.
digital images Binary-coded representations that can be interpreted by a computer and displayed on a monitor.
ergonomics Design of environment or equipment related to natural body position and physical comfort.
film digitizer Machine containing a laser that converts analog information on conventional film into digital data, which can be stored in a computer and displayed on a monitor.
film file room Place where X rays are stored.
film screen Combination of silver-coated photographic film layers, sensitive to X rays only, enclosed in a light-proof cassette.
gigabyte One billion (1×10^9) bytes.
graphical user interface Setup that allows humans to interface with software, using words, pictures, and computer tools (keyboard and mouse); a workstation monitor, for example, on which two-dimensional and three-dimensional images are manipulated.
hardware components Computers, monitors, printers, and any other peripheral computer-connected devices.
hospital information system Computerized system containing patient medical and personal identity information.
imaging device Machinery that scans and captures body images (as in computer tomography, magnetic resonance imaging, radiography, and fluoroscopy).
image fusion Digital overlap of data from different types of images.
image noise Information that interferes with interpretation of utilizable data.
imaging plate System analogous to silver nitrate film, but using phosphorescent technology to capture images digitally, rather than converting silver to form an image.
image resolution Degree to which very small objects located in close proximity can be distinguished in an image.
lossless compression Method to compress digital data without losing critical information.
lossy compression Method to compress voluminous data with some loss of information.
network Interconnected computer systems (for example, in a hospital or community health care system).
open architecture Network design that allows interconnected components to communicate using the same standards and language.
operating system Programs (software) that determine the functions and abilities of a computer; disk operating system (DOS) (examples include Windows 95 and Apple DOS).
pixel Picture element.
processing speed Time it takes a computer to accomplish a given task.
radiology information system Computerized system used for scheduling and storing pertinent patient data.
region of interest Area indicated by a circle or square on a cross-sectional image in which the computer is programmed to display a reading that may indicate a solid or fluid component.
storage archiving units Disks that are recorded and read using laser light (examples include read-only memory compact and digital video disks).
telecommunications Transmission of sounds, images, and digital data using electrical and computer technology.
three-dimensional computed tomography angiography Three-dimensional reconstruction of blood vessels, extracting background data from conventional computed tomography images to allow images to appear as if they were simply an angiogram.
three-dimensional rendering Computer reconstruction of two-dimensional data to appear as though three-dimensional.
virtual colonoscopy Three-dimensional images of the colon, simulating an endoscopic view, created using information obtained from a computer tomography scan.

A picture archiving and communication system is a network of computers and imaging devices, databases, storage devices, and display monitors, all of which communicate with one another throughout a hospital, health

 Copyright 2004, Elsevier (USA). All rights reserved.

network, or community to store, transmit, and display digital images and patient information in a rapid and convenient manner. The system eliminates conventional hardcopy film and replaces the conventional film file room and associated personnel, avoiding the inadvertent duplication and loss of information associated with an analog imaging system. A fully networked hospital-wide system facilitates simultaneous image viewing and consultation of radiographic studies by, for example, a surgeon in the operating room, a radiologist in the reading room, and an oncologist in the clinic. The system incorporates the hospital information system and radiology information system for seamless data transmission, billing, and patient scheduling.

BRIEF HISTORY

Great technological advances in the past century that set the stage for the creation of picture archiving and communication system (PACS) have included the development of digital fluoroscopy, digital image systems, computed radiography, high-resolution (2048×2048 pixels $\times$ 12 bits) liquid crystal display flat-screen monitors, personal computers with high-capacity memory, self-contained units using dry film and laser technology, and gigabyte-speed Ethernet wide area networks has enabled systematic linkages of picture archives and communication.

Dr. Paul Capp introduced the concept of digital radiology in the early 1970s. Soon after, the invention of computed tomography (CT) by Godfrey Hounsfield represented a landmark advance in imaging science. CT introduced cross-sectional imaging, but also demonstrated the value of computers in image production. Plain radiography (film screen) and its associated shortcomings, including inability to change the image once the film is exposed, inability to view the film at multiple locations, and inefficiency of manual filing and retrieval of films, are well-known to radiologists. The development of imaging plate (IP) systems (based on photostimulable phosphor technology) in the late 1970s and early 1980s allowed for replacement of film-screen imaging and creation of computed radiography (CR) in 1987. Concurrent with these advances, computer technology evolved rapidly, with increases in processing speed, more powerful operating systems and graphical user interfaces, increased storage capacity, and decreased cost. Finally, the development of the first film digitizer and large-capacity optical storage disk by Kodak further provided essential components for PACS development. Eventually, storage devices, essentially redundant arrays of inexpensive disks (RAIDs, see later), were created.

The first international conference and workshop on PACS for medical applications took place in January 1982, sponsored by the International Society of Optical Engineering (SPIE). At the time, however, much of medical imaging technology had yet to be developed. During the 1980s, Ethernet, a local area network (LAN) communications system via coaxial cable radiofrequencies, became a telecommunications standard, with data transmission rates quickly maturing from 1 megabyte per second to the current 100 megabytes per second (gigabyte Ethernet). Concurrently, data compression was created as an alternative way to speed network delivery. Lossless compression rates of 3 : 1 have evolved toward lossy compression techniques promising rates on the order of 20 : 1 or 30 : 1. The American College of Radiology and National Electrical Manufacturer's Association (ACR-NEMA) group proposed standards for communication of medical images over networks, which became official in 1985. These limited standards were revised in the 1990s into the Digital Imaging and Communications in Medicine (DICOM) standard to embrace traditional computer networks. The saga of PACS development continues as technology improves and various companies have begun to offer fiber-distributed data interfaces (FDDIs), T3 lines (carrying large-bandwidth signals on fiber-optic cable), and asynchronous transfer modes (ATMs), an international standard adopted by the telecommunications industry, promising memory-to-memory transfer rates of 2.4 gigabytes per second.

GENERAL PRINCIPLES

PACS consists of image acquisition devices [e.g., computed radiography/tomography and magnetic resonance imaging (MRI) scanners], storage archiving units (e.g., RAIDs, optical disks, read-only memory digital video disks), display workstations, computer processors, and databases. A communications network and a database management system integrate these components. The hardware components are integrated by standardized, flexible software systems for communications, error handling, database and storage management, job scheduling, interprocessor communication, and network monitoring (Fig. 1).

PACS must include system standardization, open architecture, connectivity, reliability, and security. System standards might include UNIX and Windows NT operating systems, transmission control protocol/Internet protocol (TCP/IP), DICOM communication protocols, structured query language, ACR-NEMA and DICOM image formats, C and C++ programming languages, X Window user interface, American

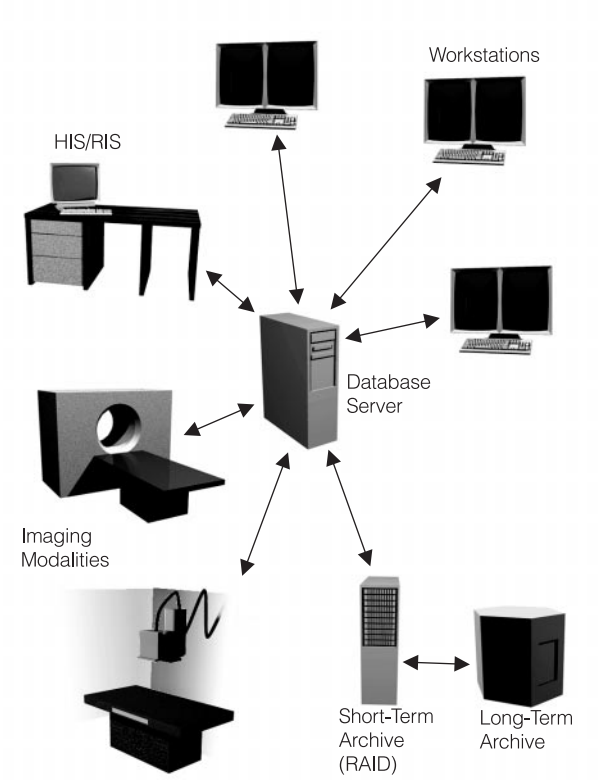

FIGURE 1 An example of a basic PACS configuration. HIS, Hospital information system; RIS, radiology information system; RAID, redundant array of inexpensive disks. © ECRI (2000). Reprinted with permission from *Health Devices* 2000 Nov; 29(11): 387.

Standard Code for Information Interchange (ASCII) text representation for message passing, and health level-7 (HL-7) for health care database information exchange.

Open architecture and connectivity describe a system in which components that are to be connected are able to "speak" to one another in the same "language," so that they are not isolated. They can also be simultaneously upgraded. Reliability (thus high "up time") is critical to patient care. Extended periods of down time cannot be tolerated. Systems must use fault-tolerant measures, including error detection and logging software, external auditing programs, and hardware redundancy. Finally, security is important in the realm of medicolegal and patient confidentiality issues. Violations can include physical intrusion and misuse of privilege.

Image compression is used in PACS to decrease data storage and transfer requirements and to increase data transfer speed. Compression can involve either no loss of information (lossless) or reduction of data with preservation of important information (lossy). Typical acceptable data compression ratios used today are 3 : 1 using the Joint Photographic Experts Group (JPEG) file format, which is DICOM compatible. Wavelet transform can allow higher rates of compression, but is not currently DICOM compatible. Image compression has become a more important issue with the emergence of thinner and more voluminous multislice CT data sets. Megibow *et al.* recently evaluated the ability to diagnose appendicitis, depending on the amount of lossy wavelet compression from 8 : 1 to 24 : 1. Beyond 8 : 1, sensitivity and eventually accuracy (at 24 : 1) decreased, suggesting that finite levels of wavelet transform may be applied to CT images without compromising diagnostic performance.

Using effective networking, many components can be interconnected in PACS. This capability is a key feature of PACS and is facilitated by the DICOM communication standard developed by ACR-NEMA to allow the sharing of information using products from different suppliers. Networks vary according to data transmission methods, architecture of the network hardware, image distribution methods, and image identification and retrieval methods. Typical setups include (1) a regular Ethernet LAN between the image modality device and the image acquisition gateway (low speed; 10 megabits/sec, because the CT scanner is slow to generate images), (2) an Ethernet or FDDI (medium speed; 100 megabits/sec) or ATM (high speed; 155–622 megabits/sec) between the gateway and the PACS controller, and (3) an ATM or FDDI between the PACS controller and the display workstations, because clinicians must access images at a rapid rate.

Network hardware architecture may be centralized (a central location for all images, with direct high-speed links to any workstation at any time), local (tailored to a specific modality, e.g., ultrasound miniPACS), or distributed (in which local modality archives—CT, MRI, and ultrasound (US)—are connected by a high-speed standardized network). Each of these network organizations has advantages and disadvantages regarding cost and demands on the server.

Image distribution methods include on-demand and routed (cached). An on-demand system allows a user to log on and access any image from any workstation (usually in centralized systems). In routed systems, studies are stored locally at a workstation or at specified workstations, but not at all of them. An example of a centralized, on-demand type system (Fig. 2) is the General Electric Pathspeed PACS. Images are sent from an imaging modality to a central database server and then to a central archive (e.g., a RAID) for short-term memory (images are typically copied from the RAID to long-term storage as well). When a user selects a study at a workstation, it is sent from the RAID to the workstation's

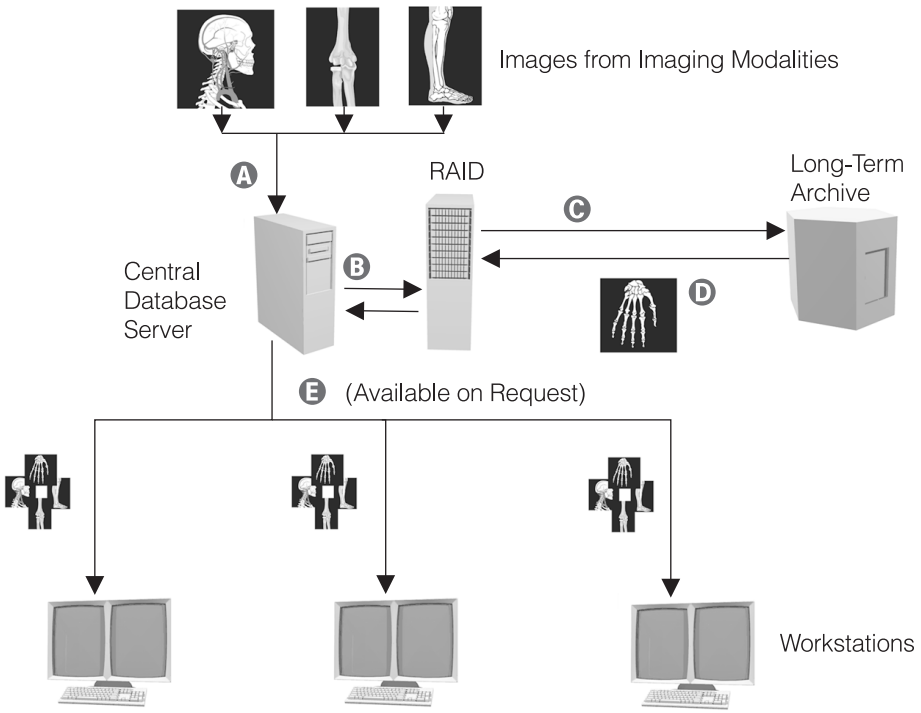

FIGURE 2 Simplified representation of the workflow in a PACS that uses an on-demand image distribution method with a centralized architecture. (A) Images are sent from an imaging modality to a central database server, which in turn (B) sends the images to a redundant array of inexpensive disks (RAID). (C) At this point, images may also be copied to the long-term archive. (D) Images requested from the long-term archive, either those retrieved before the procedure or those requested by the user at the workstation, are also moved to the RAID. (E) Users at any workstation can query the database server to receive any image in the system. © ECRI (2000). Reprinted with permission from *Health Devices* 2000 Nov; **29**(11), 395.

memory. When a user updates a study, the updates are sent back to the RAID (and also copied to long-term storage). Similarly, when a user requests a study from the long-term archive, it is sent from there directly to the RAID and then routed to the user's workstation. This same process occurs in "prefetching," whereby PACS automatically retrieves relevant studies from the long-term archive when a patient is admitted or scheduled at the radiology information system (see later). One drawback of centralized versus distributed systems is that a system failure of the central database disables the whole PACS. However, PACS today have significant built-in redundancy to prevent such system-wide failures.

ANATOMY OF PACS

Input

The database server and archive system together comprise the PACS controller. The controller organizes data from multiple sources into a coherent package. It acquires images, archives them, and distributes them to display workstations and processes image retrieval requests. PACS can also be interrogated in order to retrieve images, review patient and study information, study practice statistics, and perform outcomes analysis.

Images from the acquisition devices (e.g., CT, MRI, and CR scanners) and from devices that convert analog images to digital images (digitizers), as well as pertinent patient information, arrive at the acquisition gateway computer (AGC). The job of the AGC is to receive images from the respective modality components, extract text information describing the received study, update the database management system, determine the destination workstation, automatically retrieve necessary comparison images, determine optimal contrast and brightness parameters for display from lookup tables for cross-sectional modalities (e.g., window and level), perform image data compression, archive new studies onto the optical disk library, and service archive retrieval requests from workstations and other PACS

controllers. The AGC ensures the integrity of image data at various points along the path. At the imaging device, an image will not be deleted from the local storage device until verified by a technologist that it has been archived via the PACS connections. At the AGC, images remain on the local magnetic disk until the archive subsystem acknowledges that a successful archive has occurred, at which time space is made on the disk and these are cleared. At the PACS central node, images arriving in the archive server from various nodes are not deleted until permanently archived.

Other sources of information arriving at the database server of the PACS controller are the hospital information system (HIS) and radiology information system (RIS). The HIS serves three functions: (1) it supports clinical and medical patient care activities in the hospital, (2) it facilitates administration of the hospital's daily business transactions, including financial, personal, payroll, and bed census, and (3) it assists the evaluation of hospital performance, costs, and long-term forecast projections. RIS manages patient demographics, billing, procedure descriptions, scheduling, diagnostic reports, patient arrival scheduling, film location, film movement, and exam room scheduling. It consists of a computer system with peripheral devices such as alphanumeric terminals, printers, and bar code readers. Using the HL-7 standard, scanning a simple bar-code entry can download the relevant data from the RIS to the acquisition unit, which would then incorporate the data into the DICOM packet with the image.

RIS/HIS interfacing occurs using a standard Ethernet. Information and messages concerning patient admission, discharge, and transfer are sent to PACS only when a patient is scheduled for an examination in radiology. An HL-7 standard data format is used running on TCP/IP communication protocols. Prefetching is also initiated as soon as HIS/RIS gets an admission, discharge, or transfer message. Prefetched data are sent to display workstations prior to current exam completion. The prefetched algorithm is based on predefined parameters such as examination type, disease category, radiologist, referring physician, and location of display workstation. Integration of these systems into PACS reduces redundant data entry and storage and avoids the expense and clutter of separate office computers, terminals, and workstations.

Archive

An important advantage of PACS has been the elimination of film. Nonetheless, a busy department can generate many gigabytes (10^9) of data per day and several terabytes (10^{12}) per year. This presents a technological and economic challenge. Digitized images created over several years can be accessed on a variety of storage media, including magnetic and optical disks and tapes, on "jukebox" systems for storage of multiple disks and tapes.

A tiered approach between short- and long-term methods offers two advantages—cost control and maintaining useful retrieval times based on likelihood and immediacy of need; less expensive storage media can be used for long-term storage because the level of functionality required is less than that needed for short-term storage. Short-term storage, usually accomplished using RAIDs, can involve storing studies for only a few weeks; users can specify any length of time. The demand for rapid display of images at the display workstation is well served by RAIDs, whereby multiple disks are accessed to aggregate data fragments. As the cost of RAIDs decreases there is a greater tendency to use this method for intermediate and even long-term storage, allowing images to be retrieved quickly regardless of when they were archived.

To provide both temporary and permanent storage, long-term archive employs a variety of media, including magneto-optical disks and read-only memory compact and digital videodisks. Typically, PACS copies images to both short-term and long-term storage immediately to protect from loss of short-term memory in a system failure. Images in short-term storage are removed once they have been read.

Output

With PACS, film is no longer the medium of the radiologist. The image output is to a display workstation or to an inexpensive paper printer. This reduces costs associated with film, chemicals, film storage, and film management. Different display workstations offer various levels of functionality, resolution, and other display characteristics and can meet the needs of different users. From prior surveys, radiologists have deemed most important the ability to compare new with old studies, and rapid access to images. Certain workstation display features are considered standard, such as zooming, changing window and level, rotating an image, and obtaining density measurements. Each display workstation consists of a host computer and an image display board, a display video monitor, and a local storage device.

Workstations will differ in their physical (spatial resolution, focus, luminance, computation speed, local storage space, bus speed, and network access speed) and functional (software capabilities and human−computer interface) requirements. Important features include ergonomics, lighting conditions,

glare, and acoustic noise from hardware. A key issue determining workstation quality is image resolution. Resolution increases with an increased number of pixels. Bit depth (number of bits/pixel) is another important feature in grayscale depiction. Although 12 bits/pixel is standard for CT/MR and CR for all tissues, US requires only 8 bits/pixel. The development of monitor technology to overcome limitations and inadequacies for the accurate display of mammograms and skeletal radiographs has been a challenge.

Six types of workstations can be described: diagnostic, review, analysis, digitizing and printing, interactive teaching, and desktop. At a diagnostic workstation, radiologists make primary diagnoses using the best resolution possible. This includes 2K ($K = 1024$ linear pixels; 2048×2048 pixel imaging array) monitors for plain radiography (necessary for analysis of fine detail) and 1K (1024×1024 pixels) monitors for CT and MR. At the diagnostic monitors, a digital Dictaphone may be available. A worklist may also be available to include all studies that meet the user's selection criteria, e.g., body-MR cases. The user also can choose how to arrange the images on the monitor, including positioning of old studies, using various digital display protocols (DDPs). The resolution of review workstations in clinics and hospital wards need not be as high, because cases are primarily being reviewed after they have been interpreted, and not every minute detail need be observed.

Analysis workstations are packaged with specialized image analysis software; they can perform, for example, three-dimensional rendering, image fusion, and color enhancement. Models include the GE Navigator software for virtual colonoscopy and Vital Images Vitrea software for three-dimensional CT angiography. A digitizing and printing workstation is used by the film file room personnel to digitize historical films or films acquired outside the hospital. Elimination of film is the ideal objective of PACS, but sometimes hardcopy images will be necessary. This is accomplished with a multiformat camera and laser film, a laser scanner, and a laser or paper printer. Interactive teaching workstations emulate the role of teaching files in the film library, but with more interactive features. Finally, a desktop workstation is used to generate lecture slides and teaching and research material from images on PACS. This is done at a personal computer and requires only a 512×512-pixel monitor.

WORKFLOW SCHEMA

In a film-based department: a procedure is scheduled and patient data are entered in the RIS. Before the patient arrives, the film file room personnel retrieves prior studies for that patient and sends them to the radiologist's reading room. When the patient arrives for the study, the identifying data are reentered into the imaging modality. The patient is scanned and films are exposed at the modality. These are developed and brought to the reading room for posting on a film alternator. These are read while also reviewing prior images. If additional prior imaging studies are needed, the radiologist requests these from the file room. Once they arrive, the radiologist finishes the case and dictates a report. A transcriptionist types the dictated report and sends a printed report to the radiologist, who edits it as necessary. Once revised by the transcriptionist, the report is sent to the referring physician. This whole process may take 3–4 days.

After full PACS implementation, the workflow would proceed as follows: scheduling information and patient data are entered in the RIS and sent to the relevant imaging modality automatically. Before the patient arrives, PACS automatically retrieves prior studies from its long-term archive based on the information in the RIS and the rules established. The images are made available in local storage for ready access. At the scheduled time, the patient is imaged and digital images are transmitted immediately to PACS. These are read along with relevant prior images at a PACS workstation. Images can be easily adjusted for improved viewing or analysis. Radiologists at other locations can be consulted on the same study if necessary. If older studies are needed, they can be accessed from long-term storage within a few minutes. When review is complete, a report is dictated using speech-recognition tools. The radiologist edits the electronic report directly and sends it to the referring physician immediately through RIS or e-mail. This can take several hours or less from start to finish.

ADVANTAGES

General

As a new and evolving costly technology, PACS will need to undergo formal critical evaluation by physicians, the health care system, and society. The methodology for doing this has been set forth by Fryback and Thornbury. Categories of evaluation include safety, technical efficacy, diagnostic accuracy efficacy, diagnostic thinking, therapeutic efficacy, patient outcome efficacy, and societal efficacy.

Widely publicized studies from the hospital of the University of Pennsylvania in the early 1990s demonstrated a statistically significant reduction in time spent

TABLE I Summary of Benefits of the Picture Archiving and Communications Systems[a]

Category	Benefit
1	**Benefits to the diagnostician**
	Improved access to current patient records
	Improved access to patient history records
	File integrity and speed of retrieval
	Better diagnosis
	Quicker diagnosis/improved productivity
2	**Benefits to the referring physician**
	Better patient management/earlier intervention
	Better patient outcome
	Reduced length of stay
	Reduced legal costs arising from maladministration claims, based on loss of films, lack of patient history, etc.
3	**Benefits to the patient**
	Reduced radiation exposure from X-ray equipment
	Shorter examination times
	Reduced radiation exposure as a result of less need for retakes of images
	Reduced patient inconvenience in attending hospitals for examination and reexaminations
	Reduced chance of adverse reaction to contrast agents
4	**Benefits to the hospital**
	Better communication with physicians
	Better hospital administration
	Better training of radiology and other students through access to on-line image files and to digital teaching files
	Greater staff retention due to improved morale

[a] Data reprinted with permission from Crowe (1992).

by clinicians performing clinical activities when images were available on digital display, compared with traditional film retrieval protocols. Imagine the advantages in gastrointestinal radiology if more immediate clinical action could be taken in cases of bowel obstruction, perforation, gastrointestinal bleeding, ischemia, postoperative leaks, and the like. Other studies looking at time savings have shown that nonphysician employee staff can be reduced 26% and that significantly increased time is available to technologists when film handling is eliminated. The overall benefits to the diagnostician, referring physician, patient, and hospital are summarized in Table I. In a practice of gastrointestinal radiology, PACS can facilitate daily practice in both fluoroscopy and cross-sectional modalities.

Gastrointestinal Fluoroscopy

Fluoroscopy is a unique modality that involves the hands-on, potentially time-intensive radiological examination of a patient with repeated and continuous radiation exposure (at the radiologist's discretion). A constantly moving tube (because of peristalsis) is being examined within the patient. Characterization of this is useful in addition to information gained from static images. Intermittent distension and collapse of the bowel and variable progression of administered contrast through the gastrointestinal tract limit the examiner. The window of opportunity to capture time-dependent changes can be missed or capitalized on in a manner quite unlike the radiological examination of any other organ system.

Examining the patient using digital technology and PACS, compared to film, allows more rapid and well-timed exposure and capture of pertinent information because a cassette is not mechanically moving into place. Acquisition of rapid-sequence digital exposures (8/sec) also becomes possible (versus mechanically derived exposures of 100-mm film, limited to 3/sec). Digital exposures can be immediately reviewed on the monitor before fluoroscopy resumes. The adequacy of each film can be immediately assessed, and assessed sooner en masse, compared to cassette film. Immediate supervision of residents can be done for quality control and can minimize the number of errors caused by technically suboptimal exams. The immediate or rapid availability of old studies and correlative modalities enables very quick answers to any queries and allows reexamination while the patient is still in the department; this is a very problem-oriented and tailored approach. Waiting for development of spot radiographs is avoided, eliminating the long delays that may prevent reexamining a patient, only to find suboptimal coating and distension. Finally, compared to conventional fluoroscopic equipment, digital technology allows lower radiation exposure, depending on the number of exposures, the use of pulsed fluoroscopy, and screen capture.

Immediate image review has practical benefits. In cases in which overheads are not required, patients need no longer wait in the department while a series of cassettes is developed in a film processor. They can leave immediately after review of spot films on the workstation. This also frees up the room and the technologist more quickly, further expediting overall throughput. Significant advantages are also available during final film readout sessions at the PACS monitor. Old studies are readily available for comparison. Even old studies, performed at an outside hospital but pertinent to the current fluoroscopic studies, can be digitized in advance for later review. In addition, immediate side-by-side correlative modality comparison (to CT, MRI, PET, etc.) is a useful educational tool in gastroenterology, because the study is often being performed as followup to questionable findings on cross-sectional studies.

This process may also allow demonstration of findings more rapidly.

The software tools available at the workstation monitor allow control of brightness, contrast, magnification, and edge enhancement so that a granular or reticular mucosal pattern or small polyps or ulcers may be more easily seen. Small postoperative leaks and extraluminal gas collections may be made more apparent with these adjustments as well. The scrolling function allows scrolling through captured rapid-sequence studies for a dynamic effect and avoids obtaining more films.

PACS has improved the efficiency of communication and reporting of results to referring clinicians. Placing arrows and annotations to mark significant images allows a quick review of the pertinent findings by clinicians at remote display monitors. PACS makes a positive contribution to teaching and learning. More images can be displayed more quickly without the burden of handling many films. Residents and fellows can scroll through these images to arrive at a better gestalt for the abnormality. Instead of displaying suboptimal copy films on a light box, digital images (which can be manipulated) are automatically accessible and can be viewed and demonstrated in a conference room from a PACS monitor connected to audiovisual equipment. This facilitates better visualization for all residents/fellows in the conference room, rather than the few sitting up front or actually "taking the case."

PACS can also assist in research and publication efforts. It allows more efficient collection of similar cases, by saving them in a teaching folder in the PACS module/worklist. In the academic setting, using a personal computer web browser or workstation, production of slides quickly and without loss of image quality is an added benefit for both teaching files and publication uses. Finally, teleradiology has great potential for aiding consultations and extending expertise around the world.

Cross-Sectional

The contribution of PACS to the capture, transmission, and display of images from cross-sectional modalities has been nothing short of revolutionary. If "a picture is worth a thousand words," then one can barely do justice trying to express in any amount of words the incremental advantages of displaying a 500-"picture" MRI study on soft copy, versus on innumerable pages of laser-printed film. For example, viewing images in a rapid sequential manner on PACS offers a teleological three-dimensional gestalt that cannot be achieved with film reading. In PACS, the imaging specialist has the ability to scroll or cineloop through images and mentally reconstruct anatomy and pathology, based on training and experience. Stated in another way, many structures are anatomically aligned more longitudinally in the body, such that interpretation of axial images gives an incomplete picture of the overall organ or process. Radiologists have all had the experience of deciding if a dot is a lung nodule or lymph node based on whether it is visible on several slices above and below (is longitudinally continuous and therefore a vessel or other tubular structure), or is isolated to that slice (real pathology). Scrolling allows more rapid assessment of longitudinality. When dealing with the alimentary tract, not only is tracing the course of the colon facilitated, but an orderly tracing of the entire small bowel can be nearly achieved. Localizing obstructions and masses, intussusceptions and even accurately identifying the course of bowel and its relationship to adjacent structures become more reliable. The teleologically gifted can often draw a coronal "road map" for the surgeon after viewing the intestines in this manner. The use of specialized display workstations (e.g., GE Advantage Windows 3.1) to reformat images into coronal or sagittal views or create angled multiplanar reconstructions may assist with these tasks as well.

In the solid gastrointestinal tract (liver, gallbladder, pancreas, and intestinal mesentery), PACS offers advantages in image manipulation, archive, volume handling, and image viewing. Manipulation of images may include distance measurements, volumes (tumor burden changes with treatment, liver transplant volume estimation, lung reduction surgery evaluation, etc.), region of interest density measurements, and magnification/minification. In addition, the window and level can be easily adjusted to the observer's liking. Annotations using arrows and text can be added, and significant images can be marked for later reference or remote conferencing with other interested clinicians.

Image archive is now digital. It is not necessary to look through an entire film folder for old/misplaced/jumbled CT examinations. All prior studies are available either in short-term (prefetched) or long-term archive, which may take 1−2 minutes to retrieve, saving time and manual labor. Comparison with other types of studies is also facilitated. This efficient, invaluable process has the potential to help us learn how to better interpret various studies—in a sense, providing personal quality control.

The volume of images in a PACS folder may challenge memory capacity, depending on image compression types and ratios, but still represents a major advantage over film. Filming extra sequences (delayed images, thinner slice reconstructions, coronal or other reformats, etc.) no longer requires using more

film and personnel time, both valuable and expensive resources, but rather merely requires sending the images to PACS.

Viewing images is facilitated with PACS. Any two images from any study and any date can be placed directly next to one another. This can be accomplished with preset digital display protocols. These DDPs can be personalized and saved and shared among different users. The scrolling function, in addition to being useful in distinguishing longitudinally oriented structures from lymph nodes or lung nodules, can also be used to simulate motion in vascular perfusion studies. Finally, the timely arrival of PACS has facilitated the viewing of large data sets associated with virtual colonoscopy.

Some difficulties, disadvantages, and pitfalls have been found with PACS. Several institutions have initially found that cost savings for film attributable to PACS can be largely offset by PACS equipment maintenance costs. On the other hand, cost effectiveness also varies with intangible benefits, such as referring physicians' and support staff productivity gains. Pitfalls in PACS are usually a result of human error, whereas bottlenecks are due to imperfect design. Three errors involving the acquisition device are entering the wrong input parameters, stopping an image transmission process improperly, and incorrect patient positioning (in CR, the most common error occurs when the technologist places the imaging plate under the patient in the wrong direction).

A recent United States Department of Defense survey of PACS deficiencies at 14 sites found that the components most commonly cited for deficiencies were the radiologist's workstation (25%), the HIS/RIS/PACS broker interface (16%), the RIS (14%), monitor displays (10%), and the web-based image distribution systems (6%). Larger systems had more failures than smaller ones.

FUTURE DEVELOPMENTS/SUMMARY

PACS originated as an image management system for improving the efficiency of radiology practice. It has evolved into a hospital-integrated system dealing with information media in many forms, including voice, text, medical records, images, and video recordings. To integrate these various types of information requires the technology of multimedia: hardware platforms, information systems and databases, communication protocols, display technology and system interfacing and integration.

Future developments may include enterprise- and community-wide image distribution systems to balance workload and maximize scarce professional resources, improvements in the quality of service to referring physicians with web-based information distribution systems, wavelet compression techniques, flat-panel monitors, reduced cost of RAIDs, analysis workstations on every monitor, seamless incorporation of HIS/RIS, voice-recognition and computer-automated detection software, and temporal image database management systems to perform outcomes analysis (for example, in lung cancer screening studies by extracting volumes of lung nodules in longitudinal scans).

Pituitary Adenylate Cyclase-Activating Polypeptide (PACAP)

JOSEPH R. PISEGNA

VA Greater Los Angeles Healthcare System, and David Geffen School of Medicine, University of California

hip (SV1) Incorporates a 20-amino-acid insertion in the third intracellular loop of PAC1.
hip-hop (SV3) Incorporates a 40-amino-acid insertion composed of both the hip and hop cassettes.
hop (SV2) Incorporates a 20-amino-acid insertion in the third intracellular loop of PAC1.
PAC1 Pituitary adenylate cyclase-activating polypeptide type 1 receptor.

Pituitary adenylate cyclase-activating peptide (PACAP) is the most recently discovered neuropeptide in the vasoactive intestinal polypeptide, secretin, glucagon, and related family of peptide hormones. It is so named because, following its discovery in the rat anterior pituitary, this 38-amino-acid peptide hormone was shown to be a potent stimulator of adenylyl cyclase. This hormone was discovered in 1993 and all of its physiological functions are still not completely understood. Given the distribution of this hormone in the peripheral systems, including the gastrointestinal tract, it would be expected to have a major role in physiological regulation.

PACAP HORMONE

Discovery and Gene Structure

Pituitary adenylate cyclase-activating peptide (PACAP) was discovered by Arimura and co-workers using isolated fractions of ovine hypothalamic extracts that stimulated adenylyl cyclase activity in anterior pituitary cells. PACAP circulates as two biologically active forms, one containing 38 amino acids (PACAP-38) and the other containing 27 amino acids (PACAP-27). There is significant interspecies conservation of the amino acid structure of the PACAP hormone.

The primary sequence of the PACAP hormone has a 68% homology with vasoactive intestinal polypeptide (VIP), therefore PACAP is a member of a broader category of hormones that includes VIP, secretin, glucagon, and growth hormone-releasing factor (GRF). As demonstrated in Table I, there is significant homology amongst these peptides. The three-dimensional structure for hormones in this family also demonstrates similarities. The primary amino acid sequence similarity reflects the close similarity in gene structure among the relatives of PACAP, suggesting a similar ancestral gene and perhaps also gene duplication. The PACAP hormone gene has been cloned in several species, including mice and humans. The human gene is composed of five exons and has a structure that is similar to that of other members of this family of peptides. This close similarity suggests that all of the members of this family of peptides may have originated from a similar ancestral gene through duplication.

PACAP Hormone Distribution

In mammals, the highest concentration of PACAP is in the central nervous system (CNS). The regions of the brain that appear to have the highest concentration (in the rat) are the paraventricular and supraoptic nuclei within the hypothalamus. It is presumed that PACAP is transported from the hypothalamus to the anterior pituitary, where it can exert its effects on the endocrine system. PACAP-38 immunoreactivity has also been shown to be present in extrahypothalamic sites, such as the substantia nigra, cerebellum, pons, and the paraventricular nuclei of the thalamus. In addition, the spinal cord also contains PACAP that is mainly localized in the dorsal root ganglia and dorsal horn. Outside of the CNS, PACAP is present in the adrenal medulla, where it appears to be a potent stimulator of catecholamine release. PACAP is also present in the enteric neural plexus, where it is an important mediator of gastric acid secretion and intestinal motility.

THE PACAP TYPE 1 RECEPTOR (PAC1)

Cloning, Pharmacology, and Signaling

Through cloning studies, PACAP has been determined to have high affinity for three receptors. The first of these receptors to be cloned was the classical VIP receptor (VPAC1); subsequently cloned were the type 1 PACAP receptor (PAC1) and the VIP2 receptor (VPAC2). Although PACAP has high affinity for all three receptors, each can be distinguished by their affinities for the ligands VIP, PACAP, and helodermin, as shown in Table II (see also Table III for nomenclature of PACAP and receptors). Interestingly, PAC1 has affinity for only PACAP-38 and PACAP-27.

TABLE II Classification of Receptors in the PACAP Superfamily Based on Relative Affinities to Related Peptides[a]

IUP[b] nomenclature	Relative affinities
PAC_1	PACAP-27 = PACAP-38 ≫ VIP > Helodermin
$VPAC_1$	PACAP-27 = PACAP-38 = VIP ≫ Helodermin
$VPAC_2$	Helodermin > PACAP-27 = PACAP-38 = VIP

[b] IUP, International Union of Pharmacology.

Cloning of rat PAC1 cDNA shows that it is homologous to the VIP and secretin receptors. The PAC1 cDNA encodes a 495-amino-acid protein with a molecular mass of approximately 50 kDa. Cloning of the rat PAC1 gene shows that the receptor can exist as one of four major splice variants (Fig. 1). The major difference between these four potential splice variants is the structure of the third intracellular domain. There is a "hip" splice variant (SV1) and a "hop" splice variant (SV2), each with a 20-amino-acid third-loop insertion; a "hip-hop" splice variant (SV3) incorporates a combined

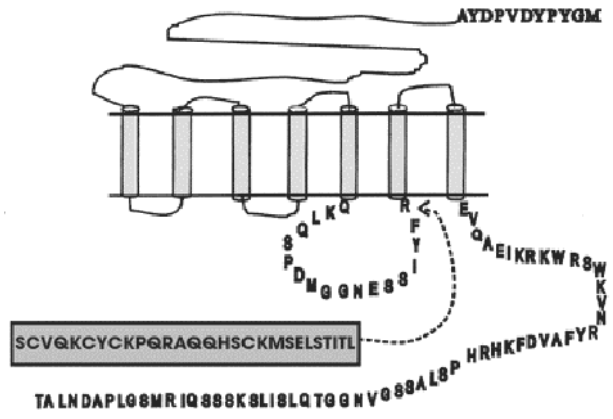

FIGURE 1 Structure of the heptahelical receptor for PACAP, PAC1. The receptor has seven transmembrane domains indicated by the cylinders and a long third intracellular loop. Splice variants are indicated in the shaded rectangle.

40-amino-acid third-loop insertion. These differences in the structure of the third intracellular loop may account for variations in signal transduction coupling to phospholipase C and differences in the tissue distribution of the splice variant. Additional splice variants, affecting either the N-terminus or the second and fourth exons, have also been identified and all of the human PAC1 receptor cDNA splice variants have been cloned. However, unlike the rat splice variants, differences in signal transduction coupling are not observed and the human gene is localized to chromosome 7, whereas in the rat it is localized to chromosome 4. What was observed was a higher efficacy for the hop variant, an intermediate coupling for the hip-hop splice variant, and a lower efficacy of the hip splice variant for coupling to phospholipase C.

The PAC1 receptor, unlike the VPAC1 and VPAC2 receptors, is coupled to a dual signal transduction pathway. A fourth transmembrane splice variant is not coupled to either adenylyl cyclase or phospholipase C yet couples to an L-type Ca^{2+} channel. The region of the native PAC1 shown to be responsible for signal transduction coupling is the COOH terminus, and two amino acids, Ser and Arg, appear to be coupled to signaling.

Localization of PAC1 Receptors

The PAC1 receptor appears to be expressed in both the CNS and peripheral tissues. In the CNS, the greatest density of receptors occurs in the hypothalamus (i.e., the supraoptic nucleus, periventricular nucleus, and lateral hypothalamus), with the predominant splice variant being the null variant without a splice variant cassette. In the retina, PAC1 has been detected and distributed in the inner plexiform layer. In peripheral tissues, the greatest density of PAC1 is in the adrenal medulla, where the predominant splice variant is the hop type; a similar predominance is found in the anterior pituitary. The human prostate gland contains PAC1 receptors that appear to be up-regulated in conditions such as benign hyperplastic prostate. PAC1 receptors are also present on germ cells of the testis as well as on spermatogonia and Sertoli and Leydig cells. PAC1 and VPAC1 receptors are expressed within the gastrointestinal (GI) tract; the PAC1 receptor is expressed on the gastric enterochromaffin like (ECL) cells and the VPAC1 receptor is expressed on the somatostatin-containing D cells and chief cells of the stomach. The liver appears to contain predominantly VPAC1 receptors. The smooth muscles of the GI tract contain VPAC1 and PAC1 receptors, and the PAC1 receptor has been described in the rat tanei coli. The PAC1 receptor has also been found in macrophages, and other PACAP receptor types have been described in a number of tumor cell lines. PAC1 receptor expression has been reported in human lung and breast cancer cell lines. Differences in splice variant expression of PAC1 receptors in pituitary tumors have also been demonstrated.

PHYSIOLOGY OF PACAP

Central Nervous System

Based on the high concentration of PACAP and its receptor, it would be expected that PACAP exerts significant neurophysiological effects. PACAP increases the activity level as well as amount of vasopressin release, and intracisternal administration of PACAP results in the release of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), prolactin, somatostatin, and the dopamine analogue 3,4-dihydroxyphenylacetic acid (DOPAC). In the pineal gland, there is a high concentration of PAC1, and PACAP can stimulate melatonin secretion. Given its expression in the hypothalamus, another potential action of PACAP is in the control of appetite. In cultured cell systems, PACAP has been shown to activate the c-fos, c-Jun, and mitogen-activated protein (MAP) kinase signaling system, indicating its role in regulating proliferation of cells. In cerebellar granule cells, PACAP appears to reduce apoptosis and have a protective effect against gp120 cultured neuroblasts, again supporting a role for this hormone as a neuroprotective factor.

Endocrine Organs

PACAP regulates the anterior pituitary to release growth hormone (GH), LH, follicle-stimulating hormone (FSH), prolactin, and adrenocorticotropic

hormone (ACTH). PACAP has been shown to stimulate somatotropic cells that release growth hormone in a way that is additive to the effects of growth hormone-releasing factor (GRF). PACAP acts synergistically with GnRH to stimulate the release of LH and FSH. No direct effect of PACAP has been shown on thyrotropic cells of the pituitary. The second major endocrine site of physiological activity is in the male and female reproductive tracts. PACAP has been localized to the smooth muscles of the female reproductive tract, where it plays a role in muscle relaxation. VPAC2 receptors have been identified in placental tissue, which was the site of initial cloning of the VPAC2 receptor. The ovary contains PACAP in the granulosa zone, where PACAP stimulates progesterone production in the preovulatory phase. PACAP and PAC1 receptors are expressed in large numbers in the male gonadal germ cells, and PACAP stimulates testosterone release in the epididymis and is involved in sperm release. A physiological reduction in PACAP may therefore play a clinical role in male impotence. Outside of the CNS, the highest concentration of PACAP is found in the adrenal gland, where PACAP is the most potent stimulator of catecholamine release.

Respiratory Organs

The major effect of PACAP in the respiratory tract is bronchodilation, an effect that is mediated primarily through the VPAC1 receptor. Expression of PAC1 in this system is unlikely.

Gastrointestinal Tract

PACAP-containing enteric nerve fibers are present and colocalized with PAC1 in the stomach and intestine. PACAP is the major neural regulator of gastric acid secretion and may account for the observed nocturnal increase in secretion. VPAC1 receptors are expressed on the surface of the D cell, where PACAP, along with galanin, inhibits acid secretion through the release of somatostatin from the gastric D cell (Fig. 2). Another important effect of PACAP is in the regulation of intestinal motility. PACAP acts mainly to promote VPAC1 receptor-mediated relaxation. In the rat colon, PACAP stimulates apamin-sensitive K^+ channels, leading to relaxation. The major colonic peristaltic reflex is mediated via VIP whereas the descending relaxation phase of intestinal peristalsis appears to be regulated by PACAP through the VPAC1 receptor. Another novel effect that has been discovered is related to nitric oxide synthesis and the interplay between the hormones VIP and PACAP, although the exact mechanism has not been discovered.

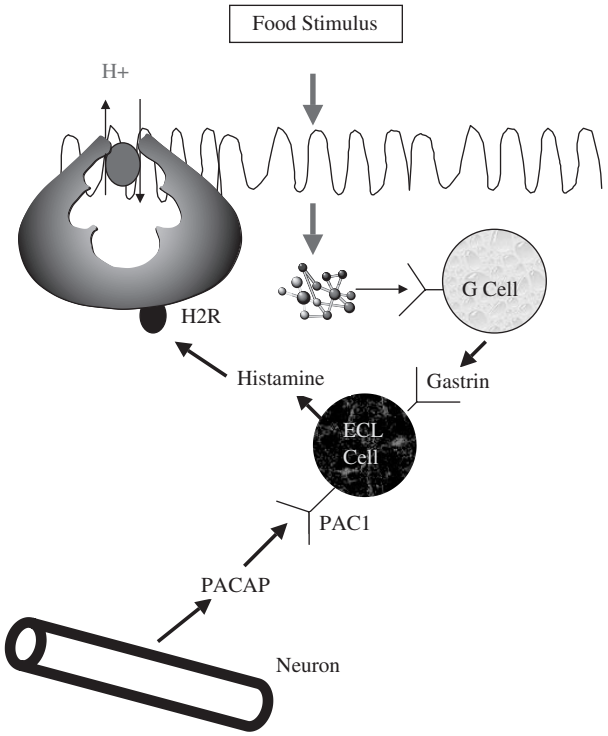

FIGURE 2 Model for the regulation of gastric acid secretion by the hormone PACAP. Released by neurons of the gastrointestinal enteric neural plexus, PACAP binds to the PAC1 receptors of nearby enterochromaffin-like (ECL) cells. PACAP stimulation of ECL cells triggers the release of histamine. Liberated histamine then binds to histamine-2 receptors (H2R) located on the surface of stomach parietal cells, thereby regulating gastric acid secretion.

Cardiovascular System

Similar to the respiratory system, the predominant effects of PACAP in the cardiovascular system occur through smooth muscle relaxation that is mediated through the VPAC1 receptor. In the cardiovascular system, PACAP relaxes smooth muscle through cAMP and protein kinase A, resulting in hypotension. In animals, PACAP administration results in a biphasic effect, with initial vasodilation and a later catecholamine release reflex causing an increase in blood pressure and heart rate. In cultured cardiac myocytes, PACAP exerts positive inotropic and chronotropic effects).

Immune System

The effects of PACAP on cell-mediated immunity have not been thoroughly investigated and only recently has the expression of PAC1 been discovered on lymphocytes. In mice, PACAP stimulates murine macrophages, which in turn stimulate T cell proliferation through VPAC1 receptors, thereby releasing

interleukin-10 (IL-10) and inhibiting IL-6 and IL-12 production. VIP and PACAP inhibit IL-2 transcription in T cells by inhibiting c-Jun. VIP and PACAP have been shown to inhibit nuclear factor κB (NF-κB) by inhibiting p65 nuclear translocation and NF-κB DNA binding. In macrophages, VIP and PACAP inhibit interferon γ (IFN γ)-induced activation of the Jak1/Jak2/STAT/IRF-1 signaling cascade.

Tumor Biology

The majority of the early work on pharmacology and signal transduction relied on tumor cells consisting of the AR42 J rat pancreatic cancer, NB-OK1, human astrocytoma, and PC-12 rat pheochromocytoma cell lines. In these cell systems, PACAP stimulates c-*fos*, c-*myc*, and c-*jun* and is a potent stimulator of cell proliferation. In human lung cancer cell lines, PACAP stimulates growth. Radioligand binding studies demonstrate expression of receptor in a large percentage of human tumors, including those of breast, prostate, pancreas, lung, colon, stomach, and liver as well as lymphomas and meningiomas.

CONCLUSIONS

PACAP is one of the most recently described neuropeptides and therefore very little is known about its function. Its physiological relevance in health and disease is now only beginning to be understood. Recent studies of gene deletion in mice may elucidate further the functional significance of the PACAP hormone and its receptor, PAC1.

hematochezia Passage of bloody stools.

lymphangioma Well-circumscribed nodule of lymphatic vessels; the vessels vary in size, are usually greatly dilated, and are lined with normal endothelial cells. They are most frequently found in the neck, axilla, arm, mesentery, and retroperitoneum.

necrotizing enterocolitis Extensive ulceration and necrosis of the ileum and colon in premature infants in the neonatal period; possibly due to perinatal intestinal ischemia and bacterial invasion.

pneumoperitoneum Presence of air or gas in the peritoneal cavity as a result of disease, but can also be artificially produced (i.e., postsurgical intervention).

pseudomembranous colitis Inflammation of the small and large bowels, with the formation and passage of pseudomembranous material in the stools usually secondary to *Clostridium difficile* toxin.

tenesmus Painful spasm of the anal sphincter, causing an urgent desire to evacuate the bowel or bladder and involuntary straining, with the passage of little fecal matter or urine.

volvulus Twisting of the intestine, causing obstruction.

Pneumatosis intestinalis is defined as multiple submucosal, subserosal, or muscularis gas-filled cysts in the wall of the gastrointestinal tract from the stomach to the rectum. Originally, these intramural cysts were referred to as pneumatosis cystoides intestinalis, but because a linear and curvilinear distribution of the cysts also exists, the term "pneumatosis intestinalis" is now used to include all intramural gas collections. The most common locations for these cysts are, in order of prevalence, the jejunum, ileocecal region, and colon. Other structures that can be involved include the mesentery, peritoneum, and falciform ligament.

INTRODUCTION

Pneumatosis intestinalis (PI) is an uncommon condition that has the highest incidence in the fourth through seventh decades of life. PI is usually an unexpected finding on plain abdominal and barium radiographs and is generally a benign condition. In fact, it is the most common cause of benign pneumoperitoneum. However, when associated with fulminant conditions such as hemorrhage or intestinal necrosis, PI has serious implications. In neonates, pneumatosis is frequently associated with necrotizing enterocolitis (NEC). As a result, it is important to recognize that the prognosis of patients with PI is a function of their underlying condition and management should be based on clinical grounds.

PATHOGENESIS

The cause of pneumatosis may be primary or secondary. The primary, or idiopathic, form is not associated with any other lesions and usually does not require

treatment. The secondary form has a variety of causes. The majority of cases, which are benign, are associated with chronic obstructive pulmonary disease (e.g., cystic fibrosis) or the immunocompromised state, (i.e., AIDS, high-dose steroid treatment, or chemotherapy). The more serious cases are classically related to conditions that cause bowel ischemia. A variety of related pulmonary and gastrointestinal (GI) disorders are listed in Table I and Table II. In the appropriate clinical setting, these conditions should be considered in the differential diagnosis of pneumatosis intestinalis.

The defining pathogenesis of pneumatosis is unknown, but as shown in Table III, several theories have been proposed. The proposed mechanisms can be summarized as follows:

- Primary: idiopathic cysts tend to resolve spontaneously, but can sometimes recur.
- Secondary:

A. The mucosal disruption hypothesis suggests that gas from the bowel lumen adjacent to the damaged mucosa dissects under pressure along the tissue spaces into the intestinal wall. Distant spread is thought to be through the mesentery. The mechanism for PI in collagen vascular disorders is unclear, but is likely related to vasculitis that eventually results in mucosal disruption.

B. Another mechanism suggests that the intestinal wall is penetrated by gas-forming organisms. For example, in bowel ischemia, there is microscopic infiltration of polymorphonuclear leukocytes with debris containing bacteria. Although this theory is based on strong clinical and experimental evidence, most cases of PI are not related to infection, and most cyst ruptures do not produce peritonitis.

C. Bacterial fermentation of carbohydrates may result in high intraluminal hydrogen tension. This hydrogen diffuses into the intestinal wall and attracts nitrogen, oxygen, and carbon dioxide from the blood. As a result, an intramural bubble, or cyst, is created, consisting of nitrogen as the other gases get absorbed.

D. A theory that explains the pulmonary causes of PI is the dissection of air from alveolar rupture along the bronchopulmonary bundles into the mediastinum, tracking along the major blood vessels into the retroperitoneum, and then along the mesenteric vessels to the visceral surface of the bowel.

E. Increased bowel wall permeability due to loss of structural integrity from the shrinkage of submucosal lymphoid tissue is a mechanism proposed to explain PI in immunocompromised patients.

PATHOLOGY

Other names for PI, cystic lymphomatosis and enteromesenteric emphysema, are based on pathologic appearance. Grossly, the cysts resemble cystic lymphangiomas, hydatid cysts, or sessile polyps. A thin layer of endothelial or simple cuboidal epithelial cell lines the cysts. The diameter of the cysts can vary, if the cysts grow, from a few millimeters to a few centimeters. On cross-section, the cysts can have a

TABLE II GI Conditions Associated with Pneumatosis Intestinalis

Peptic ulcer disease	Whipple's disease
Intestinal obstruction	Volvulus of stomach and sigmoid colon
Mesenteric vascular occlusion	Intestinal lymphosarcoma, leukemia, Hodgkin's disease
Acute necrotizing enterocolitis	Enteric feeding via needle catheter jejunostomy
Chronic inflammatory bowel disease (Crohn's disease, ulcerative colitis)	Jejunoileal bypass for obesity
Hirschsprung's disease	Postsurgical bowel anastomosis
Perforated diverticulum	Abdominal trauma
Appendicitis	Mucosa damage from caustic agent ingestion
Collagen vascular disorders (scleroderma, dermatomyositis, lupus)	After sigmoidoscopy, colonoscopy, or endoscopy
Immunocompromised (intestinal graft-vs.-host disease, organ transplantation, bone marrow transplantation, AIDS, steroids, chemotherapy)	Biliary stent perforation
	Sclerotherapy
Cytomegalovirus infection of the intestinal mucosa	Intestinal dysmotility
Intestinal parasites and tuberculosis	N_2O anesthesia
Diabetic enteropathy	Treatment with lactulose
	Systemic amyloiosis

"honeycomb" appearance without communication to the bowel lumen. This can be difficult to distinguish from dilated lymphatic channels, which have a similar appearance. The connective tissue surrounding the cysts usually consists of inflammatory changes. A fibrotic reaction can occur if the cysts do not spontaneously resolve, leading to their obliteration. Ultimately, this can lead to a rigid or dysfunctional intestinal wall. Puncture of these cysts during biopsy results in their collapse and sometimes a "popping" sound. Although variable, the pattern of the intramural cysts can aid in distinguishing the cause. A bubbly pattern is most common in necrotic bowel, whereas, in non-life-threatening causes the cysts are usually well localized, larger, and more spherical. They also tend to assume a linear or clusterlike pattern.

SIGNS AND SYMPTOMS

Symptoms are nonspecific and often depend on the location of the cysts and the extent of bowel involvement, especially in the primary form. Colonic cysts are common in the primary form and can result in crampy abdominal pain, hematochezia, mucus in stools, weight loss, diarrhea, tenesmus, and flatus. Steatorrhea has been reported in idiopathic small bowel cysts, but abdominal distension and vomiting are more common when the small bowel is involved. In the secondary form, symptoms are usually related to the associated disease. Cyst rupture, usually from the small bowel, is the most common cause of nonsurgical pneumoperitoneum that is not procedure related. In healthy patients with vague abdominal complaints and free air under the diaphragm, without evidence of a perforated viscous, PI should be suspected.

In 3% of the cases, indications require immediate intervention. These include volvulus, obstruction, hemorrhage, and intestinal perforation. Peritonitis can also occur, but is unusual. When PI complicates intestinal ischemia or pseudomembranous colitis, it should be regarded as an ominous sign. In neonates, one of the serious causes of PI is NEC. These babies often present with emesis, feeding intolerance, abdominal distension, increased gastric residuals, and bloody stools. Nonetheless, the physical exam can be misleading. The presence of abdominal free air can cause the abdomen to be tympanitic. Free air between the liver and diaphragm may obscure normal liver dullness on percussion. If the cysts are large, they may present as a palpable mobile mass. Cysts in the rectal wall can even be felt as firm nodules during a rectal exam.

DIAGNOSIS

Adults

Upright or decubitus plain abdominal radiograph or barium studies and computed tomography (CT) usually initially suggest the diagnosis. On plain radiographs, predominantly linear or segmentally clustered intramural air is seen (see Fig. 1). The cystic pattern does not consistently correlate with the severity of PI, but the location may suggest an underlying condition or predisposing factor. In the gastric wall, linear pneumatosis should raise the question of gastric outlet obstruction or mucosal disruption from prior intubation. A mottled cystic pattern has been associated with phlegmonous gastritis. Small bowel cysts have been associated with collagen vascular diseases. Colonic cysts are common in the idiopathic form, but are also present in the setting of colitis and ischemia. The latter becomes a grave sign when associated with portal venous gas (see Fig. 2).

FIGURE 1 Plain frontal radiograph of the abdomen. The arrowheads point to a linear pattern of PI secondary to inflammatory bowel disease in this 22-year-old patient complaining of abdominal pain. After steroid treatment, the patient's pain resolved and she was discharged home. Radiograph courtesy of Dr. Stephen Bloom.

FIGURE 2 Axial abdominal CT image without contrast. Portal venous gas is present throughout the hepatic veins in this 54-year-old female with sepsis (arrowhead). Shortly, after obtaining the CT, the patient continued to decompensate, developed shock, and then expired.

Procedures such as colonoscopy or sigmoidoscopy can result in linear colonic cysts. Air between the bowel loops may represent free air from a ruptured cyst, but a large mesenteric cyst can have a similar appearance. In the presence of isolated PI and pneumoperitoneum, idiopathic cyst rupture or ruptured pulmonary alveoli from prior general anesthesia administration should be considered. Pulmonary causes of PI also tend to be transient. On barium studies, radiolucencies indent the barium column as they line the intestinal wall, resulting in a smooth and undulating marginal pattern. CT with lung windows is probably the most sensitive tool in evaluating PI (see Fig. 3). Ultrasound (US) is another modality that can be used to make the diagnosis. On sonography, the intramural bubbles are seen as hyperechoic structures with shadowing, sometimes referred to as the "circle sign." Magnetic resonance imaging (MRI) can also aid in the diagnosis.

FIGURE 3 Axial abdominal CT image with contrast. Pneumatosis is present throughout the dilated large and small bowel (arrowheads) in this 45-year-old male with ischemic bowel secondary to infection. The patient was admitted and treated with antibiotics. Clinically, the patient improved and was eventually discharged home.

Pediatrics

NEC is a common GI emergency in neonates. The most common risk factor is prematurity. PI is present in 75% of patients with NEC and should be considered a diagnostic sign in the appropriate clinical setting. Although rare, patients with NEC can also have air in the gastric wall, known as pneumatosis gastralis, or emphysematous gastritis. No individual laboratory features are diagnostic or specific for NEC, which is why abdominal radiographs remain essential in the diagnosis and management of NEC (see Fig. 4). The presence of PI is considered a relatively early stage of NEC and can precede the clinical findings by several hours. The bubbly intramural gas collections can be confused with stool or meconium in a normal colon. Prone views or followup radiographs can help to make the distinction. In NEC, PI most commonly involves the terminal ileum and colon. It is usually associated with dilated bowel loops and an asymmetric bowel gas pattern. The cystic intramural

FIGURE 4 Plain frontal radiograph of the abdomen. This premature infant presented with abdominal distension. Note the diffuse pneumatosis throughout the bowel wall. The baby was treated for NEC.

pattern may present as linear stripes, a ring, or a localized cluster. If it occurs in a more diffuse pattern, it should be a marker for a more serious condition. Ileal involvement of PI can also simulate meconium ileus. Portal venous gas is usually associated with the more severe cases of NEC and heralds surgical intervention. Sonography of the portal vein during NEC will often show bubbles of gas traveling into the liver, where they collect anteriorly, giving a characteristic echogenic loss of definition of the normal liver structure.

Colonic PI has also been associated with Hirschsprung's disease. The presence of perinatal PI should also raise the question of congenital cardiac anomalies such as hypoplastic left heart. Patients with PI who are more likely to have a poor outcome are those with underlying congenital heart disease and tissue transplants. Graft-versus-host disease, colitis, and bowel ischemia are also ominous preceding events. Contrast enemas, which are not routinely performed because of the risk of perforation, especially in NEC, show mucosal irregularity and edema. Additional causes of pediatric PI include complications of chemotherapy for leukemia and lymphoma and cardiac surgery (as listed in Table IV). The disappearance of PI or portal venous gas does not always correlate with clinical improvement. The only universally agreed indication for surgery when clinical suspicion of NEC is high is pneumoperitoneum, which is not always present in all babies with a perforation.

Several conditions may be included in the differential diagnosis of PI. However, the presence of specific secondary findings helps to differentiate PI. For example, unlike PI, enterogenous cysts are usually single. Nodules of lymphosarcoma may clinically resemble PI, but on imaging studies they are not radiolucent. The reversible thumbprint-like deformity of the mesenteric border in bowel ischemia can sometimes be misinterpreted as PI. Infectious etiologies or pseudomembranous colitis should be correlated with the clinical presentation. Mucosal polyps on barium studies result in intraluminal filling defects as opposed to the smooth, scalloped margins of PI. Crohn's colitis and ulcerative colitis also result in barium filling defects, but without cystic lucencies. It is important to realize that any of the related conditions mentioned here can be included in the differential assessment of PI, but it is the clinical setting that should guide the correct diagnosis.

TABLE IV Pediatric Conditions Associated with Pneumatosis Instestinalis

Necrotizing enterocolitis (usually involves the terminal ileum, colon)
Hirschsprung's disease
Congenital cardiac anomalies (i.e., hypoplastic left heart)
Graft-versus-host disease
Ischemic bowel
Postchemotherapy for leukemia and lymphoma
Postcardiac surgery

MANAGEMENT AND CONCLUSION

PI is generally an asymptomatic benign entity, but on rare occasions can also be serious. In the absence of intestinal inflammation or necrosis or a high white blood count, and with a benign physical exam, conservative treatment is safe. Hyperbaric oxygen to decompress the cysts and antibiotics have demonstrated some efficacy, but watchful management can be sufficient. When a life-threatening complication such as bowel perforation, obstruction, hemorrhage, or intestinal ischemia occurs in the setting of PI in the adult or pediatric population, immediate surgical intervention may be crucial to the patient's outcome.

Polyamines

SHIRLEY A. MCCORMACK AND LEONARD R. JOHNSON
University of Tennessee Health Science Center

antizyme An enzyme homologue of ornithine decarboxylase capable of binding and inhibiting it.
apoptosis An endogenous program of cellular reactions that results in cell death without allowing toxic degradation products to be released into the cellular milieu.
confluent Cells in culture at high density and in contact with one another so that there are no empty spaces.
cytoskeleton The inner framework of the cell. It maintains and adapts cell shape, makes directed migration possible, and provides strength and organization for cellular functions.
dimer A molecule made up of two identical units.
down-regulating Reducing the level of a product by inhibiting its synthesis, degrading it, or transporting it out of the cell.
filopodia Narrow spike-like extensions of cell borders in cells that are not necessarily migrating.
focal adhesions Concentrated patches of stress fibers, associated proteins, and integrin receptors on the plasma membrane by which integrins attach to the extracellular matrix.
lamellipodia Wide wave-like extensions of the cell border in migrating cells.
lamina propria A layer of mostly fibroblastic cells that forms the extracellular matrix for epithelial cell attachment. It lies between the epithelium and the muscularis.
neoplastic Rapidly growing cells that are not necessarily transformed.
organelles Small intracellular "organs" that perform specialized tasks.
overexpression Production of excessive amounts of a product by cells because extra copies of the gene encoding the product have been introduced into the cell chromosomes.
26S-proteosome A specialized lysosome in cytoplasm that degrades discarded molecules.
subconfluent Cells at low density that have not yet formed a continuous layer.
transfected Cells with artificially introduced genes in their chromosomes.
transformed Cells with altered DNA that have lost normal regulatory control.
villi Finger-like projections of mucosa covered with differentiating epithelial cells that increase the absorptive area of the intestine.

Although polyamines are required in a large, but still unknown, number of the most basic functions in all forms of eukaryotic and prokaryotic life, an understanding of their participation in the life of the cell has been many years developing. With every discovery of another biological function that requires them, an entirely new interdependent set of cellular reactions previously unsuspected is found. This article attempts to describe the current knowledge of polyamines in the cellular physiology of the gastrointestinal mucosal epithelium.

INTRODUCTION

A Brief History of Polyamine Discovery

During the period of the Scientific Revolution, Antonie van Leeuwenhoek, using an early microscope, began to explore the previously invisible world of various plant and animal samples. In 1678, he wrote a now famous letter to the Royal Society of London in which he reported observing sperm as well as a slowly crystallizing substance in human semen. Two hundred forty-six years later, the "slowly crystallizing" substance was identified as spermine phosphate and the letter became the earliest documented record of a polyamine.

As chemistry evolved from alchemy, the gases oxygen, carbon dioxide, and nitrogen were fractionated from air. Methods were developed for their analyses and studies of oxidized and reduced nitrogen (ammonia) followed. In 1838, F. Wohler converted ammonium cyanate to urea. His studies led to the detection of nitrogen in more complex compounds such as uric acid, allantoin, and asparagine and established organic chemistry as a new field of chemistry. Organic chemistry, in turn, revealed the structures of the amines and polyamines and resulted in the development of other branches of chemistry, i.e., analytical chemistry, pharmacology, biochemistry, microbiology, and immunology. The beer and wine industries, searching for new methods to improve fermentation and avoid spoilage, isolated and identified the basic amino acids arginine, lysine, and ornithine and other amino acids soon followed. Other key discoveries were the structural role of nitrogen, an ornithine cycle in mammalian liver, and specific amino acid decarboxylases and oxidases. Spermine, cadaverine, putrescine and spermidine were

identified in 1881, 1886, 1889, and 1927, respectively. After that, further progress toward understanding their biological functions stalled until the 1960s when biochemists began to investigate the structure of polyamines in relation to their effects on organ function, animal metabolism, and nutrition. Research on polyamines has greatly accelerated in recent years. Over the period 2001 to 2002 alone, the National Library of Medicine lists more than 1000 reports dealing with polyamines.

The authors have borrowed much of this short history of polyamines from their first observation to the period ending with World War II from a detailed timeline published as an appendix in the 1998 book *Polyamines* by Seymour S. Cohen (see Further Reading).

The Distribution of Polyamines in Nature

Originally, biologists thought that spermine was found only in higher eukaryotes and that prokaryotes had only putrescine and spermidine. As an increasing variety of microbes, plants, and animals were investigated, many exceptions appeared. For example, in prokaryotic thermophilic microbes, nucleic acids are distorted by hydrogen bonding at the temperatures at which they live (65–75°C) and proteins can be synthesized only when the nucleic acids are bound to spermine. Some halophiles living in very-high-salt environments lack polyamines entirely. Eukaryotic photosynthetic algae, yeast, and slime molds contain putrescine and spermidine but often do not contain spermine. Spermine is absent in protozoa and shrimp but present in mollusks, arthropods, echinoderms, and tunicates. Unusual polyamines, i.e., hydroxypolyamines, branched tertiary polyamines, and quaternary polyamines, are found in prokaryotic thermophilic microbes and in some eukaryotic animals. Even more unusual are two eukaryotes, the plant *Arabidopsis thaliana* and the protozoan *Trypanosoma cruzi*, neither of which has ornithine decarboxylase (ODC), the rate-limiting enzyme that controls the biosynthesis of polyamines. Putrescine, spermidine, and spermine are present in all cells of all vertebrates.

BIOCHEMISTRY

Polyamine Structure

The four basic polyamines in mammals and in human are putrescine, cadaverine, spermidine, and spermine. Putrescine and cadaverine are primary diamines, 1,4-diaminobutane, and 1,5-diaminopentane, respectively. Cadaverine is usually a product of bacteria in the gut. Strictly speaking, the diamines are not polyamines, but they are often included with the polyamines for the sake of convenience. Spermidine is a triamine and spermine is a tetramine. Both contain primary and secondary amines (R_1R_2NH). Other natural polyamines that include tertiary (R_3) and quaternary (R_4N^+OH) amines have been found as have moieties with one carbon less than the usual 1,4-diaminobutane, called norspermidine or norspermine.

Biosynthesis of the Polyamines

Three key enzymes, all with short half-lives, are responsible for the biosynthesis of the natural polyamines, putrescine, spermidine, and spermine (see Fig. 1). The three enzymes are ODC, *S*-adenosylmethionine decarboxylase (AdoMetDC), and spermidine/spermine acetyltransferase. ODC is the rate-limiting enzyme because, by decarboxylating ornithine to synthesize putrescine, it provides both an active polyamine and a precursor of other polyamines. AdoMetDC decarboxylates *S*-adenosyl methionine to make spermidine by transferring its aminopropyl moiety to putrescine and, by another aminopropyl transfer to spermidine, to make spermine. Spermidine/spermine acetyltransferase regulates polyamine interconversion and allows cells to adjust the levels of the three polyamines. The higher eukaryotes also have another pathway by which, with acetylation and oxidation, spermine can be converted to spermidine and spermidine to putrescine. Spermidine synthase, spermine synthase, and polyamine oxidase, an enzyme that oxidatively splits the monoacetyl derivatives of spermidine and spermine, are usually present in excess and are not rate-limiting under physiological conditions. In nontumorigenic rapidly dividing cells such as embryonal cells and gut mucosal cells, ODC synthesizes transient high levels of putrescine. In nonproliferating cells, AdoMetDC provides a basal level of putrescine by conversion from spermidine. Research on the structure of ODC has shown that it is a dimer of 52 to 55 kDa subunits and is well conserved in eukaryotes from fungi to humans. In addition, it has been crystallized and found to be a group IV pyridoxal phosphate-dependent enzyme.

POLYAMINE REGULATION

How Is ODC Regulated?

The response of ODC to hormones or growth factors in tissues and cultured cells is typically a rapid 10- to 100-fold increase in ODC activity followed by an equally rapid decrease even before the cells begin DNA synthesis. The speed and extent of these responses were unexpected and investigators have wondered

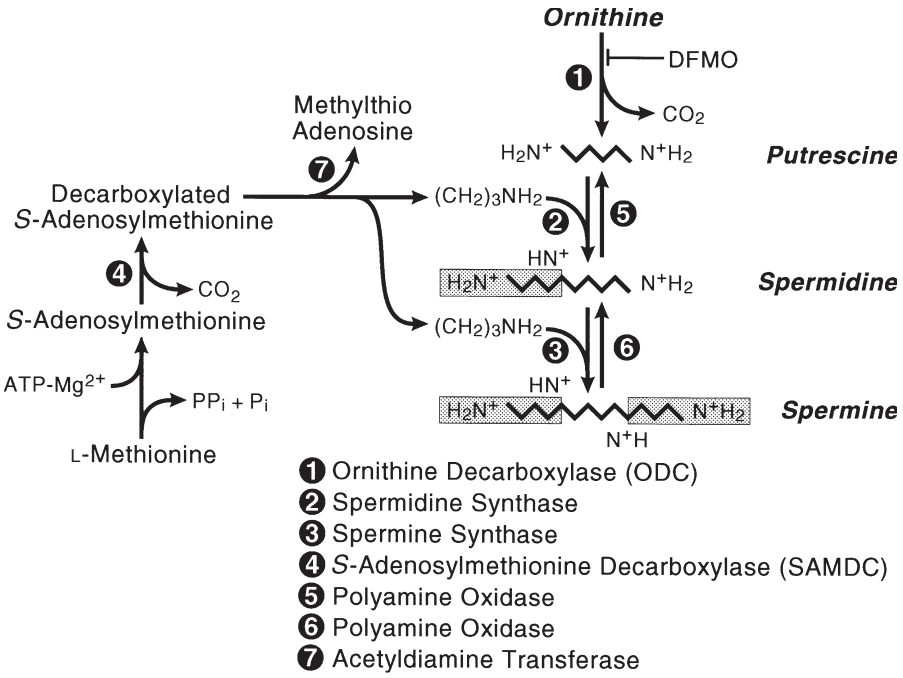

FIGURE 1 The biosynthesis of the major physiological polyamines and their precursor, putrescine. The polyamines are shown in shorthand representation, i.e., putrescine is $H_2NCH_2CH_2CH_2CH_2NH_2$. Thus, putrescine has 4 CH groups, spermidine has 7, and spermine has 10. They carry two, three, and four positive charges that reflect the strength of their ability to bind to anions. The enzymes involved in the reactions are numbered. Reprinted from McCormack, S. A., Ray, R. M., and Johnson, L. R. (2002).
