FOREWORD

People of my age often have mixed emotions about encyclopedias, probably because they conjure up memories of writing high-school term papers and reading from 26-volume encyclopedias in the library. Those individuals who came of age in the computer era may not fully understand to what I am referring. As I have grown older, I have rediscovered the usefulness of encyclopedias, especially those comprising only 1, 2, or 3 volumes. My favorite for general knowledge is the *Columbia Encyclopedia*, which was first published in 1935 and is now in its fifth edition. I have used this encyclopedia on many occasions. For example, while developing a Grand Rounds lecture on celiac disease, I discovered that the disease was described exceedingly well in the second century A.D. by Aretaeus the Cappadocian. Where is Cappadocia? Is it an ancient city of Greece? Knowing that someone would ask me these questions, I consulted the *Columbia Encyclopedia* and learned that Cappadocia was the ancient Hittite state located in what is now central Turkey. Recently, I was asked to be on the thesis committee of a young doctoral candidate in our Institute for Medical Humanities. His dissertation proposal referred to philosophies (e.g., hermeneutics and phenomenology) that I had never heard of. These topics were described in the *Columbia Encyclopedia* in a brief capsule format that did not overwhelm my untrained and uneducated mind. Therefore, I have become a fan of small-volume encyclopedias. They are quite useful.

Why, then, has a publisher not produced such encyclopedias for the fields of medicine and the biological sciences? In fact, indeed one has. Elsevier has published several such encyclopedias, including *The Encyclopedia of Cancer* (now in its second edition), *The Encyclopedia of Hormones*, and *The Encyclopedia of Toxicology*. Now, under the leadership of Editor-in-Chief Leonard R. Johnson, Ph.D., a respected gastrointestinal scientist, educator, editor, and author, Elsevier has published *The Encyclopedia of Gastroenterology*. Dr. Johnson has assembled a cadre of 15 Associate Editors, each a highly respected expert in one or more of the topics featured in the book. They have brought together over 700 authors to write 477 separate articles, divided into three volumes.

These articles go a long way toward covering the entire gamut of gastroenterology and hepatology and do so in an expert fashion. They cover gastrointestinal and hepatic diseases, as well as syndromes, diagnostic and treatment modalities, and physiological and pathological processes. Where necessary, discussions of some of the diseases are divided into separate articles describing the condition in pediatric patients and adult patients. The articles are easy to read, yet comprehensive, and usually encompass both the basic science and the clinical aspects of that disease or process. Each article begins with a glossary of terms that allows the uninitiated to read the article by filling in gaps in understanding; a brief abstract that gives a concise, but comprehensive, overview of the subject matter follows the glossary.

Modern gastroenterology and gastrointestinal science lend themselves well to an encyclopedia format. Gastroenterology is a broad clinical field comprising issues that concern human behavior and psychology, other disciplines that are useful for understanding functional gastrointestinal diseases, such as dyspepsia and irritable bowel syndrome, and very technical sciences that encompass endoscopy as a diagnostic and therapeutic tool and often surgery as definitive treatment. In the middle of the spectrum is classical internal medicine as it relates to the gastrointestinal tract and liver. Furthermore, the behavioral, medical, endoscopic, and surgical approaches may differ considerably for pediatric patients versus adult patients.

As regards basic gastrointestinal science, the gastrointestinal tract does more than simply process and assimilate nutrients and water through the action of its digestive enzymes and secretory and absorptive processes. Gastrointestinal science also encompasses diverse fields such as endocrinology, immunology, and the neurosciences. If all the endocrine cells of the gastrointestinal tract were combined into one organ, it would be the largest endocrine organ in the human body. Similarly, the mucosal immune cells and the gastrointestinal-associated lymphatic tissue together constitute perhaps the largest organ of the immune system in the body. Furthermore, this entire, complex epithelial, secretory, absorptive, endocrine,

and immunological organ is controlled by its own intrinsic brain and nervous system, the enteric nervous system.

Gastroenterology is made even more complicated by the frequency with which diseases of this system occur and by its close relationship to other disciplines. Gastrointestinal cancer is the second most common type of cancer, if men and women are considered together. The broad field of nutrition borders closely on and is intertwined with gastroenterology. Finally, the intestinal tract is colonized by commensal microbiota that are crucial for optimal health. Little is known about these microorganisms, but it is beginning to be understood that they may be a vehicle for the treatment or prevention of disease through probiotics.

This broad view of gastroenterology and gastrointestinal science must have made it difficult for the Editors to choose the individual articles that make up these three volumes. However, I find the list to be fairly complete and each article to be a good mixture of basic knowledge and clinical information. If certain subject areas are not represented as specific articles, they are reasonably well covered in other articles that are in the three volumes and can be located in the subject index at the end of the third volume.

Who will use *The Encyclopedia of Gastroenterology* and why? I believe that the range of potential users is wide. For example, medical students often have difficulty with medical textbooks. Either the textbooks are too advanced and the various words and terms are not explained, making it difficult for the student to comprehend the text, or else the content has been reduced to a "mini" textbook version that often lacks substance. I believe that many of the entries in this encyclopedia are geared perfectly for medical students new to clinical medicine. The glossary of terms at the beginning of each article and the abstracts should be extremely helpful for those who are medically naive. Furthermore, the articles are well-crafted combinations of basic science and clinical science and this is useful at the medical student level.

Physicians from other disciplines will undoubtedly find *The Encyclopedia of Gastroenterology* to be a valuable reference work. The explosion of medical knowledge has made it difficult, if not impossible, to keep up with advancements in other areas of medicine. This encyclopedia provides concise descriptions of the various gastrointestinal diseases that are easily readable, complete, and up-to-date. This should be quite useful for the primary care physician or a specialist in another discipline who needs to know about some specific gastrointestinal disease or process.

Basic scientists and nonphysician translational research scientists would certainly benefit from this encyclopedia also. For instance, the mixture of basic science and clinical science information in each article is precisely what the basic scientist needs as he or she writes the Introduction or Discussion sections of publications or the Background section of grant applications. In addition, the encyclopedia would prove quite valuable in rapidly bringing scientists up to date in a specific area of gastrointestinal disease. In this era of transgenic animals, it is not uncommon for the scientist who has been conducting research in a specific field, for example, immunology or rheumatology, to create a new knockout mouse that presents with a gastrointestinal phenotype rather than a rheumatological phenotype. Thus, the scientist who has spent his or her career gaining an understanding of rheumatologic disease will need to quickly acquire a basic understanding of Crohn's disease and ulcerative colitis.

Finally, the gastroenterologist or gastrointestinal scientist can certainly utilize this encyclopedia as well. It is impossible to stay abreast of all areas of gastroenterology and gastrointestinal science and yet the overlapping disciplines within gastroenterology may demand a more detailed knowledge of an otherwise distant field of expertise. Thus, I look forward to having these three volumes on my bookshelf. They will be helpful in my clinical practice of gastroenterology and also helpful to me as a scientist and to other research scientists in my laboratory.

In summary, the Editors should be proud of their contribution to the knowledge base of gastroenterology. They have found a niche in our field that has hitherto not been occupied. There will continue to be a need for more elementary dictionaries and for highly detailed, advanced textbooks and monographs. *The Encyclopedia of Gastroenterology* will play a role in the middle of this spectrum and should be extremely valuable to a wide range of users. I believe that the three volumes will find their way onto the bookshelves of most medical libraries, as well as those of individual practitioners of medicine and active gastrointestinal investigators. *The Encyclopedia of Gastroenterology* is an extremely useful addition to our field.

PREFACE

The *Encyclopedia of Gastroenterology* bridges basic science and clinical gastroenterology in a way that should appeal to the expert researching a topic outside his or her field of expertise as well as to students and the educated public. Although some articles on the basic medical sciences stand alone, most integrate these topics with areas of clinical medicine. These volumes appear at a time when general interest in, and knowledge of, the gastrointestinal tract is expanding at a rapid rate. Research has led to new approaches in the treatment of many gastrointestinal diseases and a plethora of new drugs have been added to the pharmaceutical armamentarium. Diagnostic procedures have advanced remarkably over the past few years, leading to an increased understanding of how diseases develop and an improved ability to detect them.

The reader will find articles related to all areas of gastroenterology. There are articles covering basic physiology, pharmacology, anatomy, immunology, and microbiology. Others relate these basic fields to specific diseases. Many of these articles are entitled with the name of a disease or pathological condition. When appropriate, nutritional aspects of clinical conditions are emphasized and several articles feature aspects of nutrition. Areas of parasitology of special importance in relation to the gastrointestinal tract are also covered. Separate articles treat topics relating primarily to pediatric gastroenterology and numerous entries are concerned with radiology, endoscopy, and surgery.

The articles are written and organized to serve as convenient, yet comprehensive sources of information. Each of the 477 entries begins with a glossary of cross-referenced terms followed by a brief abstract. Generous use of primary and secondary headings allows the reader to locate material rapidly. Tables and figures emphasize important points and concepts. Each article presents core knowledge, time-tested and generally accepted within the field. As a result, there are no specific references with the entries. Each contribution, however, concludes with a list of references for further reading. Many of these are review articles with comprehensive bibliographies.

This work began with the selection of a number of general areas of coverage. A group of 15 Associate Editors, each of whom is an expert in at least one of these areas, was subsequently recruited. The entire group, along with members of the Elsevier staff, then met for two days in San Diego. That meeting resulted in the refinement of the areas of coverage, selection of individual article topics within those areas, and identification of potential authors. The Associate Editors and I believe that we have covered the important topics of basic and clinical gastroenterology. Each article is written to stand alone as a complete subject, so there is, no doubt, a certain amount of overlap. This, however, should make it easier for the reader to locate a specific piece of information.

A product of this magnitude represents the knowledge and efforts of a large number of individuals. More than 600 authors contributed their expertise to the individual articles. I am especially grateful to those who produced articles on short notice, so that our deadline could be met. An outstanding group of 15 Associate Editors was the foundation for this project. Due to their great breadth of knowledge, they were able to propose topics for articles and recommend the authors to write them. They then recruited the authors and edited the completed articles.

Finally, I acknowledge the contributions of the staff at Elsevier. The *Encyclopedia of Gastroenterology* was initiated and supported by Jasna Markovac, Sr. vice President, Elsevier, Science and Technology. Nick Panissidi, Senior Developmental Editor, was indispensable as he contacted authors and kept up with all article submissions. Pat Gonzalez served as Production Manager, and Tari Paschall, Sr. Publishing Editor, and Judy Meyer, Associate Publishing Editor, provided overall management of the project.

Abdominal Aortic Aneurysm

GORAV AILAWADI AND GILBERT R. UPCHURCH, JR.
University of Michigan, Ann Arbor

abdominal aortic aneurysm Permanent dilation of the abdominal aorta at least 50% greater than the expected normal diameter.
arteriomegaly Diffuse arterial enlargement more than 50% above normal.
dissecting aneurysm Type of aneurysm that dissects; although aneurysms rarely dissect, a dissection may lead to aneurysmal changes over time.
ectasia Arterial dilation less than 50% of expected normal diameter.
false aneurysm (pseudoaneurysm) Type of aneurysm that involves a disruption of the arterial wall with containment by surrounding tissue or hematoma.
fusiform aneurysm Spindle-shaped aneurysm.
infrarenal aortic aneurysm In the anatomic classification scheme, limited to aorta below the renal arteries.
pararenal aortic aneurysm In the anatomic classification scheme, comprising a juxtarenal aneurysm (near, but not involving, the renal artery orifices) or a suprarenal aneurysm (involving the renal arteries but not the superior mesenteric artery).
saccular aneurysm Eccentrically shaped aneurysm.
thoracoabdominal aneurysm In the anatomic classification scheme, involving the suprarenal mesenteric vessels; may also involve the descending thoracic aorta in the chest.
true aneurysm Type of aneurysm that involves all three layers of arterial wall.

Abdominal aortic aneurysms are a disease primarily of elderly, Caucasian males; rupture risk correlates with aneurysm size. Elective repair is generally undertaken in patients with an abdominal aortic aneurysm of 5–5.5 cm. Unexplained abdominal or back pain should raise suspicion for aortic rupture. Aortic rupture carries a significant mortality.

NATURAL HISTORY

Abdominal aortic aneurysms (AAAs) are the 15th leading cause of death in the United States. AAAs have a 4 : 1 male : female predominance and are 3.5 times more common in Caucasians than in African-Americans. Nearly 90% of aortic aneurysms are infrarenal. A 5-cm aneurysm generally carries a 25–30% 5-year rupture risk, and increasing aortic size carries substantially higher risks of rupture. Ruptured AAAs result in an overall mortality of greater than 75%, with nearly one-half of these patients dying prior to reaching a hospital. Risk factors for rupture include smoking, hypertension, chronic obstructive pulmonary disease, and aneurysm size. Current recommendations are conservative management until an AAA reaches 5–5.5 cm, when the risk of rupture is greater than the risk of elective repair.

SIGNS AND SYMPTOMS

The majority of patients with AAAs are asymptomatic, and only approximately 50% of AAAs are detectable on physical exam. Many are discovered incidentally during workup for unrelated problems. The classic triad of a ruptured AAA includes a palpable pulsatile abdominal mass, hypotension, and abdominal or back pain.

SCREENING AND DIAGNOSIS

Ultrasound is an excellent screening test in an asymptomatic patient suspected of having an AAA. In preparation for AAA repair, patients often undergo an abdominal computer tomography (CT) scan with intravenous contrast to delineate the extent of the aneurysm. In addition, a CT scan with three-dimensional reconstructions may help to determine the feasibility of endovascular AAA repair (Fig. 1). Patients with significant azotemia may undergo magnetic resonance angiography to avoid the risk of contrast nephropathy. An aortogram is performed when concurrent renal or mesenteric disease is suspected.

AAA REPAIR

Charles DuBost performed the first aortic aneurysm repair in 1951 using an aortic homograft. With their contributions, DeBakey, Cooley, and Crawford improved outcomes of modern AAA repair. Despite improved survival with elective AAA repair, emergent

ruptured AAA repair is still associated with a high mortality rate. Endovascular treatment with aortic stent grafts, first performed in 1991, has become an option in patients who meet specific anatomic criteria.

POSTOPERATIVE COMPLICATIONS

Myocardial infarction and pulmonary failure may occur following AAA repair. Postoperative complications specific to the gastrointestinal system include ischemic colitis and aortoduodenal fistula. Early postoperative signs of abdominal pain, distension, or bloody stools should prompt immediate evaluation with flexible sigmoidoscopy. Aortoduodenal fistula is a late complication following AAA repair and is mainly due to erosion of the proximal aortic suture line into the duodenum. Hematemesis or hematochezia should prompt upper endoscopy in any patient with an AAA or a history of AAA repair.

Achalasia

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

achalasia Failure of the smooth muscle of the digestive tract to relax.
gastrointestinal sphincter A ring of circular muscle that contracts continuously and closes the lumen of the alimentary canal.
lower esophageal sphincter A ring of circular muscle that closes the orifice between the esophagus and the stomach.
sphincter of Oddi A ring of circular muscle that closes the entry of the bile duct into the small intestine.

The term achalasia is derived from the Greek word *chalasis*, which in English translates to relaxation. Achalasia is defined as failure of relaxation of the smooth muscle in any region of the digestive tract. It is most commonly applied to describe failure of relaxation in the various sphincters in the gut. Sphincters are regions where the circular muscle coat normally persists in a continuous state of contraction that produces a ring-like closure of the lumen. Sphincters function to prevent the back flux of lumenal contents from one digestive compartment to another. Prevention of the backward movement of the acidic contents of the stomach into the esophagus is an example of sphincteric function.

A nervous mechanism relaxes the sphincters with appropriate timing to open the lumenal orifice and permit passage from one compartment to the next. Relaxation is transient, with contraction and closure occurring after passage of the material through the sphincter. During a swallow, the lower esophageal sphincter relaxes to permit passage into the stomach. Emptying of the stomach occurs during transient relaxation of the sphincter located at the junction with the small intestine. Delivery of bile from the gallbladder to the small intestine occurs during relaxation of the sphincter of Oddi located at the opening of the bile duct into the small intestine. Passage of contents from the small intestine into the large intestine takes place during relaxation and opening of the sphincter that separates the two dissimilar compartments. The internal anal sphincter relaxes to permit passage of feces during defecation and then closes to prevent inopportune release of the contents of the large intestine. An obvious consequence of achalasia in any of these sphincters is obstruction of the forward passage of lumenal contents from one compartment to another.

PHYSIOLOGY

The specialized physiology of the sphincteric circular muscle coat accounts for the ability of the muscle to sustain contraction. The contractile apparatus of these smooth muscles consists of the two proteins actin and myosin. Contraction occurs during formation of cross-bridges between actin and myosin filaments. Contractile tension is maintained by a "catch" mechanism that latches the cross-bridges in place without expenditure of additional energy. Input from the nervous system leads to uncoupling of the cross-bridges, relaxation of contractile tension, and opening of the sphincter. The nervous input involves the release of chemical neurotransmitters at neuromuscular junctions.

Sphincteric muscles are innervated by motor neurons in the enteric nervous system. Most of the motor neurons to the sphincters are inhibitory motor neurons. Firing of nerve impulses by the inhibitory motor neurons releases inhibitory neurotransmitters at their junctions with the smooth muscle fibers of the sphincter. Two important inhibitory neurotransmitters are vasoactive intestinal polypeptide and nitric oxide. These neurotransmitters act to inhibit contraction of the smooth muscle and open the sphincter. Decisions as to when to open a sphincter are made by integrative neural networks located either in the central nervous system or in the gut itself. The neural networks control the firing of the inhibitory motor neurons. The inhibitory motor neurons are silent most of the time and the contractile behavior inherent in the muscle holds the sphincter in a closed state. Activation of the inhibitory motor neurons releases contractile tension in the muscle and the sphincter opens. Contractile tension redevelops and the sphincter closes coincident with cessation of motor neuronal firing.

PATHOGENESIS

Sphincteric physiology predicts that loss of the inhibitory motor innervation will result in achalasia. The inherent contractility of the sphincteric musculature keeps the sphincter closed and opening cannot occur when the inhibitory innervation is missing. The pathophysiologic result is an obstruction to passage of the lumenal contents through the sphincter. Material accumulates and dilates the digestive canal proximal to the sphincter because propulsive motility generally moves lumenal contents in the direction from mouth to anus. Achalasia in the sphincter between esophagus and stomach (i.e., the lower esophageal sphincter) can lead to a gross dilation of the esophagus described as a megaesophagus. Likewise, achalasia in the internal anal sphincter obstructs the passage of feces and can lead to a megacolon. Achalasia in the sphincter of Oddi obstructs the delivery of bile to the small intestine and can lead to overdistension of the biliary tree that is experienced as pain in the right upper abdominal quadrant.

Loss of the inhibitory innervation occurs in parallel with generalized dystrophy in the enteric nervous system that may be acquired or congenital. The most commonly acquired form reflects an autoimmune attack on the enteric nervous system that may be related to the presence of a tumor elsewhere in the body, may be related to an infectious agent, or may be idiopathic in nature. Autoimmune attack on the enteric nervous system occurs in association with small cell carcinoma of the lung. This is called paraneoplastic syndrome and occurs when the immune system attacks antigens on the surfaces of enteric neurons that are similar to antigens expressed by the tumor cells. Tests in patients with lower esophageal sphincter achalasia indicate that a significant proportion of these patients have circulating antibodies that react with enteric neurons. Achalasia in Chagas' disease is similar to paraneoplastic syndome in that antigenic epitopes expressed by the blood-borne parasite *Trypanosoma cruzi* are sufficiently similar to antigens on enteric neurons that an immune response to enteric neurons follows the response to the parasite.

Congenital absence of enteric neurons, including inhibitory motor neurons, occurs in Hirschsprung's disease. Mutations in Ret and endothelin genes prevent the fetal development of the enteric nervous system in a variable length of large intestine including the internal anal sphincter. The internal anal sphincter is achalastic and presents an obstruction to the passage of feces. A megacolon develops as feces accumulates proximal to the neurally deficient segment.

Aging

MAKAU LEE
University of Mississippi Medical Center

aging Postmaturational changes occurring between middle age and old age, resulting in reduction of the functional capacity of the physiological systems and increase of the vulnerability of an organism to challenges and diseases.
digestive system Organ system responsible for digestion and absorption.

Aging, the postmaturational changes occurring between middle age and old age, reduces the functional capacity of the physiological systems and increases the vulnerability of an organism to challenges and diseases, thereby increasing the likelihood of death.

PHYSIOLOGY OF AGING

There are numerous theories of aging; and they can be classified into two main categories: the "programmed" theories, which view aging as the result of a predetermined genetic blueprint, and the "wear and tear" theories, which view aging as the consequence of continual stress and injuries. Although none of the theories of aging can singularly explain the aging process, available data indicate that the ultimate mechanism of aging is that of molecular changes: all of the changes involve both informational molecules (such as DNA and RNA) and structural molecules (such as lipids, carbohydrates, and proteins) in a process that is determined genetically and epigenetically.

Both clinical and basic investigations have demonstrated that aging is associated with specific physiological and structural changes in the digestive system. These age-related changes in the digestive system may contribute to the development of various digestive disorders that are more common among the elderly. In the clinical setting, when symptoms and signs occur in elderly patients, the physician must differentiate age-associated physiological changes from the consequences of diseases.

AGING AND OROPHARYNGEAL STRUCTURES

Age-related physiological changes in oropharyngeal structures include structural alterations (such as thinning of the tongue, involving both mucosa and muscles, and weakening of muscles of the mouth and pharynx) and functional changes (such as alterations in pharyngeal sensation, proprioception, and taste acuity; discoordination of masticatory muscles, resulting in prolonged swallowing; and altered peristaltic response after deglutition). Manometric studies have shown that upper esophageal pressure is decreased and upper esophageal sphincter relaxation after deglutition is delayed in the elderly. Salivary output and flow remain unchanged in the elderly.

Clinically, these age-related changes in oropharyngeal structures may affect the elderly patient's ability to swallow liquids and may lead to reduced food intake. Reduced food intake and malnutrition in the elderly can also occur for various reasons, including endogenous or medication-induced depression, anorexia, social isolation, physical handicaps that interfere with the elderly person's ability to prepare food, dental problems or ill-fitting dentures, and forgetfulness and failure to eat as the result of diseases of the central nervous system. Furthermore, structural lesions (such as Zenker's diverticulum) and upper esophageal sphincter dysfunction (such as cricopharyngeal achalasia) occur more frequently in the elderly.

AGING AND THE ESOPHAGUS

Manometric studies have demonstrated minor to mild changes in esophageal motility with aging. For instance, there are reductions in contractile velocity and amplitude, increases in synchronous contractions, polyphasic waves and tertiary contractions, upward displacement of lower esophageal sphincter, incomplete lower esophageal sphincter relaxation, and failure of contractions after deglutition in the distal esophagus. Radiographic evaluations frequently reveal dilatation of the esophagus and increases in synchronous and tertiary contractions in the elderly. Presbyesophagus (or corkscrew esophagus), which denotes the increase in tertiary contractions detected radiographically, has no known pathophysiologic consequence. Available data suggest

 Copyright 2004, Elsevier (USA). All rights reserved.

that most esophageal motility problems in the elderly are due to other concomitant medical problems and to the intake of numerous drugs. Clinically, gastroesophageal reflux disease, achalasia (a motility disorder), and esophageal cancer occur more frequently in the elderly.

AGING AND THE STOMACH

The majority of healthy elderly individuals have normal gastric acid secretion. Clinical studies have demonstrated that there are modest reductions in pepsin output and significant decreases in gastroduodenal mucosal prostaglandin biosynthesis in the elderly. Although gastric emptying of solids in healthy, elderly individuals remains unchanged, gastric emptying of liquids may be impaired.

Clinically, peptic ulcer disease and its complications are more common among the elderly. Potential explanations for the higher peptic ulcer incidence in the elderly include an age-related increase in the prevalence of *Helicobacter pylori* infection and the increasing use of nonsteroidal antiinflammatory drugs (NSAIDs) by older individuals. Moreover, both clinical and basic investigations have shown that age-related reductions in gastroduodenal mucosal protective factors (such as gastroduodenal prostaglandin synthesis, gastroduodenal bicarbonate secretion, and expression of mucosal protective growth factors) may predispose the elderly to the development of peptic ulcer disease.

Whereas at least 75% of healthy elderly persons have normal gastric acid production, up to 25% of elderly persons have acid hyposecretion (or hypochlorhydria) because of atrophic gastritis. Gastric hypochlorhydria leads to an increase in the luminal pH of the stomach and proximal intestine and may predispose these older individuals to various enteric infections (such as typhoid, *Salmonella*, cholera, and *Giardia*), because a low intragastric pH is a known defense mechanism against bacteria introduced into the upper digestive tract. Gastric hypochlorhydria may also contribute to the development of malabsorption of iron, folic acid, vitamin B_6 and vitamin B_{12}, calcium carbonate, and various trace minerals in the elderly. Finally, epidemiological studies have suggested that chronic gastritis and associated hypochlorhydria from *H. pylori* infection may lead to the progressive development of atrophic gastritis, gastric metaplasia, and adenocarcinomas of the stomach, which occur primarily in the elderly.

AGING AND THE INTESTINES

Due to the tremendous functional reserve that the intestine possesses, digestion and absorption are well preserved in the elderly. Data from animal and human studies have shown that with increasing age, there are modest changes in digestive enzyme secretion, subtle decreases in carbohydrate absorptive capacity, and altered calcium absorption. There are no significant structural differences in the proximal intestinal epithelium between the young and the old. Despite few changes in overall intestinal absorption with increasing age, clinical malabsorption syndrome occurs more frequently in the elderly. Common causes of malabsorption in patients older than 65 years of age include pancreatic insufficiency, celiac sprue, mesenteric ischemia, and bacterial overgrowth syndrome associated with small bowel diverticulosis, intestinal strictures, and postgastrectomy states.

Studies with radio-opaque markers have shown that bowel transit time does not differ between healthy young and old volunteers. However, delays in rectal evacuation and other anorectal dysfunctions (such as reduction in rectal wall elasticity and a blunting of rectal sensation) are frequently detected in elderly patients who complain of constipation. Clinically, aging is associated with an increased incidence of constipation, fecal impaction, fecal incontinence, megacolon, cecal volvulus, pseudoobstruction (including Ogilvie's syndrome), diverticular disease, ischemic bowel disease, and colorectal cancer.

AGING AND THE LIVER

Due to the enormous reserve capacity of the liver, age-related changes in liver functions are not clinically significant. Both clinical and basic investigations have shown that there are modest reductions in liver size, blood flow and perfusion, and dynamic liver functions with increasing age. Animal studies have also shown that although the rate and time course of hepatic regeneration after partial hepatectomy are slightly delayed with aging, regeneration of the liver in old animals is as complete as in young animals. These observations have led to the important decision to raise the age limit for potential liver donors, resulting in an increased use of older donor livers for hepatic transplantation. Although the clinical course of liver diseases in the elderly does not differ from that in the young, autoimmune liver diseases (such as primary biliary cirrhosis), covert alcoholism, and hepatocellular carcinoma occur more frequently in the elderly.

AGING AND THE GALLBLADDER AND BILIARY TRACT

Age-related changes in the biliary tract include gradual narrowing of the distal common bile duct and increased incidence of juxtapapillary duodenal diverticula. Aging is also associated with an increased incidence of gallstones, reflecting the formation of more lithogenic bile (due to elevated biliary cholesterol secretion, reduced bile acid synthesis, and resultant supersaturation of bile with cholesterol) and less forceful gallbladder contractions (the gallbladder becomes more distensible with age). Consequently, gallstone disease and its complications (such as cholecystitis, choledocholithiasis, and cholangitis), biliary tract diseases, cholangiocarcinoma, and cancer of the gallbladder occur more frequently in the elderly.

AGING AND THE PANCREAS

Age-related changes in the pancreas include modest reduction in pancreatic size and weight, minor atrophic or fibrotic changes, symmetrical dilatation of the interlobular and intralobular ducts, and an increased incidence of pancreatic duct stones. Basal and stimulated exocrine pancreatic secretion changes little with increasing age. Because only 10–20% of the maximal pancreatic exocrine output is needed for normal digestive function, minor declines in pancreatic enzyme output with aging are not clinically significant. Clinically, pancreatic malignancies occur primarily in older individuals.

AGING, GASTROINTESTINAL PROLIFERATION, AND CARCINOGENESIS

The gastrointestinal tract is an epithelial organ with constant cell turnover and rapid mucosal proliferation. Both animal and human studies have shown that aging is associated with increases in gastrointestinal mucosal proliferation, impaired proliferative response to mucosal injury or to feeding, reduced capacity to repair mucosal injury and oxidative damage to key cellular molecules (such as DNA, proteins, and lipids), and altered expression of various growth factors in response to injury. In experimental models, dietary (or calorie) restriction, which is a proved antiaging intervention, retards the development of age-related hyperproliferative changes in the gastrointestinal tract and reduces carcinogen-induced gastrointestinal tumors. These observations suggest that age-associated increases in gastrointestinal proliferation may contribute to a higher risk of tumor formation, because various malignancies of the digestive tract occur primarily in the elderly.

cholangiopathy Any disease process involving the biliary system.
cholestasis Stoppage or suppression of the flow of bile due to either intrahepatic or extrahepatic causes.
endoscopic retrograde cholangiopancreatogram A procedure performed by cannulation of the common bile duct and pancreatic duct by means of a flexible endoscope and retrograde injection of radiopaque contrast media in order to demonstrate all portions of the biliary tree and pancreatic ducts.
magnetic resonance cholangiopancreatogram A noninvasive, radiological procedure performed by magnetic resonance technology that provides images of the biliary tree and pancreatic ducts.
papillary stenosis Narrowing or stricture of the papilla of Vater, the common exit site of fluid passing through the common bile and pancreatic ducts.
sclerosing cholangitis Inflammation of the bile ducts leading to fibrotic/stenotic changes.
sphincterotomy Division of a sphincter; in the case of AIDS cholangiopathy, refers to endoscopic cutting of the papilla of Vater in order to relieve biliary obstruction.

AIDS (acquired immune deficiency syndrome) cholangiopathy is a clinical condition characterized by right upper quadrant pain, fever, marked elevation in serum alkaline phosphatase levels, nausea, and vomiting. Typically, these patients do not have jaundice. The underlying pathology includes acalculous cholecystitis, papillary stenosis, and sclerosing cholangitis, conditions that often occur concomitantly. This type of biliary disease takes place only in the presence of significant immunosuppression as the typical CD4 count in these patients is less than 200/mm^3. One must keep in mind, however, that although patients with AIDS are uniquely susceptible to this type of cholangiopathy, more common conditions such as gallstone disease should still be considered in the differential diagnosis.

INTRODUCTION

Diseases of the biliary tract and gallbladder in patients with AIDS (acquired immune deficiency syndrome) have been well described. Prior to 1981, when AIDS was first recognized, there were no reports of cholangiopathy associated with opportunistic pathogens such as cryptosporidia, cytomegalovirus (CMV), or microsporidia. In 1983, the first cases of biliary tract disease associated with AIDS were published as human cryptosporidial infections of the bile ducts associated with biliary tract obstruction. These first patients, as well as those that followed, tended to be homosexual men with low CD4 counts and a history of other opportunistic infections. Investigation by endoscopic retrograde cholangiopancreatogram (ERCP) frequently demonstrated intra- and/or extrahepatic biliary changes characteristic of sclerosing cholangitis, often associated with papillary stenosis. Culture of the bile and biopsy of the immediately surrounding duodenal tissue often demonstrated the previously mentioned opportunistic organisms. Antimicrobial and endoscopic treatments were attempted, but subsequent studies demonstrated that whereas the latter led to substantial pain relief, the former did little to alter the patients' clinical course.

The prevalence of AIDS cholangiopathy is unknown. Most studies focusing on this disease have been either case reports or series. One study suggested that, at least prior to the highly active antiretroviral therapy (HAART) era, as many as 30% of patients with AIDS-associated refractory diarrhea may have had AIDS cholangiopathy. It is unknown what effect HAART has had on this disease, though one would postulate that it has been beneficial due to the resultant increase in the CD4 count.

ETIOLOGY

The exact cause of AIDS cholangiopathy is unclear. Many investigators favor an infectious etiology as different opportunistic organisms, most commonly *Cryptosporidium parvum*, microsporidia species, and CMV (see Table I), have been cultured from the bile and surrounding duodenal mucosa. Antimicrobials aimed specifically at eradicating these pathogens, however, have neither reversed the underlying disease

process nor prevented its progression. It is unclear whether these pathogens serve as inciting factors or are merely incidentally found in an environment void of the typical immunologic defenses.

Regardless of whether it is these opportunistic organisms, human immunodeficiency virus, or another causative factor that initiates the process leading to AIDS cholangiopathy, what develops is an inflammatory reaction of the bile duct epithelium leading to the hallmark cholangiographic changes. Microscopic examination of the bile duct epithelium demonstrates that the inflammatory changes are different from those seen in primary sclerosing cholangitis (PSC). In PSC, the diseased bile ducts are surrounded by T4 lymphocytes, the cell population that is depleted in AIDS patients. Instead, others have noted the presence of squamous metaplasia of the bile ducts and pancreatic ducts associated with cryptosporidial infection. Though detection of a single organism in the biliary tree has been most commonly documented, multiple organisms in individual patients have been noted also. Earlier studies reported a significant number of patients with no identifiable organism, but these investigations were conducted prior to the discovery of the presence of microsporidia in the bile ducts.

Although infection by opportunistic organisms is associated with most cases, bile duct infiltration with neoplasms such as Kaposi's sarcoma (KS) and Burkitt's lymphoma of the bile ducts may present in a similar fashion. In addition, pancreatic disorders resulting in disease of the distal common bile duct (CBD) may mimic an infectious or neoplastic process. Differentiating among these possible causes of cholangiopathic changes is important as there are potentially beneficial treatments available for some, but not others.

CLINICAL PRESENTATION

The clinical presentation of patients with AIDS cholangiopathy is variable, ranging from asymptomatic elevation in serum alkaline phosphatase to cholangitis with right upper quadrant (RUQ) pain, fever, and chills (see Table II). Patients in case series tended to be homosexual, middle-aged men who had AIDS for over 1 year. It is unknown whether an individual's sexual practice increases the likelihood of developing cholangiopathy or whether this finding is due to homosexual men, as a group, being affected and seeking medical attention earlier in the AIDS epidemic. Due to their low CD4 count, these patients often have had other opportunistic infections prior to presenting with cholangiopathy. Diarrhea commonly occurs in these patients as the organisms that have been associated with this cholangiopathy are also known to cause diarrhea by infecting the small bowel. Jaundice is uncommon and its presence should initiate the search for other coexisting disease processes.

DIAGNOSIS

Laboratory Tests

Abnormal liver tests are commonly seen in AIDS patients. The etiology of these abnormalities is varied and often multifactorial (e.g., medications, infections). Patients with AIDS cholangiopathy most commonly present with anicteric cholestasis (i.e., markedly elevated serum alkaline phosphatase levels with normal bilirubin levels). Significantly elevated bilirubin levels are uncommon (< 5%). Transaminase levels may be mildly elevated, but are usually not markedly so unless there is a coexisting disease process. Other cholestatic conditions that should be considered include granulomatous hepatitis, drugs, viral hepatitis, and intrahepatic lymphoma.

Imaging

Ultrasound

Abdominal ultrasound (US) and ERCP should be considered complementary tests for the diagnosis of this condition. The most effective initial imaging test for AIDS patients with RUQ pain and abnormal liver tests remains the abdominal ultrasound. The typical findings in patients with AIDS cholangiopathy are dilated intra- and/or extrahepatic bile ducts with focal strictures. Biliary ductal wall thickening also supports the presence of disease. Although ERCP is considered the gold standard, ultrasound has a sensitivity of 75–87%. US, however, is superior to ERCP in demonstrating ductal wall thickening, which suggests pericholangitis. In one series, a normal ultrasound was found in 25% of patients with ERCP-confirmed AIDS cholangiopathy. Therefore, ERCP should still be performed in patients with a strong clinical suspicion for cholangiopathy despite a normal ultrasound.

US findings of thickened gallbladder walls and pericholecystic fluid suggest the presence of cholecystitis. In patients without gallstones, a hydroxyiminodiazetic acid (HIDA) scan should be performed to diagnose acalculous cholecystitis. In these cases, HIDA scan will demonstrate an absence of gallbladder filling despite imaging of the CBD.

Computed Tomography Scan

CT (computed tomography) scans do not usually contribute much additional information beyond that gained by a good-quality abdominal US in patients who have only AIDS cholangiopathy. However, CT scans may provide additional insight for patients in whom an US was technically difficult (e.g., due to obesity) or who are jaundiced and are suspected of having other pathology, such as mass lesions.

ERCP

ERCP is the gold-standard diagnostic test for AIDS cholangiopathy. With the improving technological advances of magnetic resonance cholangiopancreatogram, however, it is conceivable that this noninvasive test will replace ERCP for diagnosis. ERCP should be performed only on symptomatic patients with RUQ pain, since only then would a sphincterotomy benefit the patient.

Typically, ERCP demonstrates distal CBD tapering with dilation of the larger intrahepatic ducts, proximal CBD, and common hepatic ducts. Focal intraductal debris is present as is beading of the mucosa to suggest intramural submucosal infiltration and edema. These sclerotic changes occur more commonly in the left intrahepatic system. These findings initially suggested a condition similar to PSC; however, there are some differences (see Table III). In PSC, the entire CBD and the larger intrahepatic ducts are ordinarily sclerotic with minimal focal dilations. Extrahepatic strictures rarely exceed 4–5 mm and saccular deformities involve the intra- and extrahepatic ducts. Isolated strictures of the CBD are rarely due to AIDS cholangiopathy and may be due to primary CBD lymphoma, external compression of the CBD by nodes enlarged by lymphoma, or pancreatic disease caused by chronic pancreatitis, infections, or neoplasms.

Four different cholangiographic patterns of disease have been described. These include sclerosing cholangitis with papillary stenosis, papillary stenosis alone, sclerosing cholangitis without papillary stenosis, and long bile duct strictures (see Table IV). It is unknown whether these patterns represent a progression of disease, but the detection of papillary stenosis is meaningful as sphincterotomy in these patients can lead to substantial symptom relief.

TABLE III Comparative ERCP Findings of AIDS Cholangiopathy versus Primary Sclerosing Cholangitis

AIDS cholangiopathy	Primary sclerosing cholangitis
Distal CBD tapering	Extrahepatic strictures rarely exceeding 4–5 mm
Larger intrahepatic bile ducts, proximal CBD, and common hepatic ducts are, in general, dilated	Sclerotic extrahepatic biliary system and larger intrahepatic ducts with minimal focal dilation
Irregular dilation of the intra- and extrahepatic biliary system	Entire CBD involved with irregular strictures
Beading of the mucosa	No beading of the mucosa
Focal intraductal debris	No intraductal debris
Disproportionately distorted left intrahepatic ducts	Equal distribution of deformities between right and left systems
Intrahepatic irregular focal sacculations and dilations	Saccular deformities involving the intra- and extrahepatic ducts
Pruning of the smaller intrahepatic bile ducts	Paucity of intrahepatic ducts

TABLE IV Cholangiographic Patterns of AIDS Cholangiopathies

Type	Description	Percentage of total cases
Papillary stenosis (PS)	CBD diameter greater than 8 mm with tapering of the distal 2–4 mm with marked retention of contrast beyond 30 min	7% (0–15)[a]
Sclerosing cholangitis (SC) without PS	Focal strictures and dilations of the intra- and extrahepatic bile ducts	31% (20–88)
PS and intra- and extrahepatic SC	As above	54% (13–73)
Long, extrahepatic bile duct strictures	Strictures with lengths in excess of 1–2 cm in patients without prior CBD exploration or documented chronic pancreatitis	8% (0–15)

TREATMENT

Endoscopic

Endoscopic treatment is the most effective intervention for symptomatic patients who are found to have papillary stenosis on ERCP. Sphincterotomy results in prompt and sustained pain relief. However, this procedure does not alter the course of the disease. Patients' alkaline phosphatase levels continue to increase, suggesting progression of the underlying disease process. Studies evaluating repeat ERCP have demonstrated progressive intrahepatic sclerosing cholangitis in some patients despite symptom relief after endoscopic treatment. Sphincterotomy should be viewed as an effective method of improving these patients' quality of life. Due to the good response to sphincterotomy, the pain has been postulated to be due to sphincter of Oddi dysfunction incited by infection and/or inflammation rather than to biliary obstruction.

Medical

Effective treatment is lacking for patients who are found not to have papillary stenosis. Medical treatments aimed at eradicating the underlying infection have been attempted. Studies utilizing paromomycin for cryptosporidiosis and gancyclovir for CMV infections have improved neither symptoms nor disease progression. Other studies have tried ursodeoxycholic acid, but there are no large prospective trials demonstrating efficacy. In addition, there have been no published reports describing the effect of HAART. It is plausible that HAART may improve symptoms or at least hinder disease onset or progression, but this has not been proven. In patients discovered to have KS or lymphoma, chemotherapy should be considered as there was a case report of cholangiopathy secondary to disseminated non-Hodgkin's lymphoma that resolved after treatment with chemotherapy.

Surgery

Surgical intervention has no role in AIDS cholangiopathy limited to ductal disease. However, in patients with cholecystitis, whether due to stones or infection, surgery can be both beneficial and curative.

PROGNOSIS

The prognosis in patients diagnosed with AIDS cholangiopathy is poor. This condition is rarely fatal by itself, however. Other opportunistic infections and progression of the underlying immunodeficiency are usually the more immediate causes of death. Different studies have reported a 1-year survival rate of 14–40% (median survival time being 10 months). The likelihood of survival is affected by neither the level of the liver tests nor the degree of ERCP abnormalities. Rather, the patient's CD4 count provides the best prognostic value. It is unknown whether HAART improves prognosis in patients with AIDS cholangiopathy as most studies were conducted prior to the introduction of this treatment.

Initial therapy usually includes one or two protease inhibitors together with two nucleoside analogues, or a nonnucleoside reverse transcriptase inhibitor (NNRTI) with two nucleoside analogues. Since the introduction of highly active antiretroviral therapy, there has been a marked reduction in mortality, incidence of opportunistic infections, and hospitalizations in patients on therapy.

Most recently, there has been widespread use of ritonavir-boosted regimens (lower dose ritonavir in conjunction with another protease inhibitor), which exploit the fact that ritonavir is a potent inhibitor of the P450 enzyme pathway.

Gastrointestinal manifestations are common in the human immunodeficiency virus (HIV)-positive population, occurring in up to 93% of patients in studies prior to the widespread use of highly active antiretroviral therapy (HAART). Despite the advances in the therapeutic arsenal, gastrointestinal complaints are still a major source of morbidity and mortality in this population. The use of HAART has changed the spectrum of gastrointestinal involvement in HIV disease, treating or preventing the occurrence of opportunistic infections, but at the same time, contributing to a significant cause of drug-related toxicity. Furthermore, as the life expectancy of individuals living longer with autoimmune deficiency syndrome (AIDS) is increased because of HAART, other gastrointestinal-specific causes of morbidity, such as chronic hepatitis C virus, have become increasingly important.

definitive etiology must be carefully assessed by both provider and patient, based on the impact of the symptoms on quality of life and on the invasiveness of the recommended procedure. If a patient is on HAART, it is important to carefully obtain a drug history. Many GI symptoms in individuals on HAART can be ascribed to the medicines being taken.

ESOPHAGEAL DISEASE

Although a wide range of infectious and noninfectious etiologies are possible, *Candida albicans*, found in two-thirds of patients with AIDS, causes the most disease. Patients with esophageal candidiasis usually complain of dysphagia and odynophagia. This is often a clinical diagnosis, particularly if there is oral thrush present and CD4+ cell count is $<200/\mu l$. Endoscopy provides the definitive diagnosis and is usually pursued only if symptoms persist despite at least a week of empiric therapy. Multiple yellow–white, friable plaques are visualized. Treatment is fluconazole (100–400 mg/day). Fluconazole can be used as maintenance therapy, but only if there are frequent or severe recurrences. Resistance may develop, however.

Cytomegalovirus (CMV), herpes simplex virus (HSV), and aphthous ulcers can also cause esophageal symptoms. Compared to esophageal candidiasis, patients with CMV, HSV, or aphthous ulcers typically have more odynophagia and less dysphagia. Fever is common with CMV. Extensive, deep ulcerations on endoscopy suggest these diagnoses, but biopsies are required. CMV is treated with ganciclovir (5 mg/kg, intravenously twice/day), foscarnet, or cidofovir for 2–3 weeks. Relapses may necessitate retreatment followed by maintenance therapy. Esophageal ulcers due to HSV are treated with acyclovir for 2–3 weeks and the more common aphthous ulcers can be treated with prednisone over 4 weeks or with thalidomide, observing careful precautions to avoid use in patients who are or might become pregnant.

Other less common infectious etiologies include *Mycobacterium avium*, tuberculosis, cryptosporidia, *Pneumocystis carinii*, histoplasmosis, and primary HIV infection. Neoplasms such as Kaposi's sarcoma and lymphoma may present with esophageal manifestations. Drug-induced dysphagia may be due to use of zidovudine (AZT) or didanosine (ddI).

GASTRIC DISEASE AND ABDOMINAL PAIN

Symptomatic gastric infections are rare in patients with AIDS and usually present as part of systemic and disseminated infections. CMV is the most common opportunistic infection in the stomach and is sometimes associated with gastrointestinal bleeding. Abdominal pain is a common complaint in HIV-positive patients, and can involve a variety of organs. A similar approach can be taken as for a patient without AIDS. Many of these specific etiologies are covered elsewhere in this article.

INTESTINAL DISEASE AND DIARRHEA

Diarrhea was reported to occur in as many as 90% of patients with AIDS prior to the introduction of HAART. With effective HIV medicines, diarrhea is still common but the etiologic agents responsible now include a high proportion of adverse drug effects and infections that are not HIV specific. The differential diagnosis is large but can be narrowed based on acuity, clinical presentation, and CD4+ lymphocyte count. As with HIV-negative patients, a careful history must first be obtained to exclude lactose or other food intolerance. Many of the causes of acute diarrhea mimic those seen in nonimmunocompromised patients. These include *Salmonella*, *Shigella*, *Campylobacter jejuni*, and *Clostridium difficile*. However, in patients with AIDS, enteric bacteria such as *Salmonella* are often associated with bacteremia and are more virulent. In up to 30% of HIV-infected individuals, enteric viruses (adenoviruses, picobirnaviruses, astroviruses, and caliciviruses) may predominate. Although most of these will resolve with only supportive therapy, up to one-third of patients will progress to chronic diarrhea.

The spectrum of organisms that predominate in chronic diarrhea is different. Protozoa such as cryptosporidia, microsporidia, *Cyclospora*, and *Isospora* are commonly identified, because many are unresponsive to medical therapy and cause chronic diarrhea, particularly in patients with CD4+ cell counts $<200/\mu l$. Cryptosporidia can cause clinically significant disease and associated weight loss. Large-volume, watery diarrhea occurs. Diagnosis is made by demonstrating oocysts similar in size to erythrocytes in an acid-fast stain of the stool. Therapeutic options only have marginal efficacy and include paromomycin and octreotide. The best response has been seen with HAART. Microsporidia are common in some series of AIDS patients with chronic diarrhea and have a similar presentation to cryptosporidia. These organisms are extremely small and electron microscopy is often needed for diagnosis. Albendazole can be effective for *Enterocytozoon intestinalis* but not *Enterocytozoon bieneusi*, and HAART is probably the best current therapeutic option. *Cyclospora* and *Isospora belli* are less common protozoa,

probably because both are responsive to trimethoprim–sulfamethoxazole, which is used widely for *Pneumocystis carinii* prophylaxis in the same at-risk populations. The protozoa *Giardia lamblia* and *Entamoeba histolytica* can also cause diarrhea in nonimmunocompromised hosts, but probably do not occur more frequently in patients with AIDS.

CMV is the most common viral cause of chronic diarrhea in patients with AIDS, particularly in those with CD4+ cell counts $<50/\mu l$. The most common presentation is chronic watery diarrhea in association with abdominal cramps. Diagnosis is typically made by the identification of intranuclear inclusion bodies with associated inflammation on biopsy. Treatment can be effective in about 75% of cases and options include ganciclovir or foscarnet intravenously.

Mycobacteria such as *M. avium* have been demonstrated to be a common cause of chronic diarrhea in individuals with CD4+ cell counts $<50/\mu l$. Patients can present with diffuse abdominal pain, watery diarrhea, and wasting. Diagnosis can be made by blood cultures or by acid-fast organisms in biopsy specimens. Treatment is chronic with clarithromycin and ethambutol. Rifampin is sometimes added. HAART can increase the CD4+ cell count and allows the discontinuation of therapy if immune function is regained. *Mycobacterium tuberculosis* presents less commonly with chronic diarrhea, although other extrapulmonary manifestations are common in AIDS patients.

In patients with no identifiable pathogen (up to 30% in some series), enteric HIV infection is thought to cause small bowel malabsorption via mucosal atrophy. Symptomatic treatments with bulking and antidiarrheal agents have had variable success, and HAART has been associated with some improvement. In patients with persistent large-volume diarrhea without an identifiable pathogen, Kaposi's sarcoma and lymphoma must be ruled out.

HEPATOBILIARY DISEASE

Patients with HIV disease commonly have liver disease that can be specific to AIDS or associated with therapy used to treat it. The clinical spectrum of disease is large, from isolated liver test abnormalities to liver failure, and varies by degree of immunosuppression. For organizational purposes, liver parenchymal disease and biliary disease can be considered separately.

Drug-induced liver disease, infection, and neoplasm are the principal etiologies of hepatic parenchymal disease. With the use of multiple potent antiretrovirals and antibiotics, medication-related hepatotoxicity has become quite common. Usual implicated agents include sulfonamides, zidovudine, nevirapine, and many in the protease inhibitor class, including ritonavir. HAART-related immune reconstitution is sometimes associated with an exacerbation of underlying hepatitis. Hepatic steatosis in conjunction with lactic acidosis has been observed in association with nucleoside reverse transcriptase inhibitors such as stavudine and zidovudine. Pancreatitis, myopathy, and peripheral neuropathy may coexist. Providers must be vigilant and discontinue medicines if necessary, because this syndrome has been linked to several deaths.

Hepatic infections continue to be a significant cause of morbidity and mortality in AIDS patients. Hepatitis B, D, and C viruses interact with HIV in distinct ways. Coinfection with hepatitis B virus and HIV has been associated with increased hepatitis B DNA polymerase, reappearance of hepatitis B surface antigen (HBsAg), loss of anti-HBs, and increased prevalence of hepatitis B e antigen expression. Despite an increase in the chronic carrier state, there is an attenuation of histologic and chemical hepatitis in most of these coinfected patients with more advanced immunosuppression. The institution of HAART in hepatitis B virus chronic carriers may be disastrous; immune activation can lead to hepatitis flares and even fulminant liver failure. Hepatitis D virus and hepatitis B virus act similarly in the HIV-positive patient. Unlike hepatitis B and D viruses, infection with hepatitis C virus appears to worsen with increased immune suppression in HIV-positive patients. The prevalence of cirrhosis and hepatic failure is higher, and there is a more accelerated course. The effect of HAART on hepatitis C virus disease is variable, but because patients live longer, there may be an increased risk of complications such as hepatocellular carcinoma. The role of hepatitis C virus combination therapy with interferon α and ribavirin in HIV-coinfected patients is being carefully evaluated in randomized controlled trials, and initial reports look promising. *Mycobacterium avium*-related hepatic disease is a common diagnosis in individuals with CD4+ cell counts $<50/\mu l$. Extrapulmonary tuberculosis is common in HIV-positive patients and hepatic tuberculosis can occur at all CD4+ cell counts. Although CMV inclusion bodies in the liver are commonly found in autopsy studies, CMV hepatitis is rarely diagnosed clinically. *Bartonella* spp., *P. carinii*, histoplasmosis, *Cryptococcus*, and *Candida* are rare causes of hepatic disease in patients with AIDS. Neoplasms such as Kaposi's sarcoma and non-Hodgkin's lymphoma (NHL) can have significant hepatic involvement in patients infected with HIV.

Prognosis of NHL is related to the degree of immunosuppression.

Infectious cholangitis and neoplasm are AIDS-specific causes of biliary disease. AIDS cholangiopathy is pathologically similar to sclerosing cholangitis with papillary stenosis, and is clinically indistinguishable, with right upper quadrant abdominal pain and an alkaline phosphatase elevated out of proportion to bilirubin, aspartate transaminase (AST), and alanine transaminase (ALT). This entity is thought to have an infectious etiology because *Cryptosporidium*, *Microsporidium*, and CMV have been isolated in biliary epithelium and bile. Ultrasound or CT may be diagnostic, and sphincterotomy may provide symptomatic relief. Kaposi's sarcoma, primary bile duct lymphoma, and lymph node obstruction may also manifest as biliary disease in patients with AIDS.

RECTAL AND ANAL DISEASE

Patients with AIDS have a high prevalence of anorectal disease, including anal fistulas, perirectal abscesses, and idiopathic ulcers. Proctitis can be caused by a host of infectious agents, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex. CMV can cause ulcers. Human papillomavirus is a common sexually transmitted infection that causes a high prevalence of anal intraepithelial neoplasia in HIV-positive men and women. There is a corresponding high prevalence of anal cancer in certain populations at risk, such as HIV-positive men who have sex with men. Other neoplasms such as lymphoma and Kaposi's sarcoma have anorectal manifestations. Although HAART has resulted in a decrease in lymphoma and Kaposi's sarcoma, there has been no reduction in the incidence of anal cancer or its precursors in HIV-positive men and women.

Liver disease in patients with human immunodeficiency virus and acquired immunodeficiency syndrome (AIDS) is a common, often complex, problem. The clinical presentations of liver disease in this population are highly variable, ranging from asymptomatic liver enzyme abnormalities to fulminant hepatic failure. Infections, medication toxicity, and malignancies are the most common causes of liver disease in patients with AIDS and will be the main focus of discussion in this article.

INTRODUCTION

The hepatic manifestations of acquired immunodeficiency syndrome (AIDS) often correlate with the degree of immunosuppression, success of medical therapy, and socioeconomic status of the human immunodeficiency virus (HIV)-infected individual. Patients with normal or near-normal immune function are typically susceptible to liver diseases that affect the immunocompetent population, with the exception of hepatic toxicity from highly active anti-retroviral therapy. Hepatitis B virus (HBV)- or hepatitis C virus (HCV)-related liver diseases are leading causes of morbidity and mortality in HIV patients, even in well-controlled HIV. In patients with AIDS and severe immunosuppression, the liver is often affected by opportunistic infections and neoplasms, such as Kaposi's sarcoma and lymphoma. This article will examine the general approach to liver disease in an HIV-positive patient and then specifically discuss the most common causes of liver disease in this population.

APPROACH TO THE PATIENT

When liver disease is suspected in an HIV-positive patient, a rational and focused diagnostic approach should be utilized to narrow the broad differential diagnosis (Table I). The most important initial step is a complete history and physical to search for possible risk factors or evidence of hepatic disease. The clinician should inquire about intravenous drug abuse and blood transfusions, use of hepatotoxic medications, recent travel, exposure to opportunistic infections or sick acquaintances, sexual practices, and alcohol use. Symptoms that may reveal clues to the presence or cause of liver disease include fever, weight loss, night sweats, jaundice, right upper quadrant abdominal pain, bilirubinuria, acholic stools, and skin lesions. Physical examination should focus on searching for signs of liver disease, such as jaundice, hepatomegaly, spider angiomata, gynecomastia, testicular atrophy, and proximal muscle wasting.

If liver disease is suspected, a complete hepatic function panel, complete blood count with platelets, coagulation profile, and CD4 count should be obtained. The CD4 count is probably the most important test in formulating a differential diagnosis. A patient with abnormal liver tests and a normal CD4 count is unlikely to have an opportunistic infection of the liver. However, the clinician should initially focus on ruling out opportunistic infections of the liver in patients with CD4 counts of less than 200. Other chronic liver diseases that affect the healthy population should also be considered.

The pattern of liver test abnormalities is often helpful in determining the cause of liver disease in HIV-positive patients. Elevation in transaminases out of proportion to alkaline phosphatase suggests hepatocellular injury. Chronic viral hepatitis, alcohol, medications, immunologic, and metabolic diseases should be considered. Elevations in alkaline phosphatase, direct bilirubin, and γ-glutamyl transpeptidase suggest cholestatic liver disease, commonly caused by granulomatous infiltration or biliary obstruction. If a diagnosis cannot be made with laboratory testing, the next step should be

an ultrasound and/or a computerized tomography (CT) scan of the abdomen. CT is superior to ultrasound for delineation of hepatic lesions, lymphadenopathy, cirrhosis, and splenomegaly, whereas ultrasound is more sensitive for gallbladder and biliary tract disease. Since neither test is highly specific or sensitive, liver biopsy may be required to determine the etiology or evaluate the extent and severity of liver disease. Although a specific diagnosis can be made in the majority of patients, liver biopsy should be performed only if other diagnostic measures, including cultures and less invasive procedures such as skin or bone marrow biopsy, have failed to determine an etiology.

ETIOLOGIES AND TREATMENT

Opportunistic Infections

Mycobacterium avium complex (MAC) is the most common opportunistic pathogen of the liver and can be seen in 20–55% of autopsies of patients with AIDS. Patients usually present with fever, weight loss, and diarrhea. The CD4 count is almost always <100 in these patients. Initial workup often reveals an elevated alkaline phosphatase and liver biopsy may show poorly formed noncaseating granulomas; however, with advanced immunosuppression, tissue reaction and granulomas are often absent. Cultures or special stains are required for diagnosis in patients with suspected MAC and inconclusive histopathology. Treatment requires a 6- to 12-month course of a multiple drug regimen, including either clarithromycin or azithromycin and either two or three of the following: rifampin, ethambutol, or ciprofloxicin.

Mycobacterium tuberculosis (MTB) infection presents with fever, weight loss, and cough. Unlike MAC, patients may develop pulmonary or extrapulmonary MTB with any CD4 count. Liver biopsy may show granulomas and occasional hepatic abscesses. Similar to MAC, patients with low CD4 counts may not have classic histopathology on liver biopsy. Only culture can differentiate between MAC and MTB. Patients are placed on a multidrug regimen of isoniazid, rifampin, ethambutol, and pyrazinamide for 9 to 12 months, unless there is evidence of drug resistance.

Fungal infections such as *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Pneumocystis carinii* (PCP) may affect the liver. Cryptococcal liver involvement is usually asymptomatic. Organisms may be seen on biopsy with silver stain as small round glassy structures. The treatment of *Cryptococcus* is intravenous (iv) amphotericin B $\pm$ oral flucytosine. Disseminated histoplasmosis may cause severe constitutional symptoms and systemic disease even though hepatic involvement is usually asymptomatic. Detection of the polysaccharide antigen in the blood is used for diagnosis, and liver biopsy with silver stain reveals round organisms with occasional budding, mild inflammation, and rarely granulomas. The treatment for histoplasmosis is iv amphotericin or itraconazole.

Disseminated PCP is associated with moderate elevations in transaminases and alkaline phosphatase.

Foamy periportal or diffuse nodules containing cysts on silver stain are typical of hepatic involvement and are usually detected only at autopsy. Disseminated PCP is found primarily in patients who receive aerosolized pentamidine. Treatment is usually with trimethoprim-sulfamethoxazole ± prednisone. Other less common hepatic fungal infections include *Coccidioides immitis*, *Candida albicans*, and *Aspergillus fumigatus*. Protozoal infections are also rare in the liver and include schistosomiasis, *Leishmania donovani*, *Encephalitozon cuniculi*, and *Toxoplasma gondii*.

Bacillary peliosis hepatitis has been associated with *Bartonella quintana* or *Bartonella henselae*. Peliosis lesions are blood-filled cavities distributed throughout the liver parenchyma. Gross inspection reveals gray or hemorrhagic nodules, whereas granulation tissue intermixed with neutrophils and eosinophilic material is seen on histopathology. Any macrolide antibiotic or doxycyline should be given for at least 4 months.

Cytomegalovirus (CMV) of the liver is present in 33–44% of AIDS autopsy cases, usually in patients with widespread organ involvement. Most patients who have hepatic CMV infection are asymptomatic and rarely present with fever and hepatomegaly. Transaminases are often only mildly elevated. CMV infection can be detected via polymerase chain reaction (PCR), antigen assays, and blood cultures; definitive CMV involvement of the liver is determined via biopsy. Microabscesses and CMV inclusions in hepatocytes, Kupffer cells, bile duct epithelium, and endothelial cells are characteristic but not always present. Immunohistochemical techniques and culture of tissue specimens increase the sensitivity of diagnosis. CMV can also cause mass lesions, granulomatous disease, or biliary tract disease and obstruction. Treatment options include ganciclovir, foscarnet, valganciclovir, and cidofovir. Other opportunistic viral infections of the liver in AIDS include herpes simplex virus, Epstein–Barr virus, adenovirus, and varicella-zoster virus.

CMV and other infections, such as cryptosporidia, may cause inflammation and fibrosis of the biliary tract known as AIDS cholangiopathy. Patients present with fever, jaundice, and right upper quadrant pain. The alkaline phosphatase is typically twofold higher than transaminases. Significant obstruction is associated with hyperbilirubinemia. Papillary stenosis, long extrahepatic strictures, or intrahepatic and extrahepatic sclerosing lesions resembling primary sclerosing cholangitis are seen with cholangiography. Endoscopic sphincterotomy is the treatment of choice for papillary stenosis and stenting or balloon dilation has been used for dominant strictures.

Other Hepatotrophic Viruses

With advances in antiretroviral therapy and improved life expectancy in HIV patients, chronic HCV infection has become a leading cause of morbidity and death in this population. Because of similar risk factors for transmission, it is estimated that 30–50% of patients with HIV are co-infected with HCV. Several studies suggest that HIV increases HCV replication and accelerates the progression to cirrhosis. All HIV patients should be screened for HCV with antibody testing and confirmed with either the recombinant immunoblot assay or HCV-RNA PCR. HCV in patients with advanced immunosuppression can often be diagnosed only by measurement of RNA levels. HCV infection is usually asymptomatic and liver enzymes are often normal early in the course of disease. Liver biopsy establishes the degree of necroinflammatory activity and fibrosis and should be performed if treatment is considered. In general, treatment of HIV with anti-retroviral therapy is initiated first, especially if the CD4 count is low. For patients with stable HIV disease, combination therapy with pegylated interferon and ribavirin can be administered, although safety and efficacy data in this population have been reported only in small series.

Co-infection with HIV and HBV increases the rate of HBV replication and risk of a chronic carrier state; however, the inflammatory response in the liver is generally milder in HIV–HBV co-infected patients than in patients infected with HBV alone. Reactivation of quiescent HBV may occur with progression of HIV and can lead to fulminant liver failure in patients with co-infection. Indications for treatment include evidence of ongoing viral replication, elevated liver enzymes, and histological confirmation of active or progressive disease. Lamivudine is often used as a first-line agent as it has activity against both HIV and HBV. HBV resistance in the form of the YMDD mutation occurs in patients treated with lamivudine and may respond to another nucleoside analogue, such as entecavir or adefovir.

Patients with HIV exposed to hepatitis A virus do not have more severe disease than immunocompetent patients. Hepatitis D virus requires concurrent infection with HBV and can cause severe liver disease in immunosuppressed patients. Hepatitis E virus, a fecal–orally transmitted virus found almost exclusively in poor countries, usually causes an acute self-limited disease.

Neoplasms

Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL) are the most common hepatic neoplasms in HIV patients. KS is a multicentric neoplasm derived from lymphatic endothelial cells and is predominantly

seen in homosexual men. Hepatic KS is found in 8.6% of patients with AIDS but is rarely diagnosed prior to the development of cutaneous disease. Patients are usually asymptomatic, but may occasionally present with hepatomegaly and an elevated alkaline phosphatase. KS lesions are often too small to delineate by ultrasonography, but may enhance with iv contrast on CT imaging. Gross pathology reveals multifocal purple-brown soft nodules composed of vascular endothelial cells forming slit-like spaces, extravasated red blood cells, and central necrosis. Since hepatic KS does not appear to shorten life expectancy, only symptomatic patients require treatment with chemotherapy (liposomal anthracyclines, paclitaxel, or vinorelbine).

NHL is a known complication of HIV infection. The majority are high- or intermediate-grade B-cell tumors and extranodal presentation in common. Hepatic masses are often asymptomatic, but may cause hepatomegaly and jaundice due to hepatic infiltration or biliary tract compression. B symptoms are nonspecific in AIDS patients. CT typically shows hypodense masses with rim enhancement surrounded by normal hepatic parenchyma. Biopsy may reveal lymphomatous infiltration of the portal tracts or lobules. Diffuse portal infiltrates may be seen in infiltrating lymphomas. The median survival for patients with AIDS and lymphoma is under 6 months despite chemotherapy. Other hepatic neoplasms found in HIV patients include Hodgkin's lymphoma, hepatocellular carcinoma, smooth muscle tumors, and cholangiocarcinoma. Hodgkin's lymphoma involving the liver is uncommon in HIV patients and is almost exclusively of the mixed cellularity or nodular sclerosis subtype. Hepatocellular carcinoma in HBV or HCV co-infected individuals occurs at a younger age and is more aggressive than in patients without HIV infection. Cholangiocarcinoma and hepatic leiomyoma or leiomyosarcoma are less commonly described.

Drugs

Patients with AIDS may develop a spectrum of liver problems with HIV medications, from mild liver test abnormalities to fulminant hepatic failure. Nucleoside reverse transcriptase inhibitors, such as zidovudine, have been implicated in a rare but potentially fatal mitochondrial hepatopathy. Patients usually present with nonspecific symptoms, but have severe microvesicular steatosis on liver biopsy. Mortality due to refractory lactic acidosis or hepatic failure can approach 60%. Early discontinuation of nucleoside reverse transcriptase inhibitors may improve clinical outcome, but there are reported cases of progressive acidosis despite their discontinuation. Nutritional therapy is the mainstay of treatment, although prognosis is poor. Nevirapine, a common nonnucleoside reverse transcriptase inhibitor, can cause a hypersensitivity hepatitis. Ritonavir, a protease inhibitor, is associated with toxicity via inhibition of the cytochrome P450 system. Pentamindine and sulfa drugs are often associated with hepatic granulomas and elevations of alkaline phophatase. Ethanol, antifungals, antivirals, herbal medications, and nonprescription drugs may also contribute to hepatic disease.

Miscellaneous

Nonspecific histopathologic findings are described in nearly one-third of biopsy specimens in patients with HIV. Possible causes include malnutrition with or without use of total parenteral nutrition, amyloid deposition, and HIV infection itself. HIV has been found within hepatocytes and Kupffer cells; however, the direct relationship between HIV and liver disease has not been clearly delineated.

CONCLUSION

Patients with HIV and/or AIDS can have a spectrum of liver diseases, from isolated abnormal liver enzymes to fulminant hepatic failure. Instead of considering all of the possible causes, the clinician should narrow the differential diagnosis based on the history, physical exam, pattern of abnormal liver tests, and degree of immunosuppression. The least invasive approach to diagnosis is usually the most appropriate initially. The most common causes of liver disease in HIV patients are opportunistic infections, neoplasms, and medications. Treatment should be based upon the most likely diagnosis.

Alagille syndrome A disease caused by mutations in the Jagged1 gene, resulting in variable manifestations in the liver, heart, spine, eyes, kidneys, face, and other systems.

cholestasis Decrease in bile flow, typically associated with increased bilirubin, increased bile salts, or both. Elevations typically result in the visible signs of jaundice.

embryotoxon, posterior A finding in the anterior chamber of the eye, sometimes visible as a discrete line, due to a prominent Schwalbe's ring, seen in Alagille syndrome, in some other genetic disorders, and in approximately 10% of normal individuals.

hepatitis, neonatal Term used to define a large and diverse group of structural and metabolic disorders unique to the neonatal period, resulting in hepatic disease and cholestasis.

hepatomegaly Increase in the size of the liver. In children, normal size varies with age.

hyperbilirubinemia Increase in the level of bilirubin (unconjugated, indirect hyperbilirubinemia) or conjugates of bilirubin (conjugated, direct hyperbilirubinemia).

Jagged1 mutation A defect in a gene encoding a primary ligand for the NOTCH signaling pathway, resulting in Alagille syndrome.

jaundice Eevation of bilirubin, typically conjugated bilirubin, to the point that it is visible in the eyes or skin as a yellowish pigmentation.

paucity, bile duct Decrease in the number of bile ducts present in a portal tract, defined as a ratio of bile ducts to portal tracts averaging less than 0.9.

splenomegaly Increase in size of the spleen. In children, normal size varies with age.

xanthoma, Alagille syndrome Nodular or plaque-like lipid deposits in the skin that occur commonly in Alagille syndrome when the cholesterol level exceeds 500 mg/dl.

Alagille syndrome (AGS) is a complex dominantly inherited multisystem disorder involving predominantly the liver, heart, eyes, face, and skeleton. The main clinical manifestations of AGS are cholestasis, characterized by bile duct paucity on liver biopsy; congenital cardiac defects, primarily involving the pulmonary arteries; posterior embryotoxon in the eye; typical facial dysmorphism; and butterfly vertebrae. Renal and central nervous abnormalities have also been described. A classic feature of the syndrome is highly variable expressivity of the clinical features, even within families. *Jagged1* (*JAG1*), a ligand in the evolutionary conserved Notch signaling pathway, has been identified as the AGS gene.

DIAGNOSIS OF ALAGILLE SYNDROME

Alagille originally defined the syndrome by bile duct paucity in association with at least three of five major criteria: cholestasis, characteristic facies, vertebral abnormalities, ocular anomalies, and a heart murmur. Since that time, a wide range of manifestations in many organ systems have been associated with Alagille syndrome (AGS). Renal disease, pancreatic disease, and intracranial vascular events are recognized to be significant manifestations of AGS.

Bile duct paucity on liver biopsy has been considered to the most important and constant feature of AGS. This paucity, however, is not present in infancy in many patients ultimately shown to have AGS. Overall, paucity is present in approximately 89% of patients. Several studies of serial liver biopsies have demonstrated that

paucity is more common later in infancy and childhood. Ductular proliferation is present in a small number of infants with AGS, leading to potential diagnostic confusion and misdiagnoses of biliary atresia.

Diagnosis of the syndrome is also hindered by highly variable expressivity of the clinical manifestations. Large series of patients reported by different groups have demonstrated differing frequencies of the manifestations of AGS. Diagnosis can also be difficult because several of the characteristic features are seen in normal individuals.

The identification of the disease gene in AGS and the availability of molecular testing have assisted in the confirmation of the diagnosis in affected individuals. However, it has also provided a tool for identifying individuals with few or only one feature of AGS who carry a mutation in *Jagged1* (*JAG1*). It remains to be clarified whether these individuals who carry mutations in *JAG1* but are without overt clinical disease should be classified as having AGS or merely as carriers of a gene defect with minimal expression. Since the transmission risk for progeny is high, the designation of a diagnosis of AGS seems appropriate.

Based on these considerations, the diagnostic criteria for AGS can be modified significantly. A revised list of diagnostic criteria is proposed in Table I.

CLINICAL FEATURES AND COMPLICATIONS OF ALAGILLE SYNDROME

Hepatic Manifestations

The hepatic manifestations of AGS vary from mild to severe cholestasis. The majority of symptomatic patients present in the first year of life. Hepatitis is present in many infants, but is generally less important than the cholestasis. Synthetic liver failure is extremely uncommon under the age of 1 year. Hepatomegaly is recognized in 93–100% of AGS patients and is common in infancy. Splenomegaly is unusual early in the course of the disease, but is eventually found in up to 70% of patients. Jaundice is present in the majority of symptomatic patients and typically presents as a conjugated hyperbilirubinemia in the neonatal period. In half of these infants, it is persistent, resolving only in later childhood. The magnitude of the hyperbilirubinemia is typically less than the degree of cholestasis and pruritus. The pruritus is among the most severe of any chronic liver disease. It rarely is present before 3 to 5 months of age, but is seen in most children by the third year of life, even in some who are anicteric.

Multiple xanthomas are common sequelae of severe cholestasis. The formation of xanthomas correlates with serum cholesterol greater than 500 mg/dl. They typically form on the extensor surfaces of the fingers, the palmar creases, nape of the neck, the ears, the popliteal fossa, the buttocks, and around the inguinal creases. These xanthomas increase in number over the first few years of life and then may disappear subsequently as cholestasis improves.

The most striking laboratory abnormalities are in the measures of cholestasis and bile duct damage. Elevations of bilirubin up to 30 times normal and bile salt elevations of 100 times normal are not uncommon. Bile salt elevations are common, even when the bilirubin is normal. Markers of bile duct damage, including γ-glutamyl transferase and alkaline phosphatase, are usually markedly elevated. Likewise, other substances typically excreted in bile are increased in blood. Cholesterol levels may exceed 1–2000 mg/dl. The aminotransferases are typically elevated 3- to 10-fold, but may be normal in some patients with cholestasis. Hepatic synthetic function is usually well preserved.

Liver transplantation is eventually necessary in 21–50% of patients. Indications for transplantation

include synthetic dysfunction, intractable portal hypertension, bone fractures, pruritus, xanthomata, and growth failure. The survival of AGS patients undergoing liver transplantation has been comparable to other pediatric patients undergoing liver transplantation; however, survival may be limited in patients with significant cardiac or renal complications of AGS.

Cardiac Manifestations

The presence of a heart murmur is the most common manifestation of AGS. The majority of these murmurs are due to stenosis at some level in the pulmonary outflow tract or peripheral pulmonic vessels. Peripheral pulmonic stenosis may occur in isolation or in combination with structural intracardiac disease. The most common congenital defect is Tetralogy of Fallot, which occurs in 7–11% of patients. Other cardiovascular lesions include truncus arteriosus, ventricular septal defect complex, atrial septal defect, ventricular septal defect, and isolated pulmonic stenosis.

Cardiac disease accounts for nearly all the early mortality in AGS. Patients with intracardiac disease have approximately 40% survival to 6 years of life compared to 95% survival in AGS patients without intracardiac lesions. The operative mortality for cardiac surgery in AGS patients is greater than for those without AGS. Cardiovascular disease has also been implicated in the increased posttransplantation mortality seen in some series.

Ocular Anomalies

A large and varied number of ocular abnormalities have been described in AGS. A few of the abnormalities are secondary to chronic vitamin deficiencies. Of the primary ocular abnormalities, posterior embryotoxon is the most important diagnostically. Posterior embryotoxon is a prominent, centrally positioned Schwalbe's ring (or line), at the point where the corneal endothelium and the uveal trabecular meshwork join. Posterior embryotoxon occurs in 56–95% of patients with AGS, but also occurs in 8–15% of normal eyes. Axenfeld anomaly, seen in 13% of AGS patients, is a prominent Schwalbe's ring with attached iris strands and is associated with glaucoma. Numerous other ocular anomalies have also been described, most of which have no functional significance.

Facial Features

The characteristic facial features of AGS include a prominent forehead, deep-set eyes with moderate hypertelorism, a pointed chin, and a saddle or straight nose with a bulbous tip. The combination of these features gives the face a triangular appearance (see Fig. 1). Other facial characteristics include a flat appearance of the face in profile and prominent ears. Additional abnormalities include large ears, recurrent sinusitis, recurrent otitis, and a high-pitched voice. The facies of an adult with AGS do not resemble the childhood features; the forehead becomes less prominent and the chin is more protuberant, making the face less triangular in appearance.

It has been suggested that the facies are due to the effects of chronic cholestasis, but they are not seen in other diseases with severe cholestasis. It is likely that

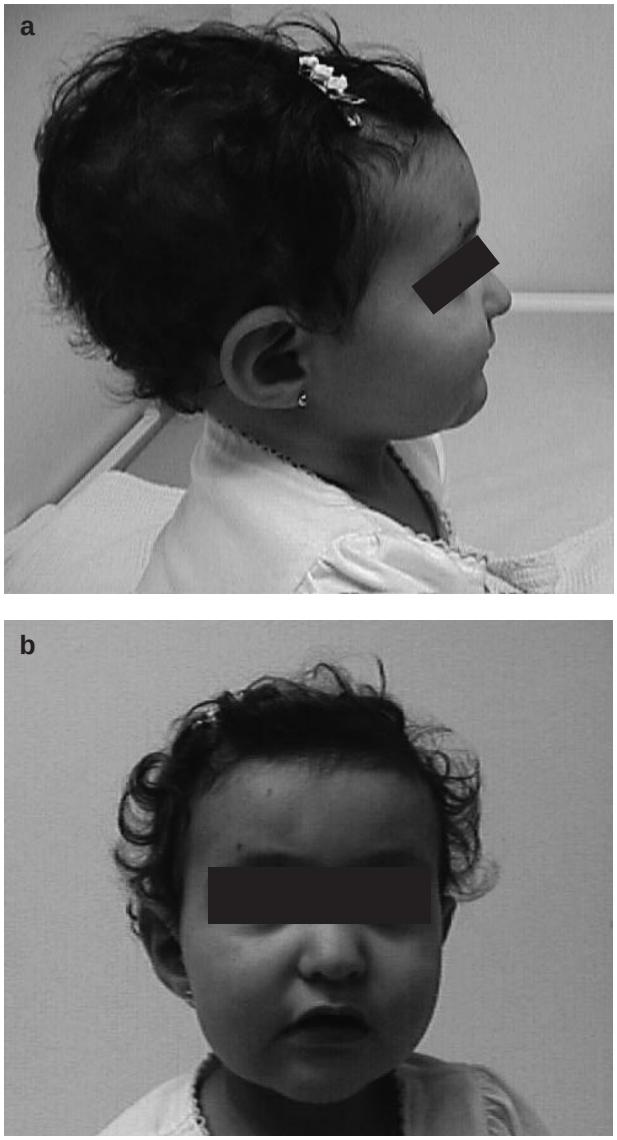

FIGURE 1 (a and b) Typical facies seen in a 4-year-old girl with Alagille syndrome.

the facial bone formation is directly affected by mutations in *JAG1*.

Skeletal Manifestations

The most characteristic skeletal finding in AGS is the sagittal cleft or butterfly vertebrae, which is found in 33–87% of patients (see Fig. 2). This anomaly may occur in normal individuals. The affected vertebral bodies are split sagittally into paired hemivertebrae, due to a failure of the fusion of the anterior arches of the vertebrae. Generally, these are asymptomatic and of no structural significance.

Other associated skeletal abnormalities include, among others, an abnormal narrowing of the adjusted interpedicular space in the lumbar spine, fusion of the adjacent vertebrae, hemivertebrae, and the presence of a bony connection between ribs. The fingers may seem short, with broad thumbs. Supernumerary digital flexion creases are also seen.

FIGURE 2 Butterfly vertebrae with variable degrees of clefting in the thoracic spine of an infant with Alagille syndrome.

Severe metabolic bone disease with osteoporosis and pathologic fractures is common in AGS. A number of factors may contribute to osteopenia and fractures, including severe chronic malnutrition, vitamin D and K deficiency, chronic hepatic and renal disease, magnesium deficiency, and pancreatic insufficiency.

Central Nervous System Manifestations

Intracranial bleeding is the most important neurologic complication of AGS and a significant cause of morbidity and mortality. It occurs in approximately 15% of patients and in 30–50% of these events the hemorrhage is fatal. The intracranial bleeding varies significantly in location and severity. The majority of this bleeding occurs in the absence of significant coagulopathy. Head trauma, typically of a minor degree, has been associated with the bleeding in a number of cases. The majority of cases of bleeding are spontaneous, however, with no clear risk factors. Structural vascular abnormalities have been identified in only some of the patients with bleeding episodes.

Renal Manifestations

Renal disease is an important feature of AGS. Structural and functional renal abnormalities occur in 40–50% of patients with AGS. These include solitary kidney, ectopic kidney, bifid pelvis, reduplicated ureters, and multicystic and dysplastic kidneys. Renal artery stenosis is a cause of systemic hypertension in AGS. Tubulointerstitial nephropathy, renal tubular acidosis, a characteristic "lipidosis" of the glomeruli, and adult-onset renal insufficiency may also occur.

Additional Manifestations

Severe growth retardation is common in patients with AGS, particularly in the first 4 years of life. Malnutrition due to malabsorption is a major factor in this failure to thrive. There appear to be limitations in linear growth even when protein-calorie malnutrition is not evident.

Intrinsic pancreatic disease may also occur in AGS. Clinically, the identification of pancreatic insufficiency is important, as therapy with enzyme supplementation is available.

MORBIDITY, MORTALITY, AND OUTCOME IN ALAGILLE SYNDROME

Diseases of the cardiac, hepatic, and central nervous systems account for the majority of morbidity and mortality in AGS. The presence of complex intracardiac

disease at diagnosis is the only predictor of excessive early mortality. Hepatic complications account for most of the later mortality, although recent series document significant mortality from intracranial bleeding. The 20-year survival has been estimated to be 75% overall.

THERAPY FOR ALAGILLE SYNDROME

Patients with AGS present significant management challenges. Cholestasis is commonly profound. Bile flow may be stimulated with the choleretic ursodeoxycholic acid, but in many patients the pruritus continues unabated. Care should be taken to keep the skin hydrated with emollients and fingernails should be trimmed. Therapy with antihistamines may provide some relief, but many patients require additional therapy with agents such as rifampin or naltrexone. Biliary diversion has been successful in a limited number of patients, but intractable pruritus continues to be an indication for transplantation in refractory patients.

Malnutrition and growth failure should be treated with aggressive nutritional therapy. There will be significant malabsorption of long-chain fat and therefore formulas supplemented with medium-chain triglycerides have some nutritional advantage. Fat-soluble vitamin deficiency is present to a variable degree in most patients. Multivitamin preparations may not provide the correct ratio of fat-soluble vitamins and thus vitamins are best administered as individual supplements.

GENETICS OF ALAGILLE SYNDROME

AGS is inherited in autosomal dominant fashion with highly variable expressivity ranging from subclinical features to severely affected individuals. It is one of the most common genetic causes of cholestasis in infancy, with an estimated frequency of 1 in 70,000 live births.

The site of the gene responsible for AGS was first suggested by the identification of cytogenetically visible deletions on the long arm of chromosome 20 in multiple AGS patients. In 1997, mutations in *JAG1* were shown to be the cause of AGS. Molecular analysis has demonstrated *JAG1* mutations in approximately 70% of patients.

JAG1 is a cell surface protein that functions as a ligand for the Notch transmembrane receptors, which are part of the evolutionarily conserved Notch signaling pathway. The Notch pathway regulates cell fate determination in many different cell types throughout development. Approximately 50% of AGS patients have protein truncating (frameshift or nonsense) mutations. The mutations are distributed widely over the entire coding region. Fifty to 70% of mutations are *de novo*. Mutations in *JAG1* are thought to cause disease by haploinsufficiency whereby there is a decrease in the amount of the normal protein.

Although the AGS phenotype is highly variable, there is no apparent genotype–phenotype correlation. No phenotypic differences have been identified based on type or location of mutation. Furthermore, the extreme variability of the AGS phenotype within families suggests that other genetic or environmental factors contribute significantly to the clinical manifestations of the disease.

Genetic evaluation for *JAG1* mutations is currently available on a research basis. Current methods cannot identify a mutation in approximately 30% of clearly affected probands. Prenatal testing is available, but only if the mutation is identified in the proband. Molecular testing has also aided in the diagnosis of AGS for patients with minor or atypical manifestations and has expanded the spectrum of AGS manifestations.

The identification of *JAG1* as the cause of AGS has opened a window on human development, which will surely lead to an enhanced understanding of embryogenesis and multisystem diseases of humans.

are typical primary physical signs of cirrhosis. Secondary phenomena include portal hypertension with splenomegaly, edema, and ascites; encephalopathy; and gastrointestinal hemorrhage from bursting esophageal or gastric varices, and bleeding tendencies due to clotting factor deficiencies resulting from hepatocyte malfunction. Tertiary complications include spontaneous peritonitis caused by anaerobic bacteria.

Typically, blood tests reveal a decrease in serum albumin with increased and abnormal globulins. Serum transaminases and bilirubin are usually only mildly elevated, with more striking increases in the end stages. As previously discussed, the outcome is often dismal, with a 1-year mortality of 50% or more in patients over the age of 60 years.

Ethanol (also called alcohol or ethyl alcohol) is the most commonly abused psychoactive drug, yet it is legal in most countries. Its metabolism is the cause of a vast array of pathologic manifestations.

INTRODUCTION

Ethanol is readily absorbed from the gastrointestinal tract but only 2 to 10% is eliminated through the kidneys and lungs; the rest is metabolized in the body. Many tissues contain enzymes capable of ethanol oxidation or nonoxidative metabolism, but significant activity occurs only in the liver (Fig. 1) and, to a lesser extent, in the stomach. Accordingly, medical consequences are

predominant in these organs and thus these two sites of ethanol metabolism are the focus of this article.

HEPATIC METABOLISM OF ETHANOL AND ITS CONSEQUENCES

The hepatocyte contains three main pathways for ethanol metabolism, each located in a different subcellular compartment: (1) the alcohol dehydrogenase (ADH) pathway of the cytosol (the soluble fraction of the cell); (2) the microsomal ethanol-oxidizing system, located in the endoplasmic reticulum; and (3) catalase, located in the peroxisomes. Each of these pathways produces specific metabolic or toxic disturbances and all three generate acetaldehyde, a highly toxic metabolite.

The ADH Pathway

This is the main pathway of alcohol metabolism.

Multiple Forms of ADH

Human ADH is a zinc metalloenzyme with five classes of molecular forms that arise from the association of eight different types of subunits (α, $\beta 1$, $\beta 2$, $\beta 3$, $\gamma 1$, $\gamma 2$, π, and χ) into active dimeric molecules. A genetic model accounts for this multiplicity as products of seven gene loci, ADH1 through ADH7.

Metabolic Disorders Associated with the ADH Pathway

In ADH-mediated oxidation of alcohol, hydrogen is transferred from the substrate to the cofactor nicotinamide adenine dinucleotide (NAD), converting it to its reduced form (NADH), and acetaldehyde is produced (Fig. 1). Thus, the first step in this oxidation of alcohol generates an excess of reducing equivalents in the cytosol, primarily as NADH, with a marked shift in the redox potential of the cytosol. The altered redox state, in turn, is responsible for a variety of metabolic abnormalities, including hyperlactacidemia, which contributes to the acidosis and also reduces the capacity of the kidneys to excrete uric acid, leading to secondary hyperuricemia. Hyperuricemia explains the common clinical observation that excessive consumption of alcoholic beverages frequently aggravates or precipitates gouty attacks.

Short-term alcohol intoxication occasionally causes severe hypoglycemia, which can result in sudden death. Hypoglycemia is due, in part, to the block of hepatic gluconeogenesis by ethanol, again as a consequence of the increased NADH/NAD ratio in subjects whose glycogen stores are already depleted by starvation or who have preexisting abnormalities in carbohydrate metabolism.

The reducing equivalents can also be transferred to NADPH, and the increased NADPH can be utilized for synthetic pathways in the cytosol and in the microsomes. Some of the hydrogen equivalents are transferred from the cytosol into mitochondria. The mitochondrial membrane is impermeable to NADH and the reducing equivalents are thought to enter the mitochondria via shuttle mechanisms such as the malate cycle (quantitatively, probably the most important), the fatty acid elongation cycle, and the α-glycerophosphate cycle. Normally, fatty acids are oxidized via β-oxidation in the citric acid cycle of the mitochondria, which serves as a "hydrogen donor" for the mitochondrial electron transport chain. When alcohol is oxidized, the generated hydrogen equivalents, which are shuttled into mitochondria, supplant the citric acid cycle as a source of hydrogen. The activity of the citric acid cycle is actually depressed, partly because of a slowing of the reactions of the cycle that depend on the NAD/NADH ratio. Consequently, the mitochondria will use the hydrogen equivalents originating from ethanol rather than those derived from the oxidation of fatty acids that normally serve as the main energy source of the liver. This substitution of alcohol for fat favors hepatic fat accumulation.

Microsomal Ethanol-Oxidizing System (MEOS)

Characterization of the MEOS and Its Role in Ethanol Metabolism

Although recognized only three decades ago, this new pathway is still the subject of extensive research,

reviewed in detail elsewhere. The first indication of an interaction of ethanol with the microsomal fraction of the hepatocyte was provided by the morphologic observation that alcohol feeding results in a proliferation of the smooth endoplasmic reticulum (SER), both in animals and in human. This increase in SER resembles that seen after the administration of a wide variety of hepatotoxins, therapeutic agents, and some food additives. Since most of the substances that induce a proliferation of the SER are metabolized, at least in part, by the cytochrome P450 enzyme system that is located on the SER, the possibility that alcohol may also be metabolized by similar enzymes was raised. Such a system was indeed demonstrated in liver microsomes *in vitro* and found to be inducible by chronic alcohol feeding *in vivo* and was named the microsomal ethanol-oxidizing system. Its distinct nature was shown by (1) isolation of a P450-containing fraction from liver microsomes that, although devoid of any ADH or catalase activity, could still oxidize ethanol as well as higher aliphatic alcohols (e.g., butanol, which is not a substrate for catalase) and (2) reconstitution of ethanol-oxidizing activity using NADPH−cytochrome P450 reductase, phospholipid, and either partially purified or highly purified microsomal P450. The purified human protein (now called CYP2E1) was obtained in a catalytically active form, with a high turnover rate of ethanol and other specific substrates. MEOS has a relatively high K_m for ethanol (8−10 m*M*, compared to 0.2−2 m*M* for hepatic ADH) but, contrasting with hepatic ADH, which is not inducible in primates as well as most other animal species, enhanced levels of both hepatic CYP2E1 protein and its mRNA were found in actively drinking patients.

The presence of CYP2E1 was also shown in extrahepatic tissues and in nonparenchymal cells of the liver, including Kupffer, but not stellate, cells. In rats, ethanol treatment caused a sevenfold increase in CYP2E1 content of the Kupffer cells.

Increased Xenobiotic Toxicity and Carcinogenicity; Oxidative Stress

Much of the medical significance of the MEOS (and its ethanol-inducible CYP2E1) results not only from the oxidation of ethanol but also from the unusual and unique capacity of CYP2E1 to generate reactive oxygen intermediates, such as superoxide radicals. Indeed, there is increased evidence that ethanol toxicity may be associated with an increased production of reactive oxygen intermediates. Increased generation of oxygen- and ethanol-derived free radicals occurs at the microsomal level, especially through the intervention of the ethanol-inducible CYP2E1. This induction is accompanied by increased oxidation of NADPH with resulting H_2O_2 generation. There is also increased superoxide radical production. This oxidative stress contributes to the lipid peroxidation associated with alcoholic liver injury. Lipid peroxidation correlates with the amount of CYP2E1 in liver microsomal preparations and it can be inhibited by antibodies against CYP2E1.

CYP2E1 also activates many xenobiotic compounds to their toxic metabolites, often free radicals. This pertains, for instance, to carbon tetrachloride and other industrial solvents such as bromobenzene and vinylidene chloride as well as anesthetics such as enflurane and halothane. Ethanol abuse also markedly increases the activity of microsomal benzene-metabolizing enzymes and aggravates the hematopoietic toxicity of benzene. In addition, enhanced metabolism (and toxicity) pertains to a variety of prescribed drugs, including isoniazid and phenylbutazone and some over-the-counter medications such as acetaminophen (paracetamol or Tylenol), all of which are substrates for, or inducers of, CYP2E1. Therapeutic amounts of acetaminophen (2.5 to 4 g per day) can cause hepatic injury in alcoholics. In animals given ethanol for long periods, hepatotoxic effects peaked after withdrawal when ethanol was no longer competing for the microsomal pathway but levels of the toxic metabolites were at their highest. Thus, alcoholics are most vulnerable to the toxic effects of acetaminophen shortly after cessation of chronic drinking. In fact, such patients hospitalized with acetaminophen toxicity related to accidental misuse had higher rates of morbidity and mortality than those who attempted suicide, even though the latter had taken more acetaminophen.

There is an association between alcohol misuse and an increased incidence of upper alimentary and respiratory tract cancers. Many factors have been incriminated, one of which is the effect of ethanol on enzyme systems involving activation of carcinogens by CYP2E1.

Alcoholics are also commonly heavy smokers, and the synergistic effects of alcohol consumption and smoking on cancer development are striking, with a 44-fold increase of esophageal cancer in human.

Most importantly, induction of the MEOS results in interaction with many nutrients, as reviewed elsewhere, and in enhanced acetaldehyde production (Fig. 2), which, in turn, aggravates the oxidative stress directly as well as indirectly by impairing defense systems against it. Acetaldehyde is a major cause of complications (Fig. 2) that contribute to the development of liver injury.

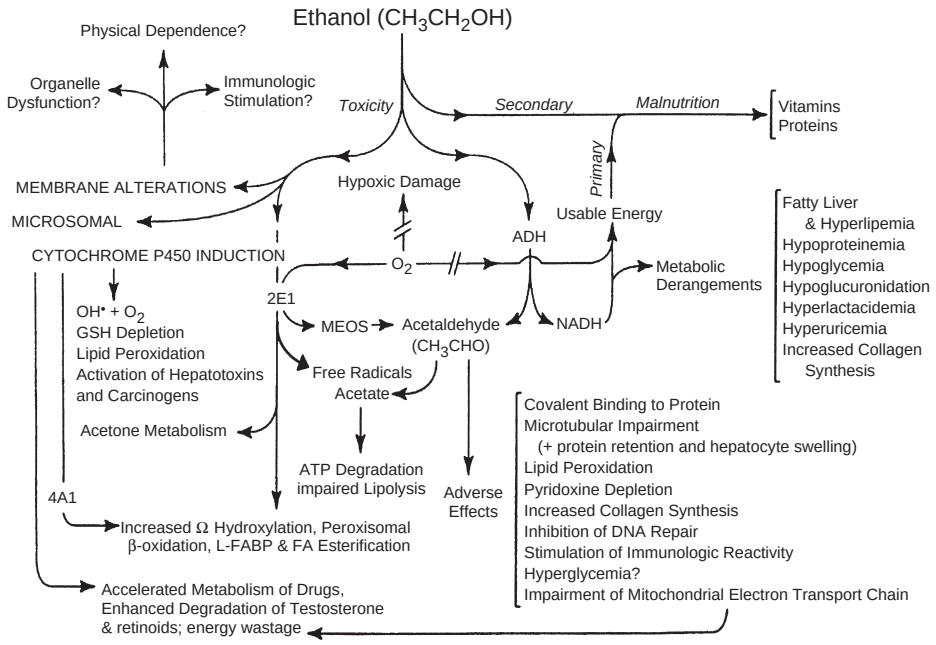

FIGURE 2 Hepatic, nutritional and metabolic abnormalities after ethanol abuse. Malnutrition, whether primary or secondary, has been differentiated from direct toxicity of ethanol. The latter results from redox changes, effects secondary to microsomal induction, the generation of acetaldehyde, direct membrane alterations, and/or hypoxia.

The Catalase Pathway

Catalase is capable of oxidizing alcohol *in vitro* in the presence of an H_2O_2-generating system and its interaction with H_2O_2 in the intact liver was demonstrated. However, its role is limited by the small amount of H_2O_2 generated and, under physiological conditions, catalase appears to play no major role in ethanol oxidation.

The catalase contribution might be enhanced if significant amounts of H_2O_2 become available through β-oxidation of fatty acids in peroxisomes. Indeed, long-term ethanol consumption is associated with increases in the content of a specific cytochrome (CYP4A1) that promotes microsomal ω-hydroxylation of fatty acids, which may compensate, at least in part, for the deficit in fatty acid oxidation due to the ethanol-induced injury of the mitochondria. Products of ω-oxidation also increase liver cytosolic fatty acid-binding protein and peroxisomal β-oxidation, an alternate but modest pathway for fatty acid disposition.

OXIDATION OF ETHANOL IN THE STOMACH: GENDER AND ETHNIC DIFFERENCES

Alcohol was known to disappear from the stomach and this was considered to be part of its "absorption" from the gastrointestinal tract (Fig. 1). It is now apparent that some of this absorbed ethanol is in fact metabolized in the gastric wall. As a result, when alcohol is taken orally, blood levels achieved are generally lower than those obtained after administration of the same dose intravenously, so-called first-pass metabolism (FPM). Indeed, the gastric mucosa contains the same diversity in isozymes of ADH (except for π) as the liver (*vide supra*). However, in addition, it has a class IV ADH (called σ-ADH) that is not present in the liver. This enzyme has now been purified, its full-length cDNA has been obtained, and the complete amino acid sequence has been deduced. Furthermore, the gene (ADH7) was cloned and localized to chromosome 4 by Yokoyama *et al*. in 1996. The upstream structure of the human ADH7 gene and the organ distribution of its expression were also defined. σ-ADH was found to have a high capacity for ethanol oxidation, greater than that of the other isozymes. Its affinity for ethanol is relatively low, with a K_m of approximately 30 m*M*, but this is not a drawback in the stomach, where ethanol is commonly present at much higher concentrations.

In vitro, gastric ADH was found to be responsible for a large fraction of the ethanol metabolism observed in cultured rat and human gastric cells. Thus, FPM reflects, at least in part, gastric metabolism.

The concept of a significant ethanol metabolism in the stomach was also supported indirectly by the observation that commonly used drugs, such as aspirin, and some histamine-2 blockers, which decrease the activity of gastric ADH and/or accelerate gastric emptying, also increase blood alcohol levels *in vivo*. This was particularly apparent after the repeated intake of low alcohol doses, mimicking social drinking. Although questioned at first, such increases in blood levels have now been widely confirmed. The blood level achieved by each single administration of a low dose is small, but social drinking is usually characterized by repetitive consumption of small doses. Under those conditions, the effect of the drug is cumulative, and the increase in blood alcohol becomes sufficient to reach levels known to impair cognitive and fine motor functions.

Some ethnic differences also support the concept of the role of gastric ADH in FPM of ethanol. Indeed, σ-ADH is absent or markedly decreased in activity in a large percentage of Japanese subjects. Their FPM is correspondingly reduced.

Gender differences have also been described: In Caucasians, gastric ADH activity is lower in women than in men, at least below the age of 50 years, a difference mainly due to lower χ-ADH activity in women. This is associated with higher blood alcohol levels, an effect more striking in alcoholic women than in nonalcoholic women because FPM is partly lost in the alcoholic, together with decreased gastric ADH activity. Furthermore, in women, the alcohol consumed is distributed in a 12% smaller water space because of a difference in body composition (more fat and less water). The larger proportion of ethanol that enters the systemic circulation in women than in men may contribute to their greater vulnerability to alcohol, not only in terms of central nervous system manifestations but also for liver disease, especially since women have less effective defense mechanisms against alcoholic liver injury than men.

The magnitude of FPM also depends on the concentration of the alcoholic beverages used. Indeed, gastric ADH isozymes require a relatively high ethanol concentration for optimal activity. Therefore, the concentration of alcoholic beverages affects the amount metabolized, with lesser gastric FPM (and hence more alcohol reaching the blood) after weak beverages (such as beer) than for equivalent amounts of ethanol consumed in strong beverages (such as whiskey). Fasting also strikingly decreases FPM, most likely because of accelerated gastric emptying, resulting in shortened exposure of ethanol to gastric ADH and its more rapid intestinal absorption.

In summary, gastric FPM of ethanol represents a useful barrier against excess penetration of ethanol into the body.

Liver disease in the alcoholic patient has long been believed to be due exclusively to malnutrition, but at present, the additional role of ethanol hepatotoxicity is well established. In the absence of dietary deficiencies, and even in the presence of protein-, vitamin-, and mineral-enriched diets, ethanol produces a fatty liver with striking ultrastructural lesions, both in rats and in human volunteers, and scarring or fibrosis with cirrhosis in nonhuman primates. In humans, there is a clear link between the amount of alcohol consumed and the incidence of cirrhosis, associated with deadly complications.

INTRODUCTION

The clinical course and ultimate outcome of alcoholic liver disease is dismal. In a prospective survey of 280 patients with alcoholic liver injury, Chedid and coworkers found that, within 48 months of followup, 30% of those with a fatty liver, more than half of those with cirrhosis, and two-thirds of those with cirrhosis plus alcoholic hepatitis died. This outcome is more severe than that of many cancers, yet it is attracting much less concern, both among the public and the medical profession. This may be due, at least in part, to a prevailing and pervasive perception that not much can be done about this major public health issue. Pathogenic concepts of alcoholic liver disease, however, are evolving, and elucidation of the biochemical effects of ethanol allows for a more optimistic outlook in terms of diagnosis and treatment.

NATURAL COURSE OF ALCOHOLIC LIVER DISEASE

Fatty Liver

Fat accumulation in the liver cells is the earliest and most common response to alcohol metabolism in the liver. The normal liver weighs about 1.5 kg, whereas the alcoholic fatty liver weighs 2.0–2.5 kg. Macroscopically, on hematoxylin- and eosin-stained sections, parenchymal accumulation of lipid is seen as clear intracytoplasmic vacuoles, or as black or red globules with various Sudan stains. In massive steatosis (Fig. 1), the hepatocytes are uniformly filled by larger fat droplets. The cell nucleus may be eccentrically placed, and when the cell membranes between adjacent hepatocytes rupture, fatty cysts are formed. Increased hepatic lipid accumulation (involving mainly a 3- to 10-fold rise in triglycerides) can be demonstrated by biochemical measurements before it becomes histologically apparent. Evidence of necrosis is usually sparse but sometimes the hepatocytes are surrounded by a mild accumulation of inflammatory cells. When pronounced, these formations are called "lipogranulomas."

containing crystalline inclusions. The endoplasmic reticulum shows vacuolar dilatation and proliferation. Despite adequate nutrition, alcohol was found to induce these alterations in rats and baboons (Fig. 2) and in alcoholic human volunteers.

The clinical spectrum of alcoholic fatty liver may extend from silent, nonsymptomatic hepatomegaly to severe hepatocellular failure with cholestasis and impaired blood flow through the liver. Most of the patients with simple fatty liver are virtually asymptomatic. Hepatomegaly is the commonest clinical sign, present on physical examination in 75% of patients. In more advanced cases, hepatic tenderness, anorexia, nausea, emesis, jaundice, and even fluid accumulation in the abdomen (ascites) are present. Severe forms of fatty liver may present a clinical picture mimicking extrahepatic obstructive jaundice, especially if associated with dark urine and light-colored stools. Typical abnormalities in laboratory tests are slightly or moderately elevated γ-glutamyl transferase (GGT) and serum (alanine and aspartate) transaminases (AST and ALT). In contrast to more advanced alcoholic liver injury, all the abnormalities of the laboratory tests tend to return to normal within the first days of abstinence.

Perivenular Fibrosis

Although it can occur anywhere in the liver, the earliest deposition of fibrous tissue is generally seen around the central veins and venules—now called terminal hepatic venules. Fibrosis around these veins has been described in alcoholic hepatitis and is often associated with a necrotizing process called sclerosing hyaline necrosis. When intensive, it may obliterate the terminal hepatic veins and lead to postsinusoidal portal hypertension with ascites prior to the development of cirrhosis. It is important to note that perivenular fibrosis can be seen in the absence of, or prior to, widespread inflammation and necrosis, in association with what pathologists would label as "simple" fatty liver.

Once perivenular fibrosis has developed, it indicates that the patient has already entered the fibrotic process and that, on continuation of drinking, he or she will rapidly develop more severe stages, including cirrhosis. Thus, this lesion can be considered as a marker of vulnerability to the development of subsequent cirrhosis and therefore can be used as an indication for active intervention.

Alcoholic Hepatitis

This stage is characterized by the appearance of necrosis with an inflammatory reaction, including polymorphonuclear cells. Although the incidence of fatty liver in alcoholics is very common, alcoholic hepatitis develops in only a fraction of heavy drinkers. Histological characteristics of alcoholic hepatitis are ballooning and a great disarray of hepatocytes (predominantly in perivenular areas) with disseminated infiltration by

polymorphonuclear inflammatory cells and varying degrees of steatosis, necrosis, fibrosis, and cholestasis. Mallory's alcoholic hyaline (irregular cytoplasmic bodies) can be considered as a diagnostic hallmark, but it is not always present. Ultrastructural changes in alcoholic hepatitis are similar but are more severe than the ones seen in fatty liver. Collagen fibers may surround the liver cells and interfere with their exposure to the blood.

The clinical spectrum of alcoholic hepatitis may thus range from mild hepatomegaly to fatal disease with jaundice, ascites, liver coma, gastrointestinal hemorrhage, and with all the complications of severe hepatic insufficiency. In general, there is a correlation between the severity of the histological features of alcoholic hepatitis (hepatocellular necrosis, leukocytic infiltration, frequency of alcoholic hyaline) and the degree of hepatomegaly, leukocytosis, and elevations of serum transaminases and the intensity of symptoms.

Among the laboratory abnormalities, an AST/ALT ratio greater than 2.0 is considered indicative for alcoholic liver injury. However, this ratio may be less helpful in the presence of cirrhosis. The depression of serum albumin and the prolongation of the prothrombin time have been shown to correlate with the severity of the histological lesions. Other common laboratory findings include serum bilirubin elevations (in 90% of patients). It should, however, be remembered that serum bilirubin may also be increased in the absence of alcoholic hepatitis (for instance, because of red cell destruction or pancreatitis, an inflammation of the pancreas).

Cirrhosis

Macroscopically, the early cirrhotic liver is golden yellow with fine uniform nodules (from 1 to 5 mm) on the surface. Traditionally, this type of cirrhosis is called micronodular, or Laennec's, cirrhosis. The size of the liver varies, depending on the degree of fibrosis, inflammation, and steatosis, from a small, shrunken, and hard liver to a large organ weighing up to 4 kg.

Microscopically, scar tissue distorts the normal architecture of the liver by forming bands of connective tissue joining portal and central zones (Fig. 3). At first, nodules are regular in size and shape. In more advanced cirrhosis, some nodules become larger and irregular.

One of the most characteristic features of cirrhosis is the change in the hepatic blood circulation. Inflammation and perivenular fibrosis (*vide supra*) may impair blood flow and the regenerative nodules may also compress the hepatic veins, resulting in localized increased blood pressure. With the progression of the fibrosis, the blood flow is further depressed. In addition, the total blood flow through the cirrhotic liver decreases. This results from extrahepatic shunts bypassing the scarred liver. These shunts further isolate the hepatocytes from their blood supply. As a result, marked deterioration in hepatic functions occurs.

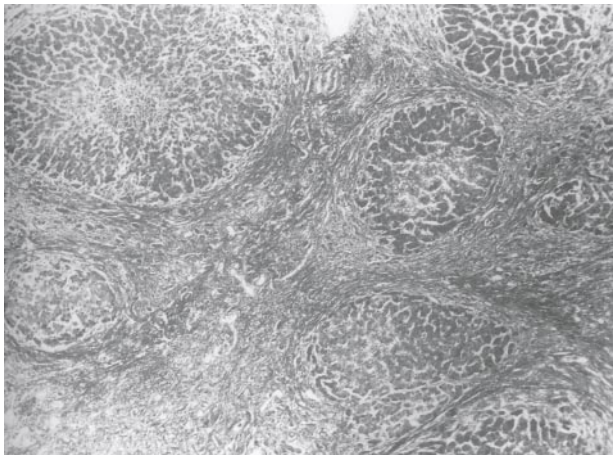

FIGURE 3 Section of liver from an alcoholic patient, showing cirrhosis. The normal liver parenchyma is replaced by nodules surrounded by abundant bands of fibrotic tissue. Hematoxylin and eosin staining, ×50. Reproduced with permission from Lieber (1992).

In addition to fibrosis, fat, inflammatory reactions, cholestasis, and histologically stainable iron deposits are common in cirrhotic livers, especially in alcoholic subjects. But total iron stores are very seldom increased and never exceed 179 mmol (10 g). The differentiation from primary hemochromatosis is possible by measuring the total hepatic iron content from liver biopsies.

Hepatocellular carcinoma (HCC) has become a relatively frequent finding in liver cirrhosis, presumably because of improved management and prolonged survival. Pathogenetically, it has been traditionally related to cirrhosis, but possible carcinogenic properties of alcohol must also be considered, because primary hepatocellular carcinoma can complicate noncirrhotic alcoholic liver disease. Furthermore, at least in some patients, there is a significant interaction between alcohol and viral hepatitis, especially hepatitis C, in hepatocarcinogenesis.

Most patients are diagnosed when they seek treatment for complications. Autopsy studies show that cirrhosis may remain unrecognized antemortem in 40% of the patients, and it is discovered fortuitously in about 20% of patients on routine examination or during the evaluation of some other, unrelated, disease.

Low-grade and continuous fever is also common in decompensated cirrhosis. Jaundice and hepatomegaly

are typical primary physical signs of cirrhosis. Secondary phenomena include portal hypertension with splenomegaly, edema, and ascites; encephalopathy; and gastrointestinal hemorrhage from bursting esophageal or gastric varices, and bleeding tendencies due to clotting factor deficiencies resulting from hepatocyte malfunction. Tertiary complications include spontaneous peritonitis caused by anaerobic bacteria.

Typically, blood tests reveal a decrease in serum albumin with increased and abnormal globulins. Serum transaminases and bilirubin are usually only mildly elevated, with more striking increases in the end stages. As previously discussed, the outcome is often dismal, with a 1-year mortality of 50% or more in patients over the age of 60 years.

Ethanol (also called alcohol or ethyl alcohol) is the most commonly abused psychoactive drug, yet it is legal in most countries. Its metabolism is the cause of a vast array of pathologic manifestations.

INTRODUCTION

Ethanol is readily absorbed from the gastrointestinal tract but only 2 to 10% is eliminated through the kidneys and lungs; the rest is metabolized in the body. Many tissues contain enzymes capable of ethanol oxidation or nonoxidative metabolism, but significant activity occurs only in the liver (Fig. 1) and, to a lesser extent, in the stomach. magnetic resonance imaging Technique that is based on the interaction between an external magnetic field and a nucleus that possesses spin. The patient is exposed to energy at a specific, correct frequency; this energy is absorbed and a short time later is released, at which time it can be detected and processed to yield images.

T1-weighted images Precontrast, provide information on abnormally increased fluid content or fibrous tissue content (e.g., low signal intensity) and information on the presence of subacute blood or concentrated protein (e.g., high signal intensity). The addition of fat suppression allows blood to be distinguished from fat. Post-Gd images increase the conspicuity of disease processes.

T2-weighted images Provide information about the presence of increased fluid in diseased tissue (e.g., high signal intensity) and the presence of chronic fibrotic tissue or iron deposition (e.g., low signal intensity).

Alimentary tract magnetic resonance imaging is an important and well-established tool for colon cancer and inflammatory bowel disease evaluation. Many more applications are emerging as higher gradients and faster imaging techniques allow for noninvasive, real-time evaluation of the gastrointestinal system.

INTRODUCTION

Hardware and software advancements have expanded the role of magnetic resonance imaging (MRI) of the alimentary tract. Breath-hold imaging (T1-weighted fat-suppressed spoiled gradient echo and T2-weighted single-shot fast spin) combined with intravenous gadolinium (Gd) chelates will result in reproducible, high-quality images that arrest bowel motion, decrease susceptibility artifacts, remove the competing high signal intensity of intraabdominal fat, expand the dynamic range of signal intensities, and facilitate distinction of bowel wall from intraluminal contents. The role of oral contrast agents remains controversial and their use is not routine. Established and evolving applications of alimentary tract MRIs include colon carcinoma evaluation (screening, staging, and distinguishing recurrent tumors from radiation therapy changes) and inflammatory bowel disease evaluation (type and severity).

TECHNIQUE

To limit peristalsis, patients should fast 4–6 hours prior to the examination; alternatively, intravenous antiperistaltics (1 mg glucagon) may be given prior to imaging. Imaging is optimized with the use of a torso-phased array coil. A standard protocol involves orthogonal T1-weighted spoiled gradient echo (T1-W SGE) sequences (with and without fat suppression), orthogonal T2-W single-shot fast spin echo sequences (T2-W SSFSE) (Fig. 1), and orthogonal post-Gd (0.1 mmol/kg) fat-suppressed T1-W SGE sequences. High-resolution (512 matrix) T2-W fast spin echo (T2-W FSE) sequences are reserved for imaging the rectum. This is because the rectum is relatively fixed in position and therefore refractory to blurring artifacts associated with bowel motion. The rectum may also be imaged with an endoluminal coil. This coil optimizes spatial resolution and improves conspicuity of the different rectal wall layers, sphincter complex, and disease states. Magnetic resonance (MR) colonography has been gaining momentum and involves distending the large bowel with a 2-liter solution of water spiked (20 ml) with gadolinium chelate (0.5 mol/liter) and obtaining coronal three-dimensional (3D) spoiled gradient echo volumetric slabs and two-dimensional (2D) T2-W SSFSE images. The 3D data sets are then postprocessed using commercially available software (Fig. 2).

Colon cancers predilect the rectosigmoid colon. Tumors may be polypoid, circumferential, or plaquelike. There is ongoing controversy concerning the most appropriate screening program (hemoccult stool testing, conventional colonoscopy, barium enema, and, most

recently, virtual colonography/colonoscopy). The diagnostic performance of MR colonoscopy is directly related to lesion size. For example, the sensitivity, specificity, positive predictive value, and negative predictive value for detecting polyps 10 mm or greater are 93, 99, 93, and 99%, respectively (Fig. 3). This falls to 75, 92, 72, and 93%, respectively, when using a lesion cutoff value of 7 mm. The performance of MR colonography is expected to improve with optimization of spatial resolution associated with advances in receiver coil technology,

faster gradients systems, and more efficient pulse sequences.

Preoperative Staging

Once colon cancer is diagnosed, MRI is useful in staging, especially when the tumor involves the rectum. Specifically, for locoregional spread, there is good correlation between MRI techniques and surgical specimens for tumor size, wall involvement, peritumoral invasion, and lymph node involvement. For distant metastases (e.g., liver metastases), a dynamic contrast-enhanced scan of the abdomen is often done at the time of pelvic imaging. Colon cancer is staged according to the TNM classification (T, tumor size assessment; N, degree lymph node involvement; M, degree of metastasis).

Primary colon tumors are often heterogeneous in signal intensity on T2-W images. Also, though many tumors have moderately high signal intensity components, these may be difficult to appreciate on T2-W SSFSE and FSE sequences, where the surrounding fat is also high in signal intensity—though this phenomenon is usually less problematic on standard T2-W FSE sequences. Tumors with a shaggy outer margin and loss of the normal low signal intensity outer bowel muscularis propria suggest lymphovascular invasion. Colon cancers enhance following the administration of contrast. Similarly, peritumoral extension, lymph node metastases, and peritoneal seeding all enhance on fat-suppressed Gd T1-W SGE imaging (Fig. 4). Lymph node metastases are common with alimentary tract malignancies and may be present in "nonpathologically" enlarged nodes; their presence may be inferred, however, when noting greater than five lymph nodes measuring < 10 mm in short axis in a regional distribution related to the primary tumor. Liver metastases are well depicted on MRIs and tend to have irregular borders.

There have been no large randomized clinical trials to compare the staging accuracy of state-of-the-art MR and multidetector computer tomography (CT) for patients with colon cancer. Summarizing older literature, the overall staging accuracy of these two modalities is equivalent, approximately 70%. And though the report from the Radiology Diagnostic Oncology Group (RDOG) II found that CT was more accurate in detection of tumor penetration of the muscularis propria; current MR techniques (e.g., breath-hold imaging and contrast-enhanced fat-suppressed imaging) render the RDOG findings obsolete.

Recurrent Tumor versus Radiation Fibrosis

Rectosigmoid cancers recur at a rate of 8–50%. This range reflects differences in the stage of primary tumor at presentation. Local recurrences are most common and, if diagnosed early, are amenable to curative resection. Recurrent rectal carcinomas are best imaged in the sagittal plane. One study reported 93.3% accuracy in detecting recurrent rectal cancers using T1-W, T2-W, and Gd T1-W sequences. Others have shown MRI to be superior to conventional CT and transrectal ultrasound (US) for identifying recurrent disease. Data on multidetector CT are at present, unknown.

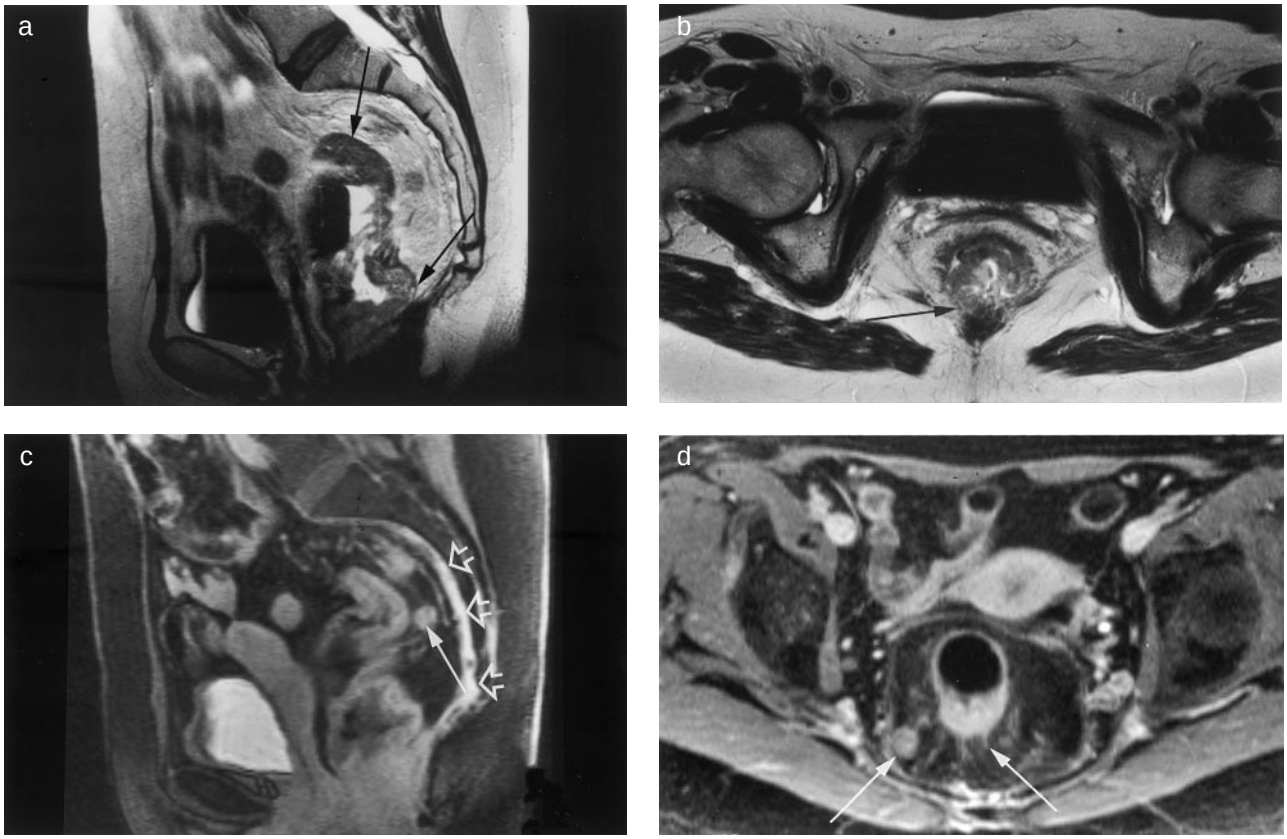

FIGURE 4 Rectal cancer. Sagittal (a) and axial (b) T2-W FSE and sagittal (c) and axial (d) fat-suppressed Gd T1-W SGE images in a patient with advanced rectal cancer. The sagittal image demonstrates the craniocaudad extent of the tumor (arrows, a). Extension to the anal verge (arrow, b) is confirmed on the axial images. On the T2-W sequences, the tumor's shaggy border suggests lymphovascular involvement that is confirmed on the contrast-enhanced images (arrows, c, d). Similarly, presacral spread of tumor is more conspicuous following gadolinium (open arrows, c). From Semelka *et al*. (2002). Gastrointestinal tract. *In* "Abdominal-Pelvic MRI." A recurrent tumor is often low in signal intensity on T1-W techniques and enhances less than primary tumors following the administration of gadolinium chelates. On T2-W images, recurrences are often moderately high in signal intensity, but, as with primary tumors, this may not be conspicuous on T2-W SSFSE sequences. Recurrent tumors tend to be more nodular and "masslike" compared to postradiation fibrosis; though the two entities may coexist.

Following 1 year of treatment, radiation fibrosis is often low in signal intensity on both T1-W and T2-W sequences and has negligible enhancement (Fig. 5). Unfortunately, associated granulation tissue may also demonstrate high signal intensity for up to 3 years posttreatment. This phenomenon is most pronounced with patients who have received >45 mGy. Similarly, overlap in signal intensity between recurrent disease and fibrosis on T2-W SSFSE can occur when normal high-signal-intensity fat is admixed with low-signal-intensity fibrosis (Fig. 6). And, though radiation fibrosis is morphologically a plaquelike process, recurrent tumor with desmoplastic features may mimic these radiation-induced changes. Because recurrent carcinoma and radiation changes share many imaging features, interpretation should be performed with appropriate clinical correlation [e.g., rising carcinogenic embryonic antigen (CEA) levels].

INFLAMMATORY BOWEL DISEASE

MRI is robust for evaluating patients with inflammatory bowel disease (IBD). It correlates well with clinical indices, endoscopy, and histology. Furthermore, MRI may aid in diagnosing the type of IBD (Crohn's disease vs. ulcerative colitis), establishing a baseline of involvement and monitoring treatment response—all without exposing a patient to ionizing radiation. It is even useful for imaging complications associated with IBD

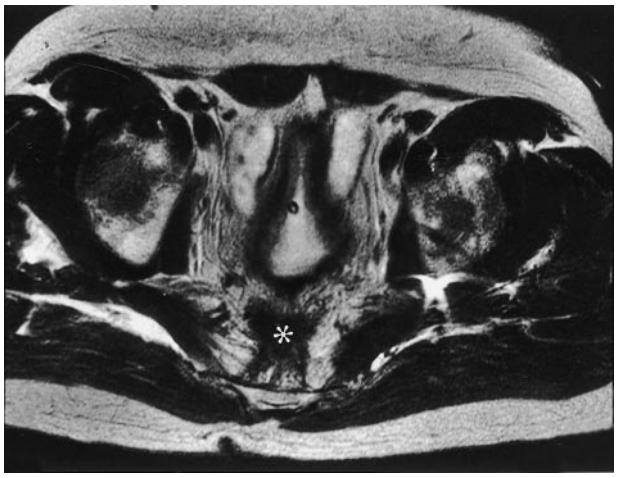

FIGURE 5 Posttreatment fibrosis. Axial high-resolution T2-W FSE image in a patient after surgery. The low signal intensity in the surgical bed (asterisk) is consistent with fibrosis. Its plaquelike morphology favors postradiation change, whereas recurrent tumor tends to be more nodular. From Semelka *et al.* (2002). Gastrointestinal tract. *In* "Abdominal-Pelvic MRI." (e.g., abscess, fistulae, strictures/obstruction, and toxic megacolon).

Crohn's Disease

For patients with Crohn's disease, T2-W SSFSE and fat-suppressed Gd T1-W SGE sequences demonstrate classic findings: transmural involvement, skip lesions, and mesenteric inflammation. The terminal ileum, alone or in conjunction with other regions of the alimentary tract, is involved in approximately 70% of cases; whereas isolated Crohn's colitis occurs in about 25% of cases. MRI correlates of clinical disease activity have been worked out. Severity of disease (mild, moderate, or severe) is based on wall thickness, length of diseased segment, and percent bowel wall enhancement (Table I) (Fig. 7). MR assessment is performed on the nondependent bowel surface. For mural enhancement, qualitative assessment is performed by comparing bowel wall enhancement to renal parenchyma. Specifically, bowel should never enhance to the same degree as renal cortex on either the initial capillary phase or the interstitial phase images. For quantitative analysis, the abnormal segment is measured 2.5 minutes after injection. Imaging at this time (interstitial phase) reflects capillary leakage and impaired venous egress in the inflamed segment. Acute-on-chronic disease may deviate from expected MR findings: there is often marked enhancement of the mucosa of the involved loop of thickened bowel, with minimal enhancement of its outer layer.

Fistulae are common complications of Crohn's disease and MR images them well. Depending on their contents, they may have high signal intensity on T2-W images (e.g., fluid filled); alternatively, they may be signal void (e.g., gas filled). Multiplanar imaging combined with fat suppression increases the

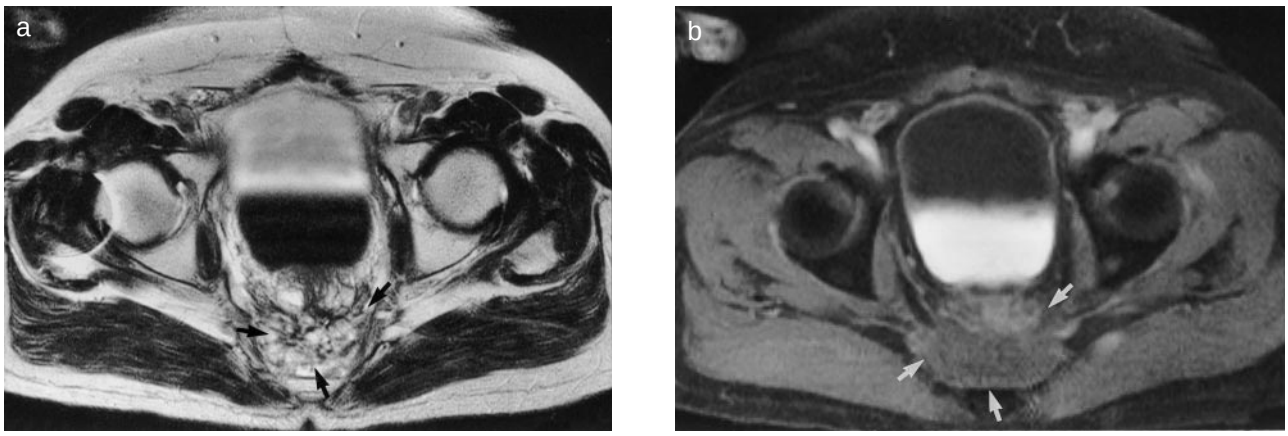

FIGURE 6 Recurrence simulating posttreatment fibrosis. Axial high-resolution T2-W FSE (a) and fat-suppressed T1-W SGE (b) images in a patient 1.5 years after treatment for rectal cancer. Heterogeneous and bulky high-signal-intensity soft tissue (arrrows, a) occupies the surgical bed, a worrisome indication for recurrent disease. Granulation tissue from radiation, inflammation, or infection may image similarly. The heterogeneity is misleading and results from high-signal-intensity fat—a phenomenon associated with fast spin echo techniques—admixed with low-signal-intensity fibrotic tissue. Negligible enhancement favors the diagnosis of fibrosis (arrows, b). From Semelka *et al.* (2002). Gastrointestinal tract. *In* "Abdominal-Pelvic MRI." Copyright 2002 John Wiley. The coronal T2-W SSFSE images demonstrate thickened loops of small bowel (arrows, a, b) to include the diseased terminal ileum entering the cecum (arrowhead, a). The corresponding enhanced images show marked transmural enhancement of the affected segments and surrounding tissues. In addition, a fistula associated with the ileo-cecal valve is highlighted (arrow, c). The wall thickness, length of involved bowel, and percent enhancement are consistent with severe Crohn's disease. From Semelka *et al*. (2002). Gastrointestinal tract. *In* "Abdominal-Pelvic MRI." conspicuity of the enhancing fistulous tracts on post-contrast images (Fig. 7c). Focal loss of integrity of the involved organ at the site of fistula penetration is diagnostic. In the case of strictures, T2-W SSFSE demonstrates dilated obstructed bowel proximal to the site of narrowing, as well as the offending stricture.

Ulcerative Colitis

Ulcerative colitis (UC) is a chronic mucosal disease that begins in the rectum and extends in a proximal fashion to involve all or part of the colon. Though the small bowel is not directly affected in UC, secondary

inflammation of the terminal ileum, or "backwash ileitis" (reflux of colon contents into the small bowel), does occur with pancolonic disease. The major complications of UC include increased risk of developing colon carcinoma and toxic megacolon.

The MRI appearance is predictable: rectal involvement with variable continuous retrograde progression and submucosal sparing. Fat-suppressed Gd T1-W imaging in the interstitial phase highlights the enhancing high-signal-intensity mucosa surrounded by the negligibly enhancing low-signal-intensity submucosa (Fig. 8). The vasa rectae also enhance prominently. In long-standing disease, the submucosal sparing is accentuated. This is a function of submucosal edema and lymphangectasia. Interestingly, the imaging features of toxic megacolon differ from that of uncomplicated UC. Toxic megacolon is a transmural process—full-thickness enhancement usually accompanies the involved segment, though regions with submucosal sparing may coexist (Fig. 9).

After contrast, there is intense enhancement of the sigmoid colon (asterisks, b, c) and vasa rectae (long arrows, b, c). Among inherited diseases, α1-antitrypsin deficiency (α1ATD) is a relatively common disorder affecting the cellular secretion of one of the body's protective proteinase inhibitors. Specific mutations of the α1-antitrypsin (α1AT) gene lead to changes in the three-dimensional structure of its translated protein, which becomes trapped in hepatocytes where it is formed. The resultant circulating deficiencies of α1AT allow destructive proteases to cause tissue injury, particularly in the lung, and accumulations of mutant α1AT in liver cells disrupt normal function, sometimes leading to cirrhosis. α1-Antitrypsin deficiency is only one member of a family of conformational diseases requiring more detailed understanding in order to counteract common pathophysiological abnormalities, namely, the improper folding and processing of critical proteins, as a means of restoring normal biological function. This article focuses primarily on the current understanding of liver-related injury secondary to α1ATD.

INTRODUCTION

In the United States alone, more than 100,000 individuals have α1-antitrypsin deficiency (α1ATD). However, the disease goes undetected in many people because the disorder is underappreciated and misinterpreted. Given the protean functions of α1-antitrypsin (α1AT), patients with inherited deficiency mutations can present in a variety of ways depending on the tissue involved (e.g., lungs, liver, blood vessels, kidneys) and the extent of injury. Clearly, multiple inherited and environmental factors are involved in the full expression of disease in patients with α1ATD. Disease is not inevitable, even in patients with the most severe forms of deficiency. Alternatively, there are individuals with heterozygous genotypes and partial deficiencies of α1AT who develop disease with all the manifestations of a homozygote carrying two mutant alleles. Cigarette smoking is one well-recognized example of an environmental factor capable of accelerating pulmonary disease in patients with α1ATD but modulating variables contributing to liver injury in these patients remain speculative and are under investigation. Nonetheless, earlier identification of patients at risk is important because manifestations of disease can be moderated in some instances by increasing awareness of potential aggravating conditions and applying preventative strategies. If liver failure develops, liver transplantation can be curative but the success of surgery is greatest when performed at an optimal time in the course of the disease. Proper monitoring of the patient plays an important role in making this determination. Genetic counseling should be available for family members but physicians must be cognizant of the potential implications of discovering an underlying genetic disorder, especially in those yet unaffected by disease.

BIOLOGICAL AND MOLECULAR CHARACTERISTICS

α1-Antitrypsin is one of a family of molecules called serine protease inhibitors that share structural homology but are functionally diverse, regulating a variety of proteolytic processes essential to life (Table I). The

activities of these molecules are highly dependent on amino acid sequence and posttranslational intracellular processing in order to evolve into a characteristic structure and shape. With proper conformational changes, these molecules expose specific reactive centers critical to their function. Misfolding of these polypeptides can change the usual interactions with target molecules and other proteins.

α1-Antitrypsin is a relatively small glycoprotein made up of 394 amino acids and three carbohydrate side chains. Its primary role appears to be inhibition of the proteolytic activities of neutrophil elastase, cathepsin G, and protease 3. The advantage of having adequate levels of circulating α1AT is most evident when considering the destructive actions of neutrophil elastase in the lungs. Inhalations of pulmonary pollutants, particularly cigarette smoke, attract and stimulate neutrophils, releasing destructive enzymes such as elastase. Controlled release of these enzymes is intended to break down components of the extracellular matrix, bacterial cell walls, and other proteins to facilitate the movement of inflammatory cells into affected areas of the lung. The presence of α1AT, with its ability to bind irrevocably with neutrophil elastase and other destructive enzymes, limits tissue injury, whereas severe deficiency of α1AT has been clearly associated with premature development of emphysema.

Synthesis of the α1AT protein complex, which occurs almost exclusively in the liver, involves a series of steps within hepatocytes before the complex is secreted into the circulation. The α1AT molecule is folded into a highly ordered three-dimensional structure composed of three β-sheets and nine α-helices as it traverses the cell. Final assembly and folding of α1AT occurs in the endoplasmic reticulum and Golgi apparatus with the help of one or more molecular chaperones (e.g., calnexin, heat shock proteins) facilitating the process (Fig. 1). When properly folded, a unique reactive site centered around two amino acids, Met^{358}–Ser^{359}, is exposed on the surface of the α1AT molecule. The interaction of this site with its target protease results in permanent inactivation of the coupled molecules. Small amounts of flawed or improperly folded proteins appear, ordinarily, to enter a separate intracellular pathway for degradation and disposal. Slight differences in the amino acid sequence of α1AT can lead to significant changes in the final shape of the molecule, altering its interactive surface. In the case of α1AT, single point mutations can alter the protein complex in such a way that the mutant α1AT molecules begin to interconnect in a process called "loop-sheet" polymerization. One polypeptide hooks into another and so on, eventually forming conglomerations of polymerized molecules that aggregate in the cell's endoplasmic reticulum, forming globules of varying size that are visible by light microscopy. These globules can be degraded over time, at different rates depending on genetically determined processes, sometimes releasing small quantities of viable α1AT molecules from the cell. Individuals with more efficient mechanisms of aberrant α1AT disposal may be less susceptible to the consequences of intracellular accumulation.

NOMENCLATURE—PROTEASE INHIBITOR PHENOTYPING

A gene located on the long arm of chromosome 14 regulates the production of α1AT. This gene locus is extremely pleiomorphic, with more than 100 different allelic variants (protease inhibitor or PI types) identified to date. Each inherited parental allele is co-dominantly expressed. Therefore, the quantity of circulating α1AT represents the combined product of the independent expression of each allele (Table II). In order to separate these variant glycoproteins into clinically recognizable "phenotypes," a classification system has been devised, making use of distinctive patterns of bands on polyacrylamide gel electrophoresis using a special technique called isoelectric focusing. Phenotypic variants are assigned letters from the alphabet based on the locations of these bands on gel slabs. During the process, faster moving molecules travel further along the gel strip and are assigned letters at the beginning of the alphabet, whereas slower moving variants are assigned letters near the end of the alphabet. It is important to note that the electrophoretic mobility does not indicate specific function or the capacity to be secreted from the hepatocyte. A majority of individuals (>95%) produce a normal M variety of α1AT, whereas several of

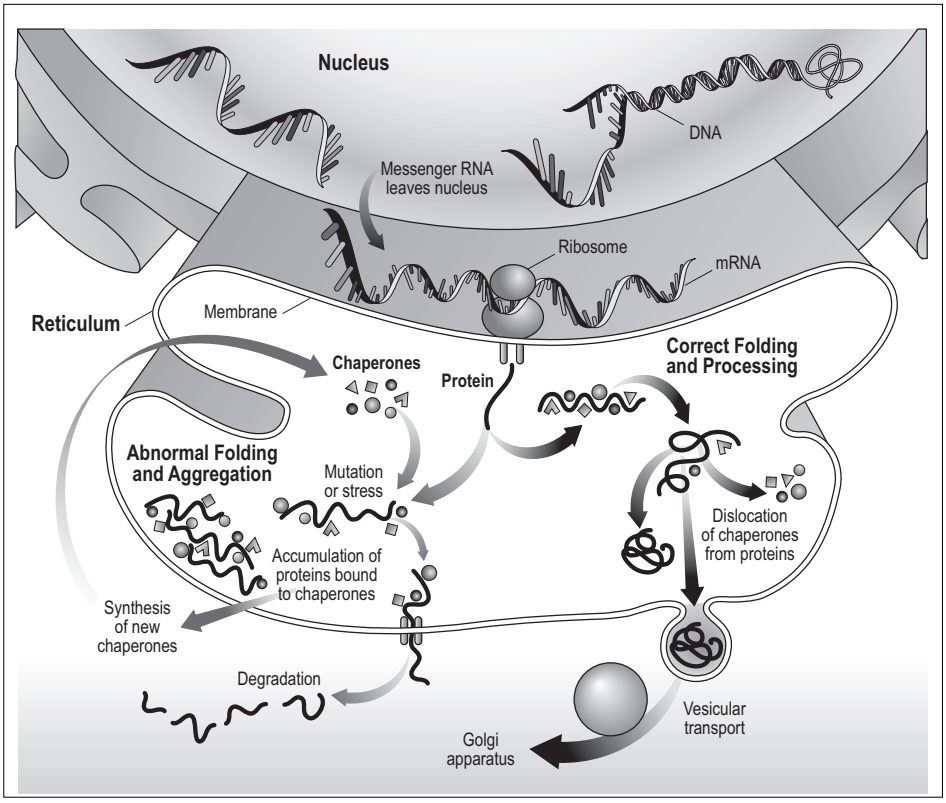

FIGURE 1 α1-Antitrypsin protein folding in the endoplasmic reticulum.

the more common "deficiency mutants" have been assigned letters such as S and Z. Homozygotes for the Z allele make up 95% of all deficiency phenotypes in patients with α1ATD and they are readily identifiable using isoelectric focusing. At times, variant molecules associated with α1ATD have patterns that are not easily detected by isoelectric focusing techniques but may be suspected by physicians because of characteristic clinical presentation, recognition of afflicted family members, detection of low circulating levels of α1AT, or detection of typical globules of mutant proteins on liver biopsy. In these instances, the specific mutation can be isolated by DNA sequencing. When determining an individual's phenotype, the laboratory will provide a letter for each of the two proteins representing the products of each allele (e.g., MM, MZ, ZZ).

The multiple different variants of α1AT generally can be placed into four groups based on circulating quantity and function: normal, deficient, null, and dysfunctional. The availability of α1AT in the blood can be normal (e.g., PI M), reduced (e.g., the deficiency alleles S and Z), or absent (e.g., extremely rare mutations called null alleles). Even though there are reduced amounts of circulating α1AT associated with many of these deficiency variants, the molecules that are excreted are usually fully functional. However, there are exceptionally rare mutations that result in a protein that escapes the hepatocyte but is folded is such a way that it changes function. The Pittsburgh variant is one example of a dysfunctional variant in which α1AT acts as a thrombin inhibitor, resulting in a severe bleeding disorder.

EPIDEMIOLOGY

Allelic frequencies of α1AT gene mutations vary considerably around the world and between study

populations. Utilizing global population studies to map the putative α1AT genes, investigators have suggested that the Z mutation originated in Scandinavia approximately 2000 years ago, eventually spreading from Northern Europe when people migrated from the area to other parts of the world. Therefore, the highest frequencies of the mutant gene are seen in Northern Europeans or in individuals of European ancestry. In Sweden, the frequency of the Z allele (PI*Z) is estimated to be 0.026 with 4−5% of the population carrying the mutation and 1 : 1600 live births being homozygous for this deficiency. The PI*Z gene frequency is somewhat lower in the United States among individuals of European descent, estimated to be between 0.01 and 0.02 with a carrier rate of approximately 3%. Some 80,000 to 100,000 people in the United States are PI ZZ homozygotes with considerable potential to develop disease. The Z allele is confined predominantly to Caucasians and is uncommon among individuals of Asian or African ancestry unless there is ethnic intermixing in the population. PI*S is a more common deficiency mutation than PI*Z, having a gene frequency between 0.02 and 0.03 in U. S. Caucasians. However, this genotypic variant is not associated with as severe a reduction in circulating levels of α1AT as the PI*Z allele and hence does not leave the individual susceptible to disease unless it is co-inherited with a Z allele. Of greater concern is the risk of disease in the 1 : 1000 to 1 : 1500 Caucasian individuals expressing a PI SZ phenotype. Although the matter is controversial, anyone carrying a single Z allele may be at some, as yet undefined, risk of developing liver disease regardless of the circulating levels of α1AT because of intracellular accumulation of the abnormally folded protein.

CLINICAL MANIFESTATIONS

The risk of developing emphysema in someone with α1ATD is closely related to the amount of circulating α1AT, especially when serum levels fall consistently below a "protective" level of 80 mg/dl (11 μ*M*). Even in patients with severe deficiencies of α1AT (< 50 mg/dl, < 7 μ*M*), a majority of patients presenting with pulmonary symptoms also report a history of smoking cigarettes. Interestingly, liver disease has not been a commonly reported problem in patients diagnosed with chronic lung disease related to α1ATD. The development of liver disease has been more closely linked to those genotypic variants associated with intracellular accumulation of polymerized polypeptides within the endoplasmic reticulum. Aside from the well-recognized Z variant, other rare mutations have been associated with intracellular globules identified in the liver (Table III). Accumulation of α1AT deposits can begin *in utero*, sometimes affecting neonates at an early stage in development. PI Z infants frequently present with low birth weight and coagulation abnormalities; as many as 70% have biochemical evidence of liver injury as indicated by elevations of liver enzymes. Prolonged cholestatic hepatitis, lasting up to 8 months, is clinically manifest in approximately 10% of these newborns. Although α1AT globules are not always easily identified on liver biopsy at this early stage, hepatocellular necrosis associated with acute and chronic portal inflammatory infiltrates, bile duct proliferation, bile plugs, and even ductopenia (intrahepatic bile duct loss) have been described in deficient individuals. Males appear to be affected more frequently than females (2 : 1) but a majority of children do not have long-term consequences at least as followed into their late teens. Approximately 3% have been shown to progress to hepatic fibrosis or cirrhosis and 12−15% have persistent mild elevations of liver enzymes.

Adults with the most prevalent form of α1ATD (PI ZZ) typically present with pulmonary symptoms (i.e., dyspnea) rather than with indicators of liver disease. It has been estimated that as many as 85% of patients with severe deficiency of α1AT have evidence of chronic obstructive pulmonary disease, often identified in the third and fourth decades of life. The prevalence of liver disease in these patients has not been well investigated even though it has been stated that few patients have liver test abnormalities when presenting with pulmonary manifestations. However, liver disease in adults with α1ATD progresses insidiously, often escaping detection until patients are beyond the age of 50 years. Commonly, a diagnosis is made when signs and symptoms of more advanced liver disease and portal hypertension (e.g., weakness, muscle wasting, ascites, splenomegaly, variceal hemorrhage, encephalopathy) appear. Therefore, a true incidence of liver disease in these patients

may be underappreciated, especially when the full expression of liver disease is attenuated by premature mortality from emphysema in younger age groups. This may be a reason that carefully conducted autopsy studies in populations with a high prevalence of severe α1ATD have estimated an incidence of cirrhosis as high as 40% over the lifetime of affected individuals. Most investigators feel that the numbers who develop cirrhosis may be somewhere between 10 and 15%, acknowledging that the risk increases with age, particularly in males. A North American study conducted in Canada found the cumulative risk of cirrhosis in susceptible men with α1ATD to be 23%, whereas the same risk in women amounted to only 5%. Of additional interest, these investigators observed that death from liver failure frequently occurred within 4 years of onset of clinical symptoms of liver disease, indicating that detection is often delayed.

Several population surveys and autopsy series find an increased risk of hepatocellular cancer in patients with severe deficiencies of α1AT and cirrhosis. In Sweden, liver cancer has been detected in approximately 15% of afflicted patients but once again the finding is predominantly in males.

A subject of ongoing interest and controversy is whether patients carrying a single Z allele (heterozygotes) are at some, as yet undefined, risk of developing cirrhosis and hepatic cancer. Studies to date have been unable to address this issue confidently because of the inherent difficulty in identifying and following subjects with the inherited trait longitudinally, along with proper controls. Nevertheless, it has been well recognized that heterozygotes for the Z allele often develop α1AT globules in the liver and can present with cirrhosis without any obvious alternative etiology for liver disease. Cohorts of patients with "cryptogenic" cirrhosis have shown a higher prevalence of α1ATD heterozygotes (e.g., PI MZ), raising suspicion about the single gene's role in the pathogenesis of liver disease. The relative importance of other variables such as viral hepatitis infection, alcohol, iron excess, generalized inflammatory conditions creating biological stress, or genetic factors in the natural history and progression of disease in these patients remains unclear. The coexistence of one or more of these factors may accelerate the accumulation or reduce the processing and breakdown of α1AT inclusions, resulting in enhanced hepatotoxicity. Despite this potential increased risk of developing significant liver disease in individuals with heterozygous α1ATD, the risk is estimated to be exceptionally small and should not alarm patients. Undue concern by the physician can have psychological consequences for the individual carrying the genetic trait. Prudent preventative measures and follow-up are all that may be recommended.

DIAGNOSIS

Laboratory tests used to screen for α1ATD should be considered in any patient, particularly Caucasians of European decent, with clinical, biochemical, radiological, or histological findings suggesting an underlying liver disorder. Additional signs or symptoms of pulmonary disease or history of an affected family member should heighten interest in pursuing this diagnosis.

Screening is best accomplished by obtaining both a quantitative level of α1AT and phenotype analysis. Reliance on semiquantitative analyses such as agarose gel electrophoresis, seeking a diminished or absent α1-globulin band, or determining quantitative levels of α1AT (e.g., immunoturbidimetry, nephelometry) alone can be misleading. Transient increases in α1AT levels have been observed in patients with putative deficiency variants, presumably as part of a general acute-phase reaction. Alternatively, several phenotypic variants, such as PI SS and null subtypes, have reduced circulating levels of α1AT but do not have the attendant risk of liver disease because of a lack of intracellular accumulation of glycoprotein. The combination of an α1AT level and phenotype helps to more directly identify patients with potential disease-causing variants.

PI phenotyping requires significant skill and experience to ensure accurate readings. Commonly, samples must be sent to a reference laboratory for interpretation. One method of phenotype identification uses a technique called isoelectric focusing (IEF) within a narrow pH gradient in polyacrylamide gel strips. Based on the isoelectric point, the α1AT molecules migrate along the gel to different positions, forming one or more bands that correspond to a particular phenotype. Some of the more unusual variants are not always easily visualized by routine IEF and can be misinterpreted as another more common pattern; for example, PI M_{malton} and PI M_{duarte} have electrophoretic patterns similar to that of PI M especially when heterozygous with a normal M allele. Null alleles do not generate any circulating product; therefore, IEF bands are absent. When the null allele is present in the heterozygous state, it may not be appreciated given the presence of bands from another allelic protein. However, a null allele should be suspected when the quantitative level of α1AT is significantly reduced in the setting of what appears to be a normal phenotype. At times, more unusual variants can be more accurately discriminated by gene analysis and other DNA-based techniques but many of these procedures are time-consuming. However, polymerase

chain reaction-based methods have been utilized as tools for screening populations when narrowing the focus of investigation to specific alleles.

After an initial screening, if an individual tests positive for a higher risk α1AT phenotype and has any indication of liver involvement, such as clinical signs, elevated liver enzymes, or hepatic architectural changes by radiological imaging, a liver biopsy should be considered. Evaluating liver histology helps to support the diagnosis of α1ATD, is useful in evaluating for alternative diagnoses, and can stage liver damage for purposes of making decisions about future management. Histological features can vary depending on the age of the individual (Table IV). A characteristic finding on biopsy is the presence of diastase-resistant, periodic acid-Schiff (D-PAS)-positive globules predominantly found in periportal hepatocytes and adjacent to fibrotic bands when present. These globules have a distinctive magenta color, making them highly visible with D-PAS staining, but they can be missed using light microscopy with standard hematoxylin and eosin staining.

Rarely, D-PAS-positive globules have been found in patients without α1ATD. D-PAS-positive globules have been found in liver biopsy specimens from patients who are elderly or terminally ill but a clue is the atypical location of the inclusions within the lobule (e.g., centrilobular region). These aberrant globules may represent lysosomes filled with proteins requiring degradation resulting from sinusoidal congestion and hypoxia. Occasionally, patients with alcoholic cirrhosis and oral contraceptive-associated hepatic tumors have D-PAS-positive globules within the liver despite normal α1AT phenotypes. If necessary, further characterization of intracellular inclusions can be performed using immunohistochemical techniques with mono-specific antiserum against α1AT.

Neonates and children
Hepatocytes vary in size with slight acinar formation
Occasional giant cell formation
Bile ducts may be normal, proliferated (sometimes confused with biliary atresia), or hypoplastic with duct loss
Low-grade inflammation, piecemeal necrosis, and fibrosis initially found in portal areas as disease progresses
D-PAS globules found in periportal hepatocytes predominantly but may be rare or inconspicuous during the first 2 months of life[a]
Adults
Low-grade lymphocytic infiltration in portal tracts, often inconspicuous
Intralobular bile ducts may be reduced in number
D-PAS-positive globules distributed in areas of inflammation and along bands of fibrosis[a]

[a] The presence, number, or size of globules does not predict occurrence of liver disease.

POTENTIAL THERAPIES

At present, there are no practical therapeutic modalities capable of halting progression of liver disease in patients with inflammation and fibrosis on liver biopsy. The usual preventative measures (i.e., vaccinations for hepatitis viruses, avoidance of aggravating factors such as alcohol), supportive care in case of complications, and monitoring to determine the optimal time for liver transplantation if it becomes necessary are useful in patients with advancing liver disease; reassurance is all that is necessary for patients with benign forms of the trait. Given that an estimated 50 to 75% of patients with liver disease secondary to α1ATD have some degree of underlying pulmonary dysfunction as well, pulmonary function testing along with a discussion of preventative behaviors (e.g., avoiding tobacco) and potential therapies should be part of the management plan. Genetic counseling and additional screening of family members, particularly first-degree relatives, can be considered in order to identify individuals at risk of developing lung or liver disease. However, a physician or genetic counselor must be aware of the potential social, psychological, ethical, and legal consequences of discovering a genetic disorder, especially in persons without obvious signs or symptoms of disease.

Patients who have progressed to end-stage liver disease should be considered for liver transplantation. Multiple transplant centers report excellent patient survival rates, ranging between 70 and 92%, in patients with liver failure secondary to α1ATD. Moreover, transplantation of a donor allograft with a normal genotype cures the disease by normalizing production of α1AT.

Therapies designed to replace or augment production of α1AT, sometimes utilized in the management of patients with progressive pulmonary disease, are not useful and may be detrimental in patients with hepatic disease arising from α1ATD. Increasing cellular production of α1AT by medications such as tamoxifen or danazol act only to increase accumulation within the endoplasmic reticulum, presumably the reason for toxicity. Intravenous replacement with purified preparations of α1AT may also result in an increased production of the mutant form of the molecule within the cell through a feedback mechanism stimulated by α1AT−protease complexes. Currently, experimental exploration of pharmaceuticals capable of augmenting the breakdown of intracellular α1AT polymers or acting

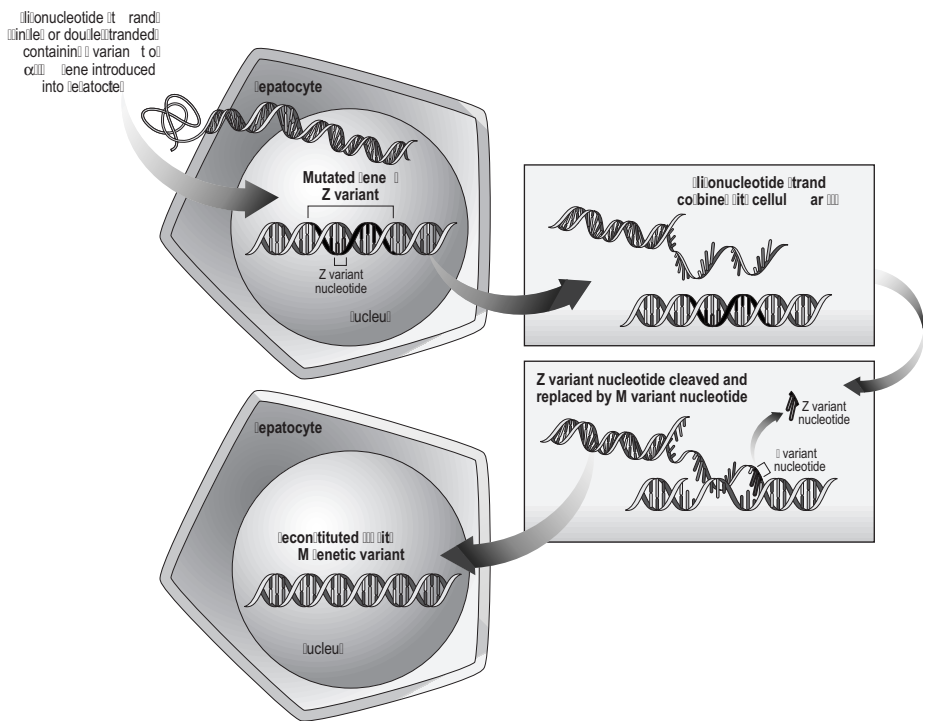

FIGURE 2 Mechanisms of gene manipulation and repair.

as chemical chaperones reducing protein misfolding and polymerization may offer some promise.

Ultimately, gene therapy for both α1ATD lung and liver disease appears to offer the best solution for cure, conceptually, but many practical problems must be solved before these therapies can be implemented clinically. Conformational diseases such as α1ATD offer unique challenges for gene therapy because it is not only important to introduce new fully functional genes to appropriate target cells but native mutant genes or their products must be removed or inactivated in order to have the desired effect—increasing production of a normal gene product without causing accumulations of abnormal proteins in the cell. Several techniques of site-directed gene repair already have proven successful in the laboratory including targeted homologous recombination and nucleotide exchange using chimeric RNA–DNA oligonucleotides (Fig. 2). Other investigators have utilized specialized ribozymes to inactivate mutant α1AT mRNA produced by cells in a human hepatoma cell line followed by transfecting the cells with a modified wild-type gene capable of producing normal α1AT. These preliminary experimental approaches are exciting but many questions must be answered before they can be used safely in human subjects.

Alpha-1-Antitrypsin (α1AT) is a glycoprotein synthesized primarily in the liver and secreted into the blood where its function is to inhibit neutrophil protease-induced host tissue damage. Homozygosity for the Z mutant allele of α1AT (PIZZ) causes the classical form of α1AT deficiency. The protein product of the mutant Z gene accumulates within hepatocytes rather than being efficiently secreted. PIZZ homozygous adults have a markedly increased risk of developing emphysema by a loss-of-function mechanism, i.e., reduced levels of circulating α1AT in the lung to inhibit connective tissue breakdown by neutrophil proteases. PIZZ homozygous children and adults may also develop liver disease and hepatocellular carcinoma by a gain-of-function mechanism; i.e., the accumulation of mutant α1ATZ protein within hepatocytes is toxic to liver cells.

CLASSICAL PIZZ α1-ANTITRYPSIN DEFICIENCY

Pathophysiology and Genetics

Classical, PIZZ α1-antitrypsin deficiency is caused by homozygosity for a point mutation in the α1AT gene encoding substitution of lysine for glutamate at position 342. The 12.2 kb α1AT gene is located on chromosome 14q and encodes a 55 kDa glycoprotein of 395 amino acids. PIZZ homozygotes occur at a frequency of 1 in 1500–3500 in North American and European populations. It is the most common genetic cause of liver disease in children and the most common genetic disease leading to liver transplantation in children and it can also cause chronic liver disease, hepatocellular carcinoma, and premature pulmonary emphysema in adults.

The Z mutation confers polymerogenic properties on the mutant α1ATZ protein molecule, which is primarily synthesized in the liver but is also found in leukocytes and other tissues. reduced levels of circulating α1AT in the lung to inhibit connective tissue breakdown by neutrophil proteases. A subgroup of PIZZ homozygous children or adults may develop liver disease and hepatocellular carcinoma by a gain-of-function mechanism; i.e., the accumulation of polymerized, mutant α1ATZ within the ER is toxic to liver cells.

The key step in the pathophysiology of α1AT deficiency is retention of the newly synthesized mutant Z protein molecule in the ER of hepatocytes. During biogenesis, the nascent mutant Z polypeptide chain is appropriately assembled on the ribosome and translocated into the ER lumen. However, in the ER the mutant Z protein molecule folds slowly and inefficiently into its final, secretion-competent conformation and has a tendency to form unique polymers. A system of proteins within the ER, termed the "quality control" apparatus, recognizes these mutant Z molecules as abnormal and directs them to a series of proteolytic pathways rather than allowing progression down the secretory pathway. The result is a significantly deficient, approximately 15% of normal, serum level of α1AT. Accumulation of the retained mutant Z protein molecules within hepatocytes appears to cause liver injury. A small proportion of the retained molecules may remain in a polymerized conformation and accumulate as aggregations within dilated areas of ER. These accumulations may become so large that they are visible by light microscopy as eosinophilic hepatocellular inclusions by hematoxylin and eosin or as the periodic acid—Schiff (PAS)-positive, diastase-resistant globules classically described within hepatocytes in this disease.

The exact role of protein polymerization in the pathophysiology of α1AT deficiency is still unclear. The presence of the Z mutation allows a protruding surface loop of one molecule to insert into a groove in a neighboring Z molecule. A conformational change in the molecules then occurs, holding them together in the absence of covalent bonds. Long chains of Z protein polymers can form in this way and physical—chemical analysis suggests that this conformation is extremely stable and long-lived. However, it is still unclear whether polymerization, the quality control apparatus, both, or neither is responsible for retention of the mutant Z protein within hepatocytes. The exact mechanism of cellular injury resulting from α1ATZ intracellular retention and/or polymerization is also unclear.

Presentation and Natural History

The presentation of patients with PIZZ α1AT deficiency can be highly varied, ranging from chronic liver disease to fulminant hepatic failure to adult emphysema. In infancy, the typical presentation is one of neonatal cholestasis (also called the neonatal hepatitis syndrome) and may include symptoms and signs of jaundice, abdominal distension, pruritis, poor feeding, poor weight gain, hepatomegaly, and splenomegaly. Laboratory evaluation may reveal elevated total and direct bilirubin, elevated serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT), hypoalbuminemia, or coagulopathy due to vitamin K deficiency or to liver synthetic dysfunction. Liver biopsy findings may be highly variable in infants including giant cell transformation, lobular hepatitis, fibrosis, hepatocellular necrosis, bile duct paucity, or bile duct proliferation. The PAS-positive, diastase-resistant hepatocellular globules characteristic of this disease may occasionally be absent in very young infants. Although life-threatening liver disease can occur in the first few years of life, prospective, population-based studies indicate that 80% of PIZZ patients with neonatal cholestasis are healthy and free of chronic liver disease by the age of 18 years. These data suggest that the overall risk of life-threatening liver disease in childhood may be as low as 3%, but that the risk of varying degrees of liver dysfunction in children may range from 15 to 60%.

In toddlers and older children, PIZZ α1AT deficiency may present as failure to thrive, possibly with poor feeding or hepatomegaly. Some children come to medical attention when asymptomatic hepatomegaly or splenomegaly is detected during routine medical checkups. Many children appear to be completely healthy, without evidence of liver injury, except for mild and usually clinically insignificant elevations in serum AST or ALT. Occasionally, children with previously unrecognized chronic liver disease and cirrhosis present with ascites, gastrointestinal bleeding, or hepatic failure. However, many PIZZ children with cirrhosis may remain stable and grow and develop normally for a decade or more before beginning a process of decompensation.

Liver disease in adults may present as chronic hepatitis, with or without cirrhosis, and the risk of clinically significant disease may increase with advancing age. The findings may be similar to those of adult alcoholic liver disease, which may lead to diagnostic confusion. There appears to be an increased risk of hepatocellular carcinoma in adults with PIZZ α1AT deficiency, although the magnitude of the risk is unclear. Liver biopsy findings in older children and adults may include lobular inflammation, variable hepatocellular necrosis, fibrosis, cirrhosis, and PAS-positive, diastase-resistant globules in some, but not all, hepatocytes in nearly every patient.

Children with PIZZ α1AT deficiency generally do not develop clinically detectable emphysema, although

they may be at increased risk for severe childhood asthma. Asthma or emphysema may develop during adulthood and chronic pulmonary disease is the most common life-threatening complication of PIZZ α1AT deficiency in adults. Smoking significantly increases the risk of progressive, irreversible lung disease as do occupational lung exposures and environmental atmospheric pollutants, all of which are thought to increase the uninhibited proteolytic attack on lung connective tissue. Some studies suggest that exposure to secondhand smoke and environmental air pollutants in childhood is also a significant risk for the development of adult lung disease.

Diagnosis

The gold standard for the diagnosis of α1AT deficiency is the analysis of the phenotype ("PI" or "PI-type") of α1AT protein in a sample of patient serum by isoelectric-focusing gel electrophoresis. It is then inferred from the PIZZ phenotype results that the patient is carrying two copies of the mutant Z α1AT gene. The phenotype gel analysis is technically demanding and is therefore best performed in an experienced reference laboratory. Since the presentations of α1AT deficiency are quite variable and the serum testing is of relatively low expense and risk, α1AT serum phenotyping is applied in a wide variety of clinical situations (Table I). Measurement of the level of α1AT in peripheral blood can be used as a complementary test to compare the phenotype result against what would be an appropriate predicted level (Table II) and to assist in the elucidation of unusual alleles whose protein products yield confusing phenotype results. Liver biopsy is not required for the diagnosis of α1AT deficiency, although it may be useful in selected cases to evaluate disease progression or to investigate the contribution of co-morbid states.

Management

There is no specific treatment for the liver disease associated with α1AT deficiency. Management focuses on preventing the complications of chronic liver disease, such as bleeding, ascites, pruritis, malnutrition, fat-soluble vitamin deficiency, infection, and growth disturbances, or attenuating the systemic repercussions if they do occur. Some authorities advocate aggressive treatment of any systemic infectious or inflammatory episodes, as there is concern that these may be important in increasing end-organ injury. However, many patients have normal health and can be monitored conservatively with infrequent visits to a physician knowledgeable in liver disease. Some patients with significant degrees of liver injury, and even cirrhosis, often remain stable for many years with very little intervention. If life-threatening liver disease does develop, then liver transplantation has been employed with excellent published success rates.

All pediatric and adult patients with α1AT deficiency should be urgently cautioned against personal smoking, secondhand smoke, and environmental lung exposures. Prospective studies indicate that identification of α1AT-deficient patients as children dramatically reduces their incidence of smoking as adults and therefore decreases morbidity and mortality from lung disease. Exogenous α1AT protein replacement is available as a treatment for the adult emphysema associated with α1AT deficiency; however, the efficacy of the therapy is controversial. Exogenous α1AT replacement has no effect on the development of liver disease since liver injury is related to the accumulation of the α1AT mutant Z protein within hepatocytes, not a lack of circulating anti-protease activity.

HETEROZYGOSITY AND OTHER ALLELES

Individuals who are heterozygous for α1AT, carrying one normal M allele and one mutant Z allele ("PIMZ" or "MZ") are generally considered asymptomatic and healthy. Data from referral center studies suggest that

some rare PIMZ adults may develop liver disease, although the possible genetic or environmental influences on the development of this injury remain unclear. Limited but unselected population-based studies have thus far failed to confirm this increased risk. PIMZ children appear to be completely healthy, and even in adults a PIMZ phenotype result is not readily accepted as the cause of otherwise unexplained liver disease.

Individuals who are heterozygous PISZ and who have developed liver disease identical to PIZZ patients, including PAS-positive, diastase-resistant globules, have been clearly described. However, the risk of liver disease to PISZ individuals, though of unclear absolute magnitude, appears to be less than the risk to PIZZ individuals. PISZ individuals may also be at risk for adult emphysema. In contrast, PISS individuals are generally accepted as normally healthy.

A large number of other mutations in the α1AT gene have been described. Some of these gene products yield a normal M result on the phenotype test but when present in the heterozygous state with a Z allele can accumulate within the liver and have been associated with liver disease. Such patients are usually recognized by a profoundly low α1AT level in peripheral blood, which is inappropriate when compared to an apparently PIMZ phenotype result. Null mutations of the α1AT gene that produce no protein secreted into the peripheral blood, resulting in unusually low blood levels and confounding phenotype results, have also been described. Several pilot newborn screening programs for α1-antitrypsin deficiency have been tested in the United States and in Europe. However, universal, population-based screening is still not recommended because there is not yet a proven, immediate health benefit or treatment available to asymptomatic newborns that would outweigh the risk of psychological trauma or genetic discrimination.

Amebiasis remains a major cause of morbidity and mortality worldwide and is responsible for as many as 100,000 deaths yearly. The details of the relationship between the causative agent, *Entamoeba histolytica*, and its human host remain the subject of much study and new insights into the role of the host response to infection are emerging rapidly. The recognition that what was previously called *E. histolytica* based on morphology is really two distinct species, *E. histolytica*, the pathogen, and *Entamoeba dispar*, a harmless commensal, has forced the rethinking of approaches to the diagnosis and treatment of infected individuals. Fortunately, the problem of drug resistance that complicates the treatment of many pathogenic microorganisms has not emerged for *E. histolytica* and the nitroimidazoles remain very effective therapy for amebiasis.

INTRODUCTION

Amebiasis was known to the Greeks, and Hippocrates wrote, "Dysenteries, when they set in with fever, alvine discharges of a mixed character, or with inflammation of the liver . . . are bad." However, it was not until 1875, when the St. Petersburg physician Fedor Aleksandrovich Lösch described amebic trophozoites in the stool and colonic ulcerations of a farmer with dysentery, that ameba were established as a cause of colitis. Since that initial description, much has been learned about the biology of the causative agent, *Entamoeba histolytica*, and effective therapies for this potentially deadly disease have been developed.

THE ORGANISM

E. histolytica is a single-celled eukaryote that lacks mitochondria (probably through secondary loss) and derives energy by the anaerobic conversion of glucose or pyruvate to ethanol. *E. histolytica* has a simple life cycle, existing as either the quadranucleate cyst form (Fig. 1) or the active, vegetative trophozoite form (Fig. 2). The cyst is the infectious form and leads to colonization and disease when it is ingested in food or water contaminated with human feces. The cysts survive the gastric acidity of the stomach and, under yet to be determined stimuli, excyst, forming the trophozoite stage. It is the highly motile trophozoites that are capable of colonizing the colon, invading into the colonic mucosa, and causing disease. The life cycle continues when the trophozoites encyst and the infectious cysts are passed out of the human host in feces.

EPIDEMIOLOGY

E. histolytica is cosmopolitan in distribution and is found wherever there are poor boundaries between human feces and food and drinking water. *E. histolytica* infects only humans and perhaps some nonhuman primates. Data on the worldwide prevalence of *Entamoeba histolytica* infection are difficult to come by, complicated by the recent recognition that what was previously considered to be *E. histolytica*, based on microscopy, is a mixture of two species, *E. histolytica*, a pathogen, and *E. dispar*, a harmless commensal. A reasonable estimate, based on newer studies using techniques that can differentiate between *E. histolytica* and *E. dispar*, is that worldwide approximately 450,000,000 individuals are infected with *E. dispar*, whereas 50,000,000 individuals are infected with *E. histolytica*. Many of the individuals infected with *E. histolytica* are asymptomatic, but have an approximately 10% chance yearly of developing disease. Looking at disease, rather than infection rates, provides a more meaningful look at the impact of amebiasis worldwide. As many as 100,000 people die yearly from amebiasis, making it the second leading cause of death from parasitic diseases. In Mexico, more than 1.3 million cases of intestinal amebiasis were reported in a single year, and in one region of Vietnam, a population center of 1 million people experienced 1500 cases of amebic liver abscess over a 5-year period. In the United States, amebiasis is primarily seen among immigrants, with most cases seen in states that border Mexico. Amebic colitis can be seen in all ages and both sexes, but amebic liver abscess is primarily a disease of men between the ages of 18 and 50, with rates that are 3 to 20 times higher than other populations. The explanation for the increased susceptibility of young and middle-aged men is unknown, but hormonal influences (postmenopausal women also have a higher rate) seem most likely.

PATHOGENESIS

Amebic colitis begins when amebic trophozoites adhere to epithelial cells in the colonic mucosa. Adhesion is primarily mediated by a surface lectin that recognizes N-terminal galactose and *N*-acetyllactosamine residues. *E. histolytica* trophozoites can lyse human cells on contact through the action of amoebapores, small peptides that assemble to form pores in the surface membranes of eukaryotic and bacterial cells. *E. histolytica* trophozoites also secrete abundant quantities of cysteine proteinases, which can lyse extracellular matrix proteins and facilitate amebic invasion into the submucosal tissue. *E. histolytica* trophozoites invade laterally through the submucosal spaces, creating the classic flask-shaped ulcer (Fig. 3) of amebiasis. There can be a marked inflammatory response to the parasite and amebic colitis may be difficult to distinguish from inflammatory bowel disease. Colonic findings can range from diffuse mucosal thickening, multiple discrete ulcers, diffusely inflamed and edematous mucosa, to necrosis and perforation of the intestinal wall (Fig. 4). In a human intestinal xenograft model of amebic colitis, the host inflammatory response is dependent on the activation of the transcription factor nuclear factor κB in intestinal epithelial cells, and the actions of interleukin-8 (IL-8), IL-1, tumor necrosis factor α, and cyclooxygenase 2. Although the inflammatory response to *E. histolytica* may actually exacerbate tissue damage, innate immunity is probably key to containing the infection, and

individuals with amebic colitis who were mistakenly given corticosteroids for what was thought to be inflammatory bowel disease had worse outcomes with an increased frequency of fulminant amebic colitis and amebic liver abscess. In approximately 10% of individuals with amebic colitis, *E. histolytica* trophozoites reach the portal circulation and cause amebic liver abscesses, well-circumscribed areas of hepatocyte death and liquefied debris (Fig. 5).

CLINICAL FEATURES

Individuals with amebic colitis usually present with the gradual onset of bloody diarrhea, abdominal pain, and abdominal tenderness. Some individuals will have multiple small-volume mucoid stools and others will have watery diarrhea, but, because *E. histolytica* is invasive, stools almost always contain blood. Fever is seen in less than 40% of patients; some individuals will report weight loss and anorexia. Fulminant amebic colitis, characterized by profuse bloody diarrhea, fever, marked leukocytosis, peritoneal signs, and extensive colonic involvement, occurs rarely, but carries a high mortality. Pregnant women, individuals treated with corticosteroids, malnourished people, and immunocompromised individuals are clearly at higher risk for this complication. Toxic megacolon has been reported with amebiasis, and amebomas, localized inflammatory masses that may mimic carcinomas by causing mass obstructing lesions, may also complicate amebic colitis.

Amebic liver abscesses arise from the hematogenous spread of amebic trophozoites from the colon to the liver and are the most common extraintestinal manifestation of amebiasis outside the intestinal tract. Individuals present with the classic triad of fever, right upper quadrant abdominal pain, and hepatic tenderness. Symptoms are usually acute (onset within the past 10 days), but some individuals present with a more chronic disease with associated weight loss and anorexia. Individuals with amebic liver abscess may present years after travel or residency in an endemic area so a careful travel history may be key to making the diagnosis. Most patients with amebic liver abscess do not have evidence for concurrent intestinal infection based on the microscopic examination of stool, but more sensitive diagnostic methods [e.g., polymerase chain reaction (PCR)] suggest that concurrent intestinal infection may be relatively common. Cough may be present and dullness and rales in the right lung base may be seen. Jaundice is unusual, as is eosinophilia, but leukocytosis and elevated alkaline phosphatase are relatively common.

The most common complication of amebic liver abscess is rupture into the pleural space, with the formation of an amebic empyema, a hepatobronchial fistula (where individuals cough up the contents of their amebic liver abscess), and/or an amebic lung abscess. Pulmonary extension of the amebic liver abscess may give rise to a clinical syndrome (productive cough, fever, chest pain) that may be confused with pneumonia. Less common, but more dangerous is amebic liver abscess rupture into the peritoneum, with associated peritonitis and shock symptoms, and amebic liver abscess rupture into the pericardium, with tamponade and/or pericarditis. Mortality associated with pericardial involvement is very high (30%).

Other extraintestinal manifestations of amebiasis are very rare, with amebic brain abscesses (seen in less than 0.1% of individuals with amebic liver

abscesses), urinary tract involvement, genital disease, perianal disease, and cutaneous lesions all reported.

DIAGNOSIS

For years the diagnosis of amebic colitis was based on the microscopic demonstration of amebic trophozoites in the stool of an individual with diarrhea. Microscopy is still used in much of the world, but the recognition that microscopy cannot distinguish between infection with *E. histolytica* and the more common commensal *E. dispar* has changed the approach to diagnosis and emphasized the need for more specific and more sensitive ways to identify *E. histolytica* intestinal infection. In the proper clinical setting, an individual with bloody diarrhea, appropriate exposure history, and a microscopic exam that shows *E. histolytica* trophozoites that have ingested red blood cells, stool microscopy may still be diagnostic for amebic colitis. However, given the high prevalence of *E. dispar* in many areas, relying solely on microscopy may lead to the false diagnosis of amebiasis in cases of *Shigella*, *Campylobacter jejuni*, or other forms of dysentery. One solution to this problem has been the development of *E. histolytica*-antigen detection enzyme-linked immunosorbent assay (ELISA) tests that use antibodies to recognize specific *E. histolytica* antigens in stool and can distinguish between *E. histolytica* and *E. dispar*. These tests performed well in initial studies and may become the diagnostic method of choice, but recent reports that some of the ELISA tests were relatively insensitive in field studies (compared with PCR or stool culture) provide a cautionary note. Molecular diagnostics using PCR to amplify *E. histolytica*-specific sequences from stool may become more widespread—these offer the advantage of allowing genotyping for strain identification. The major barrier for PCR-based tests is the requirement for specialized equipment and reagents that will be unavailable in many of the countries where the tests are needed the most.

The diagnosis of amebic liver abscess is based on the demonstration of a space-occupying lesion in the liver and a positive amebic serology. Both ultrasound and computed tomography scanning (Fig. 6) are effective in detecting amebic liver abscesses. Abscesses can be solitary or multiple spherical lesions and are most commonly found in the right lobe of the liver. Amebic serology is very sensitive (>90%) and very specific (>98%) and the only caveat is that serology may be negative very early in disease (within the first week) and should be repeated if the index of suspicion for amebic liver abscess is high.

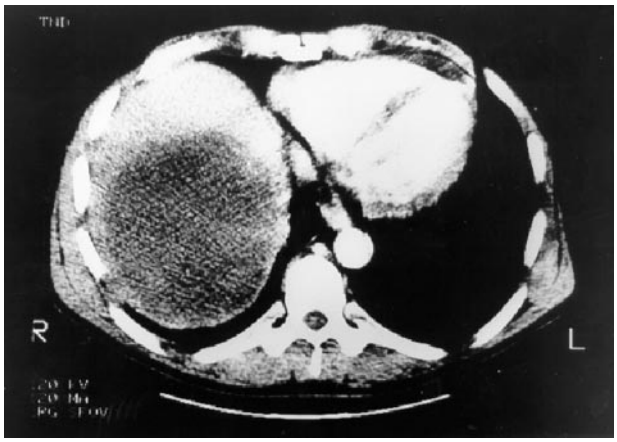

FIGURE 6 CT scan from a patient with amebic liver abscess. A large solitary lesion in the right lobe of the liver is present.

TREATMENT

The mainstay of therapy for amebiasis remains the nitroimidazole compounds. Since only metronidazole is available in the United States, the recommendations listed in Table I are focused on metronidazole. Amebic colitis is treated with metronidazole, followed by a lumenal agent to eliminate colonization. Asymptomatic individuals infected with *E. histolytica* should be treated with a lumenal agent to eliminate colonization. This is based on the fact that they are at risk to develop invasive disease and because they pose a risk of spreading *E. histolytica* infection to others. If an individual is found to be colonized with *E. dispar*, no therapy is necessary, but the physician should be alerted to the fact that the patient has ingested fecally contaminated food or water.

Amebic liver abscess is also treated with metronidazole, and, remarkably, given the size of the abscess, single-dose therapy can be used. A lumenal agent should be administered as well to eradicate intestinal colonization, even if stool microscopy is negative. Unlike most abscesses, amebic abscesses can resolve without drainage and percutaneous aspiration and drainage should be reserved for diagnostic purposes (if a bacterial abscess or suprainfection is suspected), for large abscesses in the left lobe of the liver (because of the risk of rupture into the pericardium), when individuals are not responding to therapy (continued pain, fever after 72 h of treatment), and when rupture seems imminent (large abscess, accelerated clinical course with increasing pain). Some authorities advocate the addition of dehydroemetine in complicated cases of amebic colitis or amebic liver abscess because of its rapid amebicidal activity, but there are no controlled

TABLE I Drugs of Choice for the Treatment of Amebic Colitis and Amebic Liver Abscess

Drug	Adult dosage	Adverse effects	Comments
Metronidazole	750 mg po or iv tid for 5 to 10 days; for uncomplicated liver abscess (limited experience) 2.4 g po daily for 2 days	Metallic aftertaste, nausea, vomiting, diarrhea; rarely—sensory neuropathies, central nervous system toxicity with ataxia, vertigo, seizures, and encephalopathy	Drug of choice for amebic colitis and amebic liver abscess
Dehydroemetine	1−1.5 mg/kg/day im for up to 5 days	Cardiotoxicity, diarrhea, nausea, vomiting, muscle weakness	No indication for use in standard therapy; may offer some benefit in fulminant colitis or patients with ruptured amebic liver abscess when administered in combination with metronidazole, but controlled trials are lacking
Lumenal agents			
Paromomycin	30 mg/kg/day po in three divided doses for 5 to 10 days	Nausea, vomiting, cramps, diarrhea	Drug of choice for treatment of lumenal *E. histolytica* infection; should be administered to all individuals following completion of metronidazole therapy
Diloxanide furoate	500 mg po tid for 10 days	Flatulence	Excellent alternative to paromomycin for treatment of lumenal *E. histolytica* infection; should be administered to all individuals following completion of metronidazole therapy; not readily available in the United States
Iodoquinol	650 mg po tid for 20 days	Headache, nausea, vomiting; optic nerve damage and peripheral neuropathy reported in individuals exceeding recommended dosage	Alternative to paromomycin or diloxanide furoate for treatment of lumenal *E. histolytica* infection; should be administered to all individuals following completion of metronidazole therapy

Amylase is a digestive enzyme secreted primarily by the pancreas and some salivary glands. Because of the almost exclusive production of amylase by the pancreas, serum amylase levels are of diagnostic importance in assessing acute pancreatitis.

INTRODUCTION

The digestive enzyme amylase secreted by the pancreas and some salivary glands is responsible for the initial process of digestion of dietary starch. In the Western world, adults consume about 400 g of carbohydrates each day, with starches and sucrose providing the largest sources. Starch is the storage form of carbohydrate in plants and can account for 10–80% of the plant volume. All starches are glucose polymers with molecular masses ranging from 10^5 to more than 10^6 Da. The two major starches are amylose, a straight-chain α-1,4-linked glucose polymer, and amylopectin, a branched starch with a backbone of α-1,4-linked glucose and α-1,6-linked glucose branches about every 20–25 residues. Amylose and amylopectin account for 20 and 80%, respectively, of dietary starch. Because the intestinal epithelium absorbs only monosaccharides, dietary starch, to serve as a nutrient and energy source, must first be hydrolyzed into glucose, a process facilitated by α-amylase.

PHYSIOLOGY

posttranslational modification Alteration of a protein after it has been synthesized. Examples include the addition of sugar chains, of phosphate, or of sulfate.

Amylase is a digestive enzyme secreted primarily by the pancreas and some salivary glands. Because of the almost exclusive production of amylase by the pancreas, serum amylase levels are of diagnostic importance in assessing acute pancreatitis.

INTRODUCTION

The digestive enzyme amylase secreted by the pancreas and some salivary glands is responsible for the initial process of digestion of dietary starch. In the Western world, adults consume about 400 g of carbohydrates each day, with starches and sucrose providing the largest sources. Starch is the storage form of carbohydrate in plants and can account for 10–80% of the plant volume. All starches are glucose polymers with molecular masses ranging from 10^5 to more than 10^6 Da. The two major starches are amylose, a straight-chain α-1,4-linked glucose polymer, and amylopectin, a branched starch with a backbone of α-1,4-linked glucose and α-1,6-linked glucose branches about every 20–25 residues. Amylose and amylopectin account for 20 and 80%, respectively, of dietary starch. Because the intestinal epithelium absorbs only monosaccharides, dietary starch, to serve as a nutrient and energy source, must first be hydrolyzed into glucose, a process facilitated by α-amylase.

PHYSIOLOGY

In humans and other primates and in rodents and lagomorphs (rabbits, hares, and pikas), pancreatic acini and certain salivary glands, primarily the parotids, secrete amylase. No other tissues express significant levels of amylase, although amylases are present in the fallopian

tube, lungs, tears, sweat, and human milk. Amylase represents about 5–6% of the total protein in pancreatic secretions and, along with mucins, amylase is a major secretory protein of the parotid gland. Closely related, but distinct, genes encode salivary and pancreatic amylase. In the human genome, there are three salivary genes and two pancreatic genes encoding amylase. Expression of the genes encoding human pancreatic amylase is developmentally regulated. Human newborns have little to no pancreatic amylase at birth and the levels remain low (< 1.0% of adult levels) throughout the first months of life and may not reach adult levels until the second or third year of life.

ENZYMOLOGY

α-Amylase, an endoenzyme, preferentially cleaves interior α-1,4 linkages and has very low activity against the bonds of terminal glucose units. Additionally, it cannot hydrolyze the α-1,6 linkages in amylopectin. The resulting products of amylase acting on starch, referred to as dextrins, are α-1,4-linked glucose dimers (maltose), α-1,4-linked glucose trimers (maltotriose), and branched oligosaccharides of 6 to 8 glucose units that contain both α-1,6 and α-1,4 linkages (limit dextrins). Starch digestion can begin in the mouth and in a swallowed bolus of food, but primarily occurs in the lumen of the upper small intestine. Digestion of starch is completed in the intestine by the brush border enzymes, maltase and isomaltase.

The active site of α-amylase contains multiple subsites, each of which is capable of binding one glucose residue of the substrate. The porcine and human enzymes appear to have five subsites, and subsite three is probably the catalytic site. Substrates can bind with the first glucose residue in subsite one or two so that cleavage can occur between the first and second or second and third residues. During a single enzyme–substrate encounter, multiple glucose bonds are cleaved. Three acidic residues, one glutamic acid and two aspartic acids, are thought to be the catalytic residues. The glutamic acid is believed to be the proton donor and one of the aspartic acids acts as a nucleophile. α-Amylase has an absolute requirement for calcium ions and is activated by anions such as chloride, bromide, iodide, or fluoride. Heavy metals inhibit the enzyme. The importance of serum amylase levels in the diagnosis of acute pancreatitis has generated widespread interest in its assay. Amylase is most commonly measured by absorbance or fluorescence assays in which a labeled substrate is cleaved.

PROTEIN STRUCTURE

Both the proteins and the cDNAs encoding amylase have been isolated from the pancreas and the salivary glands. α-Amylase has a molecular mass of about 57 kDa and contains a single carbohydrate chain, although an unglycosylated form is made in the parotid gland. Chromatographic and electrophoretic methods have demonstrated multiple isoenzymes of both pancreatic and salivary amylase. The presence of multiple genes for both salivary and pancreatic amylase accounts for some of the isoenzymes, but additional isoenzymes are formed by posttranslational changes. The amylases are multidomain proteins consisting of three domains. The substrate-binding site lies in a cleft between domains A and B. Residues in both of these domains contribute to calcium binding near the active site. A chloride ion binds on domain A near the active site cleft.

amyloid A hyaline eosinophilic substance, as viewed by light microscopy, that is deposited extracellularly in blood vessels and other tissues in a wide variety of disorders. At least 18 distinct proteins that can form amyloid have been identified thus far. All amyloids are fibrillar and look the same under light, polarization, and electron microscopy.

amyloid, cerebral Amyloid occurring in the brain in patients with Alzheimer's disease, in aged Down's syndrome patients, and in individuals with spontaneous cerebral hemorrhage consisting of deposits of β-protein (Aβ) or cystatin C. Prion diseases are due to another protein (PrP^{SC}) that deposits in Creutzfeldt-Jacob disease, bovine spongiform encephalopathy, and other human and animal neurodegenerative disorders.

amyloid, dialysis-related Amyloid occurring in a minority of patients on long-term (7–10 years) hemodialysis due to deposition of β2 microglobulin.

amyloid, hereditary (familial) Familial amyloid polyneuropathy occurs in patients with late-onset (midlife) polyneuropathy and is usually due to deposition of variant transthyretin. Some patients have cardiomyopathy or nephropathy. The disorders are inherited as autosomal dominant conditions. Transthyretin is also the protein found in patients with senile systemic (cardiac) amyloidosis. In some kindreds, other proteins form the amyloid (apolipoprotein A-I, gelsolin, fibrinogen Aα, lysozyme).

amyloid, light chain origin Also known as primary systemic or immunocytic amyloid; this amyloid occurs *de novo*, i.e., without coexisting or preexisting chronic disease. The protein deposited is derived from immunoglobulin light chains produced and secreted by monoclonal plasma cells (plasma cell dyscrasia).

amyloidogenesis The process by which a precursor protein undergoes proteolysis, yielding fragments that assume a β-pleated sheet conformation and deposit extracellularly in blood vessels and various tissues.

amyloid P component A nonfibrillar component of all amyloids that is derived from a normal precursor, serum amyloid P.

amyloid, reactive Also known as secondary systemic amyloid. This type, amyloid A, occurs in patients with chronic infectious or inflammatory disease and in the autosomal recessively inherited disorder, familial Mediterranean fever. It is also the type present in experimentally induced amyloidosis in mice.

Bence Jones protein Free monoclonal immunoglobulin light chains produced and secreted by a single clone of plasma cells. Fifteen to 20% of Bence Jones proteins appear to be amyloidogenic—more frequently in the λ class than in the κclass. Such amyloid is of the amyloid light chain origin type.

β-pleated sheet conformation (β-conformation) The protein conformation common to all amyloids that is responsible for Congo red staining and the fibrillar structure. Proteolysis can convert serum precursor proteins into twisted β-pleated sheet fibrils.

polarization birefringence A common physical property of all amyloid fibrils related to their β-pleated sheet conformation and associated with an apple green color after Congo red staining of involved tissue.

The amyloidoses are diverse disorders characterized by extracellular deposits of various fibrillar proteins in tissues. They constitute one group of an expanding class of conditions referred to as diseases of protein misfolding. Virtually any site in the body can be affected. Many controversies arose about the cause and composition of amyloid for a century after it was named by Rudolph Virchow in 1853. The first major breakthrough occurred in 1959, when electron microscopy showed that this apparently structureless material was actually fibrillar. The ability to solubilize the fibrils enabled subsequent characterization of their major protein constituents. At least 18 distinct proteins have been identified thus far as amyloid precursors in human diseases and it is likely that more will be described in the future. All amyloids share the same physical properties under light, polarization, and electron microscopy.

INTRODUCTION

Historically, amyloidosis was classified according to whether it occurred *de novo* ("primary") or was "secondary" to a recognizable preexisting or coexisting chronic infectious or inflammatory disease. During the past 70 years, rare hereditary amyloid syndromes have been well documented. Most primary and secondary amyloid syndromes are systemic; i.e., they involve more than one organ system. Many patients with hereditary amyloidosis have systemic disease as well. Localized

or tumor-like collections of amyloid in various organs also have been described. Recently, new amyloid disorders have been recognized.

Several amyloid syndromes involve the gastrointestinal (GI) tract. The initial presentation and/or the dominant manifestation may be due to GI amyloid deposition. Thus, the amyloid syndromes are of interest to gastroenterologists and other physicians who see patients with GI disease.

DEFINITION AND DIAGNOSIS

Amyloid is an eosinophilic substance that, under the light microscope, has a hyaline appearance and is deposited extracellularly in the walls of small blood vessels and various organs. These deposits, when extensive, interfere with normal function. Multiple proteins can form amyloid, but all share the common physical properties of polarization birefringence after Congo red staining, linear nonbranching fibrils with a diameter of 7.5 to 10 nm by electron microscopy (EM), and a twisted β-pleated sheet conformation by X-ray diffraction. All amyloid deposits also contain a nonfibrillar glycoprotein moiety, the P component. This amyloid P (AP component) is derived from a normal serum precursor [serum amyloid P (SAP)] structurally related to an acute-phase reactant, C-reactive protein. Apolipoprotein E and other proteoglycans are additional nonfibrillar components of amyloid.

The diagnosis of amyloidosis is based on biopsy of involved tissue. Apple green birefringence under polarized light after Congo red staining and the typical fibrillar structure evident by EM constitute the most reliable methods (Fig. 1).

Because the GI tract is an easily accessible biopsy site, tissue sampling from the GI tract is often employed. The sensitivity of endoscopic biopsy is dependent on the presence of amyloid involvement, the site sampled, and adequate tissue procurement. The biopsy should be obtained with standard endoscopic forceps to include submucosa since amyloid is best identified in the walls of small blood vessels. Abdominal fat pad aspirate has a 60–85% sensitivity in systemic amyloidosis and is the initial diagnostic procedure of choice since there is a low risk of complications. Bone marrow biopsies may also reveal the presence of amyloid. Liver and rectal biopsies are associated with a low but definite risk of severe hemorrhage. Whatever the biopsy site, it is important to emphasize that Congo red stains must be performed and examined under polarized light if amyloidosis is suspected.

Once amyloid is recognized on tissue biopsy by either apple green birefringence after Congo red staining or the characteristic fibrillar appearance by EM, it is important to identify the protein deposited since the

natural history and therapy vary among the different disease entities. Immunohistochemistry using antibodies to amyloid precursor proteins, such as immunoglobulin light (L) chains, serum amyloid A, transthyretin, and β2 microglobulin, is helpful, though not always definitive, in delineating the type of amyloid present in the fibrils of a particular patient. Immune EM and/or chemical analysis of extracted fibrillar protein may be necessary for unequivocal diagnosis. Radiolabeled SAP component scintigraphy has been shown to be useful in staging systemic AL (amyloid of light chain origin) and AA (amyloid A) amyloidoses, but is not generally available.

In most circumstances, a circulating precursor protein results from overproduction of either intact or aberrant molecules (plasma cell dyscrasias), reduced degradation or excretion (secondary amyloid syndromes and patients on long-term hemodialysis), or genetic abnormalities associated with variant proteins (familial autosomal dominant polyneuropathies). Amyloidogenesis is characterized by proteolysis of a larger protein precursor molecule with production of low-molecular-weight fragments that polymerize and assume a β-conformation as extracellular tissue deposits (Fig. 2). Thus, amyloidosis is a generic term referring to a final common pathophysiologic pathway for tissue protein deposition in a wide variety of diseases.

Except for their similar morphologic and physical properties, the various amyloid diseases are disparate and occur in diverse clinical settings. The classification of amyloidosis based on the major protein subunits present in the fibrils is shown in Table I. As noted, the terms primary and secondary refer to the absence or presence of a preexisting or coexisting chronic inflammatory or infectious disease. Because of significant overlap, primary and secondary designations should not be based on anatomic sites of involvement in individual patients.

PRINCIPAL AMYLOID PROTEINS AND DISEASES

Primary (Immunocytic) Systemic Amyloid

Primary (immunocytic) systemic amyloid of light chain origin is a disorder closely related to multiple myeloma in which a monoclonal immunoglobulin component, most often a free monoclonal L chain [Bence Jones protein (BJP)], is produced by a single family (clone) of plasma cells. Fragments of BJP polymerize and form β-pleated sheets that deposit as fibrillar material in tissues. Primary amyloidosis is the most common nonhereditary systemic amyloid type in the United States. Serum and urine immunofixation electrophoresis will demonstrate a monoclonal immunoglobulin component (M component) in serum, urine, or both, in 80% of cases. Amyloid deposition in these individuals tends to be distributed in the heart, tongue, gastrointestinal tract, skin, ligaments, and peripheral nerves. Involvement of liver, kidneys, spleen, and adrenals, a distribution more characteristic of secondary systemic amyloid, also may occur because of overlap in amyloid deposition in the immunocytic and reactive syndromes. Approximately 15 to 20% of Bence Jones proteins appear to be "amyloidogenic" in that they have the property of precipitating as fibrillar material resembling amyloid after *in vitro* proteolytic digestion. This amyloidogenic property is associated with the variable region of the molecule and is more commonly observed with λ than with κ monoclonal L-chains, a finding in accord with the L-chain distribution noted

in AL patients. The data are consistent with the hypothesis that patients with plasma cell dyscrasias who secrete Bence Jones proteins that possess amyloidogenic properties develop a clinical picture dominated by the features of primary systemic amyloidosis with fewer monoclonal plasma cells compared with the usual findings and cell burden observed in multiple myeloma. The resulting clinical illness therefore is more dependent on the molecular structure of the individual BJP synthesized than on any intrinsic difference between primary systemic amyloidosis and multiple myeloma. Such a hypothesis does not dictate that every patient producing amyloidogenic L-chains necessarily will develop clinical amyloidosis; some clearly do not, suggesting that additional factors play an important role in tissue deposition of amyloid fibrils.

Secondary (Reactive) Systemic Amyloidosis

Secondary (reactive) systemic amyloidosis is due to deposition of a nonimmunoglobulin protein (amyloid A) derived from a circulating protein precursor, serum amyloid A (SAA), that acts as an acute-phase reactant. This type of amyloidosis occurs in association with chronic inflammatory or infectious diseases. It occurs rarely in patients with tumors such as Hodgkin's disease, renal cell carcinoma, or other neoplasms. Chronic inflammatory diseases, especially rheumatoid arthritis and juvenile rheumatoid arthritis, are associated with amyloid of this type. Patients with other connective tissue disorders and Crohn's disease rarely develop AA amyloidosis. The same AA protein forms amyloid in patients with the autosomally recessively inherited disorder, familial Mediterranean fever (FMF). Chronic infections such as in patients with tuberculosis, leprosy, chronic osteomyelitis, bronchiectasis, decubitus ulcers, paraplegia, chronically infected burns, chronic skin infections associated with parenteral drug abuse, hypogammaglobulinemia, and Whipple's disease are associated with AA amyloidosis. Amyloid A is also the type occurring in mice with experimentally induced amyloidosis. An "amyloid-enhancing factor" that accelerates amyloidogenesis in animal models may consist of the AA fibril itself.

SAA, which has a molecular weight of approximately 12,500 Da, is a heterogeneous minor component of

normal plasma and is transported in association with high-density lipoprotein. Three forms of SAA have been described. Amyloid A is a single polypeptide chain consisting of 76 amino acids and having a molecular weight of approximately 7500 Da. Larger and smaller sizes of the protein have been identified as well.

Familial Amyloid Polyneuropathy

Familial amyloid polyneuropathy is an autosomal dominantly inherited late-onset syndrome usually due to deposits of transthyretin (TTR). TTR deposition also occurs in "senile" cardiac amyloid. TTR, previously known as thyroxin-binding prealbumin, is a transport protein that also binds retinal-binding protein. It is synthesized by the liver as a single polypeptide chain of 127 amino acids. The TTR that deposits in various tissues is a structurally abnormal protein. Over 80 amino acid substitutions at more than 50 different sites in the TTR molecule have been described. TTR is a negative acute-phase reactant; that is, its concentration decreases with inflammation; serum levels of the protein are also low in many patients with TTR amyloidosis. Not all patients with familial amyloid polyneuropathy have associated TTR deposits. In the Iowa type characterized by lower limb neuropathy, peptic ulcers, and nephrotic syndrome, a variant form of apolipoprotein A-I has been demonstrated in the amyloid fibrils. Apolipoproteins occur in other types of amyloid. Mutations of gelsolin, fibrinogen α-chain, and lysozyme rarely have been reported to cause familial amyloidosis.

Cerebral Amyloids

Cerebral amyloids are amyloid deposits in the brain occurring in Alzheimer's disease patients, in aged Down's syndrome patients, and in some individuals with hereditary cerebral amyloid angiopathy consist of a component called amyloid β-protein (Aβ), having a molecular weight of approximately 4200 Da. As with other chemical types of amyloid, the β-protein originates from a larger precursor (AβPP) and is found in blood vessels, plaques, and neurofibrillary tangles in the brain. The Icelandic form of cerebral amyloid angiopathy is characterized by a protein closely related to the cysteine protease inhibitor, cystatin C, which deposits in blood vessels. A different form of brain amyloid is present in the prion diseases, which include Creutzfeldt-Jakob disease and bovine spongiform encephalopathy ("mad cow" disease). In these disorders, a normal or variant protein appears to acquire a greater degree of β-pleated sheet conformation associated with its deposition in the brain. These amyloid diseases are generally restricted to the central nervous system.

Dialysis-Related Amyloid

Some patients on long-term (7–10 years) hemodialysis develop carpal tunnel syndrome, usually bilateral, due to amyloid deposition. It may be accompanied by cystic bone lesions or pathologic fractures. Occasionally deposits are found in other organs including those in the GI tract. The fibrillar protein in this circumstance is composed of intact β2 microglobulin (β 2M), a protein of 11,800 Da. The serum β 2M concentration in chronic hemodialysis patients is approximately 50 times higher than normal, as β 2M is too large to pass through dialysis membranes. However, elevated levels alone do not correlate well with the risk of developing amyloid. Thus, other systemic or local tissue factors may be important in determining whether amyloid deposition occurs.

CLINICAL FINDINGS

Clinical manifestations of amyloidosis vary widely depending on the organ system predominantly involved. A number of hematologic findings may occur in patients with amyloidosis, especially "scratch purpura" and spontaneous periorbital purpura after a Valsalva maneuver (Fig. 3a). Acquired factor X deficiency is an unusual but well-documented complication of amyloidosis. The coagulation factor appears to be rapidly cleared from the circulation and bound by amyloid deposits. Splenectomy may alleviate the bleeding diathesis resulting from factor X deficiency. Occasionally, factors IX and V are reduced. Other abnormalities in coagulation or fibrinolytic pathways are rare. Lytic bone lesions of the type characteristic of myeloma rarely occur in patients with amyloidosis. Uncommon sites of amyloid involvement include endocrine tumors, serosal membranes, lymph nodes, breast tissue, and thyroid.

Patients with primary AL amyloidosis most commonly present with nephrotic range proteinuria, refractory congestive heart failure, unexplained hepatomegaly, or peripheral neuropathy. Patients with AA amyloidosis present most often (90%) with proteinuria/renal insufficiency, but 20% have GI findings (diarrhea, pseudo-obstruction, constipation, or malabsorption). Patients with familial autosomal dominant amyloidosis usually present with late-onset polyneuropathy, and some have significant GI involvement.

FIGURE 3 (a) Bilateral periorbital purpura in a patient with AL amyloidosis. (b) Nodular macroglossia in a patient with AL amyloidosis.

GASTROINTESTINAL AMYLOIDOSIS

Many patients with systemic amyloidosis have involvement of the GI tract with amyloid deposition occurring anywhere from the tongue to the rectum, as well as the liver, spleen, and pancreas. The GI manifestations may be the mode of presentation and often are accompanied by evidence of organ involvement elsewhere, namely, the heart, kidney, and autonomic nervous system. The symptoms, physical signs, and clinical manifestations of GI amyloidosis are listed in Table II. Endoscopic appearance and radiographic appearance are also described below.

Endoscopic Appearance

There is no endoscopic appearance specific for amyloidosis. The most common endoscopic findings include a fine granular appearance, erosions, ulcerations, and mucosal friability. These findings are most often seen in the duodenum, followed by the stomach, colorectum, and esophagus.

Radiographic Appearance

Barium radiography is of limited diagnostic utility since the changes that may be seen are not specific for amyloidosis. Nevertheless, esophageal abnormalities include reflux and esophageal dysmotility and dilation. The stomach may show rigid gastric rugal folds, dilation with barium retention, and narrowing or obstruction in the antral region. Small intestinal radiographs are often the initial test suggesting GI amyloid involvement. Commonly reported findings include sharply demarcated thickening of the valvular conniventes, altered intestinal transit, bowel dilation, and multiple nodular lesions. Colonic contrast studies most often show involvement of the rectosigmoid characterized by altered colonic transit with dilation or multiple filling defects with narrowing and rigidity secondary to ischemia. Abdominal computerized tomography imaging may show wall thickening or bowel dilation and rarely mesenteric thickening or lymphadenopathy.

Specific Organ Involvement

Mouth

Oral amyloidosis may affect the tongue, buccal mucosa, and gingiva. Bleeding from the latter two sites is common. Tongue involvement causes macroglossia in 20–50% of primary (AL) amyloid patients (Fig. 3b). Macroglossia may cause difficulties with speech, mastication, swallowing, and breathing due to reduced tongue mobility. Tracheostomy may be necessary in severe cases. Amyloid infiltration of the salivary

glands can cause symptoms of dry mouth associated with the sicca syndrome.

Esophagus

Esophageal involvement usually presents with symptoms of dysphagia and gastroesophageal reflux. Histological studies show that amyloidosis can infiltrate both the striated and smooth muscle portions of the esophagus, vagus nerve, myenteric plexus, and vasa nervosa. Manometric studies may show a nonspecific esophageal dysmotility and abnormal lower esophageal sphincter relaxation. Treatment with a proton pump inhibitor is usually recommended.

Stomach

Patients with gastric amyloid may present with symptoms of nausea, vomiting, epigastric pain, abdominal bloating, anorexia, and weight loss. Some patients develop mucosal or gastric amyloid tumor ulcerations with signs of upper GI bleeding. Others present with gastric motility disturbances. In familial amyloid polyneuropathy with autonomic nervous system involvement, gastroparesis with delayed gastric emptying and hypotonia is common. Treatment with prokinetic agents has limited effectiveness. Total parenteral nutrition as a means of providing temporary nutrition or drainage procedures such as gastrojejunostomies have shown some benefit.

Small Intestine

In systemic amyloidosis, small intestinal deposits are present histologically in more than 70% of cases. Amyloid may be seen in the intrinsic and extrinsic nervous system, the mucosa, submucosa, and muscle wall of the small intestine. The variable location of these deposits accounts for the myriad of symptoms and clinical manifestations associated with small bowel involvement including diarrhea, constipation, malabsorption, obstruction, pseudo-obstruction, bleeding, and vascular insufficiency. Chronic intestinal ischemia may occur secondary to progressive occlusion of the vessels of the submucosa. This will lead to sloughing of the intestinal lining and hemorrhage. Rarely, protein-losing enteropathy or progression to intestinal infarction and perforation is seen. Small bowel obstruction due to an amyloid tumor also has been described.

The clinical spectrum of symptoms, course, and prognosis associated with pseudo-obstruction may depend on the type of amyloid. Patients with AL and Aβ 2M amyloidosis typically present with irreversible chronic, intermittent obstructive symptoms and have evidence of extensive infiltration of the smooth muscle of the bowel wall. On the other hand, AA amyloidosis patients may present with reversible, acute obstructive symptoms and have evidence of myenteric plexus involvement. Surgery is generally not beneficial in the treatment of amyloid-induced pseudo-obstruction. Promotility agents have not been proven effective and some patients may require long-term TPN.

Diarrhea is often severe and uncontrollable in systemic amyloidoses. Malabsorption as evidenced by steatorrhea and protein-losing enteropathy is seen in less than 5% of patients but has been reported in AL, AA, and TTR amyloidoses. Diarrhea is particularly common in familial amyloid polyneuropathy due to TTR amyloid and often leads to cachexia and early mortality. The pathogenesis of diarrhea in patients with amyloidosis is unknown. A variety of mechanisms have been advanced as possible explanations for the disruption of gastrointestinal function. These include (1) malabsorption of fat, protein, and/or carbohydrate by multiple processes including infiltration of the mucosa producing a mechanical barrier, mucosal atrophy secondary to amyloid-induced vascular ischemia, and pancreatic amyloidosis with concomitant pancreatic exocrine insufficiency; (2) bile salt malabsorption; and (3) altered intestinal transit. Slow intestinal motility may result from amyloid deposition within the muscular layer of the intestinal wall causing a myopathy or from amyloid deposition in the GI autonomic nervous system causing a neuropathy. Reduced motility permits bacterial overgrowth, bile acid deconjugation, and consequent diarrhea and steatorrhea. Treatment for amyloid-induced diarrhea includes opioids, antibiotics, cholestyramine, and octreotide.

Colon

Colonic amyloid is associated with symptoms similar to small intestinal involvement including diarrhea, constipation, abdominal pain, intestinal ischemia, and bleeding. Volvulus, megacolon, and fecal incontinence due to neuropathy or amyloid deposition in the anal sphincter have been reported in patients with colonic amyloidosis.

Liver

Hepatic amyloidosis is manifested by hepatomegaly with relatively well-preserved hepatic synthetic function. Modest elevations of serum alkaline phosphatase are the most common laboratory abnormalities. Hypoalbuminemia may be present and due to nephrotic syndrome, decreased hepatic synthetic function, or rarely, protein-losing enteropathy. Elevated serum aminotransferase levels are less commonly seen and elevated serum bilirubin levels are rare. Cholestatic jaundice portends a poor prognosis as it may lead to liver failure and is usually due to advanced AL amyloidosis. Although many patients with amyloidosis have hepatic deposits, there is poor correlation between the degree of liver dysfunction and the extent of amyloid deposition. Rarely, patients present with focal intrahepatic mass lesions and hepatic rupture, the latter usually being a fatal event.

Clinical features of chronic liver disease (e.g., spider angiomas, palmar erythema) are uncommon as most patients die of extrahepatic amyloid deposition. Portal hypertension is seen occasionally. Its complications, including ascites and esophageal variceal hemorrhage, are seen to variable degrees. Ascites may develop from portal hypertension with or without hypoalbuminemia. Treatment of hepatic amyloidosis is directed at management of these complications and the underlying mechanism of the amyloid deposition.

Hepatic amyloidosis is diagnosed by liver biopsy. Increased risk of hemorrhage with liver biopsy is thought to be secondary to amyloid infiltration of blood vessels with consequent increased fragility and inability of the blood vessels to contract. Several studies have reported cases of fracture of the liver with hemorrhage, capsular rupture, and death following liver biopsy in patients with suspected amyloid liver involvement. One series showed that all amyloidosis patients with hemorrhagic complications related to a

diagnostic procedure had a prior history of a bleeding episode. Therefore, liver biopsy should be approached with caution in patients with established or suspected amyloidosis.

Spleen

Splenomegaly is initially present in approximately 10% of patients with amyloidosis and splenic rupture has been reported rarely. Hypersplenism does not occur with splenomegaly, probably because of massive replacement of splenic tissue by amyloid. Approximately 20 to 25% of patients with systemic amyloidosis and 60% with hepatic amyloidosis develop functional hyposplenism characterized by a normal-sized or large spleen on imaging studies and a peripheral blood smear showing Howell-Jolly bodies (nuclear remnants), target cells, and large platelets. The presence of Howell-Jolly bodies on a blood smear is a highly specific, but not sensitive, indicator of splenic amyloidosis. Functional hyposplenism is a valuable clue to the diagnosis of systemic amyloidosis in the patient presenting with nephrotic syndrome, hepatomegaly, or refractory heart failure of unknown etiology. The absence of hyposplenism is not a predictable sign of the absence of splenic involvement. In rare cases, amyloidosis-related functional hyposplenism is reversible if the patient responds to treatment.

Pancreas

Amyloid deposition can involve both the exocrine and endocrine portions of the pancreas. Exocrine pancreatic involvement can cause acinar atrophy and destruction. Amyloidosis has been reported in patients with cystic fibrosis and exocrine pancreatic insufficiency. These patients respond to enzyme replacement therapy. Rarely, pancreatic involvement results in pancreatitis secondary to ductal obstruction by amyloid deposits. Deposits in the pancreatic islets occur in type II diabetes mellitus and islet cell tumors.

Crohn's Disease-Associated Amyloidosis

AA amyloidosis is an uncommon yet important complication of Crohn's disease. In the largest series of patients with inflammatory bowel disease collected over a 50-year span, Greenstein *et al*. found a 0.9% incidence of amyloidosis in Crohn's disease. The prevalence may be higher as amyloid deposits are often documented only at autopsy. The mean time from the clinical onset of Crohn's disease to development of amyloidosis was 15 years. Amyloidosis in Crohn's disease was associated with more extensive intestinal disease, suppurative complications (fistulas, abscesses), extraintestinal manifestations (arthritis, pyoderma gangrenosum, aphthous stomatitis), and male gender.

Crohn's disease-associated amyloidosis most often develops in the kidney, but generalized amyloidosis with involvement of the GI tract, heart, thyroid, liver, and spleen has been described. Patients initially present with proteinuria or renal insufficiency, which may progress to nephrotic syndrome and renal failure.

TREATMENT

Therapy of amyloidosis is unsatisfactory. Evaluation of various approaches has been hindered by the lack of ability to accurately determine the extent of involvement in individual patients and by the widely disparate etiology of the various disorders that lead to amyloid deposits. Despite its apparently inert nature and inaccessible extracellular location, amyloidosis occasionally is reversible and radiolabeled SAP scintigraphy has demonstrated that amyloidogenesis is a dynamic process. Potential therapeutic approaches consist of those directed at prevention of amyloid precursor protein synthesis, prevention of amyloid fibril deposition, and removal or dissolution of amyloid deposits from tissues.

AL Amyloidosis

For AL amyloidosis, a myeloma type of chemotherapy regimen (melphalan and prednisone) is generally employed in an attempt to reduce production of the circulating monoclonal L-chain precursor. Colchicine may have some activity though less than cytotoxic chemotherapy. Iodo-doxorubicin has been reported to have anti-amyloid activity, but its role in therapy is currently undefined. High-dose chemotherapy with stem cell autografting has been employed by several groups and preliminary reports seem encouraging. However, follow-up is limited and the heterogeneity of individual amyloid patients makes subgrouping necessary and analysis difficult. A high incidence of GI bleeding after stem cell autografting has been reported. Preclinical studies have indicated that AL amyloid resolution can be induced by passive administration of an amyloid-reactive antibody. Such an approach may be effective in other amyloid types as the antibody appears to be directed to a fibrillar epitope. This observation has potentially important implications. Clinical trials in patients with AL and other amyloid diseases are eagerly awaited.

AA Amyloidosis

AA amyloidosis sometimes improves with therapy designed to prevent initial amyloid deposition or disease progression. Effective treatment of chronic infection

may result in amyloid stabilization or reversal. Colchicine prevents amyloid deposition and further deterioration of renal and cardiac function in AA amyloidosis associated with FMF and Crohn's disease. Colchicine may induce transient diarrhea and abdominal pain that must be distinguished from FMF, Crohn's disease, or GI tract amyloidosis. Even low-dose colchicine may cause diarrhea, especially in patients who have GI tract amyloid involvement.

In selected AA amyloidosis patients, renal and cardiac transplantation has been performed. Renal transplantation appears to have a role in FMF patients. In patients with Crohn's disease-associated amyloidosis, progression of the amyloid-related disease appears to cease following effective therapy directed at the underlying inflammatory bowel disease. Resection of the inflamed bowel is controversial with a possible increased risk of postoperative morbidity and mortality.

Familial Amyloid Polyneuropathic Syndromes Due to TTR Amyloidosis

In hereditary amyloidosis due to TTR, more than 95% of the mutant transthyretin is produced by the liver. A liver transplant should replace mutated TTR with the normal (wild-type) molecule and thereby stop amyloid formation. More than 400 liver transplants have been performed for TTR amyloidosis. Techniques have included both orthotopic and living–related donor liver transplantation. Combined liver/heart or liver/kidney transplants also have been performed. The goal of liver transplantation is to prevent further disease progression and onset of new complications. Liver transplantation has been reported to halt amyloid progression in familial amyloid polyneuropathy patients. Modest improvement in peripheral and autonomic neuropathy has been claimed in some patients. Improvement in gastrointestinal symptoms and nutrition has been noted posttransplant. Factors associated with a favorable outcome after liver transplantation include the presence of the TTR Val30Met mutation, symptomatic disease duration of less than 7 years, and good nutritional status with lack of severe autonomic impairment. Use of DNA testing to identify persons at risk for development of TTR amyloidosis while still in the preclinical phase of their disease will be helpful in assessing the efficacy of various new therapeutic regimens.

TTR amyloidosis rarely involves the liver and has not been associated with liver failure. In addition, its onset occurs in the third decade of life or later and carriers of the trait may never develop the disease. For these reasons, liver explants from patients with familial amyloid polyneuropathy have been used for sequential ("domino") liver transplantation. To date, no amyloid disease has been reported in recipients of these livers.

Effective therapy for other types of amyloidosis listed in Table I awaits elucidation of further insights into the origin and pathogenesis of fibrillar deposition in patients with these disorders.

rectal neck Embryologically, the anal canal is the lower part of the hindgut from which the rectum develops. The hindgut extends down and fixes itself to the perineal skin. Therefore, the anal canal is actually the lower narrow part of the rectum and it is referred to as the rectal neck.

The rectal neck (anal canal) is the gateway to the gut; it is surrounded by sphincters and muscles that regulate the passage of the rectal contents to the exterior. These muscles are responsible for fecal continence and defecation.

EXTERNAL ANAL SPHINCTER

The external anal sphincter (EAS) is a triple-loop system consisting of top, intermediate, and base loops (Fig. 1). Each loop is separated from the others by a fascial septum (Fig. 2) and has its individual attachment, direction of muscle bundles, and innervation. The top loop comprises the deep part of the EAS and puborectalis, which are intimately fused together. Its muscle bundles loop around the upper part of the rectal neck (RN) and are attached to the symphysis pubis. It forms a downward extension, which descends along the RN and contributes to the formation of the longitudinal muscle (Fig. 2). It is innervated by the inferior rectal nerve. The intermediate loop embraces the midportion of the RN and is innervated by the perineal branch of the fourth sacral nerve. The base loop encloses the lower RN and is innervated by the inferior rectal nerve. It consists of only loop fibers in its upper part and of inner circular and outer loop fibers in its lower part.

Mechanism of Action

The EAS induces voluntary continence by a double-fold action: (1) prevention of internal sphincter relaxation on detrusor contraction, which is termed "voluntary anorectal inhibition reflex," and (2) direct compression of the RN, or the "mechanical action."

Voluntary Anorectal Inhibition Reflex

As stools enter the rectum, the rectal detrusor contracts and the internal sphincter relaxes reflexly to open the RN (Fig. 3). The latter does not open unless the EAS relaxes voluntarily. However, if there is no desire to defecate, the EAS contracts, mechanically preventing relaxation of the internal sphincter. Failure of the latter to relax reflexly inhibits contraction of the rectal detrusor, which relaxes and dilates to accommodate the new contents (Fig. 4). Voluntary EAS contraction to inhibit

reflex internal sphincter relaxation is the "voluntary anorectal inhibition reflex." This is the main action responsible for voluntary continence. The internal sphincter integrity is thus necessary not only for involuntary continence, but also for voluntary continence, because the internal sphincter mediates the voluntary inhibition reflex. For this reason, internal sphincter reconstruction should be considered an essential step in rectal incontinence repair.

Voluntary Mechanical Action

In addition to the voluntary inhibition reflex, EAS contraction firmly seals the RN by mechanical compression. Because it is a striated muscle, the EAS cannot contract for a long period to maintain continence mechanically. The mechanical compression action is thus momentary (40–60 s) and serves to occlude the RN by the time the detrusor relaxes as a result of the voluntary inhibition reflex.

Stress Defecation

Under conditions of internal sphincter damage, voluntary continence is induced only by the mechanical action of the EAS. The voluntary inhibition reflex is lost. Because it is a striated muscle, the EAS cannot contract long enough to withstand the noninhibited prolonged contraction of the loaded rectal detrusor. Detrusor contraction continues despite EAS contraction till the latter fatigues and relaxes and the detrusor evacuates itself. Hence, in cases of internal sphincter damage, once the desire to defecate is initiated, evacuation should occur. This condition, which is termed "stress defecation," is observed in patients after internal sphincterotomy for anal fissure. It could also explain the impaired control of feces and flatus after internal sphincterotomy.

Single-Loop Continence

As a result of the separate arrangement of the three EAS loops and because each loop has its own separate and bilateral innervation, any single loop can function as a sphincter. The EAS continence action can be achieved by a single-loop contraction and not necessarily by the three loops. This constitutes the basis of "single-loop continence." On contraction, a single loop induces continence by both the voluntary

inhibition reflex and mechanical occlusion. The latter action creates significantly tight loop contraction, being effected not only by direct compression but also by RN kinking.

THE ANOGENITAL MUSCLE

A recent study has demonstrated that the base loop of the EAS extends uninterrupted across the perineum to the bulb of the penis where it becomes continuous with the bulbocavernosus muscle. Lying over the bulb, the muscle bundles are arranged into three groups: the median fibers and two lateral bundles of fibers. The median fibers form the "retractor penis muscle," which is inserted into the corpora cavernosa, and the lateral fibers, which form the "compressor bulbae muscle," are inserted into the perineal membrane. Upon glans stimulation, both the EAS and the bulbocavernosus muscle contract synchronously with similar latency and action potentials. The bulbocavernosus muscle is an integral part of the EAS, and the muscle in its entirety is appropriately named the "anogenital muscle." The muscle plays a dual and synchronous role in fecal control and sexual response. It is suggested that EAS disorders lead to sexual dysfunction and vice versa.

LONGITUDINAL MUSCLE

The longitudinal muscle consists of three layers: medial, intermediate, and lateral (Figs. 2 and 5). The medial longitudinal muscle is a continuation of the longitudinal rectal muscle coat. The intermediate muscle is the suspensory sling of the levator ani, whereas the lateral muscle is the longitudinal extension of the top loop of the EAS. The fleshy longitudinal muscle ends at the level of the lower border of the internal sphincter by giving rise to a fascial condensation called the "central tendon." The latter splits into multiple fibrous septa. The medial septum attaches to the RN lining, whereas the lateral muscle passes into the ischiorectal fossa. The intermediate septa penetrate the EAS base loop, decussate to form the corrugator cutis, and insert in the perineal skin (Figs. 2 and 5). The longitudinal muscle plays an important role in the mechanism of defecation. On contraction at stool, it shortens and widens the RN. Furthermore, it helps to fix the RN during straining at defecation, thus preventing rectal prolapse. Subluxation of the longitudinal muscle shares in rectal prolapse genesis.

PERIANAL SPACES

Six perirectal spaces can be identified: subcutaneous, central, intersphincteric, pelvirectal, ischiorectal, and submucous (Figs. 2 and 5). The subcutaneous space was continuous with the ischiorectal space. The central space lies in the lower RN and is occupied by the central tendon. It is the main perirectal space; it communicates with all of the other spaces along the central tendon.

The central tendon gives rise to multiple fibrous septa. The medial tendon passes between the internal sphincter and the base loop to attach to the anal lining. The lateral septum passes between the intermediate and base loops into the ischiorectal fossa. The intermediate septa penetrate the base loop into the subcutaneous space. The central space thus communicates with all perianal spaces: the subcutaneous, submucous, ischiorectal, and intersphincteric, through which it communicates with the pelvirectal space.

There are four intersphincteric spaces that lie along the three layers of the longitudinal muscle. The most medial space communicates with the submucous space, whereas the lateral two spaces communicate with the ischiorectal space. The intermediate space communicates directly with the pelvirectal space. The intersphincteric spaces communicate inferiorly with the central space, through which they are connected to the subcutaneous space and perianal skin and to the ischiorectal space.

Fistula Classification

A new fistula classification was put forward based on pathoanatomical studies.

The route adopted by the pus to any of the six perianal spaces defines the type of fistula. According to the relation of the fistulous track to the EAS, two main types of fistulas could be recognized: intrasphincteric and extrasphincteric (Fig. 6).

Intrasphincteric Fistula

The track is medial to the EAS and the external opening is usually close to the anal orifice within the perianal skin corrugations. It starts as a central space infection that spreads either down to the subcutaneous space and perianal skin, forming a central fistula, or up into the intersphincteric spaces, forming an intersphincteric fistula (Fig. 6).

Extrasphincteric Fistula

The track is lateral to the EAS and the external opening usually overlies the base of the ischiorectal fossa away from the perianal corrugations. It arises as a central space infection that spreads laterally to the ischiorectal space (Fig. 6).

LEVATOR HIATUS AND TUNNEL

The levator ani (LA) consists essentially of the pubococcygeus, the iliococcygeus being rudimentary in humans. The puborectalis is not a part of the LA; both differ in morphology, innervation, and function. The pubococcygeus is funnel-shaped with a transverse portion called the levator plate and a vertical portion called the suspensory sling (Figs. 2 and 5). The levator plate is an oval cone, which stretches across the pelvis; the levator hiatus occupies its anterior portion and the rectococcygeal raphe exists posteriorly (Fig. 7). Two patterns of the rectococcygeal raphe can be identified: single- and triple-decussation patterns. The latter seems to give firmness to the levator plate and might be a factor in resisting rectal prolapse. The hiatal ligament connects the medial border of the levator plate to the anorectal junction. The levator plate consists of two "crura," which bind the levator hiatus, and two lateral masses (Fig. 7). Three crural patterns have been identified: classic, crural overlap, and crural scissor. The lateral masses function as visceral support and the crura are the functional mobile parts of the LA.

The LA is the principal muscle of defecation. On contraction at defecation, it opens the RN for the

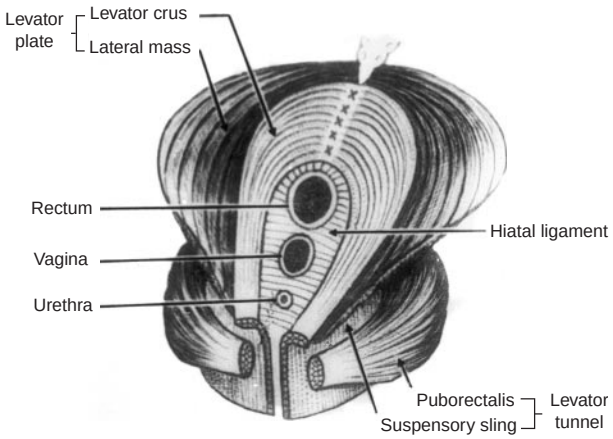

FIGURE 7 Diagram illustrating the levator plate and tunnel. Reprinted from Shafik (1981), with permission from Excerpta Medica.

stool to descend. Any interference with levator function results in disturbance of the act of defecation and leads to levator dysfunction syndrome, which presents as descending perineum, intussusception, solitary ulcer syndrome, and rectal prolapse. The different patterns of the rectococcygeal raphe and levator crura play an important role in RN support; their subluxation may eventually lead to rectal prolapse.

The "levator tunnel" is a muscular tube that surrounds the intrahiatal organs (RN, prostate in males or vagina and urethra in females) along their way down from the levator hiatus to the perineum (Fig. 7). The posterior tunnel wall (3–4 cm) is longer than the anterior tunnel wall (2.5–3 cm). The tunnel is double-sheathed with an inner coat of the suspensory sling and an outer coat of the puborectalis. Both coats are composed of striated muscle bundles. The inner coat is a tunnel dilator, which opens the RN at defecation, whereas the outer coat is a tunnel constrictor. The tunnel septum, a grayish white membrane, lines the inner aspect of the levator tunnel and separates it from the fascia propria of the intrahiatal organs. It separates the voluntary components from the involuntary components of the levator tunnel. It serves as an important landmark during mobilization of the intrahiatal organs from within the levator tunnel, e.g., in the operation of anorectal mobilization for rectal cancer.

Hiatal Ligament

The levator plate is connected to the intrahiatal organs by a fascial condensation called the hiatal ligament (Fig. 2). It arises from the inner edge of the levator plate and splits fanwise into multiple septa to insert into the upper RN, into the vesicle neck, and into the upper vaginal end. Anteriorly, the ligament fills the gap between the two levator crura at their origin, forming the puboprostatic or pubovesical ligament. The hiatal ligament plays a vital role in harmonizing the action between the levator plate and the intrahiatal organs during evacuation of their contents (defecation and urination). Hiatal ligament subluxation would interfere not only with the act of evacuation but would also lead to prolapse of the intrahiatal organs.

Puborectalis and the Double-Sphincter Control

The puborectalis (PR), as it proceeds backward from its origin in the symphysis pubis, gives off muscle bundles to each intrahiatal organ, forming "individual" voluntary sphincters for these organs (Fig. 8). It gives rise to the external urethral sphincter and deep EAS in both sexes, as well as to the vaginal sphincter in the female and the prostatic sphincter in the male. However, the PR and deep EAS were found fused together, the conjoint muscle being termed the top loop. Each intrahiatal organ is thus provided with a double voluntary sphincteric apparatus: (1) an individual organ sphincter, derived from the PR and specific for the organ, and (2) a "common" tunnel sphincter, the PR itself, which acts on the intrahiatal organs collectively. This separate sphincteric activity for the individual organs under the control of a common continent muscle secures not only an immune sphincteric function for the organ, but a harmonized action among the structures enclosed within the levator tunnel. Furthermore, the double sphincteric mechanism provided to each organ could be a guarantee of functional maintenance in case either of the two sphincters is damaged. Injury to either sphincter alone does not induce incontinence of the organ involved. Unless both the individual and the common sphincters are destroyed, continence can be maintained by either one alone.

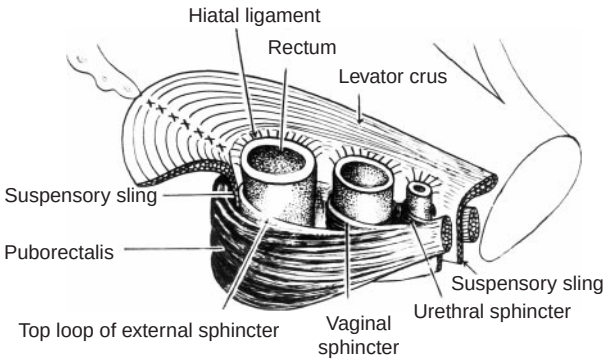

FIGURE 8 Diagram illustrating the "individual" sphincters arising from the puborectalis, which acts as a common sphincter for the intrahiatal structures. Reprinted from Shafik (1998), with permission of Springer-Verlag.

MECHANISM OF DEFECATION

Muscles of Defecation

The muscles that act on the RN are the external and internal anal sphincters, PR, LA, and longitudinal muscle. The external and internal sphincters as well as the PR are muscles of continence. Their role is to contract in order to interrupt or terminate the act of defecation. However, the principal muscles of defecation are the LA and the longitudinal muscles. They act jointly to open the RN at defecation. The two muscles are interrelated due to the fact that the suspensory sling, a part of the levator, constitutes the middle layer of the longitudinal muscle (Figs. 2 and 5).

Anatomical Mechanism of Defecation

With knowledge of the physioanatomical aspects of the pelvic floor muscles and assisted by manometric, electromyographic (EMG), and barium enema studies, the precise mechanism of defecation could be explored. As stools enter the rectum, reflex detrusor contraction and internal sphincter relaxation occur. The continuation of defecation depends on two factors: (1) EAS relaxation and (2) straining. If defecation is acceded to, the EAS is voluntarily relaxed. Straining is necessary to maintain defecation as it raises the intra-abdominal pressure, which serves a double purpose: it compresses the detrusor, which helps evacuation, and it stimulates levator contraction through the straining levator reflex. Although the intra-abdominal pressure compresses the detrusor, the RN is spared, owing to its protected location below the levator plate. When the levator plate contracts, it moves from the cone to the flat position and is elevated and laterally retracted (Fig. 9). This results in pulling on the hiatal ligament, which in turn pulls open the anorectal junction and partially opens the rectal angle. Simultaneously, the suspensory sling contracts and not only pulls up the base loop to unseal the anal orifice, but also partially opens the RN (Fig. 9).

The longitudinal muscle joins the detrusor in contraction, which results in shortening and opening of the RN as well as in complete straightening of the rectal angle. This brings the RN into alignment with the detrusor so that efficient fecal pumping occurs. The final result of the joint contraction of the detrusor, longitudinal muscle, and LA is the opening of the RN for the rectum to evacuate its contents.

Physiologic Mechanism of Defecation

The concerted functions of the anorectal musculature at defecation are initiated and harmonized by voluntary impulses and reflex actions. When the rectal detrusor is distended with fecal mass and the stretch receptors are stimulated, the recto-anal inhibitory reflex is initiated, whereby the rectal detrusor contracts and the internal sphincter relaxes. Detrusor contraction triggers two reflexes: the recto-puborectalis reflex and the recto-levator reflex. These two reflexes act simultaneously, yet have opposite functions; on detrusor contraction, the recto-levator reflex effects a reflex levator contraction, which opens the RN. At the same time, the reflex PR contraction, actuated by the rectopuborectalis reflex, functions to close or keep closed the RN as impulses reach the conscious level to evaluate the

circumstances for defecation. If the circumstances are inopportune, the PR continues voluntary contraction.

Voluntary PR contraction evokes the voluntary inhibition reflex, which effects detrusor relaxation. Meanwhile, it aborts the recto-anal inhibitory reflex, which relaxes the internal sphincter. Hence, voluntary PR contraction, through the voluntary inhibition reflex, prevents internal sphincter relaxation, which results in reflex detrusor relaxation and waning of the urge to defecate. However, as soon as circumstances would allow defecation and the sensation of desire to defecate is perceived, the PR muscle relaxes voluntarily and the detrusor evacuates its contents. This demonstrates that the act of defecation is under voluntary control despite the presence of reflex actions sharing in the mechanism of defecation. Thus, although the recto-anal inhibitory and rectolevator reflexes function to open the RN, the recto-puborectalis reflex keeps the RN closed until the decision to defecate has been made.

Mild straining at the start of defecation is a normal physiological process and as such is part of the mechanism of defecation. By elevating the intra-abdominal pressure, it triggers the straining levator reflex, which effects levator contraction and the opening of the RN for the spontaneous evacuation of the stools.

human papillomavirus Family of 60 subtypes of sexually transmitted viruses responsible for genital tract infections, such as condylomata (genital warts). Chronic infection with subtypes 16 and 18 has been identified as a strong risk factor for the development of cervix cancer and anal cancer.

Anal cancer is an uncommon condition that has served during the past two decades as a paradigm for the successful application of chemoradiation to solid tumors. This type of neoplasm also provides a good model to study the contribution of human papillomaviruses and immunodeficiency to the development of cancers.

ANATOMY AND HISTOLOGY

The various definitions of the anal area coexisting in the medical literature have been the source of considerable confusion. Anal cancer may arise from the anal canal or from the anal margin; 85% of the anal cancers occur in the anal canal and 15% occur in the anal margin. The anal canal is about 3.5 cm long and extends from the upper to the lower border of the anal sphincter. The anal margin corresponds to a 5-cm area of perianal skin, measured form the anal verge (Fig. 1). The anal verge is a visible landmark, corresponding to the external margin of the anus, which delineates the junction between the skin epithelium and the hairless and non-pigmented epithelium of the anal canal. Tumors arising within the anal canal are either squamous cell or cloacogenic carcinomas and are characterized by aggressive local growth, including extension to the sphincter muscles. Conversely, cancers originating from the perianal skin have a more favorable prognosis and tend to behave more like other skin cancers. Thus, the anal verge is an important anatomical landmark, separating two histologically distinct epithelial structures that give rise to two types of cancers with different natural histories, prognoses, and treatment.

EPIDEMIOLOGY AND ETIOLOGY

Of all digestive system cancers in the United States, anal cancer comprises 1.5%, with an estimated 3400 new cases and 500 deaths in 1999. The peak incidence is during the sixth decade, but the incidence of these tumors has markedly increased in younger males during the past three decades. In the San Francisco Bay area, the incidence of anal cancer in gay men was 10 times higher than expected in 1973–1979. In addition, the increased incidence of these neoplasms in renal transplant patients clearly suggests that immunosuppression may play a role in tumor development.

Population studies from California and Europe have documented well the relation between anal cancer and receptive anal intercourse in men. In addition, numerous reports have linked anal cancer and cervical cancer in women. Thus, in most cases, anal cancer is now considered a sexually transmitted disease, which is clinically related to the development of anal warts and infection with human papillomavirus (HPV). At the molecular level, the most well-characterized factor in the development of anal cancer is the integration of human papillomavirus DNA into anal canal cell chromosomes. It has been hypothesized that the

increased risk for anal cancer among individuals with AIDS results from HPV infection, and not from immune deficiency. However, the fact that HIV infection seems to contribute to HPV persistence within the anal canal strongly suggests a dual viral etiology in the development of some of these neoplasms.

CLINICAL FEATURES

Tumors from the anal area typically present as a mass associated with bleeding and pain (Fig. 2). Even small lesions can produce significant local symptomatology when they protrude within the anal canal, a blessing in disguise if it facilitates early detection. Unfortunately, these symptoms are often erroneously attributed to "hemorrhoids," with subsequent delay in the diagnosis and treatment. It is important for the clinician to remember that hemorrhoids rarely cause pain (unless thrombosed), thus patients presenting with anal pain should be carefully evaluated, if possible under anesthesia, and biopsies should be obtained. Untreated anal cancer spreads by local extension to adjacent tissues and organs of the pelvic floor, including sphincter muscles, vagina, or prostate. When present, tenesmus, the painful urgency to defecate, suggests that the tumor has spread through the sphincter muscles. Anal margin and anal canal tumors have different patterns of lymphatic drainage. Cancers arising from the more proximal anal canal drain predominantly into the perirectal lymph nodes, whereas tumors within the distal canal and the anal margin drain exclusively into inguinal lymph nodes. Roughly 90% of anal tumors present with locoregionally confined disease, whereas 10% have distant metastases at the time of diagnosis.

Once the diagnosis of anal cancer has been proved by biopsy, it is important to assess the locoregional extension of the tumor and to further characterize its stage. Prognosis for anal cancer is related to tumor size, but it is unclear whether the independent variable is the actual tumor size or the depth of invasion. Neither the histology type nor the degree of differentiation has major prognostic significance, and therefore these criteria have not been included in the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) staging system. Tumors larger than 5 cm in greatest dimension (T3) and lesions with metastases in regional lymph nodes (N1–3) have an increased risk for tumor recurrence after chemoradiation. Of note, the staging system for most solid tumors rests on the pathologic analysis of a complete surgical specimen. Because most cases of anal cancer are treated initially without surgery, a satisfactory staging method for these cancers remains to be developed.

FIGURE 2 Anal cancer.

TREATMENT AND OUTCOME

Anal Margin Cancer

The rationale behind the therapeutic strategies for anal margin cancer derives from the proportionally increased risk for metastases with increasing tumor size. Wide local excision is usually recommended for early-stage lesions of less than 5 cm, and excellent results are reported. As for most skin cancers, the prognosis is good, with 5-year survival rates of 80 to 90%. Recurrences rarely occur and can be managed by reexcision in most cases. Larger (>5 cm) and node-positive lesions are best managed with combined radiation and chemotherapy (as for anal canal cancers). Abdominoperineal resection (APR) remains an option in patients with locally advanced tumors.

Anal Canal Cancer

Although small tumors (<2 cm) arising in the anal canal may be amenable to local excision, most patients present with lesions of greater dimensions. Thirty years ago, these neoplasms were treated routinely with an abdomino-perineal resection, resulting in a definitive colostomy. Thanks to the pioneering work of Nigro in the 1980s, it is now widely accepted that the majority of cases can be cured by a combination of chemotherapy and radiation therapy (CRT). The standard of care consists in the combination of radiation and chemotherapy; external-beam radiation (60 Gy over 5 weeks) with fluorouracil and mitomycin-C results in local eradication of tumors in 70 to 80% of patients. Complete response usually (but not always) results in cure, and

no additional treatment is required. Following chemoradiation, patients should be examined at 3-months intervals; local inspection, digital examination, anoscopy, and biopsy of any suspicious areas are recommended. It is important to differentiate residual disease (positive biopsies less than 6 months after completion of chemoradiation) from tumor recurrence (more than 6 months after cessation of treatment). In most cases, recurrence occurs within 2 years after chemoradiotherapy. The functional results are usually good, and most patients retain a functional anal sphincter, with no alteration in their lifestyle. However, it is known that radiation negatively affects the internal sphincter function, and in a small percentage of cases radiation-induced anorectal dysfunction may result in severe fecal incontinence.

For patients with locally recurrent anal canal cancer, an abdomino-perineal resection remains the treatment of choice. Relatively good results can be achieved with salvage APR in patients with recurrent anal canal cancer; 5-year survival rates up to 50 to 60% have been reported in patients who had evidence of residual disease after CRT. Research is ongoing to determine whether recurrent anal cancer is amenable to a cisplatin-based chemotherapy associated with additional radiotherapy.

SUMMARY

Anal cancer shares many features with cancer of the uterine cervix, including its association with human papillomavirus infection. As such, this type of tumor is now considered a sexually transmitted disease, with homosexual men being a high-risk population. Screening for anal cancer with anal Papanicolaou tests has proved clinically and cost-effective. Future research should investigate the molecular biology of these neoplasms and the genetic features associated with resistance to chemoradiation. In addition, the complex role of immunosuppression in facilitating persistence of HPV infection in the anal canal should be further investigated.

anal sphincters Rings of smooth muscle or skeletal muscle that surround the distal rectum and anal canal; contract to obstruct the passage of feces.
enteric nervous system Independent integrative nervous system in the gastrointestinal tract; sometimes referred to as the "brain in the gut."
external anal sphincter Rings of skeletal muscle that surround the distal rectum and anal canal; respond to volitional commands to maintain continence when feces have moved into the rectum.
internal anal sphincter Ring of smooth muscle that surrounds the distal rectum and anal canal; obstructs the passage of feces when contracted and permits passage when relaxed.
rectoanal reflex Relaxation of the internal anal sphincter in response to distension of the rectum.

Anal sphincters are rings of muscle surrounding the distal rectum and anal canal. There are two anal sphincters in this region, the internal anal sphincter and the external anal sphincter. Either sphincter, when contracted, assists in closing the anal canal to the passage of feces and flatus. The anal sphincters, in concert with the musculature of the pelvic floor, are responsible for the maintenance of fecal continence.

INTERNAL ANAL SPHINCTER

The internal anal sphincter is an extension of the circular muscle layer of the colon and rectum (Fig. 1A). The sphincter is a ring of smooth muscle that surrounds the terminal rectum and proximal anal canal. Contraction of the internal sphincter closes the anal canal and opposes the passage of feces. Like most smooth muscle sphincters in the alimentary canal, the internal anal sphincter contracts continuously and relaxes only in response to inhibitory neural input. It is the primary barrier to leakage of feces between acts of defecation.

Specialized physiology of the smooth muscle in the sphincter accounts for its ability to exist in a state of sustained contraction. The contractile apparatus of the muscles consists of the two proteins, actin and myosin. Contraction occurs during formation of cross-bridges between actin and myosin filaments. Contractile tension is maintained by a "catch" mechanism that latches the cross-bridges in place without expenditure of additional energy. Inhibitory input from the nervous system leads to uncoupling of the cross-bridges, relaxation of contractile tension, and opening of the sphincter. Excitatory input from the nervous system facilitates the latch mechanism and increases contractile strength and efficiency of the sphincter.

The internal anal sphincter is innervated by motor neurons in the enteric nervous system and postganglionic neurons of the sympathetic nervous system. Most of the enteric motor innervation is inhibitory. Firing of nerve impulses by the inhibitory motor neurons releases inhibitory neurotransmitters at their junctions with the smooth muscle of the sphincter. Two important inhibitory neurotransmitters are vasoactive intestinal polypeptide and nitric oxide. These neurotransmitters act to inhibit contraction of the smooth muscle and open the sphincter. Activation of the sympathetic innervation of the sphincter releases norepinephrine at the neuromuscular junctions. Norepinephrine acts at α-adrenergic receptors on the muscle to increase contractile force and "tighten" the sphincter.

EXTERNAL ANAL SPHINCTER

The external anal sphincter is composed of skeletal muscle that functions like other postural muscles in the body. It is a voluntary muscle that responds to volitional commands to contract and maintain continence when feces are propelled through a relaxed internal anal sphincter into the rectum. The external anal sphincter is composed of a deep external sphincter, a superficial external sphincter, and a subcutaneous external sphincter. These muscle groups form three loops surrounding the anus (Fig. 1C). The deep external sphincter attaches anteriorly to the pubis and forms the uppermost loop. The superficial external sphincter attaches posteriorly to the coccyx and forms the intermediate loop. The subcutaneous external anal sphincter attaches to the

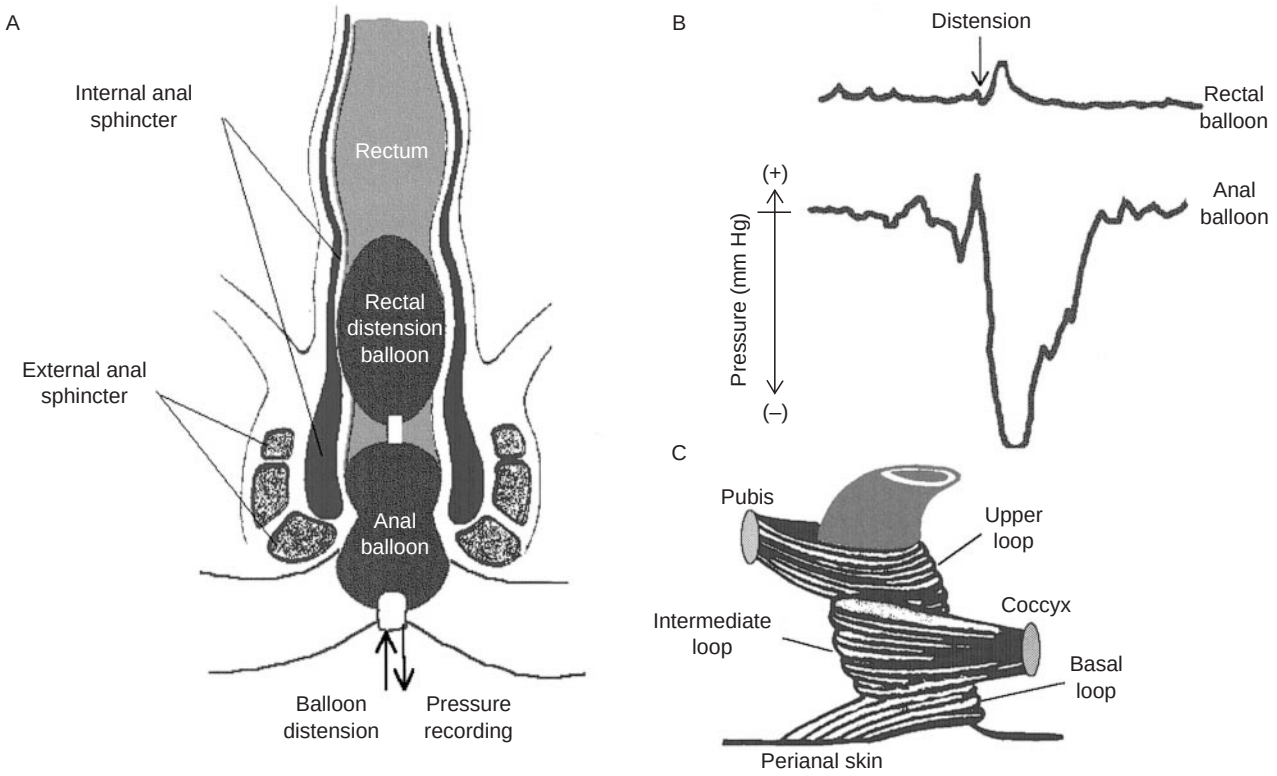

FIGURE 1 Anal sphincters are involved in the rectoanal reflex and are responsible for maintenance of fecal continence. (A) The internal and external anal sphincters surround the anal canal. Distension of a balloon in the rectum evokes reflex relaxation of the internal anal sphincter. (B) Recording of pressure in a balloon placed in the anal canal shows reflex relaxation of pressure in a balloon in the anal canal in response to distension of the rectum. (C) The external anal sphincter is a skeletal muscle consisting of three parts that loop around the anal canal. The upper loop inserts anteriorly on the pubis; the intermediate loop inserts on the coccyx, and the basal loop inserts in the perianal skin. perianal skin and forms the lower loop. Simultaneous contraction of the three loops effectively occludes the anal canal.

RECTOANAL REFLEX

Distension of the rectum activates a rectoanal reflex (sometimes called rectosphincteric reflex) to relax the internal anal sphincter. Like other enteric reflexes, this involves a stretch receptor, interneurons in the enteric nervous system, and ultimately activation of firing of inhibitory motor neurons to the smooth muscle sphincter. The rectoanal reflex can be evoked experimentally by inflating a balloon in the rectum and recording changes in pressures in a balloon positioned in the anal canal (Fig. 1A). Distension of the first rectal balloon is followed by a reflex relaxation of pressure in the second balloon in the anal canal. This can be a diagnostic test of the functional integrity of the enteric nervous system in the anorectum. Due to loss of the enteric nervous system in the distal large intestine in Hirschsprung's disease, absence of the rectoanal reflex is a diagnostic hallmark for this disorder.

Reflex relaxation of the internal sphincter allows contact of the rectal contents with the sensory receptors in the lining of the anal canal. This is believed to be the mechanism by which an individual discriminates between gas, liquid, and solid in the anorectum. It also provides an early warning of the possibility of a breakdown of the mechanisms of continence. When this occurs, continence is protected by voluntary contraction of the external anal sphincter, which serves to close the anal canal. Whereas the rectoanal reflex is mediated by the integrative neural networks of the enteric nervous system, the neural circuitry for reflexes

of the external anal sphincter resides in the sacral portion of the spinal cord.

enough to maintain even a minimally normal body weight for age and height. The formal diagnosis of anorexia nervosa requires that the body weight be below 85% of the average, expected weight for age, height, and bone structure as determined by standardized scales, such as pediatric growth charts or actuarial tables. As an alternative method to assessing body weight, body mass index (BMI) can be used (BMI = weight in kilograms divided by height in meters squared). A BMI below 17.5 is regarded as in the anorexic range. At an anorexic body mass, ovulation and menstruation (or pubertal development) cease and secondary sexual characteristics regress.

The individual with anorexia nervosa is excessively influenced by her body shape and weight and does not "see" her body accurately (for example, the anorexic adolescent girl who should optimally weigh 135 pounds but thinks that she is fat when she weighs only 85 pounds). In an emaciated, starving individual, the intense fear of becoming fat in combination with the belief that one's body is already fat (or perilously close to fatness) constitutes a delusional-like self-assessment. Some individuals with anorexia nervosa feel globally fat, whereas others are particularly concerned about parts of their bodies, such as the arms, abdomen, or thighs. Individuals with anorexia nervosa usually weigh themselves excessively, frequently view themselves in mirrors, and even measure body parts. Self-esteem becomes linked to self-perception of body weight wherein weight loss is perceived as an extraordinary accomplishment to be proud of and weight gain is perceived as a despicable failure of self-control.

TABLE I DSM-IV Criteria for Anorexia Nervosa

A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D. In postmenarcheal, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles (a woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration).

Restricting type

During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Binge-eating/purging type

During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

ANOREXIA NERVOSA SUBTYPES

In 1980, a distinction was formally made between two subtypes of anorexia nervosa, the restricting type and the bulimic (binge-eating/purging) type (or so-called "bulimarexia") (Table I).

The restricting anorexic individual engages in a range of "restricting" behaviors including fasting, skipping meals, stringent dieting, food avoidance, and strict exclusion of certain foods from the diet, but does not purge. The restricting anorexic tends to be closed and guarded, with strict boundaries between herself and others, as if guarding against excessive permeability of the self to outside influence and, ultimately, against dissolution of the self. Superficially, however, an apparent smugness or arrogance is sometimes manifested as a strong feeling of accomplishment for being able to refrain from eating, unlike many other individuals.

The binge-eating/purging type is characterized by anorexia combined with regular episodes of binge eating and purging or, in some cases, purging without binge eating or after eating only small amounts of food. Additional methods of weight loss are sometimes employed by individuals with the binge-eating/purging type (bulimic anorexia or bulimarexia) of anorexia nervosa. Like persons with bulimia nervosa, individuals with the bulimic type of anorexia nervosa may self-induce vomiting, misuse laxatives, diuretics, and enemas, and exercise excessively.

As an overgeneralization, patients with the bulimic subtype of anorexia nervosa have a higher premorbid weight, a stronger family history of obesity, and higher impulsivity than restricting anorexic patients. Patients with the restricting subtype have greater levels of obsession and may be more isolated socially than those with the binge-eating/purging subtype.

VARIANTS OF ANOREXIA NERVOSA

In addition to the full syndrome of anorexia nervosa, which is in itself seen in forms ranging from the moderate to the severe, low-grade (subclinical) anorexia nervosa, mild anorexic-like syndromes, and other variants of anorexia nervosa also exist. The combination of weight preoccupation and chronic or excessive dieting

is in itself related to the syndrome of anorexia nervosa and, moreover, constitutes a major risk factor for the development of the eating disorder (especially in adolescents). However, severe dieting does not in itself equate with anorexia nervosa. If dieting is excessive, leading to a BMI 5–10% below ideal in the presence of a morbid fear of fatness and unrealistic overestimation of one's own body size, then low-grade or subclinical anorexia nervosa is present. Another example of low-grade or subclinical anorexia nervosa is illustrated by a thin young woman, weighing perhaps 90% of expected, who is intensely afraid of becoming fat, who is rigorously controlled in her emotions and behavior, and who is preoccupied with food preparation. Yet another example of a mild variant of anorexia nervosa, or of a mild anorexic-like syndrome, includes the athletic young woman who trains rigorously and compulsively, is amenorrheic, strictly restricts fat intake, is careful about what she eats, and is at the low margin (90%) of normal body weight. Similarly, slightly underweight persons with bulimia nervosa are not anorexic per se, but have a syndrome that is related to anorexia nervosa. Of course, bulimia nervosa shares in common with anorexia nervosa intense preoccupation with body shape and size and the fear of becoming fat. The bulimic type of anorexic patient—the bulimarexic—further shares compensatory behaviors, such as postprandial vomiting, and even binge eating itself, with the patient with bulimia nervosa. The distinction between bulimia nervosa and the binge-eating/purging type of anorexia nervosa revolves around the degree of weight loss and food restriction. Some individuals show alternating anorexia nervosa and bulimia nervosa.

Misperception or distorted self-evaluation of one's body, or one of its parts, is present not only in anorexia nervosa, but also in body dysmorphic disorder. The essential criterion for body dysmorphic disorder is preoccupation with an imagined or exaggerated defect in appearance.

Another clinical situation related to anorexia nervosa is the food-obsessed individual with obsessive–compulsive disorder, who may show obsessions and/or compulsions related to food, food intake, and food preparation. The essential diagnostic feature of obsessive–compulsive disorder is the presence of either recurrent obsessions or compulsions that are severe enough to cause significant suffering or functional impairment. However, if cachexia and distorted body image are not present, then neither is anorexia nervosa proper.

Individuals with a range of abnormal eating patterns that do not meet diagnostic criteria for bulimia nervosa, binge eating disorder, night eating syndrome (itself a provisional diagnosis), or anorexia nervosa are given the nonspecific diagnosis "Eating Disorder Not Otherwise Specified" according to the Diagnostic and Statistical Manual (DSM) of the American Psychiatric Association.

EPIDEMIOLOGY

Anorexia nervosa has an estimated prevalence of 0.2 to 1% in adolescent females; there is an even higher prevalence if milder, so-called subclinical forms of the illness are taken into account. Anorexia nervosa is an uncommon condition in males, accounting for only approximately 5% of patients with this illness. Most disordered eating emerges during adolescence. Weight and body shape concerns commonly develop in late childhood and in puberty. The typical age of onset of anorexia nervosa is between early adolescence and early adulthood (ages 12–24 years), although there are childhood onset cases and some case reports of anorexia nervosa in elderly persons.

Though very little is known about the true prevalence of eating disorders in non-Western and nonwhite populations, ethnic and cultural differences seem to play a role in their development. Anorexia nervosa appears to be rare in developing or non-Western cultures, more commonly emerges from a background of affluence, and is rarely encountered in persons from impoverished circumstances. In this regard, people who were raised in impoverished environments and who were chronically hungry as children are not likely to value fasting as adults. Young females who emigrate from a non-Western culture into a Western, industrialized environment increase their risk of developing an eating disorder. Anorexia nervosa is less prevalent among blacks than among whites and Hispanics; although substantial intraracial variability exists and this heterogeneity should not be minimized, in general thinness as an element of feminine beauty is more valued in white culture than in black culture.

RISK FACTORS, COMORBIDITIES, AND ASSOCIATED FEATURES

Anorexia nervosa, like bulimia nervosa, clusters in families; however, not enough data are available to apportion inheritable and environmental causality. An interaction between the environment and genes most likely confers vulnerability to develop the eating disorder. However, the limited data that are available indicate that monozygotic twins are at least two to four times more likely to show concordance for anorexia

nervosa than dizygotic twins. Elucidation of inheritable factors, such as genetic polymorphisms in neurochemical receptors, may eventually help explain why a small minority of girls, and an even smaller minority of men, deteriorate into anorexia following a period of successful dieting, whereas most individuals can diet without worry of becoming anorexic.

Strict dieting is a major risk factor for the development of anorexia nervosa, with severe dieting most likely to evolve into anorexia in vulnerable individuals. However, pinpointing dieting as a risk factor can be misleading, because, although dieting predates the onset of the illness, dieting is also one of the eating behaviors of the illness, once the illness becomes established. Furthermore, dieting is not the sufficient cause of an eating disorder. Nevertheless, the cultural impact of the high acceptability and popularity of dieting, combined with the social status associated with thinness in women, cannot be ignored. The internalization of the thin ideal for feminine beauty introduces a risk for anorexia in females, wherein the successful pursuit of thinness seems to (superficially) solve life's problems. Moreover, many anorexics do not reach a point where enough body satisfaction occurs to permit nutritious eating. Achieving an ideal body is nearly an impossibility given that many media portrayals of cover girls and professional models use special lighting, makeup, and airbrushes to remove imperfections, thus creating unrealistic body standards and increasing body dissatisfaction among many in the general population. Body dissatisfaction is itself another risk factor for the development of anorexia nervosa.

The presence of psychiatric morbidity is quite common among anorexia nervosa patients (especially among those with the bulimic type of anorexia) and, if preexisting, increases the risk for developing anorexia nervosa. Anorexia nervosa is often accompanied by depressive symptoms such as depressed mood, social withdrawal, irritability, insomnia, and obliteration of interest in sex. Apparent depression—with apathy, sadness, decreased energy, and anxiety—may indicate that the anorexic individual suffers from comorbid major depressive disorder or may be manifesting symptoms of semistarvation. Therefore, after partial or complete weight gain, the possibility of a comorbid full-blown depression should be reevaluated.

Comorbid features of anorexia nervosa commonly include obsessive–compulsive symptoms, which may or may not warrant an additional diagnosis of obsessive–compulsive disorder. At the very least, most individuals with anorexia nervosa are preoccupied with or obsessed with thoughts of food. According to DSM-IV criteria, the diagnosis of obsessive–compulsive disorder requires a pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency. These obsessive–compulsive symptoms are frequently components of anorexic symptomatology and premorbid obsessive–compulsive perfectionism increases the chances of developing anorexia nervosa.

Exercise in individuals with anorexia nervosa is often excessive and compulsive, directed mainly at losing weight and molding body shape, rather than at maintaining fitness or at improving athletic performance in itself. It is remarkable to see emaciated girls with metabolic disturbances and other physiologic signs of starvation vigorously perform pushups and run in place in their hospital rooms.

Within the family, apparent or subtle focus on food, appearance, or weight, the reinforcement of superficially perfectionistic behavior, avoidance of intense feelings and conflict, chaos, and unpredictability, overinvolvement or enmeshment between family members, and lack of respect for boundaries and privacy (or, conversely, neglect) all incrementally conspire to create the context wherein anorexia nervosa can develop. Restricting food intake is one way that an anorexic can control her environment, construct boundaries, assert her individuality, gain a sense of self-satisfaction and esteem, and become a focus of attention. Importantly, anorexia prevents unwanted sexual maturity. Maternal body dissatisfaction increases the chances that her children will develop an eating disorder. Any type of abuse, whether sexual, physical, or emotional, increases the odds of developing an eating disorder.

COMPLICATIONS, PHYSICAL STIGMATA, AND MORBIDITY

Malnutrition is an essential component of anorexia nervosa and starvation-related adaptations or attempted adaptations, complications, and morbidity are routinely encountered. Mortality is high in the disorder, much higher than in uncomplicated bulimia nervosa, with starvation-related cardiac failure often the terminal event. The suicide rate, too, is high in anorexia nervosa. Available data suggest that gross mortality in anorexia nervosa, from all causes, is between 5 and 15%. The mortality rate for actively anorexic patients is roughly 1% per year—somewhat lower among those patients showing recognition of having an eating disorder and somewhat higher among those patients who deny weight abnormalities and who have required involuntary hospital commitment to prevent starvation.

The adverse effects of chronic cachexia are many and essentially involve cessation of growth and development in combination with an attempt to preserve function and life, in the absence of nutrients or fuel. More specifically, these adaptations to starvation involve slowing of metabolism and slowing of the heartbeat, the shutting down of systems related to sex and reproduction, and the activation of the neurohormonal stress response system (of which the hypothalamic–pituitary–adrenal axis is an important component) in a kind of physiologic fight-or-flight reaction. Thus, on some level, the anorexic's body recognizes and reacts to mortal threat even while she blithely denies being underweight. Shrinkage of the cerebrum (brain) occurs during severe anorexia and this contributes to impairments in thinking, reduced ability to achieve insight, and the worsening of any delusional beliefs about body shape, size, and weight. These aforementioned complications, or adaptations, are reversible upon, or within a few months of, weight renormalization.

Common complications of anorexia that are not necessarily reversible are osteopenia and osteoporosis, which can persist throughout life even after recovery from anorexia. In this regard, the risk of bone fractures is greatly increased in former anorexics, hence, the critical importance of vitamin D and calcium in the treatment of this condition.

The many anorexia-related cardiac abnormalities include arrythmias, bradycardia, with heart rates as low as 30 beats per minute not uncommon, decreased blood pressure, and dehydration. Low blood volume causes posture-related (orthostatic) hypotension (low blood pressure) that, in turn, often results in dizziness and even fainting.

Gastrointestinal adaptations or complications include delayed gastric emptying after eating, decreased intestinal movement, postprandial abdominal pain, and constipation. Acute gastric dilation (stomach enlargment), manifested in nausea, vomiting, and painful abdominal distension, can occur upon refeeding.

Other complications of anorexia nervosa include hair loss, brittle nails, reduced secretory activity of the sebaceous glands with dry yellowish skin, pruritis, and sometimes the growth of soft, downy hair on the torso, limbs, and face (so-called lanugo hair).

Anemia, leukopenia, and hypoglycemia are among the many laboratory abnormalities seen (Table II).

Reduced basal metabolic rate

Refeeding Syndrome

Ironically, it is when the anorexic patient finally begins to ingest adequate nourishment that major anorexia-related complications often ensue. These complications in aggregate are regarded as a "refeeding syndrome" and include hypophosphatemia (wherein phosphorus utilization by tissues increases dramatically and depletes circulating phosphate stores), edema, bloating, constipation, abdominal pain, and, rarely, heart failure due to the inability of the weakened cardiac muscle to cope with sudden increases in body fluid and metabolic demands.

PATHOPHYSIOLOGY AND PSYCHOPATHOLOGY

Anorexia in young women has been observed for centuries and in the 19th century was attributed to hysteria. Hysteria itself has long been associated with repressed sexuality or sexual conflict, albeit less so in modern times. Nevertheless, it is significant that anorexia nervosa typically has its onset during early adolescence, slows or halts development during a normally rapid growth phase, and serves to suppress the development of secondary sexual characteristics at a time when genital sexuality normally begins to emerge.

Patients with the restricting form of anorexia nervosa generally show a personality structure that is more emotionally, cognitively, and behaviorally controlled than do both bulimic patients and healthy persons. Patients with bulimic anorexia, however, are more likely to show impulsivity, depression, and substance abuse.

Reduced metabolic rate is achieved in part through reduced activity of the hypothalamic–pituitary–thyroid system. The hypothalamic–pituitary–gonadal endocrine axis is impaired, with major reductions in the circulating sex hormones testosterone and estradiol. Sexual development ceases in adolescents and sexuality is impaired in adults. Due to impairment of the brain–gonad system, amenorrhea and infertility are present in the overwhelming majority of anorexic females. The hyperactivation of the hypothalamic–pituitary–adrenocortical "stress axis" is manifested by increased urinary free-cortisol secretion and increased brain-derived corticotropin-releasing hormone in the cerebrospinal fluid. Derangements in appetitive sensations are also commonplace.

COURSE AND TREATMENT

Approximately one-third to one-half of individuals with anorexia nervosa recover more or less completely, whereas up to two-thirds of patients continue to have problems including morbid food and body weight preoccupation, amenorrhea, and chronic anorexia. Full recovery often requires years of treatment, but is highly variable and more likely in younger patients, those with the restricting type of anorexia, those with strong support systems (including understanding, supportive families), and those who receive adequate treatment early in the course of illness. The amount and duration of weight loss, the severity of the fear of fatness, and the degree of misperception the patient has of her own body are also major prognostic factors. Severe familial psychopathology and major psychiatric comorbidities are associated with more negative outcomes. Very-low-grade cases of anorexia nervosa, or subclinical anorexia nervosa, have been known to resolve with general support or care but without specialized treatment. The anorexic individual whose maximal weight loss leaves her still close to a minimally acceptable body weight and who acknowledges that she is not fat has, of course, a better prognosis than the chronically skeletal patient who insists, against all evidence to the contrary, that she is fat.

The treatment plan of anorexia nervosa is inextricably tied to the severity of the syndrome. Inpatient hospitalizations are used mainly in dangerous or life-threatening situations to stabilize the patient at an acceptable body weight and to devise the outpatient treatment plan that will ultimately be the vehicle for extended recovery. Severe anorexia nervosa—wherein body weight or body mass index has fallen below 75% of that expected, has fallen very rapidly, or is associated with serious complications or comorbidities—virtually demands inpatient treatment, with supervised, structured, or, if need be, forced refeeding, via a small nasogastric tube, to protect against death. Once an acceptable target weight is reached, most often regarded to be 90% of the expected body mass, and briefly maintained, treatment can be transferred to an outpatient basis. The return of menses (or the resumption of sexual development in the youngest patients) usually occurs if a body mass of at least 90% of expected is sustained.

"Moderate" anorexia nervosa, with body weight 15–25% below what would be expected for height and bone structure, also requires intensive treatment, usually in a structured, inpatient or partial hospitalization setting. Outpatient treatment can be used alone if weight loss can be reversed or stemmed before dangerous cachexia is reached. Mild anorexia nervosa, wherein weight loss is less than 15% of the expected body mass, is by definition subclinical, not because it is not of clinical significance but because it does not satisfy the weight loss criterion necessary to receive a formal diagnosis of anorexia nervosa. Outpatient treatment is usually the treatment of choice here, unless supervening factors, such as a highly unstable mood disorder or severe dehydration and electrolyte abnormalities, exist.

The inpatient treatment of anorexia nervosa is highly structured and best accomplished by an experienced team that ideally includes a psychiatrist, internist, dietician, psychologist and/or social worker, and nurses. Calculation of the precise nutritional requirements necessary to promote slow tissue regrowth and development is necessary to avoid overwhelming the depleted organism and precipitating a refeeding syndrome. Supervised, oral intake of food by the anorexic patient is greatly preferred, with liquid feeding via a thin nasogastric tube used if necessary (parenteral nutrition is practically never indicated)—although some very young patients appear relieved to turn over the responsibility of eating to hospital-provided nasogastric tube feedings. Weight gains of 1 to 3 pounds per week are generally targeted in inpatient refeeding programs, whereas somewhat more modest weight gains are generally accepted in outpatient settings. Calcium (and vitamin D) supplementation is administered to counter decreased bone density and its long-term negative consequences. Mineral and electrolyte levels, among other measures, are closely monitored and corrected

if abnormal. Weight gain often precipitates acute depressive and anxiety symptoms in anorexic patients.

In most cases, anorexic patients will consent to voluntary hospital admission and treatment, but compulsory admissions are sometimes necessary for sicker patients (including those with a history of childhood abuse, self-harm, psychosis, and treatment resistance). If the medical and nursing staff, parents, relatives, and judicial system take the patient's life-threatening illness seriously even when the patient does not seem to, this ultimately appears to have a therapeutic effect on the patient, who ultimately understands the admission as an act of compassion even if it is initially experienced as very distressing. Importantly, that an anorexic patient is admitted for refeeding against her will does not mandate that tube feeding be instituted.

Once weight stabilization occurs, intensive psychotherapy, often for a period of years, becomes a critical therapeutic undertaking. Psychoanalytic psychotherapy or cognitive behavioral therapy (CBT), or a combination of both, is an effective option for treating a patient with anorexia nervosa. CBT focuses on eliminating maladaptive thoughts about body shape and weight and seeks to replace food restriction with normal eating habits. Psychoanalytic psychotherapy—or exploratory, psychodynamic psychotherapy—is valuable because it provides a presuppositionless context for the deep exploration of unconscious needs, desires, and conflicts.

In conjunction with psychotherapy, antidepressant medications (specifically selective serotonin reuptake inhibitors) have been shown to be effective in treating comorbid symptoms, such as depressed mood, low energy, poor concentration, impaired cognition, and obsessive–compulsive symptoms, such as preoccupations with weight and shape. Anxiolytics, mood stabilizers, and other psychotropic drugs are used as needed on a case-by-case basis. Psychopharmacologic interventions are generally less helpful during the acute refeeding phase and more helpful during later stages of recovery and relapse prevention.

SUMMARY

Anorexia nervosa, one of the most common causes of nonaccidental death among young women, is a complex, serious, often long-term condition that may require a variety of treatment modalities (e.g., individual psychotherapy, hospitalization, outpatient treatment, nutritional rehabilitation, family psychotherapy, and pharmacotherapy) that may change throughout the course of illness and recovery. Early intervention is a key in preventing negative sequelae and chronic problems. Variable issues related to self-understanding and self-expression, conflicts regarding sexual maturity, a tendency toward isolation and guardedness, perfectionism, and the pressure of psychosocial and cultural influences that promote an overfocus and overvaluation of thinness, long-term psychotherapy is almost always indicated. Despite substantial progress in the diagnosis and treatment of anorexia nervosa, its cause remains to be determined.

Antacids

CHARLES T. RICHARDSON
Baylor University Medical Center, Dallas

antacid A medication that neutralizes hydrochloric acid in the lumen of the stomach.
pepsin A proteolytic enzyme produced by chief cells in the stomach.

Antacids reduce hydrogen ion concentration (gastric acidity) and increase intragastric pH. This mechanism of action is in contrast to medications that inhibit acid secretion such as histamine 2-receptor antagonists and proton pump inhibitors.

PHARMACOLOGY

Most antacids contain magnesium hydroxide and/or aluminum hydroxide. Some antacids contain calcium carbonate. Sodium bicarbonate in the form of baking soda is used also as an antacid. A few commercial antacids contain sodium bicarbonate. The duration of action of sodium bicarbonate is less than that of many antacids because sodium bicarbonate reacts rapidly with hydrochloric acid and the mixture empties quickly from the stomach.

The duration of action of an antacid is related primarily to the length of time a dose of medication remains in the stomach. In the fasting state, the duration of action is relatively short. Doubling the dose of antacid will lengthen only slightly the time during which gastric acidity is reduced. The duration of action can be prolonged by giving an antacid after food. For example, if a dose of antacid is taken at 1 and 3 h after a meal, the duration of effect is prolonged for up to 4 h.

Chemical equations illustrating the reaction between an aluminum hydroxide [$Al(OH)_3$]-containing antacid or a magnesium hydroxide [$Mg(OH)_2$]-containing antacid are shown as follows:

$$Al(OH)_3 + 3HCl \rightarrow AlCl_3 + 3H_2O$$
$$Mg(OH)_2 + 2HCl \rightarrow MgCl_2 + 2H_2O$$

CLINICAL EFFICACY

The clinical benefit of antacids in treating patients is likely due to their ability to reduce gastric acidity and, perhaps, peptic activity. Pepsin, a proteolytic enzyme produced by chief cells in the stomach, is not active at pH levels above 4.0. Thus, when an antacid reduces gastric acidity and increases intragastric pH, peptic activity also is reduced. This, along with the reduction in gastric acidity, may be beneficial in treating some so-called acid/peptic diseases. There is some evidence that aluminum-containing antacids may also absorb pepsin, which also may reduce the harmful effect of pepsin.

Antacids may be useful in the symptomatic therapy of gastroesophageal reflux disease, nonulcer dyspepsia, and gastric and duodenal ulcer disease. An antacid regimen, when compared with a placebo regimen, given during a 4-week period, has been shown to be effective in healing duodenal ulcers in a statistically significant number of patients. In practice, antacids have been replaced by histamine 2 (H2)-receptor antagonists and proton pump inhibitors in the healing of gastroesophageal reflux disease and gastric or duodenal ulcers. Products combining antacids with H2-receptor antagonists have been developed for over-the-counter use in dyspepsia and heartburn. Pure aluminum hydroxide-containing antacids may be useful in reducing phosphate absorption and serum phosphate levels in patients with renal disease.

SIDE EFFECTS

Diarrhea is the major side effect of antacids containing magnesium hydroxide. Magnesium hydroxide-containing antacids should not be given to patients with reduced renal function as these antacids may lead to magnesium toxicity. High magnesium levels also have been reported in rare patients with normal renal function. Antacids can interact with other medications and may alter the absorption or renal elimination of some medications. Sodium bicarbonate can cause metabolic alkalosis and contribute to renal stone formation.

antibiotic-associated diarrhea Any case of diarrhea associated with the use of antibiotics.

DNA fingerprinting A laboratory method elaborating a battery of molecular biology techniques in order to generate a pattern of DNA restriction fragments that is unique to an individual or a microbe. In the latter case, one of the aims is microbial source tracking. The method has been used to compare the identity of *Clostridium difficile* strains isolated from both the environment and infected patients.

pseudomembranes Adherent inflammatory exudates overlying sites of colonic mucosal injury; they are characteristic lesions of *Clostridium difficile* colitis overlying sites with dense polymorphonuclear infiltration of the colonic lamina propria. In cases where glandular disruption accompanies the polymorphonuclear cell infiltrate, the histologic picture may resemble a volcanic eruption (volcano lesion), characteristic of pseudomembranous colitis.

pseudomembranous colitis Acute colitis associated primarily with *Clostridium difficile* infection.

toxins A and B High-molecular-weight protein exotoxins released from toxigenic strains of *Clostridium difficile*. The genes for toxins A and B have been cloned and found to be separated by only 1.2 kb on the *C. difficile* chromosome. Both toxins have cytotoxic properties and cause cytoskeletal disorganization and cell rounding in human colonocytes. Toxin A, but not toxin B, is an enterotoxin in animal intestine and causes inflammatory diarrhea in intestinal loops of experimental animals.

Diarrhea associated with antibiotic intake is a common clinical entity with an estimated incidence of 5–25%, depending on the antibiotic used. It is generally accepted that antibiotics cause alterations in the intestinal microecology, which subsequently lead to the diarrheal syndrome. In approximately 20% of cases, it is well established that antibiotic-mediated alterations in intestinal microflora allow *Clostridium difficile*, a toxigenic bacterium, to colonize the intestine and develop a diarrheal infection. *C. difficile* is considered the most commonly identifiable cause of antibiotic-associated diarrhea and represents the offending factor in almost all cases of antibiotic-associated colitis. Thus, *C. difficile* has been studied extensively by both basic and clinical research groups. However, several other causes have been implicated in the pathogenesis of this clinical entity and these are also discussed in this article.

calmodulin An intracellular high-affinity calcium-binding polypeptide forming a calcium/calmodulin complex that regulates ion transport through the modification of cellular regulatory proteins.

enteric nervous system Largely autonomous nervous system, which regulates intestinal function. The cell bodies of enteric neurons lie in plexi within the intestine.

enterochromaffin cell Specialized intestinal epithelial cell that detects lumenal stimuli and activates signaling cascades through the release of mediators such as 5-hydroxytryptamine.

enterocytes Specialized epithelial ion-transporting cells, which collectively form a continuous monolayer lining the intestinal lumen. Tight junctions separate enterocytes, hence creating a selective barrier to electrolytes and nutrients.

secretagogue Substance that induces intestinal secretion.

To those who suffer from diarrhea, the descriptions "too fluid" and "too frequent" stool must seem self-evident. However, the precise definition of this condition requires that the daily stool output exceed 200 g for adults in the developed world. Anti-diarrheal drugs are intended to ameliorate this pathology.

INTRODUCTION

Diarrhea may be acute and a consequence of viral or bacterial infection or it may be chronic and a symptom of an underlying, ongoing disorder, such as malabsorption or inflammatory bowel disease. Diarrhea may also be present where there is a bowel tumor, diabetic autonomic neuropathy, hyperthyroidism, or a number of other conditions. It can also be drug-induced, such as in laxative abuse.

Such variable pathophysiologies will necessitate different therapeutic approaches, often directed at correcting the underlying primary cause rather than the resulting symptom of diarrhea. Pharmacotherapy for diarrhea per se is in the main restricted to irritable bowel syndrome, where the predominant symptom is diarrhea, and in the mild acute infective condition typified by traveler's diarrhea.

The mainstay of anti-diarrheal drug therapy, even after centuries of use, remains the opiate group of drugs. Surprisingly, despite the devastating effects of this condition in the underdeveloped world, there is still no effective, safe, anti-secretory drug for the treatment of acute secretory diarrhea.

PATHOPHYSIOLOGY

Normally, approximately 8–10 liters of fluid enters the lumen of the small intestine daily both from ingestion and from endogenous salivary, gastrointestinal, and pancreatic secretions. Net absorption occurs in the small intestine, driven by osmotic gradients that result from the transport of electrolytes (mainly Na^+ and Cl^-), sugars, and amino acids across the epithelial monolayer lining the length of the small intestinal lumen. Approximately 1 to 1.5 liters of fluid enters the colon and from there approximately 100 ml will be excreted in the feces. Both the small intestine and large intestine have spare absorptive capacity and can absorb a maximum of 16 and 5 liters, respectively. As stool consists mainly of water, especially in diarrhea, most cases of diarrhea can be ascribed to disorders of intestinal electrolyte and water transport. From a mechanistic viewpoint, diarrhea may have several causes.

Secretory Diarrhea

Secretory diarrhea results from excessive secretion or diminished absorption, or both, of electrolytes (mainly Na^+ and Cl^-) and water by epithelial cells of the intestinal mucosa. Maturing cells in the crypts of Lieberkuhn of the small intestine normally secrete electrolytes and water into the lumen. This process, stimulated by gastrointestinal hormones and neurotransmitters released after a meal, is essential for maintaining the liquidity of small intestinal contents, thereby allowing efficient digestion and absorption of nutrients. Mature epithelial cells on the intestinal villi are responsible for absorption of electrolytes, water, and nutrients. Secretory diarrhea can be produced by microbial

infection, gastrointestinal hormone-producing tumors, bile salt malabsorption, and inflammatory mediators, such as prostaglandins and leukotrienes.

Osmotic Diarrhea

Osmotic diarrhea occurs when an increased lumenal osmotic load results in retention of fluid in the intestinal lumen. Both electrolytes and nutrients, such as sugars and amino acids, can contribute to osmosis. If their absorption is reduced, then osmotic diarrhea can occur. Causes include celiac disease, laxative use, and lactase deficiency.

Increased Propulsive Motility

Increased propulsive motility may result in diarrhea as the extent of absorption can be diminished by a decreased transit time of intestinal contents. This may occur in hyperthyroidism and also in irritable bowel syndrome.

ORAL REHYDRATION THERAPY

In acute infectious diarrhea, rehydration is the first priority of treatment. This is particularly important in infants, the frail, and the elderly, where the risks of dehydration and electrolyte or pH imbalance are greatest. Promptly administered oral rehydration therapy (ORT) saves many lives and is the only therapy needed for the diarrhea of viral gastroenteritis in the young. Recourse to intravenous electrolyte and fluid replacement may be required in severe cases. ORT will not immediately reduce the volume of diarrhea, but absorption of the glucose electrolyte solution leads to the correction of fluid and electrolyte imbalances. ORT utilizes the ability of small intestinal epithelial cells to absorb sodium and glucose even in secretory states. This cotransport mechanism sets up an osmotic gradient across the intestinal mucosa, resulting in the transport of water from the intestinal lumen to the bloodstream. There are a number of approved formulations for ORT. Most have, as their basis, NaCl, KCl, sodium citrate, and glucose.

ANTI-MOTILITY, ANTI-SECRETORY AGENTS

Opioids and Enkephalinase Inhibitors

Opioids are compounds that are chemically related to opium, which is obtained from the juice of the opium poppy. Opiate drugs include those derived from opium, such as morphine and codeine, as well as synthetic compounds, such as loperamide and diphenoxylate. The realization that these chemicals were reacting with receptors in the body led to the discovery of endogenous opioid peptides, Met- and Leu-enkephalin, which are the naturally occurring ligands for opioid receptors. Opioid receptors are divided into three main groups, designated mu (μ), delta (δ) and kappa (κ). Morphine acts primarily on μ receptors, whereas the enkephalins act on μ and δ receptors. Historically, morphine was the first drug widely used for the treatment of diarrhea and today opiates still remain the most useful class of anti-diarrheal drug. Opiates slow intestinal transit, thereby allowing increased time for the absorption of lumenal contents. Their action is complex, involving increased tone (muscle contraction) and rhythmic contraction of intestinal smooth muscle but diminished propulsive activity. The pyloric, ileocecal, and internal anal sphincters are all contracted. The overall effect in healthy individuals is to produce an increase in "nonpropulsive" motility, resulting in constipation. The main opiates used for diarrhea are loperamide and diphenoxylate. Unlike morphine, very little of these drugs crosses the blood–brain barrier and they are given exclusively for their actions on the gastrointestinal tract. In addition to its anti-motility effects, loperamide acts as an anti-secretory agent through the inhibition of calmodulin (see below). Extensive studies on the action of morphine reveal that it can act centrally where stimulation of μ receptors in the central nervous system results in the slowing of transit throughout the intestine. Within the intestinal wall, opioid receptors have been found on enteric nerves, epithelial cells, and smooth muscle cells. Although most cases of diarrhea result from reduced absorption or increased secretion, or both, by the intestine, there is still much debate as to whether anti-secretory actions or slowing of intestinal transit is the primary mechanism underlying the anti-diarrheal actions of opiate drugs. Certainly there appear to be differences in the pharmacological profiles of morphine compared to the enkephalins and loperamide. The peptides act on δ receptors and may thus produce anti-secretory effects and a similar action would result from the inhibition of calmodulin by loperamide (see below).

Although slowing intestinal transit relieves the symptoms of diarrhea, there is a risk that this may prolong the contact time of infectious agents with the intestinal mucosa. Such concerns turned out to be largely unfounded, but stimulated a search for compounds with a more favorable therapeutic profile. Despite their anti-secretory effects, enkephalins were unsuitable due to a short duration of action. However, inhibitors of

enkephalinase, the enzyme that metabolizes enkephalins, are a novel class of drugs with marked anti-secretory actions. Racecadotril (acetorphan) is a selective inhibitor of enkephalinase and reduces stool volume and disease duration in infectious diarrhea without the side effect of constipation.

α-Adrenergic Receptor Agonists

Noradrenergic neurons with projections to the gastrointestinal tract influence motility, mucosal transport, and blood flow. Reduction of gastrointestinal motility occurs as a result of presynaptic inhibition of acetylcholine release from cholinergic neurons. Some sphincters are also contracted by a direct action on the sphincteric smooth muscle. Noradrenergic neurons also stimulate absorption and inhibit electrolyte and water secretion by an indirect inhibitory action on cell bodies of submucosal secretomotor neurons and also by a direct action on enterocytes. All these actions are mediated through α2-adrenergic receptor stimulation. Neural α2 receptors are located presynaptically on nerve terminals and inhibit the release of neurotransmitters. Not surprisingly, α2 agonists, such as clonidine, have proved effective anti-diarrheal agents in some circumstances, such as diabetic neuropathy where there was a loss of noradrenergic innervation. A disadvantage of clonidine is that it readily crosses the blood–brain barrier, causing hypotension.

Somatostatin Analogues

Immunohistochemical and radioimmunoassay techniques have demonstrated the presence of a number of peptides in enteric nerves where they presumably function as neurotransmitters. Many of these neurons either directly innervate the gastrointestinal mucosa or terminate around neural cell bodies in the submucosal plexus, thus indicating a role in the control of electrolyte and water transport. Somatostatin, a 14-amino-acid peptide, serves a number of physiological functions in the gastrointestinal tract, including inhibition of exocrine, gastric, and pancreatic secretions, inhibition of secretion of several gastrointestinal hormones, decrease of gastrointestinal motility, and inhibition of chloride secretion by epithelial cells. The usefulness of somatostatin as an anti-diarrheal agent is limited by a short half-life, necessitating administration by intravenous infusion. Newer agents such as octreotide, a synthetic analogue of somatostatin, have a longer duration of action and increased potency, providing greater therapeutic potential. Octreotide has been used successfully in cases of diarrhea due to peptide-secreting tumors such as 5-hyroxytryptamine (5-HT)-secreting carcinoid tumors or vasoactive intestinal peptide (VIP)-secreting VIPomas. Octreotide has also been used in dumping syndrome, where rapid emptying of gastric contents, usually seen postoperatively, results in excessive release of enteric peptides into the general circulation. The beneficial effects of octreotide probably result more from its actions on decreasing gut motility and release of gastrointestinal peptides than from a direct pro-absorptive or anti-secretory action.

Cholestyramine

After surgical resection of the terminal ileum, the normal enterohepatic circulation of bile salts is interrupted. Loss of bile salt absorption results in elevated lumenal concentrations in the colon, where they stimulate electrolyte and water secretion. Cholestyramine is an anion exchanger that is not absorbed and effectively binds and neutralizes bile salts.

Bismuth

Bismuth has anti-microbial properties, which probably account for the majority of its anti-diarrheal actions. Bismuth subsalicylate has been used successfully for the treatment of traveler's diarrhea.

5-Hydroxytryptamine Receptor Antagonists

Intestinal secretion induced by 5-HT is complex. It may be released from neurons and enterochromaffin cells and can act on enteric nerves, smooth muscle, and epithelial cells to produce its effects. 5-Hydroxytryptamine type 3 (5-HT_3) receptors are located on sensory neurons and 5-HT_3 antagonists have been used in the treatment of chemotherapy-induced vomiting as well as diarrhea associated with irritable bowel syndrome. 5-HT_3 antagonists do not prevent all the intestinal secretory effects of 5-HT. 5-HT is also implicated in the pathogenesis of cholera toxin-induced diarrhea. Cholera toxin releases 5-HT from enterochromaffin cells; 5-HT then activates the sensory neurons of a neurosecretory reflex.

Berberine

Berberine is a plant alkaloid that may have anti-microbial as well as anti-secretory and anti-motility effects. In China and India, it has been used as an anti-diarrheal agent for centuries. In humans, it has

been shown to be effective against enterotoxigenic *Escherichia coli*-induced diarrhea.

Calmodulin Inhibitors

Some secretagogues such as acetylcholine and 5-HT act by increasing intracellular calcium. Calcium combines with calmodulin, a calcium-binding protein, and the complex increases adenylate and guanylate cyclase activity, resulting in elevated concentrations of cyclic AMP and cyclic GMP. These nucleotides are fundamental intracellular messengers in electrolyte and water transport, causing enhanced chloride secretion and diminished sodium chloride absorption. A positive correlation between calmodulin binding and anti-diarrheal activity has been demonstrated for loperamide, chlorpromazine, and a number of other compounds. Zaldaride maleate, a selective and potent inhibitor of intestinal calmodulin, demonstrated a reduction of stool frequency and duration in traveler's diarrhea.

FUTURE DIRECTIONS

Potassium Channel Inhibition

The opening of chloride channels in the apical membrane plays a central role in the promotion of intestinal secretion and is the final common pathway of agents that cause acute secretory diarrhea (Fig. 1). Chloride secretion is an electrogenic process and the intestinal lumen becomes more negative, causing paracellular flow of sodium ions and a concomitant osmotic flow of water. It is possible to reduce chloride secretion by reducing the intracellular negative potential of the epithelial cell as this cellular hyperpolarization normally drives chloride ions through apical chloride channels into the intestinal lumen. Hyperpolarization is produced by the exit of potassium ions from the cell through basolaterally located (in the small intestine) potassium channels. It follows, therefore, that drugs blocking or inhibiting such channels have anti-secretory potential. In the human colon, patch-clamp single-channel recording and the use of agents that block potassium channels have demonstrated more than one type of potassium channel. More recent investigations have revealed that the established anti-secretory agents berberine, clonidine, and loperamide possess potassium channel-blocking effects. Finally, secretory responses of human ileal mucosa to VIP and *E. coli* heat-stable enterotoxin can be inhibited by potassium channel blockade. With the multiplicity of potassium channels in existence, it is possible that those on basolateral membranes of intestinal epithelial cells may have individual characteristics that can be exploited for the development of selective anti-diarrheal agents.

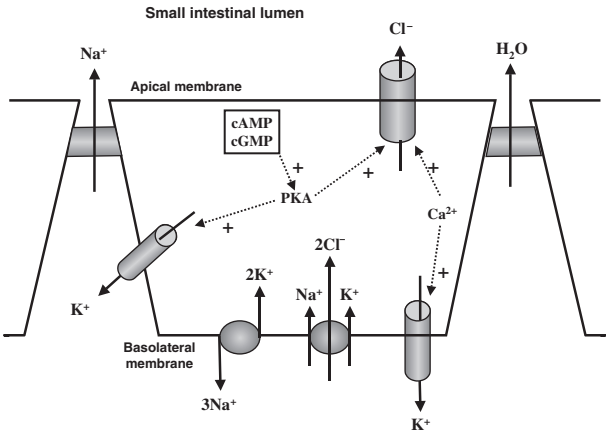

FIGURE 1 Chloride ion secretion and its regulation. The effects of cyclic AMP (cAMP) and cyclic GMP (cGMP) are mediated through the actions of protein kinase A (PKA). This enzyme phosphorylates intestinal membrane proteins of ion channels, leading to increased apical conductance of chloride ions and basolateral conductance of potassium ions. The basolateral exit of potassium ions hyperpolarizes the cell, providing an electrical driving force for the exit of chloride ions. Not shown are receptors for secretagogues located on both the apical and basolateral membranes. Cholera toxin and *Escherichia coli* heat-stable toxin act apically to elevate cAMP and cGMP, respectively. Acetylcholine and vasoactive intestinal polypeptide act basolaterally to elevate calcium and cAMP, respectively.

Vasoactive Intestinal Polypeptide Receptor Antagonists

The demonstration of VIP receptors on basolateral membranes of epithelial cells and the presence of VIP within enteric neurons innervating mucosal epithelial cells and blood vessels indicate a physiological role for this peptide in the control of mucosal ion transport. There are two main types of secretomotor neuron: cholinergic and noncholinergic. The noncholinergic neurons appear to mediate most of the local reflex responses and utilize VIP as their neurotransmitter.

VIP causes an increase in intestinal secretion in humans, both in normal volunteers and in those individuals with VIPomas. It is thought that the enteric nervous system is responsible for a significant proportion of the change in fluid transport induced by cholera toxin (Fig. 2) and antagonism of VIP receptors has been shown to reduce intestinal secretion produced by the toxin *in vivo*.

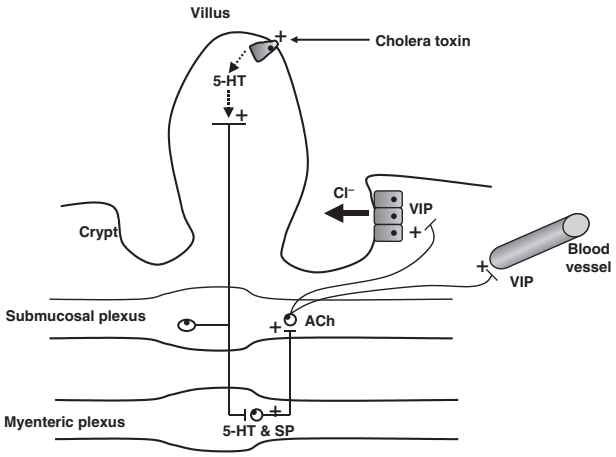

FIGURE 2 Putative neurosecretory reflex of cholera toxin. Cholera toxin stimulates 5-hydroxytryptamine (5-HT) release from enterochromaffin cells. 5-HT activates sensory neurons that synapse with cholinergic interneurons in the myenteric plexus. Secretomotor neurons that project to both epithelial cells and mucosal blood vessels are stimulated by acetylcholine (ACh) to release vasoactive intestinal polypeptide (VIP). VIP causes intestinal secretion and vasodilation of mucosal blood vessels.

antibiotic-associated diarrhea Any case of diarrhea associated with the use of antibiotics.

DNA fingerprinting A laboratory method elaborating a battery of molecular biology techniques in order to generate a pattern of DNA restriction fragments that is unique to an individual or a microbe. In the latter case, one of the aims is microbial source tracking. The method has been used to compare the identity of *Clostridium difficile* strains isolated from both the environment and infected patients.

pseudomembranes Adherent inflammatory exudates overlying sites of colonic mucosal injury; they are characteristic lesions of *Clostridium difficile* colitis overlying sites with dense polymorphonuclear infiltration of the colonic lamina propria. In cases where glandular disruption accompanies the polymorphonuclear cell infiltrate, the histologic picture may resemble a volcanic eruption (volcano lesion), characteristic of pseudomembranous colitis.

pseudomembranous colitis Acute colitis associated primarily with *Clostridium difficile* infection.

toxins A and B High-molecular-weight protein exotoxins released from toxigenic strains of *Clostridium difficile*. The genes for toxins A and B have been cloned and found to be separated by only 1.2 kb on the *C. difficile* chromosome. Both toxins have cytotoxic properties and cause cytoskeletal disorganization and cell rounding in human colonocytes. Toxin A, but not toxin B, is an enterotoxin in animal intestine and causes inflammatory diarrhea in intestinal loops of experimental animals.

Diarrhea associated with antibiotic intake is a common clinical entity with an estimated incidence of 5–25%, depending on the antibiotic used. It is generally accepted that antibiotics cause alterations in the intestinal microecology, which subsequently lead to the diarrheal syndrome. In approximately 20% of cases, it is well established that antibiotic-mediated alterations in intestinal microflora allow *Clostridium difficile*, a toxigenic bacterium, to colonize the intestine and develop a diarrheal infection. *C. difficile* is considered the most commonly identifiable cause of antibiotic-associated diarrhea and represents the offending factor in almost all cases of antibiotic-associated colitis. Thus, *C. difficile* has been studied extensively by both basic and clinical research groups. However, several other causes have been implicated in the pathogenesis of this clinical entity and these are also discussed in this article.

SYMPTOMATOLOGY AND CLINICAL EVALUATION

The clinical evaluation of a patient with suspected antibiotic-associated diarrhea (AAD) involves a detailed

 Copyright 2004, Elsevier (USA). All rights reserved.

history to identify other etiologies of diarrhea, as well as careful review of the concomitant medications and nutritional supplements. A long list of drugs such as antacids, anti-arrhythmics, anti-neoplastics, antihypertensives, cholinergics, laxatives, caffeine, and magnesium and potassium supplements can cause diarrhea that usually starts shortly after initiation of therapy, but can also occur following chronic drug treatment or after an increase in the dose of the drug. Antibiotics such as clindamycin, lincomycin, ampicillin, and cephalosporines are more likely to cause AAD, whereas aminoglycosides, erythromycin, and trimethoprim-sulfamethoxazole are considered safer. However, the clinician should be aware that virtually all antimicrobial agents, including antifungals and antivirals, can cause AAD, irrespective of the route of administration. In addition, several case reports implicate even metronidazole and vancomycin, the antibiotics most commonly used to treat *Clostridium difficile* infection, in the development of *C. difficile*-induced AAD.

AAD causes mild symptoms and it is clinically significant when there are more than three mushy or watery stools per day. However, when *C. difficile* is the underlying causative agent, the clinical presentation may vary from mild diarrhea to a severe bloody diarrheal syndrome accompanied by abdominal pain and systemic complications such as dehydration, fever, leukocytosis, and hypoalbuminemia.

Sigmoidoscopic examination is not always warranted in AAD, but, if performed, reveals either normal mucosa or mild edema or hyperemia. In cases of suspected *C. difficile* infection, endoscopy is not always necessary since the presence of *C. difficile* toxins in the stool establishes the diagnosis. However, in highly suspicious cases, and when toxin assays are negative, endoscopy is indicated. In these cases, colonoscopy should be performed instead of sigmoidoscopy, because *C. difficile*-induced mucosal lesions may occasionally spare the rectum and sigmoid colon.

Development of pseudomembranes, identified as raised yellow small plaques on the colorectal mucosa, is the characteristic endoscopic finding in *C. difficile* colitis and a sign of severe infection. In milder cases, nonspecific, diffuse, or patchy erythematous colitis without pseudomembranes may be observed.

Endoscopy should be either avoided in patients with suspected fulminant *C. difficile* colitis or cautiously performed with minimal air inflation to avoid bowel perforation. In such cases, clinical signs such as high fever, diffuse abdominal pain, involuntary guarding, or rebound tenderness together with radiologic findings should guide management decisions. Computed tomography findings in severe cases include thickening of the bowel wall in affected sites, signs of intestinal obstruction in cases of ileus, or intraperitoneal fluid when perforation has occurred. Dilated colon (>7 cm in its greatest diameter) in plain abdominal images can safely diagnose toxic megacolon.

PATHOPHYSIOLOGY OF AAD

Microbes Other Than *C. difficile* as Causative Agents of Antibiotic-Associated Diarrhea

Overall, it is generally accepted that 2–3% of AAD cases may be due to infections other than *C. difficile*. Several reports implicate the overgrowth of specific microorganisms following antibiotic therapy as the cause of AAD. *Staphylococcus aureus* was reported to be the cause of AAD in the 1950s and 1960s. However, it is now believed that the vast majority of these cases were actually caused by *C. difficile* infection, which had not been connected to the etiology of AAD at that time. *Clostridium perfringens* enterotoxin and high counts of enterotoxigenic strains of *C. perfringens* have been found in the stools of patients with diarrhea that developed after antibiotic treatment. It must be pointed out, however, that although *C. perfringens* spores can be found in the hospital environment, nosocomial *C. perfringens* infections can occur without prior use of antibiotics, thus calling into question the association of the microorganism with AAD.

Klebsiella oxytoca has been also implicated as the causative agent of acute segmental hemorrhagic penicillin-associated colitis. This is a rare complication of penicillin treatment, characterized by acute hemorrhagic diarrhea and painful abdominal cramps. The disease is thought to result from infection by cytotoxin-producing *K. oxytoca* strains.

A single study found that multidrug-resistant *Salmonella newport* was the cause of AAD in 12 patients who had consumed contaminated beef from animals fed subtherapeutic doses of antimicrobials. Although this is the only report, the findings are well documented and *Salmonella* may be considered a rare causative agent of AAD.

Overgrowth of *Candida* species (*Candida albicans* and *Candida tropicalis*) as a result of antibiotic treatment has also been associated with the development of AAD in pediatric and adult patients. Animal studies have shown that the yeast is able to depress lactase activity, potentially leading to lactose intolerance and malabsorption and, through release of endotoxin-like substances, to lumenal secretion of ions into the jejunum. Irrespective of the underlying mechanism(s),

Candida species should be considered a putative cause of AAD, especially in immunosuppressed patients.

Mechanisms Related to Direct or Indirect Effects of Antibiotics on Intestinal Functions

Antibiotics may exert various effects on the gastrointestinal tract, independent of their antimicrobial activity. Erythromycin, for instance, is a motilin-receptor agonist and can accelerate the rate of gastric emptying, which has been reported to cause functional diarrhea. Amoxicillin/clavulanate, another commonly prescribed antibiotic combination, mediates nonspecific motility disturbances in the gastrointestinal tract, leading to diarrhea. Moreover, neomycin, an aminoglycoside antibiotic frequently used as an adjunct in the treatment of hepatic encephalopathy, induces morphologic alterations of the intestinal mucosa, leading to malabsorption and diarrhea. In addition to these "direct" effects on intestinal motility or absorptive capacity, antibiotics cause alterations in the bacterial population of the colon, mainly by decreasing the number of anaerobes such as *Bacteroides* species. Anaerobic bacteria metabolize carbohydrates that escape absorption, reach the colon, and produce short-chain fatty acids such as acetate and butyrate. Short-chain fatty acids are subsequently absorbed by the colonic epithelium together with fluids and electrolytes. Antibiotics reduce the number of colonic anaerobes, thereby decreasing the fermentation of nonabsorbable carbohydrates, which eventually accumulate in the colonic lumen and may lead to osmotic diarrhea. Although this mechanism may explain some published observations, other studies found discrepancies between suppression of carbohydrate metabolism and manifestations of diarrhea. Therefore, it seems likely that other mechanisms, such as an adaptive increase in colonic transit time that has been described in cases of osmotic diarrhea, may operate to compensate for the increased osmotic load in the colonic lumen.

Another metabolic function of colonic anaerobes is the dehydroxylation of unabsorbed bile acids. It is well known that hydroxylated bile acids, especially the dihydroxy bile acids, chenodeoxycholic acid and deoxycholic acid, exert a cathartic effect on colonic mucosa. Thus, defective bile acid dehydroxylation, due to suppression of bacterial populations after antibiotic therapy, might represent a mechanism that contributes to AAD.

CLOSTRIDIUM DIFFICILE INFECTION

C. difficile is a gram-positive anaerobic bacterium and the most commonly identified causative agent of AAD. *C. difficile* infection represents one of the commonest nosocomial infections around the world and is responsible for approximately three million cases of diarrhea and colitis per year in the United States. The bacterium is primarily acquired in hospitals and chronic care facilities following broad-spectrum antibiotic therapy. It has been estimated that 20% of patients admitted to a general hospital either are colonized on admission or acquire the microorganism during their hospital stay, but only one-third of them develop AAD. Although it is not clear why only a fraction of the colonized patients develop AAD, risk factors associated with disease expression include advanced age, severity of the patient's clinical condition, and most likely defective immunity against *C. difficile* toxins.

Contamination of the hospital environment appears to be the main reservoir of *C. difficile* and is considered to be responsible for perpetuating human infections. This notion is reinforced by recent prospective epidemiological studies reporting the same *C. difficile* strains in both symptomatic patients and ward environments, after molecular characterization of the isolates by DNA fingerprinting. Moreover, molecular characterization revealed that some *C. difficile* strains have a greater propensity for nosocomial transmission (epidemic clones).

C. difficile exerts its effects in the human intestine by the release of two large toxins, toxins A and B. *C. difficile* toxins bind to and damage colonocytes by disrupting the cellular cytoskeleton and increase intestinal permeability by altering tight junctional integrity. The toxins also lead to a severe inflammatory reaction, which, in concert with colonocyte damage, results in micro-ulcerations and the volcano lesion seen in pseudomembranous colitis patients. These micro-ulcerations are usually covered by inflammatory pseudomembranes, containing cellular debris, leukocytes, fibrin, and mucin. A large number of animal studies also indicate that intestinal nerves, by release of neuropeptides, are important mediators of both diarrhea and inflammation in response to *C. difficile* toxins *in vivo*.

Several studies have shown that the majority of healthy adults and children have serum and mucosal antibodies directed against *C. difficile* toxins that may play a protective role in *C. difficile* disease expression. Animal studies showed that immunization against toxin A protects against *C. difficile* infection. It is therefore believed that humoral immunity is important in the development of *C. difficile* infection. A recent prospective study examined whether the presence of serum antitoxin antibodies is associated with the development of *C. difficile* infection in hospitalized patients. The results indicated that antibodies against *C. difficile* toxins or nontoxin antigens did not affect the development of colonization. In contrast, patients who were

colonized and had low serum immunoglobulin G (IgG) antibodies to toxin A were more likely to develop diarrhea. Another prospective study showed that low serum IgG antitoxin A antibodies after an initial episode of diarrhea predispose to recurrent *C. difficile* infection. These studies suggest that antibodies play a significant role in disease development and that vaccination or passive immunotherapy may be an effective strategy to control *C. difficile*-associated diarrhea and colitis.

DIAGNOSIS OF ANTIBIOTIC-ASSOCIATED DIARRHEA

The challenge for a clinician facing a patient with suspected ADD is to document whether this particular case is caused by *C. difficile* infection, a potentially serious but also manageable condition. Laboratory diagnosis of *C. difficile* is based on the demonstration of *C. difficile* toxins in stool. The commonest methods used for diagnosis are summarized in Table I. The most accurate diagnostic assay is the tissue culture assay for the detection of *C. difficile* cytotoxin (toxin B) in stool samples. In brief, phosphate-buffered saline stool suspensions are applied to monolayers of human fibroblasts after centrifugation and filtration. A positive test is indicated by cell rounding, which can be easily seen by light microscopy after 24 or 48 h. Results are reported as positive or negative since there is no clinical correlation between levels of *C. difficile* toxins and severity of disease. Moreover, a recent study suggests that the yield of toxin detection increases by 15% if *C. difficile* is isolated and cultured from stool samples before the cytotoxicity assay ("second-look" cytotoxicity assay). Although tissue culture assays are highly sensitive and specific tests, they are time-consuming and therefore rapid immunoassays have been developed with the goal of replacing them.

The latex agglutination test is not sufficiently sensitive or specific to justify routine use. On the other hand, enzyme-linked immunosorbent assays (ELISAs) that detect toxins A and B in stool samples represent quick and reliable methods. They have high specificity and although they are not as sensitive as the tissue culture assay, their sensitivity improves if more than one stool sample is tested. ELISA is now the method most frequently used by clinical laboratories for diagnosis of *C. difficile* infection, because it is quick, is easy to perform, is acceptably accurate, and does not require highly trained personnel or tissue culture facilities. Specific tests to target the other causes of AAD reported above are not readily available in clinical laboratories. However, in suspicious cases, a quantitative test for *Candida* in stool should be performed.

THERAPY OF ANTIBIOTIC-ASSOCIATED DIARRHEA

In cases of non-*C. difficile* AAD, discontinuation of the inciting antibiotics with or without administration of anti-peristaltic agents is usually sufficient. If continuation of antibiotic therapy is necessary, switching to antibiotics thought to have less risk of causing AAD, such as fluoroquinolones, macrolides, and tetracycline, together with the administration of a probiotic agent, such as *Saccharomyces boulardii* or *Lactobacillus* species, is a therapeutic option. Probiotics have been shown to reduce the risk of AAD, although their mechanism of action is not completely understood. If *Candida* is documented as the causative agent for the AAD, nystatin (250,000 or 1,000,000 U orally three to four times daily) should be given for 7 days.

In approximately 25% of patients with *C. difficile*-associated AAD, symptoms resolve after antibiotic discontinuation, corresponding to reconstitution of

TABLE I Diagnostic Tests for *Clostridium difficile*

Type of assay	Advantages	Disadvantages
Anaerobic culture	Identify carriers in *C. difficile* outbreaks	3–5 days; expensive; also detects nontoxigenic strains
Cytotoxicity assay for toxin B	Excellent sensitivity and specificity	1–3 days; expensive; requires tissue culture facilities
"Second-look" cytotoxicity assay	Excellent sensitivity and specificity	At least 3 days; expensive; requires tissue culture facilities
Enzyme immunoassays for toxins A and B	Very good sensitivity and specificity; takes 4 h; does not require special facilities; less expensive	Less sensitive than cytotoxicity assays

normal bowel flora. Therefore, specific therapy should be given when conservative therapy fails, when the administration of the offending antibiotic must continue, or when symptoms are severe.

No therapy is required for asymptomatic carriers. Per oral metronidazole (250–500 mg four times daily) and vancomycin (125 mg four times daily), for 10–14 days, are equally effective in *C. difficile* AAD, with response rates ranging between 95 and 100%. Metronidazole is usually the first-line treatment due to its lower cost. Moreover, metronidazole, in contrast to vancomycin, is effective when there is a need for intravenous administration, as in patients with ileus and *C. difficile* infection. The use of oral vancomycin recently has been restricted because of the growing rates of resistance among gut enterococci; metronidazole has side effects including nausea, abdominal pain, and an unpleasant metallic taste.

Despite the excellent initial response to specific treatment, 20–25% of patients will relapse, usually 3 to 21 days after discontinuation of metronidazole or vancomycin. This is a serious and difficult to manage complication of *C. difficile* AAD. Prolonged treatment with the same antibiotic is usually what is attempted initially. Unfortunately, a substantial fraction of patients relapse again. In cases of multiple relapses, several therapeutic schemes have been developed and exhibit varying degrees of success, underscoring the difficulty of treating this condition. Many experts suggest prolonged administration of vancomycin followed by gradual tapering; others advocate the coadministration of probiotics, such as *S. boulardii*, in an attempt to help in the reconstitution of normal colonic microflora. Intravenous immunoglobulin has also been given, based on putative defective antitoxin immunity in these subjects, with promising results. However, this approach is expensive and requires hospitalization. In severe cases that are resistant to aggressive medical treatment or when bowel perforation is suspected, subtotal or total colectomy with temporary ileostomy may be required.

As indicated above, therapy of AAD is simple and effective in the majority of patients. However, some cases may prove very difficult to treat and represent therapeutic dilemmas. It is anticipated that future research will provide more rational therapeutic alternatives, by means of preventive or therapeutic immunization against *C. difficile* infection.

chylomicrons Triglyceride-rich lipoprotein particles produced by the small intestine after a meal; larger in size than very-low-density lipoproteins, chylomicrons transport absorbed cholesterol and triglycerides to different parts of the body.

high-density lipoproteins Class of serum lipoproteins; like other lipoproteins, their core consists of neutral lipid surrounded by an envelope of polar lipid and specific proteins called apoproteins. High-density lipoproteins protect against atherosclerosis through a process known as reverse cholesterol transport, the pathway responsible for transporting excess cholesterol from the peripheral tissues back to the liver for excretion.

lecithin cholesterol acyltransferase Enzyme involved in the esterification of free cholesterol present in circulating plasma lipoproteins; a major determinant of the circulating level of high-density lipoproteins (for instance, overexpression of this enzyme in animals significantly increases the circulating plasma high-density lipoprotein levels).

peroxisome proliferator-activated receptors Regulators of differentiation and homeostasis; the γ form has been found to function as a regulator of adipogenesis and lipid homeostasis.

Pluronic L-81 Member of a family of nonionic detergent surfactants that contains block copolymers of propylene oxide and ethylene oxide. Duodenal infusion of Pluronic L-81 inhibits the formation of chylomicrons by the small intestine.

very-low-density lipoproteins Triglyceride-rich lipoproteins produced by the gut and liver. The gut produces apolipoprotein B48 and the liver produces apolipoprotein B100, both of which contain very-low-density lipoproteins.

The small intestine synthesizes several of the apoproteins associated with chylomicrons, very-low-density lipoproteins (VLDLs), and high-density lipoproteins (HDLs), which are all secreted by the small intestinal epithelial cells (enterocytes). Chylomicrons are secreted only during active lipid absorption, whereas VLDLs and HDLs are secreted all of the time. The major apoproteins synthesized by enterocytes are apolipoprotein (apo) AI, apo AIV, apo B48, and apo CIII. Regulation of the production of these apoproteins by the gut is specific to each apoprotein. For instance, it has been demonstrated that the synthesis and secretion of apo AIV are markedly stimulated during lipid absorption, whereas the synthesis of apo AI and apo B48 is stimulated only marginally. Less information is known about how apo CIII responds to lipid absorption.

APOLIPOPROTEIN AI

Apolipoprotein AI is abundantly expressed in the small intestine, and as much as 2% of total mRNA in intestinal enterocytes is ascribed to this protein. It has a molecular mass of about 28 kDa and plays an extremely important role in lipid metabolism because it is a major protein associated with circulating HDLs and is a cofactor for the circulating enzyme lecithin cholesterol acyltransferase. Both the liver and small intestine are major sources of circulating apo AI, and animal studies have indicated that as much as half of the circulating apo AI comes from the gut. Numerous animal and human studies have demonstrated that an inverse relationship exists between circulating HDL levels and the risk of coronary arterial disease, which is thought to result from the involvement of HDLs in "reverse cholesterol transport." High-density lipoproteins desorb free cholesterol from the membranes of cells and return it to the liver for storage or secretion.

Regulation of Intestinal Apo AI Synthesis and Secretion

The synthesis of apo AI by the small intestine has been studied quite thoroughly, because it is an integral component of HDL and because of the role it plays in reverse cholesterol transport. The absorption of fat seems to affect the synthesis and secretion of apo AI by the small intestine only marginally. For instance, it has been demonstrated in both rats and suckling pigs that active lipid absorption results in only a small increase (between 10 and 20%) in apo AI production by the small intestine, as measured by [^{3}H]leucine incorporation studies. In Caco-2 cells, it has been demonstrated that oxidized fatty acid, a ligand for

peroxisome proliferator-activated receptor-γ (PPAR-γ), stimulates both the mRNA level and the synthesis of apo AI. Incubation of porcine enterocytes with fatty acids stimulates the production of apo AI. Unsaturated fatty acids are more potent than saturated fatty acids in stimulating cellular apo AI production, and polyunsaturated fatty acids are more efficient in enhancing the cellular production of apo AI compared to monounsaturated fatty acids. Regulation of apo AI production following dietary consumption of different fatty acids by animals, however, is far more complex. For example, it has been shown that intestinal apo AI synthesis is twofold higher in preweaning piglets than in adult pigs, mainly as a result of the effect of saturated fats. Following weaning, however, polyunsaturated fats appear to play a more important role in maintaining apo AI production by the gut. In many of these studies, however, the fact that polyunsaturated fatty acids are taken up by enterocytes more efficiently than are saturated fatty acids may have been ignored. Therefore, distinguishing between the effects of polyunsaturated and saturated fatty acids and determining the differing amounts of fatty acids that are taken up by the cells following ingestion of either polyunsaturated or saturated fats may be difficult.

It has been reported that intestinal apo AI production is altered during different physiological and disease states. For instance, the production of apo AI appears to increase during aging; studies in rodents have demonstrated that apo AI synthesis by the small intestine is increased in older animals compared to younger animals. Increasing the circulating level of ethinylestradiol appears to down-regulate gene expression of apo AI in the gut whereas ovariectomy increases the apo AI mRNA level. As would be expected, supplementing ovariectomized animals with ethinylestradiol decreases the apo AI mRNA level in the intestine. Thyroidal status also impacts the synthesis of apo AI by the gut. Hyperthyroidism is associated with increased apo AI synthesis and secretion by the gut, but this increase is not associated with increased triglyceride secretion. How gastrointestinal (GI) hormones affect apo AI gene expression is an exciting area of investigation yet to be explored.

Clinical implications of intestinal apo AI production have been demonstrated in humans as well as in animals. Patients suffering from abetalipoproteinemia have reduced apo AI synthesis. It has been reported that apo AI production is stimulated by copper deficiency and that tumor necrosis factor α (TNFα) decreases apo AI production by the small intestine. Both mRNA levels and synthesis of apo AI are stimulated in nephritic animals. Further, the intestinal mucosa of patients with celiac disease show decreased apo AI synthesis, which is reflected by a marked reduction in circulating apo AI (∼40%).

APOLIPOPROTEIN AIV

Apolipoprotein AIV was discovered in the 1970s, but its physiological role was not firmly established until recently. Apo AIV is a protein secreted by the human small intestine; in rodents, apo AIV is secreted by both the small intestine and liver; although the small intestine is the organ most responsible for circulating levels of apo AIV. It has been recently demonstrated in rodents that the brain, specifically the arcuate nucleus, produces apo AIV as well. The production of apo AIV is regulated physiologically, i.e., it decreases with fasting and increases with feeding.

Regulation of Intestinal Apo AIV Synthesis and Secretion

Circulating apo AIV in rodents exhibits a circadian rhythm—the level increases at the beginning of the dark period and peaks midway through the dark cycle. Fasting significantly reduces the circulating level of apo AIV but it does not affect the pattern of the circulating apo AIV circadian rhythm. This circadian rhythm is abolished in animals when enterohepatic circulation is interrupted by bile diversion. Furthermore, it has been demonstrated that bile diversion significantly reduces apo AIV synthesis by the intestinal mucosa. Thus, intact enterohepatic circulation is necessary both for normal basal lymphatic output of apo AIV and for maintaining its circadian rhythm.

In vivo studies have demonstrated that the synthesis and secretion of apo AIV by the GI tract are regulated by fat absorption as well as by peptides secreted by the lower small intestine, e.g., peptide YY. It has been demonstrated by numerous groups that intestinal lipid absorption stimulates the synthesis and secretion of apo AIV in a dose-dependent manner. Apo AI and apo B48, however, are not stimulated in this way. Evidence to date suggests that increased synthesis of apo AIV following fat absorption results via a transcriptional mechanism, although the precise cellular mechanism responsible has not yet been determined. Increased apo AIV production probably occurs locally and does not involve the nervous system, because complete vagotomy fails to inhibit an increase. It has been demonstrated that intestinal lymphatic apo AIV transport increases in a gradient manner with increasing steady-state levels of intestinal triglyceride transport. It is tempting to think that measuring the circulating level of apo AIV may be an effective way of determining

fat ingestion. If this correlation can be demonstrated, measuring the circulating apo AIV level may be a convenient and effective way of following fat absorption by the gut. It may also be a convenient way of monitoring the intestinal absorptive function; formation and secretion of chylomicrons by the small intestine are among the most complex functions performed by the enterocytes, involving lipid synthesis, apoprotein synthesis, and carbohydrate synthesis (glycosylation of apoproteins).

Understanding the mechanisms responsible for stimulating intestinal apo AIV synthesis and secretion during fat absorption is crucial. Evidence gathered thus far suggests that the assembly and transport of chylomicrons are necessary for stimulating intestinal apo AIV synthesis. A unique inhibitor of chylomicron formation, Pluronic L-81 (L-81), a hydrophobic surfactant that specifically inhibits the formation of chylomicrons, has been used to explore the relationship between chylomicron formation and the stimulation of apo AIV synthesis and secretion by the gut. L-81 does not inhibit the digestion, uptake, or reesterification of absorbed lipid to form triglyceride inside the enterocytes. Because of the inhibition of chylomicron formation by enterocytes, the absorbed lipid accumulates in the intestinal mucosa. When L-81 is removed, lymphatic lipid transport as chylomicrons resumes because the accumulated mucosal lipid is cleared from the mucosa. These results demonstrate that L-81 inhibits lymphatic transport of chylomicrons and abolishes the increase in lymphatic secretion of apo AIV normally associated with active fat absorption. As expected, removing L-81 causes chylomicron formation as well as the stimulation of lymphatic apo AIV secretion, suggesting that the formation of chylomicrons stimulates apo AIV synthesis and secretion.

Further evidence of the dependency of lymphatic apo AIV output on chylomicron transport comes from animal studies examining intestinal synthesis and lymphatic secretion of apo AIV in response to intestinal infusion of fatty acids of different chain lengths (and therefore the route of transport from the intestine, i.e., lymph vs. blood). Infusion of long-chain fatty acids (oleic, C_{18}; arachidonic, C_{20}), which are transported via the lymph in chylomicrons, stimulates synthesis and output of apo AIV. However, medium- and short-chain fatty acids (caprylic, C_8; butyric, C_4), primarily transported as free fatty acids in the portal vein, did not elicit an apo AIV response. This finding in rodents differs from findings in neonatal swine, in which similar increases in jejunal apo AIV mRNA expression and synthesis in response to infusions of both medium- ($C_{8:0}$ and $C_{10:0}$) and long-chain triglyceride mixtures are observed. Additional studies are warranted to determine if the relationship between chylomicrons and apo AIV synthesis and secretion is common to all species and developmental stages. An extremely interesting but still unanswered question is how the formation of chylomicrons is signal transduced to stimulate intestinal apo AIV synthesis and whether this event occurs intracellularly.

It has been demonstrated that lipid infused into the ileum of rats stimulates both ileal and jejunal apo AIV synthesis. This finding is different from that of lipid infused into the duodenum, because only duodenal and jejunal synthesis of apo AIV is stimulated. Animals equipped with jejunal or ileal Thiry—Vella fistulas (segment of the intestine isolated luminally from the rest of the GI tract, but still connected to the body via the circulation and nervous system) increase proximal jejunal apo AIV synthesis when lipid is infused into the ileum. This stimulation of jejunal apo AIV synthesis by ileal lipid absorption is independent of the presence of lipid in the jejunum. These results strongly suggest that a signal released by the ileum in response to the presence of lipids stimulates apo AIV synthesis in the proximal gut. Recent evidence suggests that peptide YY (PYY) is potentially a primary factor contributing to the stimulation of jejunal apo AIV synthesis and secretion by the presence of lipids in the ileum. Continuous intravenous infusion of physiological doses of PYY in fasting animals elicits significant increases in both synthesis and lymphatic transport of apo AIV; this process is mediated through the vagus nerve, because vagotomy abolishes a jejunal increase in apo AIV synthesis. Thus, jejunal stimulation of apo AIV synthesis and secretion by fat absorption in the ileum is mediated by PYY, which, in turn, acts centrally to send a signal via the vagus nerve to the gut. This is the first demonstration of GI hormone involvement in controlling the expression and secretion of an intestinal apolipoprotein, thus bringing together two areas of research in GI physiology.

Physiological Functions of Apo AIV

In vitro studies have suggested the role of apo AIV in lipoprotein metabolism. Whether apo AIV plays the same role *in vivo* is uncertain, but the fact that apo AI can also perform such a role casts doubt on this physiological function of apo AIV. Here we discuss only *in vivo* functions of apo AIV that are not shared by apo AI. Apo AIV has been shown to protect apo E knockout mice from developing atherosclerosis despite their atherogenic plasma lipid profile (increased total plasma cholesterol with no significant change in HDL cholesterol).

Moreover, apo AIV deters the formation of diet-induced atherosclerotic lesions. These studies therefore suggest that apo AIV protects against atherosclerosis, possibly as a result of the ability of apo AIV to protect against lipid oxidation. Presently, the extent of this antioxidant effect is unclear.

Apo AIV also plays a unique role in the regulation of food intake. It is probably a satiety signal released by the GI tract following the ingestion of fat. Animals administered intravenous intestinal lymph from fasted rats did not respond normally to food intake. However, animals administered intravenous intestinal lymph from rats actively absorbing lipid demonstrated a marked suppression in food intake. These data implicate the presence of an active component in chylous lymph responsible for inhibiting food intake, and this active component is apo AIV. This is supported by a study demonstrating that the infusion of 200 μg of apo AIV (a physiological dose) inhibits food intake to the same degree as chylous lymph in 24-hour food-deprived rats. This unique function of apo AIV is not shared by apo AI. Thus, it has been proposed that apo AIV is a circulating signal released by the small intestine in response to fat feeding and likely mediates the anorectic effect associated with the ingestion of lipids. That the inhibiting effect of apo AIV on food intake is centrally mediated is based on a number of observations. First, administration of apo AIV in the brain results in an inhibitory effect on food intake. Second, removing apo AIV in the cerebrospinal fluid via apo AIV antibody results in feeding.

As well as inhibiting food intake, apo AIV has also been shown to inhibit gastric acid secretion and gastric motility. Administered doses of apo AIV, thought to reproduce the levels of apo AIV in cerebrospinal fluid after lipid feeding, markedly inhibit both gastric acid secretion and gastric motility. This suggests that apo AIV acts as an enterogastrone, a humoral mediator released by the intestine that mediates the humoral inhibition of gastric acid secretion and gastric motility following the ingestion of fat. Recent data from investigators interested in vagal neural activities have provided convincing evidence showing that apo AIV also inhibits intestinal motility. These findings have important physiological implications. The distal intestine is known to play an important role in the control of GI function. Nutrients, including lipid, delivered to the ileum result in inhibited gastric emptying, decreased intestinal motility and transit, and decreased pancreatic secretion. Ileal nutrients also inhibit food intake. The mechanism responsible for producing these effects has been collectively termed the "ileal brake" and is believed to be related to the release of one or more peptide hormones from the distal intestine. These effects have traditionally been considered operative only in the abnormal delivery of undigested nutrients to the distal gut, such as the malabsorptive state. Most GI physiologists as well as gastroenterologists interested in lipid absorption consider the upper small intestine the primary site for absorbing fat, with the lower small intestine absorbing fat only in the case of fat malabsorption by the upper small intestine. This notion has been recently challenged by investigators demonstrating that nutrients frequently reach the distal gut, even under normal conditions, due to rapid gastric emptying during the early phases of food ingestion. Consequently, it appears that a much greater length of intestine is involved in the absorption of lipid and in the control of gastric and upper gut functions, even under normal conditions, than has been previously recognized. Thus, the ileal brake may play an important role in the normal control of gut function and the control of lipid absorption. Once the ileal brake sets in, the upper small intestine unquestionably is the primary site for fat absorption.

As mentioned earlier, a potential peptide mediating the ileal brake phenomenon is peptide tyrosine-tyrosine (PYY). It is synthesized by the endocrine cells in the ileum and large intestine and is released in response to intestinal nutrients, especially long-chain fatty acids. PYY is also a potent stimulator of the synthesis and secretion of apo AIV by the jejunum. Because apo AIV exerts many of the actions associated with the ileal brake, and PYY stimulates the synthesis and secretion of apo AIV and PYY, apo AIV and the ileal brake phenomenon may possibly be related. Recently, PYY has been demonstrated to inhibit food intake, with this action centrally mediated. Interestingly, stimulation of apo AIV synthesis by PYY also involves the central nervous system, and this stimulation can be abolished by total vagotomy. The question of whether the action of PYY on food intake and upper GI function is mediated through apo AIV can be tested in apo AIV knockout mice.

APOLIPOPROTEIN B

Two different forms of apo B are formed in humans—enterocytes produce apo B48 and hepatocytes produce apo B100. Apo B48 is a 264-kDa protein that is colinear with the apo B100 amino terminus and is 48% of the apo B100 molecule, hence the name apo B48. Both apo B48 and apo B100 utilize the same apo B gene. In the production of apo B48, however, translation is stopped by substituting the CAA codon that encodes glutamine with the codon UAA, which specifies an in-frame stop codon. This interesting mechanism is referred to

as apo B mRNA editing and has since been found in other proteins as well. Apo B editing has a very important consequence. Apo B48 lacks the functional domain for the binding of low-density lipoproteins. The lack of LDL binding domain has led investigators to postulate that a different set of receptors, other than LDL receptors, is involved in the metabolism of chylomicrons. In contrast, apo B100 containing VLDLs produced by the liver, are catalyzed to form LDLs, which are subsequently taken up by the liver and other peripheral organs via the LDL receptors.

Synthesis of Apo B48 by the Small Intestine

Adult human small intestinal cells produce mostly apo B48, suggesting that the editing efficiency is very high in the adult intestine. Evidence to date indicates that neither apo B editing in the human small intestine nor apo B synthesis by the rat small intestine is regulated by fat absorption. Even chronic feeding of a high-fat diet fails to stimulate intestinal apo B synthesis in rodents. Not only are apo B editing and apo B synthesis unaffected by fat absorption, but the secretion of apo B into lymph as chylomicrons is also unaffected by the absorption of fat. This is very different from apo AIV, which is markedly stimulated by fat absorption. This is also very different from the synthesis of apo B100 in the liver, the secretion of which by the hepatocytes is markedly increased by the increase in VLDL secretion. Whether this is related to the fact that the liver makes apo B100 and the intestine makes apo B48 has not been studied.

Bile is required for the secretion of apo B48 by the small intestine, because the diversion of bile results in a marked reduction in the synthesis and secretion of apo B48 by the small intestine. The reintroduction of bile salts, fatty acids, or phospholipids into the intestinal lumen restores apo B biosynthesis by the enterocytes. Using current molecular and cellular biology techniques, the precise involvement of these various components of bile in regulating apo B synthesis will become clear. Perhaps the regulation of intestinal apo B synthesis by bile components is species specific, because bile diversion in the suckling pig has little or no effect on intestinal apo B synthesis.

Physiological Functions of Apo B

The clinical disorder abetalipoproteinemia, an autosomal recessive disorder, provided the first clue that apo B is important for the secretion of triglyceride-rich lipoproteins by the gut as well as by the liver. Patients suffering from abetalipoproteinemia experience fat malabsorption and the accumulation of large lipid droplets in both enterocytes and hepatocytes. Other symptoms associated with this disease are acanthocytosis and retinitis pigmentosa, mostly resulting from fat-soluble vitamin deficiency. However, some studies have questioned whether the mechanism for abetalipoproteinemia is caused by failure to produce apo B. For instance, immunohistochemistry has shown that enterocytes of abetalipoproteinemic patients contain apo B. Furthermore, it has been determined that abetalipoproteinemic patients have elevated levels of apo B mRNA. Thus, it is either the elevated levels of posttranslational apo B degradation or some other factor(s) critical to the association of apo B and absorbed lipids to form intestinal chylomicrons and liver VLDLs that are absent. The "other factor(s)" may be the microsomal triglyceride transfer protein (MTP), because convincing evidence points to either the absence or the mutation of MTPs in abetalipoproteinemic patients. Modern tools of molecular biology should provide a better understanding of the relationship between apo B, MTP, and chylomicron formation.

Because apo B is critical to chylomicron formation, it might be assumed that the availability of apo B is rate limiting for the formation of chylomicrons and, consequently, for the absorption of fat by the small intestine. However, this is not the case. A number of studies have found that apo B48 synthesis by the small intestine and its subsequent secretion into lymph are unaffected by fat absorption. This is different from the process in the liver, where increased VLDL secretion is associated with increased apo B100 secretion. Whether the relationship between lipid transport and apo B secretion is different in the small intestine than it is in the liver is because the gut makes apo B48 and the liver makes apo B100 is yet to be determined. The availability of the apoBEC-1 knockout mouse, whose small intestine produces only apo B100 due to its inability to perform apo B editing, will open this field of study.

APOLIPOPROTEIN CIII

Apolipoprotein CIII is another apoprotein synthesized by the small intestine. It is a much smaller protein compared to apo AI, apo AIV, and apo B48. The mature apo CIII is a 79-amino-acid protein with a molecular mass of 9 kDa. Apo CIII is secreted by the small intestine and the liver. It is probably secreted in association with chylomicrons, but it may also be secreted as a free protein by the enterocytes of the small intestine. In the circulation, it is mostly associated with VLDLs and HDLs.

Synthesis by Enterocytes

Relative to the other apolipoproteins, little is known about the regulation of apo CIII. Whether fasting and

lipid feeding affect the intestinal gene expression of apo CIII is unclear, although results of an older, isolated study show that fat absorption is inversely related to the subjects' fasting plasma HDL cholesterol and HDL apo CIII and directly related to plasma triglycerides. Vitamin A has been reported to regulate apo CIII positively in the small intestine. Apo CIII gene expression is down-regulated by insulin both in animals and in cultured cells.

Physiological Function of Apo CIII

The role of apo CIII in lipoprotein metabolism is best illustrated by the occurrence of hypertriglyceridemia, which is associated with increased expression of apo CIII, as in the case of transgenic animals. Two plausible explanations for the occurrence of hypertriglyceridemia might be that (1) apo CIII inhibits lipoprotein lipase activity or (2) apo CIII decreases tissue uptake of triglyceride-rich particles from the circulation as a result of increased apo CIII and decreased apo E in VLDL particles.

population will have appendicitis in their lifetime, with the peak between the ages of 10 and 30. Males are affected more often than females (1.6 : 1) and perforation rates are higher in the elderly. The very young and the elderly also incur a higher rate of rarer complications such as fistula formation, intestinal obstruction, or systemic sepsis. Mortality of appendicitis is low (0.6% in nonperforated), but delay in appropriate treatment has a significant morbidity of 15–20%, especially considering the generally young population it most commonly affects.

HISTORY

In the early 1800s, right lower quadrant inflammation was thought to arise from near the cecum and the term "perityphlitis" was used to describe this entity. Amyand performed the first recorded appendectomy in 1736 when he removed the appendix upon exploration of a hernia sac. Melier described autopsy cases of inflammation of the appendix and outlined a pathophysiology similar to the present understanding. Then in 1886, Reginald Fitz first used the term "appendicitis" and recommended surgical treatment for the inflammatory disease. Several years later, Chester McBurney described the classic pain of appendicitis and the localization of pain to the point that bears his name, on an oblique line from the anterior superior iliac spine to the umbilicus. As the understanding of appendicitis as a surgical disease evolved and antibiotics became readily available by the mid-1900s, the mortality decreased to less than 2%. Early recognition and surgical therapy then greatly reduced the morbidity.

ANATOMY

The appendix is believed to be a vestigial organ, without a functional purpose in humans. However, because of its lymphoid aggregates, there are some who speculate that the appendix may be involved in immune surveillance. Embryologically, the cecal diverticulum (the origin of the cecum and appendix) presents in the sixth gestational week as a swelling on the antimesenteric border of the midgut loop. The appendix, which is initially a small diverticulum of the cecum, arises from the inferior tip of the cecum, becoming delineated during the fifth gestational month. The anatomic position of the appendix is variable depending on embryologic development, contributing to difficulty in diagnosis. After birth, the appendix rests on the medial side of the cecum because the wall of the cecum grows unequally. During elongation of the colon, the appendix may settle posterior to the cecum, anterior or posterior to the ileum, below the cecum, or over the brim of the pelvis. In over half of the population, the appendix is not fixed in one position but can move freely with postural and colonic changes.

The appendix opens to the cecum with a valve formed by a fold of mucosa. Average appendiceal length is 9 cm, and the width of the lumen is generally between 1 and 3 mm. The appendiceal artery, off the ileocolic artery, provides the blood supply to the appendix. The lymphatics drain to the ileocolic nodes along the ileocolic artery. Sympathetic fibers from the superior mesenteric plexus and parasympathetic fibers from the vagus provide innervation. Histologically, from outside to inside, the appendix consists of the serosa; longitudinal muscle fibers, which form taeniae continuous with the colonic taeniae coli; circular muscle; the submucosa, which contains lymphoid tissue; and the mucosal lumen. The taeniae coli of the ascending colon converge at the base of the appendix, enabling localization of the appendix during appendectomy by following the cecal taeniae.

PATHOPHYSIOLOGY

Most commonly, appendicitis results from obstruction of the appendiceal lumen. In older adults, fecaliths are a frequent cause of obstruction, whereas the most common cause in children and young adults is lymphoid hyperplasia. Fecaliths and appendicitis occur more frequently in populations that have a lower fiber and higher fat content in the diet, suggesting that diet plays a role in disease development. In less than 2% of cases, a foreign body, carcinoma, or carcinoid causes obstruction.

The appendix secretes an increased amount of mucus in response to the obstruction. Bacterial overgrowth also develops secondary to obstruction and subsequent stasis. The increased mucus and bacterial load lead to appendiceal dilation, eventually causing compromise of venous and lymphatic flow. The appendiceal artery can thrombose as the appendix enlarges. Ischemic injury can then lead to necrosis, and if the gangrene becomes full-thickness, perforation occurs. With rupture, fecal contents enter the abdominal cavity and produce peritoneal irritation. An abscess results when local inflammation produces adhesions and walls off the perforated appendix. If the rupture is not contained within an abscess, gross spillage and generalized peritonitis result.

Histopathologically, the gross specimen shows edema of serosal vessels early in appendicitis. The appendix then develops a dilated lumen, thickened wall, dusky serosa, and fibrinous serosal exudates. Late in the progression of the disease, there is mucosal necrosis, wall gangrene and softening, and purulent

serosal exudates. Microscopically, appendicitis demonstrates a neutrophilic infiltrate early, which progresses to mucosal necrosis and eventually to muscularis necrosis and microabscesses in the appendiceal wall. If allowed to progress untreated, the appendix ultimately perforates and leads to a walled-off abscess or generalized peritonitis.

DIAGNOSIS

The classic history of appendicitis is one of dull periumbilical pain followed by anorexia and then localized pain developing in the right lower quadrant (RLQ). Nausea and then vomiting generally precede localization of pain to the right lower quadrant, although nausea is present at some time during the clinical course in 90% of patients with appendicitis (Table I). The absence of anorexia makes the diagnosis of appendicitis questionable and the "hamburger sign" (asking the patient if he or she would want to eat a favorite food) is one way to assess this.

The usual order of events is as follows: epigastric or periumbilical pain, anorexia, nausea, vomiting, RLQ tenderness, fever (usually low grade), and leukocytosis. Since the innervation of the appendix migrates to the right lower quadrant from autonomic efferents associated with the spinal cord around T10 and the abdominal organs lack direct innervation by pain fibers, dull pain is initially felt around the umbilicus. As inflammation progresses, the parietal peritoneum in the right lower quadrant becomes more irritated, resulting in localized pain. The pain becomes constant as the lumen of the appendix develops increasing distension and ischemia results. Approximately 40% of patients will present with atypical pain. Perforation is rare if symptoms have been present for less than 24 h.

The differential diagnosis of abdominal pain that can mimic appendicitis is broad (Table II). Conversely, because of its potential for variable presentation, appendicitis should always be considered when evaluating any acute abdominal pain. Tenderness to percussion demonstrates peritoneal irritation, as does guarding and pain with motion. Occasionally, a tender mass,

which is either the distended, inflamed appendix or an appendiceal abscess, can be palpated in the right lower quadrant. Hyperesthesia of the skin overlying the right lower quadrant is an occasional finding in the distribution of the 10th through 12th dorsal spinal segments and 1st lumbar spinal segment.

Various physical signs are often present in appendicitis. The psoas sign elicits pain on passive extension of the right thigh with the patient lying on the left side since the inflamed appendix overlies the psoas muscle. Pain on passive internal rotation of the flexed thigh is called the obturator sign. Additional findings include Rovsing's sign, which is pain in the right lower quadrant on palpation of the left lower quadrant, and Dunphy's sign, which is pain on coughing. The presence of these signs helps to confirm the diagnosis, but they are by no means sensitive or specific. Tenderness on rectal exam may be helpful in making the diagnosis if there is an abscess or pelvic appendicitis. Bimanual/speculum exam should be performed in women to evaluate for gynecologic causes of pain such as pelvic inflammatory disease.

Laboratory tests often demonstrate an elevated white blood cell count and/or bandemia. The BUN to creatinine ratio may be elevated if the patient is dehydrated from decreased intake and vomiting. Urine analysis is useful in assessing for ureteral stones, which produce hematuria, or urinary tract infections (bacteruria, pyuria). Local inflammatory reaction to appendicitis, however, can also give white blood cells and red blood cells in the urine. A test for human chorionic gonadotropin in the urine should be checked in all women of childbearing age, both to exclude normal or ectopic pregnancy as a cause of pain and to tailor diagnostics and treatment if necessary.

Although the diagnosis of appendicitis is generally made on the basis of history and physical exam, radiologic studies are effective tools in equivocal diagnoses. Plain film rarely contributes to the diagnosis, although findings in appendicitis can include a visible fecalith, localized ileus, loss of the peritoneal fat stripe from the right lower quadrant inflammatory process, and right psoas muscle deformation from the patient splinting away from right lower quadrant pain. Ultrasound and computed tomography (CT) scan are the most effective methods of elucidating a diagnosis of appendicitis. On ultrasound, a positive study shows a distended appendix that measures greater than 6 mm in diameter, is noncompressible, and is tender with probe compression. The transverse images show a "target" or "bullet" sign, which is the side view of the distended, thickened appendix (Fig. 1). A normal appendix must be seen to rule out appendicitis. Depending on the operator, appendiceal ultrasound has a sensitivity of approximately 85% and a specificity of 90%.

The use of CT images to diagnose appendicitis has greatly affected management of suspected appendicitis. Although the initial studies with CT-diagnosed appendicitis were performed with rectal contrast, Brigham and Women's Hospital favors a standard abdominal/pelvic CT scan with oral and intravenous contrast. If the radiologist is unable to make or exclude the diagnosis with the initial scan and there is a high index of suspicion, a rectal contrast CT scan can then be performed. An advantage of this technique is contrast-aided imaging of the entire abdomen for other possible diagnoses. Positive studies show a thick-walled, distended, non-contrast-filling appendix, periappendiceal inflammation, fluid collections or abscess, and often, an appendicalith (Fig. 2). If contrast fills the appendix and there is no evidence of surrounding inflammation, the diagnosis is considered to be excluded.

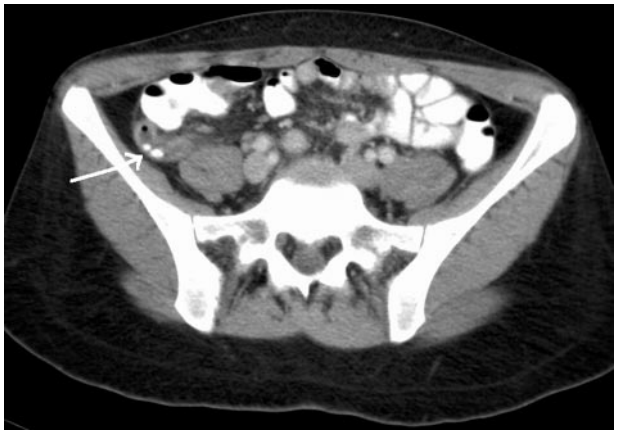

FIGURE 2 CT of appendicitis. A spiral CT with oral and intravenous contrast demonstrates two appendicaliths obstructing a fluid-filled, distended, thick-walled appendix (white arrow) with surrounding fat stranding consistent with local inflammation. Figure courtesy of Stephen Ledbetter, M.D., Department of Radiology, Brigham and Women's Hospital, Boston, MA.

Depending on the radiologist, appendiceal CT scans have a sensitivity of approximately 90–99% and a specificity of 97%. Multiple studies have demonstrated the cost effectiveness of CT when used in equivocal cases of appendicitis. In general, patients with a questionable history and physical who would have been observed closely in the past are now undergoing CT scans and either being discharged or taken to the operating room. As clinicians become more comfortable with using CT scans as a diagnostic tool, the rate of negative exploration is expected to decrease.

TREATMENT

Operative removal of the inflamed appendix is the accepted treatment for appendicitis. In nonperforated cases, broad-spectrum antibiotics are usually administered prior to the start of the operation. No further antibiotics are routinely necessary. However, in cases of perforation, the broad-spectrum antibiotics are generally continued to complete a course of 5 to 7 days.

The appendix can be removed through an open incision or using a laparoscope. Incisions for the open approach include a transverse right lower quadrant (Rockey–Davis), oblique RLQ (McArthur–McBurney) with muscle splitting in the direction of the fibers, or less commonly, a paramedial incision. If the diagnosis is in question, an abdominal exploration can be performed through a periumbilical midline incision.

The appendix is located by following the taeniae coli to the cecum and lifting the appendix out of the incision. After it is dissected off the mesoappendix, the specimen can be removed by stapling across its base or suture ligation. Some surgeons use either a Z-stitch or a purse-string stitch to invert the stump. There is no evidence, however, that this maneuver reduces the incidence of stump leak or fistulae. The wound is closed in nonperforated cases. In perforated appendicitis, a Penrose or other drain is often placed in the wound and/or the wound is left open with packing. Neither practice has been definitively shown to reduce the incidence of postoperative wound infection. The patient then completes a course of broad-spectrum antibiotics.

The laparoscopic approach involves longer operative time but is supposed to result in less pain and a quicker recovery time. However, a significant overall advantage of the laparoscopic procedure compared to the open procedure has not been shown in routine appendicitis. The main benefit of the laparoscopic approach is that it can be helpful initially as a diagnostic tool and then the surgeon can proceed to appendectomy in positive cases. The appendix is divided at its base using a linear stapler and there is no inversion of the stump.

Classically, a 15–20% rate of removal of normal appendix was acceptable given the broad differential diagnosis and high morbidity of missed appendicitis. With the use of ultrasound and CT, rates of negative appendectomy are expected to decrease. Despite this expectation with technological advances, recent studies have not yet demonstrated a reduction in the rate of perforation or negative exploration.

SPECIAL CASES

The existence of "chronic appendicitis" is controversial but generally involves chronic waxing-and-waning RLQ pain from intermittent obstruction and inflammation. Patients usually feel better after the appendix is removed and almost all surgical specimens demonstrate abnormal histology.

Rarely, patients may present with a RLQ mass that is an abscess or a phlegmon associated with a perforated appendix. Standard treatment is to percutaneously drain the abscess using image guidance and give intravenous antibiotics. An interval appendectomy, using either the open or the laparascopic procedure, can then be performed 6 to 8 weeks later.

Incidental appendectomy (removal of the appendix when an operation is being performed in the abdomen for another reason) is not warranted unless future diagnostic difficulties are anticipated. It can lead to increased infectious complications during certain procedures such as those involving vascular grafts.

Even in operations not associated with increased complications from incidental appendectomy, it is associated with increased operative time and cost with questionable benefit. Most patients who develop appendicitis are young, whereas most people who undergo other intra-abdominal operations are elderly and have a much smaller chance of ever needing an appendectomy.

Appendicitis in pregnancy poses a particularly difficult diagnostic problem because the enlarging uterus displaces the appendix. Appendicitis can occur during any trimester, although perforation is more common in the third trimester. The pregnant woman may complain of abdominal pain at any location to which the appendix is shifted. However, right lower quadrant pain is still the most common location of discomfort in pregnant women with appendicitis. Symptoms such as nausea, vomiting, and anorexia occur in both appendicitis and pregnancy and thus do not contribute to differentiating the diagnosis. Ultrasound is particularly helpful in making a diagnosis in pregnant women, both because it does not pose a radiation risk and because it enables visualization of pelvic pathology. Early appendectomy is preferable because ruptured appendicitis can lead to fetal death and maternal morbidity, whereas appendectomy prior to perforation and negative explorations generally pose less risk to the fetus.

Appetite dysregulation exacerbates disease, thus mechanisms that regulate appetite are a major research focus in the fields of obesity, cancer, eating disorders, and AIDS.

REGULATION BY THE HYPOTHALAMUS

Eating behaviors are chemically encoded in the hypothalamus. Orexigenic signals of neuropeptide Y, galanin, endogenous opioid peptides, melanin-concentrating hormone, glutamate, and γ-aminobutyric acid promote food consumption behavior. Anorexigenic signals, including the entire family of corticotropin-releasing hormone (CRH)-related peptides, neurotensin, glucagon-like peptide-1, melanocortin, and agoutiprotein, promote the cessation of food consumption. Each neuropeptide has its own specific cellular receptors, occurring in high concentration in the paraventricular nucleus of the hypothalamus but present in other areas of the brain. All appear interconnected with feedback loops whereby one signal peptide can alter the secretion of another signal peptide. No single peptide is the gatekeeper to turning on or off appetite; what is apparent is an entire network of signals, and their frequency and amplitude are responsible for triggering behaviors.

The network of appetite signals accounts for the behavioral observations that appetite and food consumption patterns are dynamic. Biological, environmental, and psychological events readily influence behavior. Habitual intake, memories of food-related activities, and the sheer anticipation of consumption have been shown to influence single meal consumption of specific foods. External clues, such as the appearance of food, aroma, anticipated palatability, and the number of food choices, have been shown to modify the perception of appetite as well as the behaviors of eating. Psychosomatic consequences of eating, such as reduction in anxiety, can exert additional influences on behavior. Appetite appears analogous to memory; although memory and appetite are chemically encoded, every individual has their own unique signal circuitry underlying their eating behaviors. Just as memories change over time, the circuitry for appetite can also be modified.

REGULATION BY FAT CELLS

A major breakthrough in the physiology of appetite regulation came with the discovery of leptin and resistin, two hormones synthesized by adipocytes.

Leptin secretion increases as adipocytes enlarge, and decreases during fasting. Identification of leptin receptors in the hypothalamus has provided an intriguing biochemical explanation for the ability of an animal to regulate body weight tightly within a fairly narrow set point range. The leptin signal may serve as an anorexin by its ability to alter secretion of orexins and anorexins. Obese persons have appropriately elevated leptin levels, but whether this is an epiphenomenon of obesity or a clue to its pathologic cause is uncertain.

Resistin secretion increases during feeding and during adipose tissue exposure to insulin. In contrast to leptin, a hypothalamic receptor for resistin has not yet been identified. Instead, resistin appears to induce adipocyte resistance to insulin. Resistin also inhibits adipocyte differentiation. Rosiglitazone, a drug classified as an "insulin sensitizer," reduces resistin levels, suggesting that resistin plays a key role in determining insulin resistance.

GENETIC DISORDERS OF APPETITE REGULATION

The importance of the orexigenic and anorexigenic signals and their receptors has been highlighted by the identification of rare families with specific genetic defects associated with childhood obesity. Mutations in leptin, the leptin receptor, prohormone convertase 1 (PC1), pro-opiomelanocortin (POMC), melanocortin 4 receptor (MC4-R), and peroxisome

these biological actions, one of the most significant is the major role played by eicosanoids in inflammation, where they contribute to all of the clinical symptoms associated with the inflammatory condition, namely, pain, redness, and swelling. The ever-growing number of molecules derived from AA includes other families such as lipoxins (LXs), hepoxilins, hepoxides, monohydroxyeicosatretraenoic acids (HETEs), dihydroxyeicosatretraenoic acids, and their hydroperoxy precursors. Whereas synthesis of most of these mediators involves the non-heme iron catalytic center typical of cyclo- and lipoxygenases, hepoxilins and hepoxides originate via heme proteins such as hematin and cytochrome P450.

ARACHIDONATE RELEASE

Although the number of compounds originating from AA exceeds the hundreds, an overarching consistency is found as to the carefully orchestrated synthesis of these mediators. A hallmark of these tightly regulated syntheses is the controlled release of esterified AA from the membrane phospholipid storage, a task accomplished via stimulus-induced activation of cytosolic and secreted forms of phospholipase A_2 ($cPLA_2$, $sPLA_2$) that cleave AA from the *sn*-2 position and lead to accumulation of the free acid form, the initial substrate for subsequent enzymatic catalysis. Upon availability of substrate, a second level of regulation involves the COX and LOX enzymes that require several cofactors and are subject to so-called "suicide inactivation," a self-inactivation process that effectively limits the amount of bioactive mediators that can be generated.

ARACHIDONATE BIOLOGY

AA per se is endowed with biological activities such as activation of leukocyte responses and is known to interact and modulate the function of several intracellular targets such as guanosine 5′-triphosphate-binding proteins. Structurally related molecules such as anandemide are known to play an important role in regulating specific central nervous system activities, and specific gastrointestinal (GI) activities for AA include the modulation of gallbladder contraction.

THE CYCLOOXYGENASE PATHWAYS: PROSTANOIDS

An impressive list of gastroenterological-specific actions can be assigned to the COX- and LOX-derived AA products. Prostaglandins (PGs), for example, in addition to acting as cellular and physiological mediators (i.e., their receptor-mediated regulation of cyclic AMP levels and their role in parturition), are known to carry out important physiological tasks in mucosal secretion and motility as well as pathophysiological activities contributing to mucosal inflammation, injury, and tumor progression. PG-mediated gastric protective activities include mucus production, production of surface-active phospholipids, and bicarbonate secretion as well as regulation of mucosal blood flow and cell proliferation. The physiological role of PGs in mucosal protection is exemplified by the well-known gastrointestinal adverse events (dyspepsia, bleeding, and ulceration) caused by inhibitors of PG synthesis. The largest and most widely used class of drugs inhibiting PG synthesis targets the COX enzymes and is better known as the family of nonsteroidal anti-inflammatory drugs (NSAIDs), which includes agents such as aspirin and ibuprofen. Only in the past 10 years has the discovery of two COX isoforms, the constitutive form, or type 1 (COX-1), and the inducible form, or type 2 (COX-2), allowed the issue of gastric toxicity of NSAIDs to be addressed. In an ongoing effort to elucidate the specific role of these two enzymes, it is now generally assumed that COX-1 is mainly involved in the physiological aspects of prostanoid biology, whereas the inducible COX-2 is associated with expression of inflammatory events and the pathophysiology of several disease conditions. In addition to the GI toxicity of NSAIDs, which has at least been partially addressed by the development of new drugs such as rofecoxib and colecoxib that take advantage of the slightly larger substrate pocket of COX-2 to selectively inhibit this enzyme sparing the COX-1 isoform, recent epidemiological studies suggest that selective NSAIDs have chemopreventive properties toward solid tumors including colon adenocarcinoma. At present, however, it is highly debated whether this NSAID property is linked to suppressed synthesis of PGs [and most notably the major product prostaglandin E2 (PGE2)] or involves an as yet to be identified mechanism of action. Conversely, PGE2 is known to contribute to accelerated tumor progression, with marked pro-angiogenic properties, and animal models show a positive correlation between overexpression of COX-2 and progression from early stages of adenoma and polyp formation to adenocarcinoma. These active areas of investigation will likely provide critical new knowledge about the extensive networks of interactions mediated by PGs in the GI tract including inflammatory bowel disease (IBD), for which, in contrast to the *ex juvantibus* criteria by which the beneficial use of anti-inflammatory drugs such as sulfosalazine suggests that eicosanoids are relevant to IBD pathogenesis, it has not yet been

demonstrated that excess synthesis of lipid mediators plays a major role in establishing or maintaining the disease condition. In addition to PGE2, the prostaglandin family of mediators in the GI tract includes PGI2, $PGF2_{\alpha}$, and thromboxanes. To each of these compounds have been attributed specific actions within various segments of the GI system. The response to each group of PGs is determined not only by their structural specificity but also by the specific form of the receptors that are expressed. Four major subtypes of prostaglandin receptors, EP_1-EP_4, have been identified to date, in addition to a thromboxane receptor and a PGI2 receptor. The tissue distribution and the intrinsic properties of these G-protein-coupled receptors are under active investigation and selective agonists as well as antagonists are in early or late stages of *in vivo* animal studies, clinical trials, or clinical use (i.e., misoprostol, iloprost).

THE LIPOXYGENASE PATHWAYS: LEUKOTRIENES AND LIPOXINS

Although the experience in GI clinical practice highlights the role of COX-derived prostanoids, other families of eicosanoids, such as the LOX-derived LTs, play a significant role in modulating GI functions. Elevated LTB_4 levels, for example, are found in GI tissues affected by inflammatory conditions and peptido-leukotrienes LTC_4 and D_4 are known to be among the most potent stimuli causing intestinal smooth muscle contraction. Based on this evidence, inhibitors of the 5-lipoxigenase enzyme, a common biosynthetic element in LTB_4, $-C_4$, $-D_4$, and $-E_4$ synthesis, have been used in an IBD clinical trial leading to improvement of symptoms and sigmoidoscopic appearance. In manner analogous to PGs, many of the LT-induced responses are mediated by specific G-protein-coupled receptors. Two forms have been identified thus far for both peptido-leukotrienes (cys-LT1 and cys-LT2) and LTB_4 (BLTR1 and BLTR2) and they are characterized by specific tissue distributions. For example, cys-LT2 seems to be the main receptor involved in peptido-leukotriene-induced contraction of ileum smooth muscle cells and BLTR1 and BLTR2 are present on leukocytes and lymphocytes, respectively. BLTR2 is of particular interest because of its expression on T cells and its role in mediating the immune-regulatory effects of HETEs and LTB_4. The activation of these signaling pathways and the resulting interactions between immune competent cells and inflammatory infiltrates and the gastrointestinal tissues are recognized as an increasingly important contribution to the pathophysiology of GI disorders and may play an important role in IBD.

The interactions between leukocytes and lymphocytes and the intestinal mucosa cell components also play a major role in eicosanoid production. In fact, it is mostly via transcellular routes of biosynthesis that specific classes of AA-derived mediators are formed. Among these, the LXs, a class of compound generally endowed with anti-inflammatory/inhibitory effects originated by sequential recruitment of multiple LOX enzymes (three major LOX enzymes are expressed in mammalian cells: 5-, 12-, and 15-LOX), have been the subject of specific studies examining their gastrointestinal effects. Inhibition of neutrophil transmigration across intestinal epithelial monolayers, inhibition of pathogen-induced release of cytokines from the intestinal epithelium, and reduced severity and mortality in an animal model of dextran sodium sulfate-induced colitis are some of the GI-specific effects observed to date. As with the previously described PGs and LTs, LX specificity is also based on the interaction with specific G-protein-coupled receptors (ALXR, LXA_4R).

renin–angiotensin–aldosterone system Vasoactive system that causes renal vasoconstriction and retention of sodium and water.
spontaneous bacterial peritonitis Primary infection of ascitic fluid in patients with advanced liver disease.
venoocclusive disease Hepatic venous outflow obstruction that occurs in patients undergoing bone marrow transplantation, radiation therapy, liver transplantation, or ingestion of alkaloid toxins; the result of occlusion of hepatic sinusoids and small venules.

Ascites is defined as the excessive accumulation of fluid in the peritoneal cavity. Cirrhosis is the most common cause of ascites, followed by malignancy and cardiac failure. Patients with advanced liver disease develop infections of the ascitic fluid, a condition known as spontaneous bacterial peritonitis. Moreover, these patients can develop hepatorenal syndrome, a functional renal failure. Finally, patients may have hepatic hydrothorax, which involves symptomatic pleural effusions.

MALIGNANT ETIOLOGY

Cirrhosis is the cause of ascites in up to 80% of cases; malignancy and cardiac failure are the causes in 10% and 5%, respectively. Other causes account for fewer than 5% of cases of ascites. About 5% of patients have ascites due to more than one cause. Fifty percent of cirrhotic patients eventually develop ascites; up to 10% of these have ascites refractory to treatment. Ovarian cancer is the most common cause of malignant ascites and accounts for almost 50% of cases of the disease. Occult malignancies account for 20% of cases of malignant ascites and the remaining 30% of cases result from pancreatic cancer, gastric cancer, colon cancer, lung cancer, breast cancer, or lymphoma. The causes of ascites are summarized in Table I.

PATHOGENESIS

Ascites in cirrhotic patients results from a combination of portal hypertension and renal retention of sodium. As a result of factors such as nitric oxide (NO), which are present in excess in cirrhosis, there is splanchnic and peripheral vasodilatation. This results in a decrease in the effective arterial blood volume (EABV). In an attempt to correct the EABV, there is stimulation of the renin–angiotensin–aldosterone system (RAAS), the sympathetic nervous system (SNS), and vasopressin. These vasoactive systems work in concert to cause renal retention of sodium and water, as well as renal vasoconstriction. The result is an increase in plasma volume. The excessive fluid retained is compartmentalized to the peritoneal cavity as a result of portal hypertension, which is an increase in pressure within the hepatic

sinusoids. A hepatic sinusoid pressure greater than 12 mmHg is usually required for ascites to develop.

Malignant ascites results from exudation of fluid from peritoneal carcinomatosis and occlusion of diaphragmatic lymphatics, with impairment of peritoneal fluid absorption. Tumor infiltration in the liver, leading to hepatic venous obstruction, is a less common cause of malignant ascites. Ascites in patients with hepatocellular carcinoma may be secondary to portal hypertension or to portal vein thrombosis due to tumor.

Tuberculous peritonitis leads to exudation of proteinaceous fluid into the peritoneal cavity, and resultant ascites. Pancreatic ascites can be seen in both acute and chronic pancreatitis and results from disruption of the pancreatic duct and leakage of pancreatic secretions into the peritoneum. Chylous ascites occurs from a lymphatic disruption as a result of trauma or malignant obstruction of the lymphatic ducts.

PHYSICAL EXAMINATION

Normally there is less than 75–100 ml of fluid in the peritoneal cavity. Ascites can be detected by eliciting shifting dullness when peritoneal fluid collection exceeds 500 ml. Fluid wave is positive in the presence of tense ascites; patients with tense ascites may also have concomitant lower extremity edema. Ultrasonography, which is frequently used to confirm the diagnosis, can detect as little as 100 ml of peritoneal fluid.

Peripheral stigmata of chronic liver disease, including spider angiomata, palmar erythema, caput medusae, gynecomastia, and testicular atrophy, may be seen when ascites results from cirrhosis and portal hypertension. Some patients may have generalized anasarca. The cirrhotic liver in patients with an advanced stage of disease is usually shrunken and may not be palpable. The spleen may be palpable following a therapeutic paracentesis.

Patients with congestive heart failure and ascites have elevated jugular venous pressure, peripheral edema, and presence of S3 or S4 (low-pitched sounds detected using the stethoscope) on cardiac examination. Constrictive pericarditis is characterized by presence of pulsus paradoxicus, rapid X and Y descents of the jugular venous pulse, pericardial knock, and ascites out of proportion to peripheral edema. The presence of hepatojugular reflux confirms a cardiac cause for the ascites.

DIFFERENTIAL DIAGNOSIS

Other etiologies of a distended abdomen, including pregnancy, ovarian mass, gaseous distension from bowel obstruction, and obesity, must be excluded in a patient suspected to have ascites. On percussion of the abdomen, ascites presents with flank dullness, whereas an ovarian mass typically presents with central dullness and tympanitic flanks.

DIAGNOSIS

Abdominal paracentesis is the most rapid and cost-effective method of diagnosing the etiology of ascites. Paracentesis should be performed in all patients with new-onset ascites and at the time of every hospital admission in all patients with ascites. A low threshold must be maintained for repeating the paracentesis, because infection may present with only minimal symptoms. The only absolute contraindication to paracentesis is an uncooperative patient. Complications occur in fewer than 1% of cases and include abdominal wall hematomas. Serious complications such as hemoperitoneum and bowel perforation occur in less than 1 in 1000 paracenteses. Ascitic fluid analysis should include total protein and albumin concentration, total and differential cell count, and, in selected patients, gram stain, bacterial culture, and cytology. The serum-ascitic fluid albumin gradient, which is the difference between the serum albumin and ascitic fluid albumin, has a

sensitivity and specificity of greater than 95% in differentiating ascites secondary to portal hypertension from other causes (Table II).

Other tests include ascitic fluid amylase, triglyceride, glucose, and lactate dehydrogenase (LDH) concentration. The nucleated cell count is less than 500 cells/mm^3, with fewer than 250 neutrophils/mm^3 in uninfected ascites secondary to portal hypertension. Ascitic fluid cytology has a low sensitivity in the diagnosis of malignancy but is highly specific. Ascitic fluid culture has a sensitivity of only 50% in the diagnosis of tuberculous peritonitis. Chylous ascites is diagnosed when ascitic fluid triglyceride concentrations are higher than simultaneously drawn serum triglyceride concentrations. Grossly hemorrhagic ascites may occur in 22% of cases of malignant ascites and in 50% of cases of ascites secondary to metastatic hepatocellular carcinoma. Hemorrhagic ascites due to malignancy is differentiated from hemorrhage caused by a needle trauma during paracentesis by the absence of clotting of the sample in malignant ascites.

MANAGEMENT

The goal of the management of ascites is to maintain a negative sodium balance. This is achieved with dietary sodium restriction and the use of diuretics. Response to dietary sodium restriction alone, manifesting as weight loss of between 250 and 500 g/day and a decrease in ascites, occurs in 10–20% of patients. Most patients with ascites can be managed with dietary sodium restriction (90 mEq/day) along with use of a diuretic. Spironolactone is the diuretic of choice administered as a single dose. The initial dose is 50 mg/day and can be increased to a maximum dose of 400 mg/day as tolerated. Weight loss should not exceed 0.5–0.75 kg/day in patients without pedal edema, because this can lead to intravascular volume depletion and azotemia. Furosemide can be used in combination with spironolactone, but is associated with a greater likelihood of azotemia. The metabolic alkalosis and hypokalemia induced by excessive diuretic use may be associated with precipitation or worsening of hepatic encephalopathy.

REFRACTORY ASCITES

Most patients with ascites that is difficult to manage are noncompliant with their sodium restriction. A 24-hour urine sodium in excess of the restriction, in the presence of increasing ascites, indicates noncompliance. Refractory ascites includes diuretic-resistant ascites and diuretic-intractable ascites. Diuretic-resistant ascites is defined as ascites that cannot be managed with dietary sodium restriction and intensive diuretic use of spironolactone (400 mg/day) and furosemide (160 mg/day) for at least 1 week, or ascites that reaccumulates early despite this treatment regime. Diuretic-intractable ascites is defined as ascites that cannot be treated or that recurs as a result of inability to use an adequate diuretic regime due to diuretic-induced complications.

The mortality rates for patients with refractory ascites exceed 50% in 1 year and 80% in 2 years. Most patients with refractory ascites belong to Child class C. Medications that inhibit prostaglandin synthesis, such as nonsteroidal antiinflammatory drugs (NSAIDs), worsen renal function in patients with ascites and should not be used.

HEPATORENAL SYNDROME

Hepatorenal syndrome is the presence of impaired renal function as demonstrated by a glomerular filtration rate below 40 ml/minute or a serum creatinine >1.5 mg/dl in the presence of advanced liver disease and portal hypertension. Shock, bacterial sepsis, nephrotoxic agents, fluid loss, or excessive diuretic use should be excluded before the diagnosis is made. Patients with hepatorenal syndrome have proteinuria <500 mg/day with normal renal structure on light microscopy. Hepatorenal syndrome is of two types. In type 1 hepatorenal syndrome, there is a rapid progression in renal dysfunction, with the creatinine reaching a level >2.5 mg/dl or the creatinine clearance decreasing to <20 ml/minute in a period of less than 2 weeks. The progression in renal dysfunction is more gradual in type 2 hepatorenal syndrome. Type 1 hepatorenal syndrome is probably a more advanced stage of type 2 hepatorenal syndrome. Type 1 hepatorenal syndrome is seen predominantly in patients with alcoholic hepatitis and in patients with spontaneous bacterial peritonitis or other infections.

On the other hand, type 2 hepatorenal syndrome presents predominantly with refractory ascites.

The initial step in the approach to a patient suspected to have hepatorenal syndrome is to demonstrate a reduction in glomerular filtration rate or worsening in renal function by measuring serum creatinine or creatinine clearance. The next step is to rule out other causes of renal dysfunction. The fractional excretion of sodium helps in these cases, with a fractional excretion of sodium of <1.0 being seen in prerenal azotemia, hepatorenal syndrome, and glomerulonephritis. In glomerulonephritis, the urine sediment is grossly abnormal, whereas in prerenal azotemia, renal function improves with volume expansion. It must be emphasized that in the presence of aggressive use of diuretics, the fractional excretion of sodium can be >1.0, even when the underlying diagnosis is hepatorenal syndrome.

MANAGEMENT OF REFRACTORY ASCITES AND HEPATORENAL SYNDROME

Therapeutic Paracentesis

Refractory ascites can be managed with repeated large-volume paracentesis. However, removal of excessive peritoneal fluid can result in decreased effective intravascular volume, with decreased pulmonary capillary wedge pressure and atrial natriuretic peptide levels, and increased renin–angiotensin–aldosterone activity, the so-called postparacentesis circulatory dysfunction. Therefore, 6–8 grams of albumin should be infused intravenously for every liter of ascitic fluid that is removed to counteract this circulatory dysfunction. Patients undergoing large-volume paracenteses have been shown to have a higher response rate, shorter hospital stay, and fewer complications, with similar survival as compared to patients treated with diuretics.

Peritoneovenous Shunt

The LeVeen shunt is a subcutaneous peritoneovenous shunt placed between the superior vena cava and peritoneum via the internal jugular vein. It has no benefit in the reduction of mortality or complication rate as compared to patients undergoing repeated paracenteses for the treatment of refractory ascites. Complications include catheter infection, thrombosis, occlusion, and low-grade disseminated intravascular coagulation. Peritoneovenous shunts are currently seldom used because the alternative of transjugular intrahepatic portosystemic shunts is available for patients who fail paracentesis therapy.

Transjugular Intrahepatic Portosystemic Shunt

The transjugular intrahepatic portosystemic shunt (TIPS), placed by interventional radiologists, has largely replaced surgical shunts in the management of refractory ascites. The TIPS is effective in reducing activity of the renin–angiotensin–aldosterone system and hence leads to diuresis and natriuresis. Relatively normal renal function is required for a TIPS procedure to be effective in reducing ascites. The TIPS has been shown to be more effective than paracentesis in the treatment of ascites, but without a significant survival benefit and at increased costs. Small studies suggest a potential benefit of using the TIPS for type 1 hepatorenal syndrome, but the results may be influenced by patient selection. Important predictors of survival after a TIPS procedure include etiology of liver disease, prothrombin time, serum bilirubin, and serum creatinine. Complications include a high incidence of encephalopathy and shunt stenosis. The recommended indication for the TIPS in the management of refractory ascites is for patients who have an unsatisfactory response to paracentesis.

Surgical Portosystemic Shunts

Creating a side-to-side anastomosis between the portal vein and inferior vena cava leads to a reduction in portal pressure, natriuresis, diuresis, and relief of ascites. However, the high rates of mortality and complications from the procedure have led to the abandonment of the procedure for refractory ascites.

Orthotopic Liver Transplantation

Liver transplant is the only therapy for refractory ascites and hepatorenal syndrome associated with an improvement in long-term survival.

Summary

In summary, treatment of type 1 hepatorenal syndrome involves treatment of the underlying sepsis. A few studies have shown the benefit of using volume expansion with albumin in association with splanchnic vasoconstrictor agents such as terlipressin or midodrine, octreatide, or norepinephrine. The treatment of type 2 hepatorenal syndrome, which in effect is treatment of refractory ascites, is with large-volume paracentesis and, if this fails, transjugular intrahepatic portosystemic shunts. The role of a TIPS in the treatment of type 1 hepatorenal syndrome is not established. Liver transplantation is the only treatment option associated with long-term improvement in survival in patients with hepatorenal syndrome.

SPONTANEOUS BACTERIAL PERITONITIS

Ascitic fluid paracentesis should be carried out in all patients with new-onset ascites, at the time of hospital admission, and in patients with fever, abdominal pain, worsening encephalopathy, or renal insufficiency. An ascitic fluid absolute neutrophil count of $\geq 250/mm^3$ (neutrocytic ascites) is required for the diagnosis of spontaneous bacterial peritonitis (SBP). The ascitic fluid protein concentration is usually less than 1 g/dl. Most common organisms seen in SBP include *Escherichia coli, Streptococcus pneumoniae,* and *Klebsiella pneumoniae*. Diagnostic yield of ascitic culture is increased if ascitic fluid is inoculated into blood culture bottles immediately on paracentesis. Secondary bacterial peritonitis is polymicrobial, as opposed to monomicrobial SBP. SBP is characterized by a very low bacterial count and thus gram stain carries a sensitivity of 10% or lower in the diagnosis of spontaneous bacterial peritonitis. Secondary bacterial peritonitis should be suspected if ascitic fluid protein is more than 1 g/dl, glucose is less than 50 mg/dl, and ascitic fluid LDH is greater than serum LDH. The antibiotic of choice for the treatment of SBP is a third-generation cephalosporin, usually cefotaxime. Response to treatment is determined by demonstrating a reduction in the ascitic fluid neutrophil count of greater than 25%. Patients who have experienced even one episode of SBP should be treated indefinitely with quinolones such as norfloxacin to prevent subsequent episodes. The only other indication for antibiotic prophylaxis is in the patient with cirrhosis who has acute gastrointestinal bleeding, for which norfloxacin is given for up to 7 days. SBP is associated with a 1-year survival of between 40 and 70%, and consequently all patients with SBP should be evaluated for liver transplantation.

HEPATIC HYDROTHORAX

Hepatic hydrothorax is defined as pleural effusions >500 ml in patients with cirrhosis of the liver in the absence of cardiopulmonary or subdiaphragmatic pathology. The pathophysiology of hepatic hydrothorax is similar to the pathophysiology of ascites. In fact, it is ascitic fluid that moves from the peritoneal cavity into the pleural space through diaphragmatic defects. Because intrathoracic pressure is negative, this favors movement of fluid into the thoracic space. Thus, patients may have hepatic hydrothorax even in the absence of ascites. The right pleural space is more commonly involved. Similar to patients with ascites, patients with hepatic hydrothorax can have spontaneous bacterial infection of the fluid that results in spontaneous bacterial empyema.

Patients with hepatic hydrothorax have advanced liver disease and are usually candidates for liver transplantation. Therapy in such patients is directed at relieving symptoms and preventing pulmonary complications until such time that a liver transplant can be carried out. The initial management is with sodium restriction and diuretics, similar to the management of patients with ascites. Therapeutic thoracocentesis is carried out to relieve symptoms of dyspnea. Pleurodesis and chest tube placement should be avoided at all costs. If sodium restriction and diuretics fail, then transjugular intrahepatic portosystemic shunts can be placed. These shunts are usually effective in preventing the accumulation of fluid in the pleural space.

MANAGEMENT OF MALIGNANT ASCITES

Diuretics are not effective in the treatment of malignant ascites. Therapeutic paracenteses may be employed to alleviate pressure symptoms related to large-volume ascites. Peritoneovenous shunts have occasionally been placed in patients with malignant ascites and may have a role in treating patients with a life expectancy greater than a few months. There is no evidence to support the theory of widespread metastases due to dissemination of malignant cells via the shunt, leading to decreased survival rates.

Atrophic Gastritis

atrophic gastritis Loss of the glandular structures and a collapse of the reticulin skeleton of the gastric mucosa, with thinning of the glandular layer of the mucosa and replacement of glands by fibrosis and sometimes by intestinal-type cells.

chronic active gastritis Condition of chronic inflammation of the gastric mucosa associated with neutrophilic infiltration.

Helicobacter pylori Gram-negative rod-shaped bacterium that is able colonize the human gastric mucosa and induce chronic active gastritis.

intestinal metaplasia Condition in which the intestinal cells in the gastric mucosa become metaplastic.

The anatomy and function of the gastric mucosa remain unchanged throughout life, but can be disturbed by the occurrence of chronic active gastritis. Although this can be due to a variety of conditions, the most common cause is colonization with *Helicobacter pylori*. In a considerable proportion of affected subjects, chronic active gastritis leads to a loss of the glandular structures and a collapse of the reticulin skeleton of the mucosa, a condition called atrophic gastritis. As a result, the glandular layer of the mucosa becomes thinner and glands are replaced by fibrosis and sometimes by intestinal-type cells. This intestinal metaplasia may resemble either small bowel mucosa with sialomucin-containing goblet cells or colonic mucosa with sulfomucin-containing columnar cells, or a mixture of both.

INTRODUCTION

The exact mechanisms by which inflammation leads to atrophic gastritis and intestinal metaplasia are still unknown, but toxic bacterial and inflammatory products, dysregulated cell turnover, and autoimmunity may all play a role. In those with *Helicobacter pylori* gastritis, *H. pylori* eradication may halt the process, or even lead to a partial regression of atrophic gastritis. The risk for atrophic gastritis in subjects with chronic active gastritis particularly depends on the severity and distribution of inflammation.

SYMPTOMS

Chronic active gastritis and atrophic gastritis are mostly symptomless conditions, although some *H. pylori*-positive subjects may suffer from dyspepsia and may possibly benefit from *H. pylori* eradication. Subjects with severe atrophic gastritis of the corpus mucosa may ultimately develop megaloblastic anemia or myelopathy; these signs of vitamin B_{12} deficiency are due to impaired vitamin uptake as a result of insufficient intrinsic factor secretion and reduced peptic digestion of food–B_{12} complexes.

DIAGNOSIS

Atrophic gastritis is usually diagnosed by means of microscopic evaluation of gastric biopsy specimens obtained during endoscopy. Endoscopy without biopsy sampling is insufficient to diagnose or rule out atrophic gastritis. The demonstration of reduced basal and stimulated gastric acid output may support a diagnosis of atrophic gastritis, but this test is not routinely used. Serum pepsinogen and gastrin levels can also help to

diagnose atrophic gastritis, in particular for the purpose of population screening. A diagnosis of chronic active gastritis is then usually based on a positive serology for *H. pylori*, and a diagnosis of atrophic gastritis is based on a combination of increased serum gastrin levels and decreased serum pepsinogen levels, in particular a decrease of the serum pepsinogen I/pepsinogen II ratio.

ASSOCIATION WITH GASTRIC CANCER

The major clinical importance of atrophic gastritis is the increased risk for the intestinal type of gastric cancer. This risk may be elevated up to 90-fold in subjects with severe atrophic gastritis throughout the entire stomach. The annual incidence of gastric cancer among patients with atrophic gastritis is estimated to be between 0.3 and 1.0%.

Different factors may play a role in the increased risk for gastric cancer. Among these are the persistently increased cell turnover in atrophic mucosa, the increased mutagenesis caused by higher levels of nitrite and decreased levels of ascorbic acid in the gastric juice, and the lack of acid secretion, leading to decreased clearance of cells from newly arising carcinoma *in situ* microlesions.

Mayo Clinic and Foundation

autoimmune hepatitis Self-perpetuated liver inflammation of unknown cause associated with autoantibodies, increased serum gamma globulin level, interface hepatitis on histological examination, and responsiveness to corticosteroid therapy.

bridging necrosis Histological pattern of severe liver inflammation in which the inflammatory infiltrate and evidence of hepatocyte damage extend from portal tract to portal tract or portal tract to central vein.

interface hepatitis The *sine qua non* for the histological diagnosis of autoimmune hepatitis involves disruption of the limiting plate of the portal tract with extension of a mononuclear, frequently plasmacytic, infiltrate into acinar tissue in association with evidence of hepatocyte damage.

multiacinar necrosis Histological pattern of severe liver inflammation in which the inflammatory infiltrate and evidence of hepatocyte damage extend across and collapse lobules of liver tissue.

primary biliary cirrhosis Autoimmune liver disease characterized by antimitochondrial antibodies, cholestatic laboratory indices, and histological features of bile duct injury, including destructive or granulomatous cholangitis ("florid duct lesions").

primary sclerosing cholangitis Autoimmune liver disease, frequently associated with inflammatory bowel disease, that is characterized by cholangiographic changes of bile duct narrowing, cholestatic laboratory indices, and histological features of bile duct injury or biliary obstruction.

relapse Recrudescence of clinical, biochemical, and histological activity after discontinuation of corticosteroid therapy following induction of remission.

remission Disappearance of symptoms, improvement in serum aspartate aminotransferase activity to normal or less than twice normal, normal serum bilirubin and gamma globulin levels, and histological resolution to normal or near normal.

treatment failure Worsening of symptoms, laboratory indices of liver inflammation, and/or histological features despite compliance with therapy.

variant Lack of classical features of a single disease.

Autoimmune hepatitis is a self-perpetuated inflammation of the liver of unknown cause; it is characterized by interface hepatitis on histological examination, hypergammaglobulinemia, autoantibodies, and responsiveness to corticosteroid therapy. There are no pathognomonic features, and the diagnosis requires exclusion of virus-related, drug-induced, and hereditary conditions that may resemble it.

PREVALENCE

In the United States, 100,000–200,000 persons have autoimmune hepatitis and the condition accounts for 5.9% of the liver transplantations. The incidence of autoimmune hepatitis among Caucasian Northern Europeans is 1.9 per 100,000 population and its point prevalence is 16.9 per 100,000 population. Women have a threefold greater incidence of the disease compared to men, and the disease occurs in all age groups, in diverse ethnic populations, and in far-flung geographic regions.

DIAGNOSIS

The diagnostic criteria for autoimmune hepatitis have been codified by an international panel. An acute, occasionally fulminant, presentation has been recognized, and the requirement for 6 months of disease activity to establish chronicity has been waived. Cholestatic biochemical changes and histological features of bile duct destruction dissuade the diagnosis, whereas viral infection or drug-induced injury precludes it.

Clinical Criteria

The definite diagnosis requires a normal α1-antitrypsin phenotype; normal serum ceruloplasmin, iron, and ferritin levels; absence of markers of active hepatitis A, B, and C virus infection; daily alcohol intake of less than 25 g; no recent exposure to hepatotoxic drugs; predominant serum aminotransferase abnormality; serum globulin, gamma globulin, or immunoglobulin G levels of at least 1.5 times the upper limit of normal; presence of antinuclear antibodies (ANAs), smooth muscle antibodies (SMAs), or antibodies to liver/kidney microsome type 1 (anti-LKM1) in titers $\geq$1 : 80; absence of antimitochondrial antibodies (AMAs); at

least moderate to severe interface hepatitis on histological examination; and no histological evidence of biliary lesions, granulomas, or other prominent changes suggestive of another disease.

The probable diagnosis is justified by partial α1-antitrypsin deficiency; nonspecific abnormalities in serum ceruloplasmin, iron, and ferritin levels; alcohol intake of up to 50 g/day; low-level hypergammaglobulinemia; and low titers ($<1:80$) of ANA, SMA, or anti-LKM1, or the presence of other autoantibodies, including antibodies to soluble liver antigen/liver pancreas (anti-SLA/LP), asialoglycoprotein receptor (anti-ASGPR), actin (anti-actin), neutrophil cytoplasm (perinuclear anti-neutrophil cytoplasm antibodies, pANCAs), or liver cytosol type 1 (anti-LC1). Moderate to severe interface hepatitis must be present in the liver tissue, and prominent biliary lesions, granulomas, or features suggesting another diagnosis must be absent.

Scoring Criteria

A scoring system has been promulgated by the International Autoimmune Hepatitis Group to quantify the strength of the diagnosis, prevent isolated inconsistent findings from discounting the disease, and ensure the homogeneity of patient populations in clinical reports and treatment trials (Table I). The score based on pretreatment features can be upgraded or downgraded by the response to treatment. The sensitivity of the scoring system for definite autoimmune hepatitis ranges from 97 to 100%, and its specificity for excluding the disease in patients with chronic hepatitis C ranges from 66 to 92%. Its major weakness has been in discounting cholestatic syndromes with autoimmune features. In most instances, the scoring system is unnecessary for diagnosis, and its major value may be in the objective assessment of variant or atypical syndromes.

TYPES

Three types of autoimmune hepatitis have been proposed based on their autoantibody profiles. This subclassification has not been established because the various types do not have different etiologies, outcomes, or treatment requirements.

Type 1 Autoimmune Hepatitis

Type 1 autoimmune hepatitis is the most common form of autoimmune hepatitis worldwide, affecting at least 80% of all patients. ANAs and/or SMAs are its serological hallmarks. Concurrent immune diseases, especially autoimmune thyroiditis, are present in 38% of patients, and cirrhosis is established at presentation in 25% of patients. The target autoantigen is unknown.

Type 2 Autoimmune Hepatitis

Type 2 autoimmune hepatitis is characterized by anti-LKM1. It affects mainly children from ages 2 to 14 years, and it can occur in the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy

TABLE I Scoring Criteria for Definite and Probable Diagnoses of Autoimmune Hepatitis[a,b]

Feature	Score	Feature	Score
Female	+2	Hepatotoxic drug exposure	−4
AP:AST ratio		No drug or toxin exposure	+1
Low ratio (<1.5)	+2	Average alcohol <25 g/day	+2
High ratio AP (>3.0)	−2	Average alcohol >60 g/day	−2
Globulin, gamma globulin, or immunoglobulin G level		Interface hepatitis	+3
		Lymphoplasmacytic infiltrate	+1
High level (>2 ULN)	+3	Rosette formation	+1
Moderate level (1.5−2 ULN)	+2	No typical histologic features	−5
Mild level (1−1.5 ULN)	+1	Biliary changes	−3
Autoantibodies (conventional)		Other features (fat, granulomas)	−3
Titer > 1:80	+3	Concurrent immune disease	+2
Titer 1:80	+2	Other autoantibodies	+2
Titer 1:40	+1	HLA DR3 or DR4	+1
Antimitochondrial antibodies	−4	Response to corticosteroids	+2
Active hepatitis A, B, or C	−3	Relapse after drug withdrawal	+3
Absent hepatitis markers	+3

(APECED). The disease is most common in Germany and France, where 20% of patients are adults. The target autoantigen is the cytochrome monooxygenase, CYP 2D6. Concurrent immune diseases include insulin-dependent diabetes mellitus, autoimmune thyroiditis, and vitiligo.

Type 3 Autoimmune Hepatitis

Type 3 autoimmune hepatitis is characterized by the presence of anti-SLA/LP. The target autoantigen may be a transfer ribonucleoprotein complex involved in the incorporation of selenocysteine into polypeptide chains. The clinical features and outcome are indistinguishable from type 1 autoimmune hepatitis.

PATHOGENESIS

Loss of Self-Tolerance

The negative selection of autoreactive immunocytes within the thymus can be defective during ontogeny. Polymorphisms in autoimmune regulator genes can enhance this defect. Molecular mimicry between foreign and self-antigens can result in cross-reactive immunological responses. Autoimmunity induced against one self-antigen can spread via intermolecular epitope mimicry to other homologous self-antigens and to anatomically distant tissue sites. The degree of antigenic homologies, the antigenic dose, and the genetic predisposition of the host determine the risk of disease.

Genetic Predisposition

The risk factors for type 1 autoimmune hepatitis in Caucasian North Americans and Northern Europeans are human leukocyte antigens (HLAs) HLA DR3 and HLA DR4. HLA DR3 is associated with early age-onset disease and a higher frequency of treatment failure and requirement for liver transplantation, compared to HLA DR4. In contrast, HLA DR4 is associated with late age onset, responsiveness to corticosteroid therapy, and frequent concurrent immune diseases.

The principal susceptibility allele of type 1 autoimmune hepatitis is *DRB1*0301*, and the secondary and independent susceptibility allele is *DRB1*0401*. Each allele encodes an identical six-amino-acid sequence (LLEQKR) between positions 67 and 72 on the DRβ polypeptide chain of the class II molecule of the major histocompatibility complex (MHC). A lysine residue (K) at position DRβ71 is the critical contact point between the antigenic peptide, class II MHC molecule, and T cell antigen receptor of the CD4 T helper cell. It may be the principal single determinant of susceptibility.

Other HLA DR4 alleles affect susceptibility in different ethnic groups, but they each encode an amino acid of charge and structure similar to that of lysine at position DRβ71. The principal susceptibility allele in Mestizo Mexicans is *DRB1*0404*, and it is *DRB1*0405* in Japanese and Argentine adult patients. The principal susceptibility allele among Argentine children and Brazilian patients is *DRB1*1301*, which may predispose to protracted infection with hepatitis A virus and prolonged exposure to hepatic self-antigens.

Polymorphisms of disease-nonspecific autoimmune promoters may act in synergy with the principal risk factors to affect disease susceptibility and outcome. Among Caucasian North Americans and Northern Europeans, polymorphisms of the tumor necrosis factor-α gene (*TNFA*2*), at position −308, and the cytotoxic T lymphocyte antigen-4 gene (*CTLA-4*) are associated with the risk of disease.

Cytodestructive Mechanisms

The principal effectors of liver cell destruction are antigen-specific clones of liver-infiltrating CD8 cytotoxic lymphocytes, the differentiation of which is modulated by type 1 cytokines, including interleukin-2, interferon γ, and tumor necrosis factor α. Antibody-dependent cell-mediated cytotoxicity is also involved under the mediation of type 2 cytokines, especially interleukin-10, and antigen−antibody complexes on the hepatocyte surface can attract natural killer cells that destroy the cell.

TREATMENT

Indications

Symptoms of fatigue, myalgia, and/or jaundice; serum (asparate aminotransferase, AST) levels of at least 10-fold normal or at least 5-fold normal in conjunction with serum gamma globulin levels of at least twice normal; and the presence of moderate to severe interface hepatitis, bridging necrosis, or multilobular necrosis on histological assessment are absolute indications for treatment. Less severe indices of disease activity are relative indications for treatment, and inactive disease does not require therapy.

Schedules

Regimens based on prednisone alone or a lower dose of prednisone in combination with azathioprine are equally effective and superior to no therapy or nonsteroidal schedules in managing all forms of autoimmune hepatitis (Table II).

TABLE II Treatment Regimens in Autoimmune Hepatitis

	Starting treatment dose (mg/day)			Withdrawing treatment dose (mg/day)		
Week	Prednisone only	Prednisone	Azathioprine	Prednisone only	Prednisone	Azathioprine
1	60	30	50	15	7.5	50
2	40	20	50	10	7.5	50
3	30	15	50	5	5	50
4	30	15	50	5	5	25
5	20	10	50	2.5	2.5	25
6		Fixed daily doses thereafter		2.5	2.5	25
7		Maintenance until end point		None	None	None

End Points

Treatment should be continued until disappearance of symptoms; normal or near normal serum AST, bilirubin, and gamma globulin levels; and inactive or minimally active histological findings. The average duration of treatment until remission in severe disease is 22 months. Therapy should then be withdrawn in a tapered fashion over a 6-week period while serum AST, bilirubin, and gamma globulin levels are monitored for relapse (Table II). Deterioration despite compliance with therapy (treatment failure) and drug intolerance are other end points of standard therapy.

TREATMENT FAILURE

Worsening symptoms, an increase in the serum AST and/or bilirubin levels by 67% of pretreatment values, and/or histological progression to bridging necrosis or multiacinar collapse indicate treatment failure. The management strategy must be modified by increasing the doses of medication or proceeding to liver transplantation.

Drugs

The dose of prednisone is increased to 60 mg daily if it is the sole drug or to 30 mg daily if it is combined with azathioprine. The dose of azathioprine is increased to 150 mg daily. The prednisone dose is then reduced by 10 mg and the azathioprine dose is reduced by 50 mg after each month of improvement until conventional maintenance levels are reached.

Liver Transplantation

Manifestations of decompensation despite therapy compel liver transplantation. Patient and graft survival rates after liver transplantation for autoimmune hepatitis range from 83 to 92%, and the actuarial 10-year survival is 75%. Autoimmune hepatitis recurs in 17% of patients, especially in those who are receiving inadequate immunosuppression, but it is usually managed satisfactorily by adjustments in the immunosuppressive regimen.

RELAPSE

Recrudescence of symptoms, increase in the serum AST level to more than threefold normal, and/or histological features of interface hepatitis after corticosteroid withdrawal connote relapse of the disease and the need for retreatment. Reapplication of the original treatment schedule reliably induces remission, but another relapse is common after drug withdrawal. Long-term maintenance schedules based on low-dose prednisone alone (less than 10 mg daily) or azathioprine alone (2 mg per kg daily) are effective indefinite management strategies after multiple relapses following conventional treatment and withdrawal.

PROMISING TREATMENTS

Drugs

Anecdotal successes with cyclosporine (5–6 mg per kg daily), tacrolimus (3 mg twice daily), mycophenolate mofetil (1 g twice daily), and 6-mercaptopurine (1.5 mg per kg daily) have been reported in the treatment of small numbers of patients recalcitrant to conventional corticosteroid therapies. Rigorous clinical trials are necessary to establish fully their benefit–risk ratios and their superiority to prednisone and azathioprine.

Site-Specific Interventions

Treatments based on targeted interruptions of the critical pathogenic pathways are the hopes for the future. These would include (1) peptides that could compete with self-antigens for the antigen-binding

groove of class II MHC molecules, (2) soluble cytotoxic lymphocyte antigen-4, which could dampen immunocyte activation, (3) T cell vaccines that could protect against clonal expansion of antigen-sensitized, liver-infiltrating CD8 cytotoxic T cells, (4) oral tolerance programs that could induce CD4 T helper cell anergy or apoptosis, (5) cytokine antibodies or recombinant products that could modulate the cytokine profile, and (6) gene therapies that could deliver regenerative growth factors and/or counterbalance polymorphic genes promoting immune reactivity.

VARIANT FORMS

Variant forms are conditions in which the classical features of autoimmune hepatitis are intermixed with features of primary biliary cirrhosis, primary sclerosing cholangitis, or chronic viral hepatitis. Eighteen percent of patients with autoimmune liver disease can be reclassified as having variant syndromes. Treatment is empiric and based on the predominant manifestations of the disease. Corticosteroids are used in the treatment of patients with serum alkaline phosphatase levels of less than twofold normal. Ursodeoxycholic acid alone or in combination with corticosteroids is appropriate for patients with pruritus and/or higher serum alkaline phosphatase levels. Patients with chronic viral hepatitis and autoimmune features must be distinguished from patients with autoimmune hepatitis and coincidental viral infection, because antiviral or immunosuppressive drugs are treatment options.

Autonomic Innervation

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

ganglia Clusters of nerve cell bodies outside the central nervous system.

postganglionic neuron A ganglionic neuron that receives synaptic input from the central nervous system and sends its axon to innervate peripheral organs.

preganglionic neuron A neuron that projects from the brain or spinal cord to form synapses with neurons in ganglia.

Innervation of the digestive tract by the autonomic nervous system (ANS) automatically controls contractile behavior of the musculature, secretion and absorption across the mucosal lining, and blood flow inside the walls of the esophagus, stomach, intestines, and gallbladder. Autonomic control is ongoing and normally occurs below the level of conscious perception. Depending on the kind of neurotransmitter released, ANS motor neurons may evoke muscle contraction or actively inhibit contraction. Secretion of water, electrolytes, and mucus into the lumen and absorption from the lumen are determined by motor neurons of the ANS innervation. The amount of blood flow and the distribution of flow between the muscle layers and mucosa are also controlled by ANS nervous activity.

AUTONOMIC INTEGRATIVE CENTERS

Autonomic integrative centers are positioned both in the central nervous system (CNS) and in peripheral locations. The autonomic nervous system (ANS) control centers are hierarchically structured with five basic levels of integrative organization that can be identified (Fig. 1). Level 5 is the enteric nervous system (ENS), which behaves like a local "minibrain" within the gut itself. The next higher level of integrative organization is in the prevertebral ganglia of the sympathetic division of the ANS. Levels 1, 2, and 3 are within the CNS. Sympathetic and parasympathetic divisions of the ANS transmit signals to the digestive tract. The signals originate in central parasympathetic and sympathetic centers represented by Levels 2 and 3 in the medulla oblongata (Fig. 1). The nerves that carry the outflow from these medullary centers are the final common pathways out of the CNS en route to the gut. Level 1 includes higher brain centers that provide input for integrative functions at Levels 2 and 3. The peripheral ANS innervation, which connects the CNS to the gut, is subdivided into three parts consisting of the sympathetic, parasympathetic, and enteric divisions (Fig. 2).

The pathways formed by the sympathetic and parasympathetic divisions represent the extrinsic component of ANS innervation. Neurons of the enteric division form the local intramural control networks and are the intrinsic components of innervation. The parasympathetic and sympathetic divisions are identified by the location of the last neuron in the pathway to the gut and by the point of outflow from the CNS.

PERIPHERAL AUTONOMIC CONNECTIONS

The cell bodies of the last neurons in autonomic pathways to the gut are in structures called ganglia. A

Level 1 includes higher brain centers that provide input for integrative functions at Levels 2 and 3. Sympathetic and parasympathetic signals originate at Levels 2 and 3 in the brain's medulla oblongata and represent the final common pathways for outflow of information from the central nervous system to the gut. ganglion is defined as a cluster of neuronal cell bodies located outside the ENS. Cell bodies of the next to last neurons in the autonomic pathways are in the CNS.

Sympathetic Division

Figure 3 illustrates the location of the ganglia of the sympathetic nervous system in relation to the spinal cord and ENS. The neurons in the spinal cord are called preganglionic neurons. Preganglionic sympathetic neurons have their cell bodies in the intermediolateral horn of the spinal cord between the first thoracic and the third lumbar spinal segments. The locations and areas of emergence of sympathetic preganglionic neurons from the spinal cord are the basis for sometimes referring to the sympathetic nervous system as the ANS thoraco-lumbar division. Preganglionic sympathetic neurons project their axons out of the spinal cord to form synapses with neurons in ganglia that are located in the abdomen. The ganglia in the abdomen are called prevertebral sympathetic ganglia. There are three prevertebral ganglia. One is the celiac ganglion, the second is the superior mesenteric, and the third is the inferior mesenteric ganglion. Neurons in the prevertebral ganglia are postganglionic neurons. These postganglionic sympathetic neurons form synapses with neurons in the ENS. The primary neurotransmitter released at synapses between pre- and postganglionic neurons is acetylcholine. The main neurotransmitter released at synapses with enteric neurons is norepinephrine.

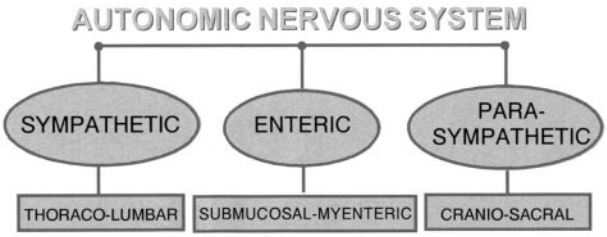

FIGURE 2 Three divisions of the autonomic nervous system innervate the digestive tract. The digestive tract is innervated by the autonomic nervous system and by sensory nerves that project from the gut to the brainstem and spinal cord. The cell bodies of autonomic neurons are found in the brainstem, in the sacral region of the spinal cord, in ganglia within the walls of the digestive tract, and outside the digestive tract in the abdomen. The sympathetic, parasympathetic, and enteric divisions make up the autonomic innervation. Sympathetic and parasympathetic pathways transmit signals from the brain and spinal cord to the gut. This is called the extrinsic component of innervation. Neurons of the enteric division form the local intramural control networks making up the intrinsic component of innervation. The parasympathetic and sympathetic divisions are identified by the positions of the ganglia containing the cell bodies of the second-order postganglionic neurons and by the point of outflow from the brain or spinal cord. Postganglionic neurons of the sympathetic division are located in prevertebral sympathetic ganglia located in the abdomen and the outflow is from the spinal cord between the first thoracic and third lumbar segments. The sympathetic division can therefore be referred to as the thoraco-lumbar division of the autonomic nervous system. Second-order parasympathetic neurons are part of the neural networks that make up the enteric division and the outflow is from the medulla oblongata of the brain and the sacral segments of the spinal cord. Another term for the parasympathetic division is therefore the cranio-sacral division of the autonomic nervous system. The neurons of the enteric division are synaptically interconnected into local neural networks that behave like a "brain-in-the-gut." The cell bodies of the neurons of the enteric division are positioned in the submucosal and myenteric plexuses within the walls of the gut.

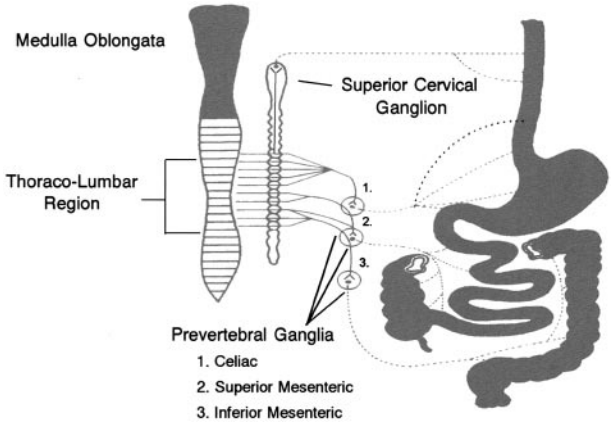

FIGURE 3 Sympathetic neural pathways to the digestive tract consist of preganglionic neurons that have their cell bodies in the spinal cord and postganglionic neurons with their cell bodies located in prevertebral sympathetic ganglia in the abdomen. There are three prevertebral ganglia known as the celiac, superior mesenteric, and inferior mesenteric. There are two synapses in the sympathetic pathways. One is a synapse in the prevertebral ganglia between pre- and postganglionic neurons that uses acetylcholine and nicotinic receptors in neurotransmission. The second is a synapse between postganglionic sympathetic neurons from the sympathetic ganglia and neurons of the enteric nervous system that uses norepinephrine as a neurotransmitter.

Parasympathetic Division

Cell bodies of neurons of the parasympathetic division of the ANS are located either in the brainstem (medulla oblongata) or in the sacral region of the spinal cord. The parasympathetic division is sometimes referred to as the ANS cranio-sacral division, based on the anatomical distribution of the parasympathetic neuronal cell bodies. These neurons project their axons to form synapses with neurons in the ganglia of the ENS (Fig. 4). The terms "preganglionic" and "postganglionic"

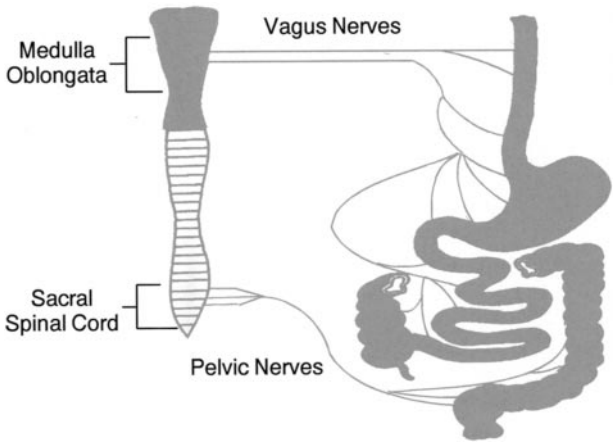

FIGURE 4 Neurons of the autonomic parasympathetic division project from the medulla oblongata and sacral regions of the spinal cord. The parasympathetic division of the autonomic innervation is subdivided anatomically into cranial and sacral divisions due to the neuroanatomic organization in which neurons that project to the digestive tract are located both in the brainstem and in the sacral region of the spinal cord. Neuronal cell bodies of the cranial division reside in the medulla oblongata and project in the vagus nerves. Cell bodies of the sacral division are located in the sacral regions of the spinal cord and project in the pelvic nerves to the large intestine. Efferent vagal fibers form synapses with neurons in the enteric nervous system of the esophagus, stomach, small intestine, colon, gallbladder, and pancreas. Efferent fibers in the pelvic nerves form synapses with neurons in the enteric nervous system.

are no longer used in discussion of the parasympathetic innervation of the gastrointestinal tract. These terms imply that ganglia of the enteric nervous system are like parasympathetic ganglia in other organs and function as simple relay-distribution centers for information from the central nervous system. Ample evidence suggests that the neurophysiology of enteric ganglia is more complex than that of other parasympathetic ganglia that function as simple relay-distribution stations.

ENTERIC DIVISION

The vagus nerves are a major parasympathetic transmission pathway for control signals from the brain to the digestive tract as far down as the proximal to mid large intestine and the sacral nerves represent the major pathway to the distal large intestine. Both vagal and sacral parasympathetic nerves are a source of synaptic input to neurons in the ENS. Earlier concepts portrayed the ganglia of the ENS as a simple relay-distribution function for transmission from the CNS to the gut musculature and secretory glands. This concept has been modernized and changed.

New awareness of the independent integrative properties of the ENS has led to revision of earlier concepts of mechanisms of vagal and sacral nerve influence. Earlier concepts of parasympathetic innervation presumed that ganglia of the digestive tract were the same as parasympathetic ganglia in other visceral systems where the ganglia generally have a relay-distribution function. The previous concepts assumed that parasympathetic innervation of the gut was similar. Preganglionic parasympathetic fibers were believed to form synapses directly with ganglion cells that innervated the muscles and thereby evoke muscle contractions. This concept, illustrated in Fig. 5, is inconsistent with later evidence and has been abandoned.

The earlier concept placed the "computer" entirely within the brain. Current concepts place integrative neural networks in the ENS in close proximity to the motor and secretory systems that require control. Numbers of neurons equal to those of the spinal cord are present in the ENS. The large number of neurons required for program control of the digestive processes would greatly expand the volume of the CNS if situated there. Rather than having the neural control circuits packed exclusively within the CNS and transmitting control information over long transmission lines to the gut, vertebrate animals have most of the neural circuits for automatic feedback control (i.e., setpoint control) located in close apposition to the musculature, secretory glands, and blood vessels.

Figure 5 illustrates the current concept of CNS involvement in gut function. Local integrative circuits of the ENS are organized for program operations independent of input from the CNS. Subsets of neural circuits are preprogrammed for control of distinct patterns of behavior in each effector system (i.e., musculature, glands, and blood vascular system) and for the coordination of activity of multiple systems. Enteric motor neurons are the final common transmission pathways for the variety of different programs and reflex circuits required for ordered gut function.

Rather than controlling a multitude of motor neurons individually, messages transmitted by parasympathetic efferent fibers are command signals for the activation of expanded blocks of integrated circuits positioned in the gut wall. This explains the strong influence of a small number of parasympathetic efferent fibers (only 10% of fibers in the vagus nerves go to the gut and other viscera; 90% of the fibers are sensory afferents) on the musculature and glands over extended

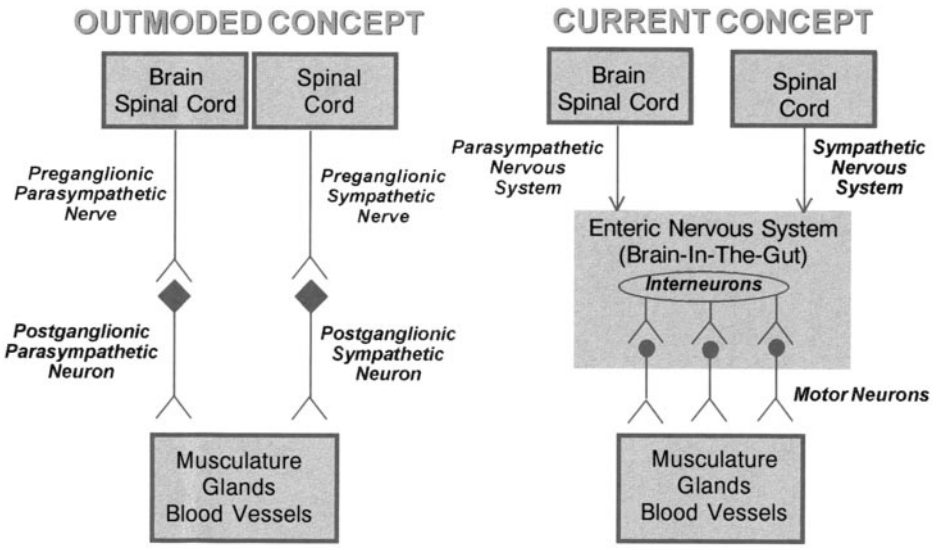

FIGURE 5 Concepts of how the autonomic nervous system controls the behavior of the digestive tract have been changed by improved knowledge of the neurophysiology of the enteric nervous system. The current concept (right) recognizes that the enteric nervous system, like the brain and spinal cord, consists of networks of interneurons and motor neurons with directional flow of neural information from interneurons to motor neurons to the effectors (i.e., the musculature, glands, and blood vessels). Commands to the enteric nervous system from the central nervous system are transmitted by parasympathetic and sympathetic neural pathways. The outmoded concept (left) assumed that all of the integrative circuitry for the minute-to-minute control of the digestive tract resided in the central nervous system and that parasympathetic and sympathetic postganglionic neurons were the motor neurons to the effector systems of the digestive tract.

regions of the stomach or intestine. In this respect, the ENS is analogous to a microcomputer with its own independent software, whereas the brain is like a larger mainframe with extended memory and processing circuits that receive information from and issue commands to the enteric computer.

SENSORY INNERVATION

The ANS is an automatic control system that maintains the many parameters of digestive function at constant levels, sometimes referred to as setpoint determinations. Examples are the determination of constant acidity (i.e., pH setpoint) in the small intestine, constant osmolarity in the small intestine, and a set amount of contractile tension in a given muscle. In order to control a parameter so that its value remains at or close to the setpoint, the integrative neural networks of the ANS must be able to make continuous calculations of the deviation of the actual value of the parameter from the setpoint. Calculation of the deviation from setpoint requires a continuous flow of information on the actual value of the parameter as various perturbations cause the parameter to increase or decrease. Information on parameters such as acidity, osmolarity, and muscle tension is generated by the sensory innervation of the gut. The sensory information is transmitted to the central nervous system by sensory afferent nerves that project to the spinal cord and the brainstem.

Sensory projections to regions of the spinal cord above the sacral region are called splanchnic afferents; the projections to the sacral cord are known as sacral afferents. Splanchnic afferent fibers from the intestines and sympathetic efferent fibers to the intestine occur in the same "mixed" nerves. The mixed nerves accompany the blood vessels in the mesentery and carry two-way traffic between the spinal cord and the gut. A common error of referring to the sensory nerves as "sympathetic afferents" has emerged from the anatomical presence of splanchnic afferents and sympathetic efferents in the same mixed nerves. The sympathetic division of the autonomic nervous system does not include sensory nerves and to apply the term sympathetic afferent is incorrect.

Bacterial Overgrowth

PHILLIP P. TOSKES
University of Florida College of Medicine

Crohn's disease Chronic disorder characterized by patchy transmural inflammation; may affect any portion of the gastrointestinal tract, but most commonly involves the ileum and colon.
malabsorption Failure to digest and absorb dietary nutrients.
steatorrhea Increased fat in stool due to malabsorption.

The development of malabsorption in a patient with overgrowth of bacteria within the small intestine is known as bacterial overgrowth, a condition that develops when the mixture of bacterial flora of the proximal small intestine becomes more like that of the healthy colon. When colonic-type flora inhabit the proximal small intestine, the bacteria compete for the nutrients ingested by the human host. What ensues is a complex array of clinical problems resulting from intraluminal bacterial catabolism of nutrients, often leading to toxic metabolites and direct injury to the small intestinal enterocyte.

NORMAL ENTERIC FLORA

The proximal small intestine is normally inhabited by a few bacteria, usually lactobacilli, enterococci, gram-positive aerobes, or facultative anaerobes, present in concentrations of up to 10^3 viable organisms per milliliter of jejunal secretions. Qualitative and quantitative changes appear at the ileum and become quite striking in the colon. In the colon, the bacterial population increases up to 1 million times and reaches 10^9–10^{12} bacteria per gram of colonic content. In the colon, in contrast to the proximal small intestine, the anaerobic bacteria outnumber the aerobic bacteria by as much as 10,000 to 1. In bacterial overgrowth, *Bacteroides*, anaerobic lactobacilli, and *Clostridium* are prevalent. Enterobacteria, including coliforms, are abundant in the overgrowth flora.

CLINICAL CONDITIONS ASSOCIATED WITH BACTERIAL OVERGROWTH

Table I lists the recognized clinical conditions associated with bacterial overgrowth. In the past, bacterial overgrowth was usually associated with structural abnormalities of the gastrointestinal tract, such as Billroth II anastomosis, Crohn's disease, stagnant loops of intestine resulting from fistulae or surgical enterostomies, and multiple duodenal and/or jejunal diverticula. It became appreciated that obstruction of the small intestine caused by Crohn's disease, adhesions, radiation damage, lymphoma, or tuberculosis may lead to small bowel bacterial overgrowth. In those conditions, although a primary disease may lead to malabsorption, superimposed overgrowth may be the most treatable form of malabsorption. Currently, motility disturbances in the gastrointestinal tract are the most important settings for bacterial overgrowth to occur. This is particularly important if this dysmotility syndrome is associated with hypo- or achlorhydria. In this category, diseases such as scleroderma, intestinal pseudo-obstruction, and diabetic autonomic neuropathy are found.

Certain individuals have been demonstrated to have clinically important malabsorption associated with bacterial overgrowth, but no radiographic abnormalities. Some of these individuals have an absent or disordered migrating motor complex. Their intestinal "housekeeper" is not operating appropriately. Elderly patients may develop malabsorption secondary to bacterial overgrowth and many believe that bacterial overgrowth is the most frequent cause of clinically important malabsorption in the elderly. The elderly are at risk for bacterial overgrowth because of their often-associated motility disturbances, either from the aging gut or from previous gastrointestinal surgery, and the decreased acid secretion that many elderly patients manifest. The importance of having normal motility and appropriate acid secretion is underscored by the observation that patients with scleroderma, who are manifesting esophageal reflux and doing well on histamine-2 (H2) receptor antagonists, have developed severe malabsorption secondary to bacterial overgrowth when the H2 receptor antagonist was replaced with a proton pump inhibitor. Patients with chronic pancreatitis may have malabsorption secondary to bacterial overgrowth because they manifest hypomotility as a result of pain, the use of narcotics, and previous surgery. of such patients may be quite difficult unless pancreatic enzymes are given along with antibiotic therapy to treat the maldigestion of the chronic pancreatitis and the associated overgrowth.

Further observations have also confirmed that an appreciable number of patients with irritable bowel syndrome may develop bacterial overgrowth. Just how frequently this occurs is still being defined and is rather controversial. Several other clinical entities listed in Table I are associated with bacterial overgrowth. Their pathogenesis in respect to the overgrowth is ill understood. These entities include end-stage renal disease, cirrhosis, myotonic muscular dystrophy, fibromyalgia, chronic fatigue syndrome, and various immunodeficiency syndromes such as chronic lymphocytic leukemia, immunoglobulin deficiencies, and selected T cell deficiency.

CLINICAL FEATURES OF BACTERIAL OVERGROWTH

The clinical features noted in patients with bacterial overgrowth are listed in Table II. it is now rather common that the presenting symptoms of a patient with bacterial overgrowth are often very nonspecific. Diagnosis should not be delayed until cobalamin malabsorption or steatorrhea is present. Again, it is important to underscore the observation that bacterial overgrowth may be superimposed on a number of common clinical conditions that may be primary causes of malabsorption, but the overgrowth that is present may be the most easily treatable part of the patient's malabsorption. The clinical conditions that comprise dysmotility syndromes usually do not present with malabsorption due to the dysmotility per se but will have malabsorption, not infrequently, due to superimposed bacterial overgrowth. These would include patients with gastroparesis, irritable bowel syndrome, diabetes, and scleroderma. Weight loss associated with clinically apparent steatorrhea has been observed in about one-third of patients with bacterial overgrowth severe enough to cause cobalamin deficiency. Osteomalacia, vitamin K deficiency, night blindness, hypocalcemic tetany, and vitamin E deficiency may ensue.

PATHOGENESIS OF METABOLIC ABNORMALITIES ASSOCIATED WITH BACTERIAL OVERGROWTH

The malabsorption that is observed in patients with bacterial overgrowth results from an abnormal intraluminal catabolism of substrates by the bacterial flora and direct injury to the small intestinal enterocyte induced by the overgrowth flora. A patchy, intestinal mucosal lesion has been demonstrated in both experimental animals and human subjects with bacterial overgrowth; at times, this overgrowth can obliterate the intestinal villi and lead to a flat biopsy. Steatorrhea in this condition may be due to bacterial alteration of bile salts, which leads to a decrease in micelle formation. The accumulation of toxic concentrations of free bile acids may also contribute to the steatorrhea by inducing a patchy intestinal mucosal lesion. The anemia of bacterial overgrowth is primarily a cobalamin deficiency. The anemia is megaloblastic and serum cobalamin levels are low. Patients may develop neurological abnormalities, both central and peripheral, from the cobalamin deficiency. The anemia can be corrected by the administration of cobalamin. The cobalamin deficiency is primarily due to gram-negative anaerobes. Iron deficiency may also occur in bacterial overgrowth due to blood loss resulting from the patchy ulcerated areas. Thus, in some patients, there may be two populations of red cells; those that are macrocytic and those that are microcytic. Folate deficiency, however, is not a common occurrence in bacterial overgrowth. Indeed, patients with bacterial overgrowth may manifest high levels of folate because the overgrowth flora can synthesize folate. Low levels of albumin in the serum occur and occasionally this is severe enough to lead to edema. The reasons for the hypoalbuminemia are multifactorial but include decreased uptake of amino acids by the damaged small intestinal enterocyte, intraluminal breakdown of protein and protein precursors by the bacteria of the overgrowth flora, and a protein-losing enteropathy. It has been appreciated for a long time that as many as 60% of patients with bacterial overgrowth may have a decreased urinary xylose excretion. The primary reason for the decreased urinary xylose excretion is catabolism of the xylose by the intraluminal bacterial flora. Diarrhea in the overgrowth state can come from the production of organic acids caused by the overgrowth flora, leading to an increased osmolarity of the small intestine and decreased intraluminal pH. Bacterial metabolites such as free bile acids, hydroxy fatty acids, and organic acids can stimulate water secretion and electrolytes into the lumen.

DIAGNOSIS OF BACTERIAL OVERGROWTH

In any patient who presents with unexplained diarrhea, steatorrhea, macrocytic anemia, or weight loss, bacterial overgrowth should be suspected. This suspicion should be very great if the patient is elderly or has had a previous abdominal surgery. At most medical centers, the most common causes of clinically important malabsorption are bacterial overgrowth or chronic pancreatitis. Figure 1 speaks to that issue. It presents an algorithm for the evaluation of patients with malabsorption, including those with bacterial overgrowth. The algorithm emphasizes the use of noninvasive and inexpensive tests. An attempt should be made to document the presence of steatorrhea. If the patient has clinically significant bacterial overgrowth, cobalamin absorption is usually impaired, even though the patient may not have yet developed cobalamin deficiency. Intrinsic factor administration will not improve the cobalamin malabsorption in patients with bacterial overgrowth. The urinary excretion of xylose is often decreased, in contrast to patients with pancreatic steatorrhea, for whom the urinary excretion of xylose is usually normal. It is remarkable that the serum folate level may be increased in some but not all patients with bacterial overgrowth.

The definitive diagnosis of bacterial overgrowth requires a properly collected and appropriately cultured aspirate from the proximal small intestine. This specimen should be collected under anaerobic conditions, serially diluted, and cultured on selected media. In patients with bacterial overgrowth, the total concentration of bacteria usually exceeds 10^5 organisms/ml of the jejunal secretions. However, it is important to stress that patients are now presenting with symptoms of bloating, abdominal distension, and pain with bacterial levels as low as 10^4/ml of jejunal secretions. Usually, these patients do not have cobalamin malabsorption or steatorrhea, compared to patients with higher amounts of organisms. Qualitatively, the organisms are colonic-like flora, i.e., *Bacteroides*, anaerobic lactobacilli, coliforms, and enterococci. Intestinal cultures, properly done, are time consuming, uncomfortable for the patient, and expensive. Consequently, they are not usually done in clinical practice. Therefore, a variety of surrogate tests for detecting bacterial overgrowth have been devised based on the various metabolic actions of the bacteria within the overgrowth flora. Table III lists various tests done worldwide and reports on their ease of performance, sensitivity, specificity, and safety. A number of these tests cannot distinguish malabsorption from other causes from that caused by bacterial overgrowth. A 1-g ^{14}C-labeled xylose breath test has been found to be

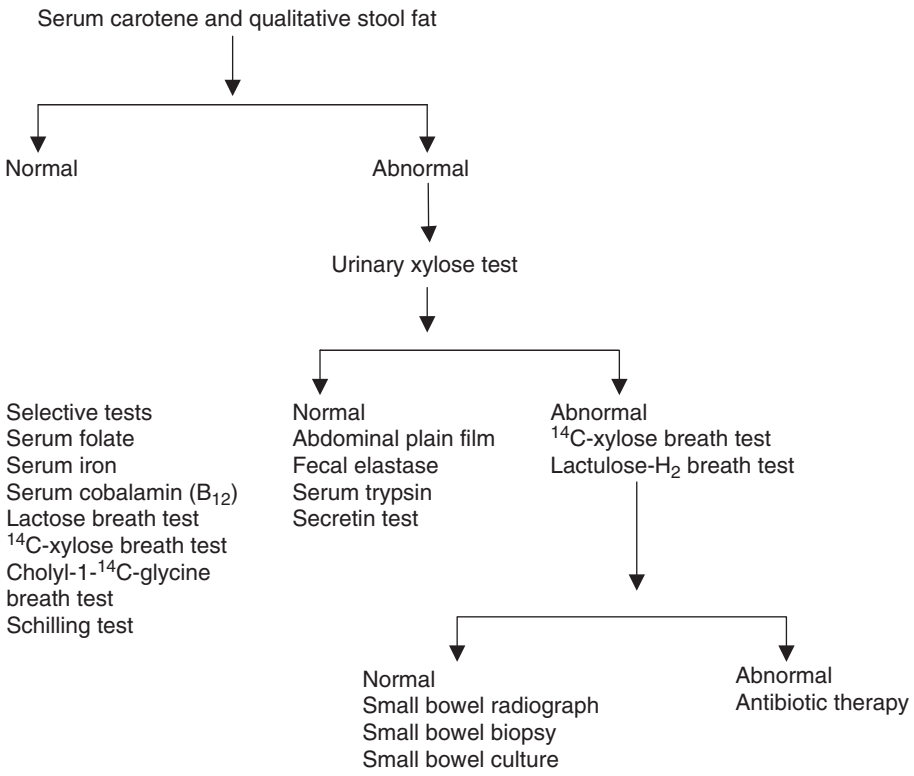

FIGURE 1 Algorithm for evaluation of malabsorption. From Toskes, P.P. (2002), with permission from Lippincott Williams & Wilkins.

a sensitive and specific test for detecting the presence of bacterial overgrowth. When this test is evaluated in comparison to a properly performed intestinal culture, the reliability is around 90%. It is not recommended that the ^{14}C-labeled xylose be used as a substrate in the diagnosis of bacterial overgrowth in children. Therefore, nonradioactive substrates such as ^{13}C-labeled sorbitol have been developed and appear to be excellent tests for detecting bacterial overgrowth while affording no radiation risk to the human host. These ^{13}C-labeled substrates have not yet been approved for clinical use. Analysis of breath hydrogen following the administration of various carbohydrate substrates has been employed as a test for overgrowth, but this test suffers greatly from a lack of sensitivity and specificity. It is noteworthy that an elevated fasting level of hydrogen is present in up to 30% of people with bacterial overgrowth, and if found, can be used to make the diagnosis.

MANAGEMENT OF BACTERIAL OVERGROWTH

The aim of therapy is to correct, when appropriate, the cause of the stasis, but surgery is often impractical for patients with scleroderma, multiple diverticula, diabetes, intestinal pseudo-obstruction, etc. Thus, antimicrobial therapy is the cornerstone of treatments. Remarkable improvements can be achieved in most patients such that they have a cessation of diarrhea and steatorrhea, and gain weight, leading to a better quality of life. Sensitivities of a culture obtained from the proximal intestine for selection of the proper therapy are not employed because of the many different bacterial species present, which often with very different antimicrobial sensitivities. Thus, it is important to select an antimicrobial agent that will be effective against the two main groups of bacteria responsible for the abnormalities observed in bacterial overgrowth. Antibiotics that have been shown to be effective, either by controlled trials or extensive clinical practice, against both the aerobic and anaerobic enteric bacteria are shown in Table IV. Antibiotics that are known to have poor activity against anaerobes should not be utilized in treating bacterial overgrowth. Such antibiotics include penicillin, ampicillin, the oral aminoglycosides, kanamycin, and neomycin. In most patients, a single 10-day course of therapy will markedly improve symptoms and the patient may remain symptom free for a considerable time. In others, the symptoms recur quickly after treatment and acceptable results can be obtained only

with cyclic therapy, such as 10 days out of each month. In still others, continuous therapy may be needed for up to 30 days. If the antimicrobial agent is effective, there will be a resolution or marked diminution of symptoms within 7 days. Diarrhea and steatorrhea will decrease and cobalamin malabsorption will be corrected.

Prolonged antibiotic therapy poses potential clinical problems, including diarrhea, enterocolitis, patient intolerance, and bacterial resistance. A prokinetic agent that could help clear the intestine of the overgrowth flora would be most advantageous. Salutary results have been obtained with both cisapride and octreotide (50 μg, nightly) in a small number of studies. Hydroxytryptamine (HT3 and HT4) antagonists are available to use in patients with dysmotility syndromes. The value of these agents in patients with overgrowth remains to be defined, but their use is provocative. Other recommendations for managing the patient with bacterial overgrowth include supplementation with cobalamin, calcium, fat-soluble vitamins, and iron. A lactose-free diet is suggested because the patients often develop lactase deficiency secondary to mucosal injury, and this may linger on even though the patient's antimicrobial therapy has decreased most of their symptoms. The use of medium-chain triglycerides instead of long-chain triglycerides is recommended because the medium-chain triglycerides, in contrast to the long-chain triglycerides, are not rendered ineffective by the bile salt-deconjugating activity of the overgrowth flora. The use of probiotics for the treatment of bacterial overgrowth has been disappointing. Controlled trials comparing antibiotic therapy to treatment with *Saccharomyces boulardii* have demonstrated the effectiveness of antibiotics but the ineffectiveness of the administered probiotic supplements.

The clinician should have a very low threshold for suspecting bacterial overgrowth as a cause of malabsorption, because this condition can be easily diagnosed and well treated. An appropriate attempt should be made to document whether bacterial overgrowth is present and then to administer proper therapy.

Bacterial toxins derived from enteric pathogens participate in the pathophysiology of intestinal infections; enterotoxins trigger intestinal fluid secretion and inflammation, cytotoxins cause cytopathogenic effects, and further damage involves stimulating host immune responses. Toxins are enzymes that can biochemically modify specific molecules on the plasma membrane or cytosol of target cells. They are secreted or released by pathogenic bacteria and often utilize existing host cellular pathways to cross the plasma membrane barrier. Enterotoxins traffic to subcellular organelles of intestinal epithelial cells, where they can be proteolytically processed, leading to the release of enzymatically active toxin fragments. These toxin fragments are able to alter specific host cell signaling cascades, leading to cell injury and inflammation. Some bacterial toxins share structural similarities in their enzymatically active toxin domains, which are different from the receptor-binding domains that are responsible for toxin internalization and trafficking to the target site. Various molecular mechanisms involving the receptors, enzymatic activity, and cell targets play a role in the pathophysiology of the most common bacterial toxins that affect the gastrointestinal tract (Table I).

fluid that may lead to metabolic acidosis and death. Cholera toxin (CT) is encoded in the genome of a filamentous phage (CTXϕ) that is integrated into one of the two bacterial chromosomes. CT, which belongs to the AB_5 type family of toxins, consists of one A subunit, containing A1 and A2 peptide chains linked by a disulfide bond, and five identical B subunits. The AB_5 family of toxins also includes the *Escherichia coli* heat-labile enterotoxin and shiga and pertussis toxins. The binding domain, or the B subunit, of CT forms a pentamer and binds stoichiometrically to cell surface glycolipid receptor GM1 ganglioside. The internalization of CT into target cells is mediated via a lipid raft-dependent mechanism. CT, which is transcytosed in membrane vesicles pinched off form the plasma membrane, passes through the Golgi cisternae and enters the endoplasmic reticulum, where the holotoxin is unfolded. A luminal chaperone protein, protein disulfide isomerase, aids in the unfolding of CT and in the subsequent proteolytic release of its A1 chain. The A1 chain exits the endoplasmic reticulum through a protein-conducting channel (Sec61p) and travels back to the plasma membrane. This enzymatically active toxin peptide modifies (by adenosine diphosphate ribosylation) the heterotrimeric G protein, $G_{\alpha s}$, resulting in activation of adenylyl cyclase and increased cyclic adenosine monophosphate (cAMP) levels. This leads to the opening of chloride channels in intestinal epithelial cells and loss of salt and water, a major characteristic of cholera diarrhea.

Physiology studies in whole animals demonstrate that in addition to its cAMP stimulatory mechanism, CT-mediated intestinal fluid secretion *in vivo* may involve extensive interactions between enterochromaffin cells, intestinal nerves, and epithelial cells. Evidence indicates that CT binds to enterochromaffin and intestinal epithelial cells in the intestinal mucosa and stimulates release of serotonin and prostaglandins, respectively. These molecules activate neurons in the intestinal submucosa region, leading to release of substances that interact with crypt cells, i.e., acetylcholine, substance P, and vasoactive intestinal peptide (VIP), resulting in secretion of chloride and water. Thus, pharmacologic blockade of CT-associated neuroendocrine pathways may have a place in the treatment of cholera diarrhea.

In addition to the stimulation of secretory pathways, CT also induces the release from epithelial cells of several antiinflammatory cytokines, such as IL-1 antagonist, IL-6, and IL-10, and inhibits antigen presentation by macrophages. This is believed to increase the virulence potential of CT by compromising the host's immune defense. The binding subunit of CT also modulates host immune responses and includes the depletion of CD8+ T cells, alterations of CD4+ T-cell differentiation, activation of B cells, and promotion of antigen processing and presentation by macrophages. The potent capacity of the CT B subunit to modulate immune responses suggests its potential application in the treatment of inflammatory autoimmune diseases and/or as an adjuvant for mucosal or systemic delivery of specific antigens.

Zonula occludens toxin (Zot) is an enterotoxin produced by *V. cholerae*. Zot, like CT, is encoded in the genome of filamentous phage CTXϕ integrated into one of the two chromosomes of *V. cholerae*. Newly synthesized Zot (45 kDa) is transported across the inner membrane of the bacterium and undergoes proteolytic cleavage to an N-terminal polypeptide (33 KDa), and to a small C-terminal domain (12 KDa). The N terminus may aid in the assembly of the CTXϕ phage whereas the C terminus induces paracellular permeability changes in intestinal epithelial cells. Zot binding to cell surface receptors decreases along the axis of the intestinal tract and correlates with its effect on intestinal permeability, which is more pronounced in the jejunum and ileum and absent in colon. After binding, Zot is internalized and activates the signaling molecule phospholipase C. This leads to production of inositol 1,4,5-trisphosphates and diacylglycerol and activation of protein kinase C-α (PKC-α), leading

to actin polymerization and opening of epithelial tight junctions. Thus, both Zot and CT may be responsible for the diarrheal effects of *V. cholerae*.

Escherichia coli TOXINS

Heat-labile enterotoxin (LT) has been isolated from enterotoxigenic *E. coli* (ETEC), representing the most frequent cause of traveler's diarrhea worldwide. LT is highly homologous to CT, and the tertiary structures of these two toxins are almost superimposed. The mode of LT action is also similar to that of CT in that the A chain of LT possesses adenosine diphosphate (ADP)-ribosyltransferase activity against the $G_{\alpha s}$ substrate. The loss of GTPase activity results in activation of adenylyl cyclase followed by massive loss of fluid and solutes. The LT-mediated fluid secretion involves secretomotor neurons, but, in contrast to CT-mediated fluid secretion, serotonin and substance P do not appear to be involved in LT-induced intestinal fluid secretion. Moreover, intestinal diarrhea induced by LT is less severe than CT-induced diarrhea, possibly because of different intestinal cell receptors for these two toxins. Several LT variants (LTI, LTIIa, and LTIIb) have been isolated from different ETEC serogroups. LTIIa binds to ganglioside GD1b with high affinity, but it also binds to the gangliosides GD1a, GT1b, GQ1b, and GM1 with lower affinity. Binding of LTIIa to the CT receptor GM1 fails to produce CT-like effects in cultured colonocytes. In contrast, LTIIa binds to lipid raft-associated GD1b and mediates trafficking of the toxin into host cells, eliciting a chloride secretory response.

Heat-stable enterotoxins (STs) represent a family of cysteine-rich peptides that bind to specific intestinal receptors and cause diarrhea. STa and STb are two subfamilies of STs that display structural and immunological differences. STa consists of toxins secreted by enterotoxigenic *E. coli, V. cholerae* non-O1 strains, *Yersinia enterocolitica*, and *Citrobacter freundii*. STa from ETEC is synthesized as a 72-amino-acid precursor that is proteolytically cleaved to a mature C-terminal 23-amino-acid peptide. The conserved "toxic domain" of mature STa contains six cysteine residues, forming intramolecular disulfide bonds that are essential for the tertiary structure and the biological activity of toxin. STa binds to receptors belonging to the family of natriuretic peptide receptors characterized by an extracellular ligand binding site and a cytoplasmic guanylyl cyclase domain. Activation of guanylyl cyclase C increases intracellular cyclic GMP and cyclic GMP-dependent protein kinase activity, leading to the phosphorylation and opening of the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel. This results in the net efflux of ions and water into the intestinal lumen.

ETEC STb contains 48 amino acids and resides in the C-terminal end of a precursor protein. The four conserved cysteine residues in STb form two disulfide bonds that are essential for toxicity. STb does not alter cAMP or cGMP levels in the intestinal mucosa. However, injection of STb into rabbit intestinal loops increases secretion of serotonin and prostaglandin E2, known intestinal secretagogues that may mediate STb-induced diarrhea.

Shigella dysenteriae TOXINS

Shiga and shiga-like toxins are produced by *Shigella dysenteriae* (type 1) and some strains of enterohemorrhagic *E. coli* (EHEC) O157:H7. Humans are often infected by these pathogens after ingestion of contaminated food and develop symptoms ranging from mild gastroenteritis to hemorrhagic colitis and hemolytic uremic syndrome. The amino acid sequence of shiga toxin is almost identical to that of shiga-like toxin-1, but shares only 56% sequence homology with shiga-like toxin-2. These toxins are members of the AB_5 family that include one enzymatic (A) and five binding (B) peptide chains. The B subunit binds with high binding affinity to its glycolipid receptor globotriasoyl ceramide (Gb_3), which is highly expressed in the gastrointestinal tract, kidney, and brain, reflecting the ability of the toxin to affect these organs. The holotoxin is internalized from the apical side of host cells via endocytosis, and travels in a retrograde fashion to the endoplasmic reticulum. The A polypeptide is then released into the cytosol whereas the B polypeptide may be delivered to the basolateral membrane and released into the subepithelial layer. The A chain is proteolytically cleaved to the A1 and A2 peptides. The cytosolic target of the A1 chain is the 28S RNA of the 60S ribosomal unit. The specific cleavage of an N-glycosidic bond in the 28S RNA by the A1 chain blocks the binding of aminoacyl-tRNA to its acceptor site, resulting in inhibition of cellular protein synthesis and cell death.

Shigella dysenteriae invades the intestinal mucosal epithelium and induces severe inflammation in the ileum and colon. Shiga toxin may penetrate the intestinal epithelial barrier either by transcytosis or via a paracellular route that can be compromised by epithelial cell damage during inflammation. On entering the intestinal microcirculation, shiga toxin affects vascular endothelial cells and causes vascular thrombosis. Subsequently, the toxin travels to the kidney via the systemic circulation and causes severe histopathological

kidney changes known to be associated with hemolytic uremic syndrome.

Clostridium difficile TOXINS

Clostridium difficile mediates diarrhea and pseudomembranous colitis in some patients receiving antibiotic therapy. *Clostridium difficile* is the most frequently diagnosed cause of infectious diarrhea in hospitalized patients and is associated with significant morbidity and mortality. This bacterium releases two exotoxins, A and B, which belong to the large clostridial toxin family that includes *Clostridium sordellii* and *Clostridium novii* toxins. Clostridial toxins have large molecular masses (>250 kDa), demonstrate extensive amino acid similarities, and are characterized by absence of subunits and similar cytopathogenic (cell rounding) effects on cultured cells. *Clostridium difficile* toxins A and B share 49% amino acid sequence homology and overall structural similarity. The cytotoxic effects of toxins A and B involve modification of the Ras superfamily small GTP-binding proteins that regulate cellular actin. The N-terminal domains of toxins A and B possess glucosyltransferase activity that catalyzes the transfer of a glucose moiety from UDP-glucose to the Rho family of the small GTP-binding proteins RhoA, Rac, and Cdc42, the major regulators of cellular actin dynamics. Glucosylated RhoA exhibits reduced intrinsic GTPase activity and loses its ability to couple with its downstream effectors, leading to actin depolymerization and cell death. The C-terminal receptor-binding domain contains several repetitive oligopeptide subunits that, in animal intestine, are responsible for toxin A binding to enterocyte receptors containing terminal α-galactose epitopes. The human intestinal receptor for these toxins, however, has yet to be identified.

Both toxins A and B can damage colonic epithelial cells and increase paracellular flux in human colonic explants. However, only toxin A has enterotoxic activities in animal intestine. Toxin A-induced paracellular permeability changes are mediated by a protein kinase C α/β-dependent pathway and involve translocation of the proteins ZO-1, occludin, and claudins from the tight junction to the cytoplasmic compartment. The *in vivo* pathophysiology of toxin A-induced inflammation involves activation of immune cells and neurons and secretion of proinflammatory cytokines from colonic epithelial and lamina propria cells. Pharmacologic blockade of receptors for the neuropeptides substance P, calcitonin gene-related peptide, and neurotensin inhibits toxin A-induced intestinal inflammation and fluid secretion, suggesting participation of intestinal neurons in toxin A-mediated host inflammatory responses. Toxin A triggers interleukin (IL-8) secretion via stimulation of mitogen-activated protein kinase cascades and activation of the nuclear transcription factor NF-κB in monocytes and colonic epithelial cells. Proinflammatory cytokines, released in response to *C. difficile* toxins from intestinal mucosal cells, may be responsible for activation of intestinal nerves observed in animal models of toxin A-induced enterocolitis.

Antibodies against *C. difficile* toxins A and B are present in the majority of healthy adults and children, and immunization against toxin A protects animals from *C. difficile* infection. Recent evidence indicates that the development of symptomatic *C. difficile* infection is well correlated with the immune response to *C. difficile* toxins and that a defective antibody response to toxin A is linked to recurrent *C. difficile* infection. Thus, vaccination or passive immunotherapy for *C. difficile*-associated diarrhea and colitis may represent exciting possibilities for prophylaxis and treatment of this disease.

Bacteroides fragilis ENTEROTOXIN

Bacteroides fragilis enterotoxin (BFT) has been associated with strains of *B. fragilis* isolated from animals and children with diarrheal disease. BFT, also known as fragilysin, is synthesized by enterotoxic strains of *B. fragilis* (ETBF) as a precursor protein (397 amino acids) and is proteolytically cleaved into a mature toxin (amino acids 212–397). Three distinct BFT-encoding genes (*bft-1, -2*, and *-3*) have been cloned from different ETBF strains with 92–96% amino acid homology. Sequence comparison reveals that BFT contains a zinc-binding metalloprotease motif. The C-terminal 20 amino acids of the *bft-2* gene product exhibits an amphipathic structure and may be responsible for membrane insertion of BFT-2 into host cells. The mature toxin cleaves the extracellular domain of the transmembrane adherence junction protein E-cadherin. This is followed by degradation of the remaining cytoplasmic domain of E-cadherin by cellular proteases. The degradation of E-cadherin apparently triggers reorganization of cell actin filaments, leading to increased cell volume and diminished tight junction barrier functions.

Purified BFT stimulates fluid secretion in ligated ileal and colonic loops in experimental animals. Analysis of the fluid content of intestinal loops reveals increased levels of sodium, chloride, albumin, and protein. In addition, mildly hemorrhagic fluid and patchy mucosal wall hemorrhage are observed, suggesting that BFT evokes an intestinal inflammatory response. BFT stimulates release of the proinflammatory cytokine IL-8, increases paracellular permeability, and causes

alterations of tight junctional proteins in cultured intestinal epithelial cells. These data indicate that BFT is the virulent factor responsible for ETBF-induced intestinal diarrhea and inflammation.

Barium radiographic examinations are often crucial in the investigation of patients with suspected gastrointestinal disease. The examination involves a certain element of routine, although every examination can and should be specifically tailored to answer the clinical question. Barium radiography should be tailored to the patient's ability to undergo the examination. It is therefore of extreme importance that the radiologist be given all of the appropriate clinical information to ensure that the examination yields useful diagnostic information.

INTRODUCTION

Gastrointestinal tract contrast examinations can be performed using what is commonly known as single- or double-contrast technique, or in some circumstances, a combination of both techniques (biphasic technique). The single-contrast technique is performed by filling the lumen with a relatively low-density barium preparation and utilizing compression for detection of contour irregularities or abnormalities or filling defects in the barium pool. Because of the density of the barium-filled organ, the compression helps to displace barium into ulcer craters and to better allow detection of polypoid and ulcerated lesions *en face*. Unfortunately, several technical problems occur with this technique. Superficial mucosal abnormalities cannot be easily recognized, the rectum and gastric fundus become very dense and are relatively inaccessible to compression, thereby precluding demonstration of *en face* lesions, and compression may be impossible because of obesity or because of recent abdominal surgery or trauma. Double-contrast examinations are performed with a smaller amount of high-density barium to coat the mucosal surface and

with swallowed effervescent carbon dioxide granules to distend the viscus with gas. This allows visualization of lesions *en face* and in profile. Compression is routinely performed and is especially helpful for anterior wall lesion demonstration and for lesions characterized by areas of narrowing. Double-contrast techniques allow detection of contour abnormalities as well as fine mucosal abnormalities and irregularities and are also often helpful in detecting lesions that cannot be detected by endoscopy, are missed or misinterpreted at endoscopy, and are often helpful in evaluating patients who refuse or are not candidates for endoscopy. Double-contrast examinations are, however, not adequate where there is poor coating, where there is insufficient distension (which may hide lesions), or where there is overdistension (which can obscure lesions). In some cases, in addition to the double-contrast examination, it may be necessary to perform a single-contrast examination afterward to gain additional information.

PHARYNX

Swallowing and feeding problems are common in all age groups, but particularly in older patients and are becoming an increasingly frequent problem in medical practice.

Applications

A radiographic pharyngeal examination is most frequently performed on patients with feeding difficulty or difficulty swallowing, and is also helpful in evaluating patients with respiratory problems, for whom laryngeal penetration and aspiration may result in aspiration pneumonia, chronic bronchitis, chronic coughing, or choking. Radiographic pharyngeal examination may also be helpful in detection of soft palate insufficiency, which may result in nasal regurgitation or a nasal quality to the voice. In addition, radiologic evaluation of the pharynx may be helpful in assessing pharyngeal morphology and function in patients with certain neurologic diseases and degenerative neurologic or muscular abnormalities, cerebrovascular accidents, head injury, pharyngeal neoplasia, and complications of head and neck surgery or radiation. Radiographic evaluation of swallowing is often needed to assist the swallowing therapist in the choice of an appropriate nutritional option in those patients suspected of aspiration with different nutritional consistencies. In addition, the swallowing therapist can visualize the effect of various therapeutic maneuvers that can be performed to help diminish laryngeal penetration and aspiration. Pharyngoesophagrams are useful in evaluating patients for suspected foreign body, fistula, or abscess. A prominent cricopharyngeus muscle, which may cause patients to complain of dysphagia, may be detected during a pharyngogram. Pharyngography may be helpful in diagnosing lateral pharyngeal pouches and diverticula, which may result in spillage of contents into the hypopharynx with resultant aspiration into the larynx and tracheobronchial tree, and may be complicated by ulceration or neoplasia. Zenker's diverticula are usually detectable with radiographic examinations of the pharynx (Fig. 1). Barium studies are of limited value in patients with viral, bacterial, or fungal infection of the pharynx because these patients usually have normal pharyngograms or lymphoid hyperplasia of the palatine tonsil or base of the tongue. Occasionally, *Candida* or herpes pharyngitis may be detected, especially in patients with AIDS. Barium studies may also be helpful in patients with chronic sore throat, in which underlying gastroesophageal reflux or reflux esophagitis may be the contributing factor. Double-contrast pharyngography plays a role in the detection and workup of pharyngeal neoplasms. The size, level, and extent of the lesion can

be determined and regions of the pharynx that are difficult to visualize or easily missed at endoscopy (such as submucosal masses) can be visualized.

Contraindications

Contrast examination of the pharynx may be dangerous in a patient with acute airway obstruction. The most notable clinical example for which barium studies are contraindicated is suspected epiglottitis. Patients with suspected airway obstruction should have plain films of the neck as the initial radiographic examination.

Technique

Radiographic examination of the pharynx includes a cine or video pharyngoesophagram to evaluate motility, and a series of spot films to evaluate structural abnormalities. In a patient with suspected foreign body, fistula, or abscess, frontal and lateral plain films of the neck should be obtained in addition.

The videofluoroscopic swallowing examination is normally limited to the oral cavity, pharynx, and cervical esophagus and is designed to study the anatomy and physiology of the oral preparatory, oral, pharyngeal, and cervical esophageal stages of deglutition. Small amounts of contrast material are used to minimize the risk while evaluating the physiology of the oral cavity and pharynx. Four consistencies of material are used to investigate patient complaints of variable swallowing disability: thin and thick liquid barium, barium paste mixed with applesauce, and material requiring mastication (crackers mixed with barium paste). Swallowing therapists who may be involved in the care of the patient often attend the radiographic examination and assist in deciding in the types and amounts of testing materials to be used. The cine or video recording of each swallow allows a frame-by-frame analysis of the various parameters of swallowing. Movement of the tongue, soft palate, and epiglottis, as well as laryngeal closure and cricopharyngeal opening, symmetry of tongue motion, pharyngeal peristalsis, and epiglottic tilt, can be assessed using a combination of lateral and frontal projections.

Double-contrast views of the pharynx are obtained in frontal and lateral projections to demonstrate the contours of the valleculae and piriform sinuses, lateral walls of the tonsillar fossae and hypopharynx, superior and inferior borders of the base of the tongue, the soft palate, the posterior pharyngeal wall, the anterior hypopharyngeal wall, the epiglottis, and the cricopharyngeus.

UPPER GASTROINTESTINAL TRACT

Currently, most patients presenting with epigastric pain or other gastrointestinal symptoms are initially treated empirically with a trial of medication without undergoing any diagnostic investigations. However, compliant patients who fail to respond to this therapy will usually undergo either endoscopy or an upper gastrointestinal radiographic examination as the first diagnostic test, with proponents existing for both endoscopy and upper gastrointestinal radiographic examinations. Those that advocate endoscopy feel that the additional expense and definite risk of the procedure are warranted because of its perceived greater accuracy and possibility for definitive treatment. With the use of the biphasic technique (combination of single- and double-contrast techniques), the ability to diagnose accurately disorders of the esophagus, stomach, and duodenum has dramatically improved. A meticulously performed biphasic examination, although not as sensitive for detection of mild inflammatory conditions, remains an excellent cheaper, less risky, and relatively accurate alternative. In addition, although the upper endoscopy can only directly evaluate the mucosa, the radiographic upper gastrointestinal examination is capable of evaluating the mucosa as well as the wall of the upper gastrointestinal tract and is helpful in evaluating motility disorders.

Applications

Esophagus

The esophagus should be evaluated with a dedicated examination directed to the esophagus, if patient symptoms suggest localized esophageal disease. Alternatively, if the symptoms cannot be specifically localized to the esophagus, the esophagus can be evaluated as part of a dedicated upper gastrointestinal examination.

In patients presenting with reflux symptoms, the barium examination may be helpful for documentation of a hiatal hernia (Fig. 2), for demonstration of suspected reflux, and for detection of possible reflux sequelae, such as reflux esophagitis and ulceration, strictures, Barrett's esophagus, and esophageal adenocarcinoma (Fig. 3).

Patients presenting with dysphagia often benefit from a barium examination, whereby abnormalities of both structure and function responsible for the dysphagia may be detected. Structural lesions include benign lesions such as rings, webs, and strictures; benign neoplasms; and malignancies such as adenocarcinoma, lymphoma, or Kaposi's sarcoma. In addition, esophageal motility disorders, both primary and secondary, can cause dysphagia. Primary motility disorders such as

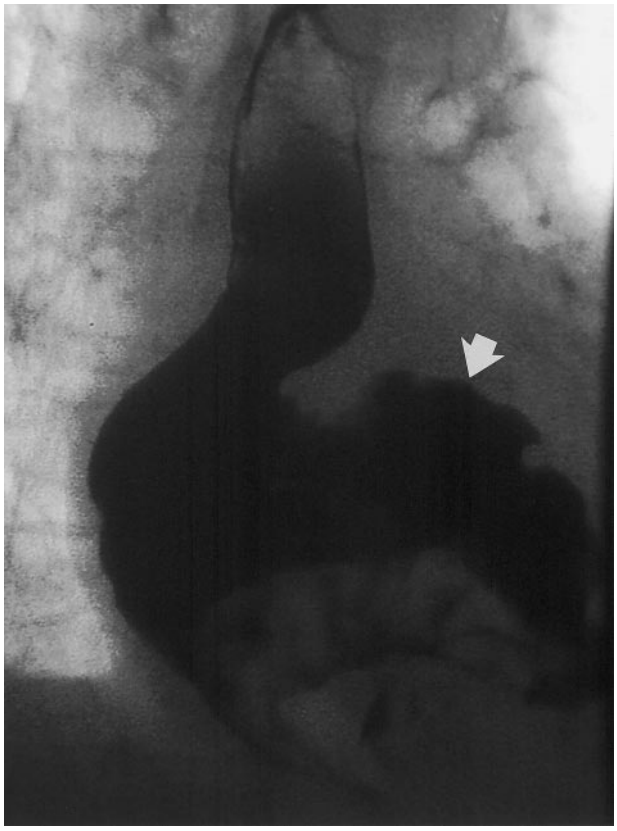

FIGURE 2 A large hiatal hernia (arrow) containing most of the gastric fundus in the chest.

achalasia (Fig. 4), diffuse esophageal spasm (Fig. 5), nonspecific esophageal motility disorder, and presbyesophagus can all be evaluated with barium examinations of the esophagus. Nutcracker esophagus, and hypertensive lower esophageal sphincter, which can cause dysphagia, are best diagnosed with manometry. Secondary motility disorders such as those occurring with collagen vascular disease, especially scleroderma, mixed connective tissue disease, dermatomyositis, and polymyositis, may be detected with barium radiography. Other secondary motility disorders that can be evaluated with barium studies include motility abnormality secondary to reflux esophagitis, caustic esophagitis, and radiation therapy. In addition, other secondary causes of motility abnormality and subsequent dysphagia include infectious disorders such as Chagas' disease, metabolic and endocrine disorders such as diabetes mellitus, and alcohol abuse, and many neuromuscular disorders, including cerebrovascular accidents, multiple sclerosis, amyotrophic lateral sclerosis, myasthenia gravis, and postpoliomyelitis. All these entities may be evaluated with barium studies of the esophagus.

Infectious esophagitis has become a relatively recent problem, particularly in patients who are immunocompromised and present with dysphagia. When a patient is suspected of having infectious esophagitis, double-contrast examination of the esophagus may confirm the diagnosis and often helps to diagnose the offending organism (Fig. 6).

Barium radiography is of use in evaluating patients with dysphagia caused by any of the other forms of clinically suspected esophagitides, including drug-induced and radiation-induced esophagitis, caustic esophagitis, Crohn's disease, epidermolysis bulosa, pemphigoid, nasogastric intubation esophagitis, eosinophilic esophagitis, alcohol-induced esophagitis, graft-versus-host disease, Behcet's disease, and esophageal intramural pseudodiverticulosis.

Various other abnormalities of the esophagus can be detected using barium radiographic examinations. These include Mallory–Weiss tears, varices, esophageal hematomas, esophageal perforations (Fig. 7), foreign body impactions, fistulas, diverticula, congenital esophageal stenosis, and extrinsic impressions on the esophagus. Water-soluble contrast media, rather than barium, are used as the initial materials to diagnose esophageal

FIGURE 4 Fluoroscopic image from an esophagram showing marked narrowing in the distal esophagus with the "bird's beak appearance" (arrow), with dilatation of the esophagus proximally, all features characteristic of achalasia.

perforations. Barium has been shown to excite an inflammatory reaction in the mediastinum with subsequent fibrosis, whereas water-soluble media have not. Water-soluble media are also rapidly absorbed from the mediastinum so that followup studies are not compromised by residual contrast in the mediastinum. Because water-soluble contrast media are less dense than barium, some perforations may be missed solely with the water-soluble contrast materials. Therefore, if the initial study performed with water-soluble contrast media does not show a leak, the examination should be repeated with barium to detect subtle leaks. In these cases, the harmful effects of barium in the mediastinum are less serious than that of missing a potentially life-threatening condition.

The integrity of esophageal anastomoses in the postoperative patient can also be assessed with radiography by utilizing the same technique as that for detection of esophageal perforations.

Stomach and Duodenum

Radiographic examinations of the stomach and duodenum are helpful in the evaluation of patients who present with dyspepsia, bloating, belching, early satiety, weight loss, and signs and symptoms suggestive of upper gastrointestinal bleeding such as hematemesis, melena, and guaiac-positive stool. The double-contrast examination will often lead to a diagnosis of various gastric and duodenal processes that may explain the above symptoms. These processes include peptic disease, other inflammatory and infectious conditions such as erosive gastritis of any cause, antral gastritis, *Helicobacter pylori* gastritis, hypertrophic gastritis, Menetrier's disease, atrophic gastritis, eosinophilic gastritis, emphysematous gastritis, caustic ingestion, radiation-induced abnormalities, gastric ulcers of any cause (Fig. 8), duodenitis, granulomatous conditions such as Crohn's disease, sarcoidosis, tuberculosis, syphilis, fungal diseases, and other infectious diseases such as cytomegalovirus, cryptosporidiosis, toxoplasmosis, and strongyloidiasis. In addition, benign and malignant neoplasms of the stomach and duodenum can be detected with barium radiography. Other miscellaneous abnormalities, including varices, diverticula, diaphragms and webs, hypertrophic pyloric stenosis, gastric outlet obstruction, duodenal obstruction, gastric

dilatation without outlet obstruction, extrinsic processes such as pancreatic disease, renal and liver masses, gallbladder disease and colonic masses (all of which may cause mass effect on the stomach and duodenum), bezoars, foreign bodies, hematomas, gastric volvulus (Fig. 9), gastroduodenal and duodenojejunal intussusceptions, fistulas, gastric and duodenal perforations, and amyloidosis, can all be detectable with the upper gastrointestinal examination. Patients who have undergone surgery to the stomach and duodenum may be evaluated for postoperative problems using various upper gastrointestinal radiographic techniques. In these patients, it is essential that the operative procedure performed be described to the radiologist before the procedure is performed in order that the postoperative anatomy, the efficiency of the procedure, and possible postoperative complications can be accurately determined if necessary.

If a diagnosis can be confidently made from the upper gastrointestinal examination, there is no need for confirmation with endoscopy. If, however, the upper gastrointestinal examination reveals findings that cannot be confidently diagnosed definitively or if the findings are equivocal or suspicious for malignancy, upper endoscopy with biopsy, if indicated, should be performed. If the upper gastrointestinal examination is unrevealing, the decision to perform upper endoscopy should be dictated by the clinical scenario.

Contraindications

As mentioned previously, barium is contraindicated with suspected esophageal perforation, but is also contraindicated with suspected gastric or duodenal perforation. Water-soluble contrast media should be used instead. Double-contrast examinations may be difficult or impossible to perform on elderly or debilitated patients who are not able to perform the various turning maneuvers required for this technique. In those patients, single-contrast techniques can be performed, but the limitations of this technique have to be kept in mind. Patients who are unable to follow commands enabling them to ingest the contrast materials because of diminished consciousness or severe dementia are not candidates for barium radiography, unless the examination can be performed with a single-contrast technique through an indwelling nasogastric tube.

Technique

The routine upper gastrointestinal examination should ideally be performed as a biphasic study, utilizing double-contrast techniques followed by

FIGURE 7 An image from an esophagram performed with water-soluble contrast showing extravasation of contrast to the right of the esophagus related to an esophageal perforation (arrow).

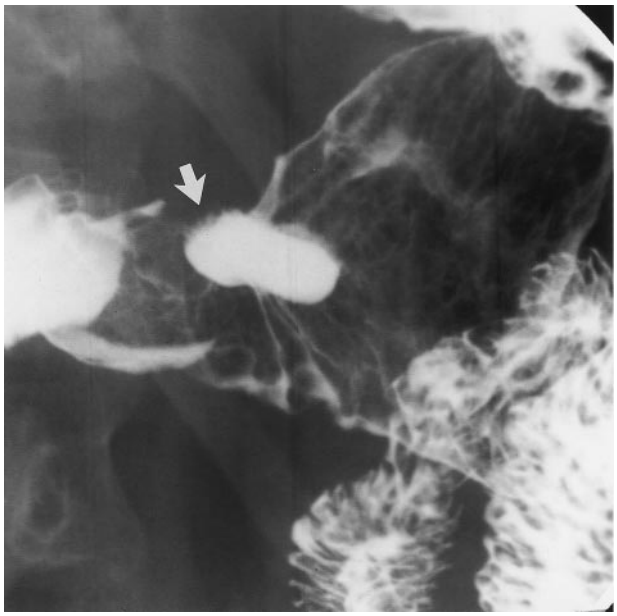

FIGURE 8 Double-contrast image of the stomach showing a large, contrast-filled ulcer in the gastric antrum (arrow).

single-contrast techniques. The routine double-contrast portion of the examination is designed to coat the mucosal surface with a thin layer of high-density barium, while the lumen is distended with gas obtained from effervescent granules. Double-contrast views of the esophagus, stomach, and duodenum are obtained in different projections utilizing various turning maneuvers to achieve adequate coating and distension. This is followed by single-contrast views of the esophagus, stomach, and duodenum, using low-density barium liquid and varying degrees of compression.

SMALL BOWEL

Barium radiography remains relatively unchallenged by endoscopy in evaluation of a large portion of the small bowel. Although small bowel enteroscopy is becoming more prevalent, for evaluating the proximal small bowel, this procedure can only detect mucosal disease, and cannot evaluate the distal small bowel, although a skilled colonoscopist can frequently evaluate the terminal ileum.

The entire small bowel is best evaluated radiographically with either a dedicated fluoroscopic small bowel series and/or enteroclysis. Barium small bowel examinations should be ordered only in the presence of clinical symptoms and signs specifically pointing to the possibility of small bowel disease. Vague, nonspecific symptoms have a very low yield of positive findings on small bowel examinations, and ordering of these examinations in this instance exposes patients to unnecessary radiation and anxiety.

Applications

In most radiologic practices in the United States, the majority of small bowel problems are evaluated with the small bowel series. The major advantage of the fluoroscopic small bowel series is that it does not require intubation and is therefore better tolerated. In addition, expertise in performing enteroclysis (small bowel enema) is not widespread. The enteroclysis provides a more detailed double-contrast examination of the small intestine. By better distending the lumen, the shape and thickness of the small bowel folds are better demonstrated, regions of partial obstruction are more readily delineated, and mucosal nodularity is more easily identified.

At our institution and at many others, the enteroclysis is not the initial examination in all patients but is reserved for the following indications when there remains a high index of suspicion for small bowel disease despite an unremarkable or inconclusive fluoroscopic

small bowel series:

1. Evaluation of patients with suspected or known malabsorption states, such as celiac disease, tropical sprue, scleroderma (Fig. 10), lymphangiectasia, Whipple disease, bacterial overgrowth syndromes, short bowel syndrome, adult cystic fibrosis, abetalipoproteinemia, systemic mastocystosis, and Waldenström's macroglobulinemia.

3. Preoperative evaluation of Crohn's disease to determine extent of disease, and search for proximal segments of disease (Fig. 11).
4. Gastrointestinal blood loss of obscure origin, when upper gastrointestinal and colonic radiologic examinations, small bowel series, and/or endoscopic studies are negative.
5. Evaluation of patients with radiation-induced damage to the small bowel.
6. Detection of small bowel tumors, such as carcinoids, primary and secondary malignancies, polyps, and lymphoma.

8. For patients, presently asymptomatic, in whom physicians suspect clinical symptoms were caused by partial small bowel obstruction(s) secondary to adhesions (Fig. 12).

Barium examinations of the small bowel may also be helpful in evaluation of various inflammatory conditions of the small bowel, such as parasitic infestations, bacterial and viral infections, and inflammatory

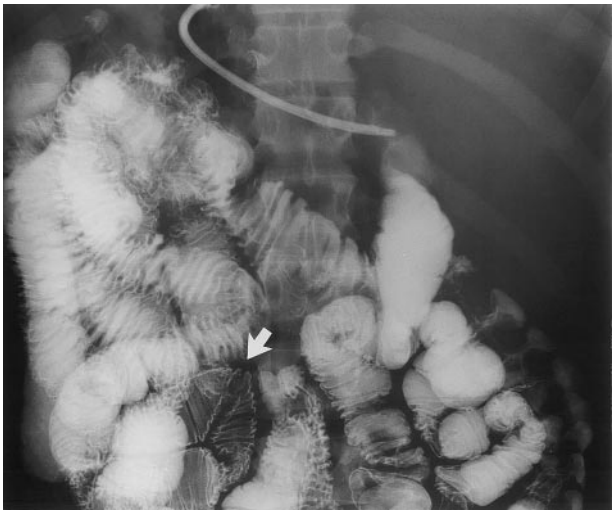

FIGURE 12 Overhead view from an enteroclysis showing an acutely angulated, narrowed small bowel loop, related to an adhesion (arrow).

conditions occurring in association with immunodeficiency. Vascular disorders of the small bowel, such as mesenteric ischemia and infarction, intramural hemorrhage, vasculitis and vascular malformations, may also be evaluated utilizing barium small bowel examinations. Post-operative complications, malrotations, hernias, gut duplications, intestinal edema, foreign bodies, enteroliths, bezoars, posttransplant lymphoproliferative disorder, and graft-versus-host disease are other miscellaneous small bowel processes that can be evaluated with barium radiography.

Contraindications

Suspected intestinal perforation is the only absolute contraindication to performance of a barium small bowel examination. Barium in the peritoneal cavity in these patients leads to a fulminant chemical peritonitis, which should be avoided whenever possible. Water-soluble contrast materials such as gastrografin should not be used in small bowel evaluation because they become diluted by the luminal fluid, thereby precluding adequate visualization. They may be satisfactorily used only in evaluating for suspected perforation of the very most proximal small bowel. In addition, they should not be used in patients with obstruction, because they are hyperosmolar and may draw fluid into the bowel lumen, thereby aggravating what may be an already altered fluid and electrolyte balance.

Technique

Dedicated Fluoroscopic Small Bowel Series

The patient ingests approximately 3 cups (500–600 ml) of 40–50% (weight/volume) barium sulfate solution, followed by abdominal radiographs obtained at 15-minute intervals for the first half-hour, and then every 30 minutes until the right colon is opacified. Each abdominal film is reviewed, followed by intermittent fluoroscopy with compression until all small bowel loops have been demonstrated and evaluated. The intermittent fluoroscopy with compression is an essential portion of the examination because lesions can be missed if only the overhead views are evaluated, due to the tendency of loops to overlap and obscure lesions. Periodic spot films are obtained to document any suspicious areas, and once the right colon is opacified, spot films of the terminal ileum are obtained.

Enteroclysis (Small Bowel Enema)

Small bowel transit is accelerated by administration of 20 mg of oral metoclopramide. Gastric intubation with a balloon catheter using either the oral or the transnasal route is then performed, followed by fluoroscopically directed manipulation of the catheter into either the distal duodenum or the proximal jejunum, just beyond the ligament of Treitz. The balloon is then inflated under fluoroscopy to prevent reflux of contrast into the stomach. Approximately 200–250 ml of a 75–80% (weight/volume) barium suspension is injected into the small bowel followed by approximately 1000–2000 ml of a 0.5% methylcellulose solution to obtain a double-contrast effect. The radiologist is present during the entire procedure, and the entire small bowel is examined with intermittent fluoroscopy utilizing graded abdominal compression. Periodic spot films of the small bowel are obtained to document the fluoroscopic findings. The examination is completed with an overhead radiograph of the abdomen to include the entire small bowel.

COLON AND RECTUM

Barium examination of the colon and rectum is predominantly utilized to detect mucosal abnormalities. Its greatest competitor is colonoscopy, whereby the mucosa can be directly visualized and diagnostic biopsies obtained. A carefully performed barium examination of the colon is, however, an excellent, less invasive, safer, and cheaper alternative for detection of most colonic and rectal lesions. Colonoscopy remains more accurate than barium radiography in detection of subtle mucosal abnormalities of the colon, such as polypoid lesions less than 1 cm in diameter, and the early preulcerative changes of inflammatory bowel disease. Because barium radiographic examination can also be used for the detection of mural colonic and rectal lesions, it has a competitive advantage over colonoscopy, because colonoscopy has not been proved to be an adequate test for mural or extrinsic lesion detection. Because colonoscopy and barium radiography both have limitations, the double-contrast barium enema and colonoscopy should be viewed as complementary techniques for the diagnosis of various colonic processes. Computer tomography (CT) and in some cases magnetic resonance imaging (MRI) and endoscopic ultrasound are the cross-sectional imaging modalities that directly compete with barium radiographic examination in the detection and evaluation of mural and rectal colonic entities. Although CT, MRI, and endoscopic ultrasound are superior to barium radiographic examination in the detection of extrinsic processes affecting the colon and rectum, these lesions can sometimes be detected and evaluated with barium examinations. Barium

radiography is often used to complete the colonic examination in those patients in whom the colonoscopist is unsuccessful in passing the endoscope to the cecum.

Adequate preparation is essential in the satisfactory performance of a colonic and rectal barium examination, because residual feces will obscure polypoid lesions and the early manifestations of inflammatory pathology. Although a variety of preparatory regimens exist, the most effective protocol consists of a clear liquid diet for 24 hours prior to the procedure, laxatives on the afternoon and evening before the test, and a suppository the morning of the examination. Cleansing enemas preferably should not be used, because they result in significant residual intraluminal fluid, which may degrade the quality of mucosal coating. In our institution, patients in renal failure are prepared with Golytely (polyethylene glycol solution), because magnesium citrate, which is the normally utilized laxative, is contraindicated in the presence of renal compromise. The one, but unavoidable, drawback of utilizing oral lavage regimens such as Golytely in renal failure patients is that the quality of mucosal coating may be degraded because of the presence of residual intraluminal fluid. In patients with inflammatory bowel disease, milder laxatives should be used, or the preparation may consist solely of clear liquids by mouth. Preparation may not be necessary in patients with acute colonic obstruction, in those for whom the study is simply being performed to evaluate the anatomy, or when there is a clinical suspicion of a perforation.

Applications

The most common indications for barium radiography include detection of colorectal polyps (Fig. 13) and carcinoma (Fig. 14), assessment of inflammatory bowel disease (Fig. 15), diagnosis and assessment of diverticular disease (Fig. 16), and evaluation of colonic extrinsic mass lesions. Barium radiography can also be used to evaluate other inflammatory conditions of the colon, including infectious processes such as bacterial, viral, parasitic, and fungal diseases and noninfectious colitides, when colonoscopy is not feasible. Other tumors of the colon, including lymphoma, hemangioma, lymphangioma, Kaposi's sarcoma, carcinoid tumors, lipomas, stromal tumors, squamous cell and cloacogenic carcinoma, and metastases, can be detected with double-contrast barium enemas. Other miscellaneous disorders of the colon, including colonic ischemia, radiation colitis, rectal hemorrhoids, rectal varices, and cathartic colon; functional disorders of the colon, including irritable bowel syndrome, chronic constipation, collagen vascular disorders, and Ogilvie's syndrome;

and extracolonic diseases affecting the colon, such as endometriosis, benign gynecologic tumors, gynecologic malignancies, and pelvic inflammatory disease, can also be evaluated with barium enema examinations. Postoperative colonic abnormalities can be assessed and postoperative anatomic evaluations can be performed with barium radiography. Finally, evaluation of defecatory

disorders is performed with barium evacuation proctography as part of a multimodality evaluation.

Contraindications

Barium colonic examinations should not be performed in patients with toxic megacolon, ischemic colitis, suspected diverticulitis with signs of an acute abdomen, active colitis or with other diseases in which the bowel wall is potentially friable and could perforate during the procedure. In addition, barium examinations are contraindicated in patients with suspected colonic perforation. In these patients, the examination should be performed with water-soluble contrast materials, which do not incite a peritoneal reaction if extravasated and can be reabsorbed from the peritoneal cavity. Barium examinations should never be performed immediately postbiopsy with large biopsy forceps because this predisposes to perforation. In these cases, the barium examination should be postponed for at least 5 days. Barium enema should not be performed as the first test in patients with active bleeding to determine the site of bleeding. This is best shown with a nuclear medicine bleeding scan and/or angiography. The barium enema, if still necessary, should be postponed until adequate preparation can be performed.

Relative contraindications to barium radiography include inability of the patient to roll and turn during the examination, thereby not allowing adequate filling and coating of the colon, and colonic obstruction. Patients with colonic obstruction are better evaluated with water-soluble contrast media, which does not become inspissated proximal to an area of obstruction in the colon. Incomplete bowel preparation and residual oral contrast in the abdomen are other relative contraindications.

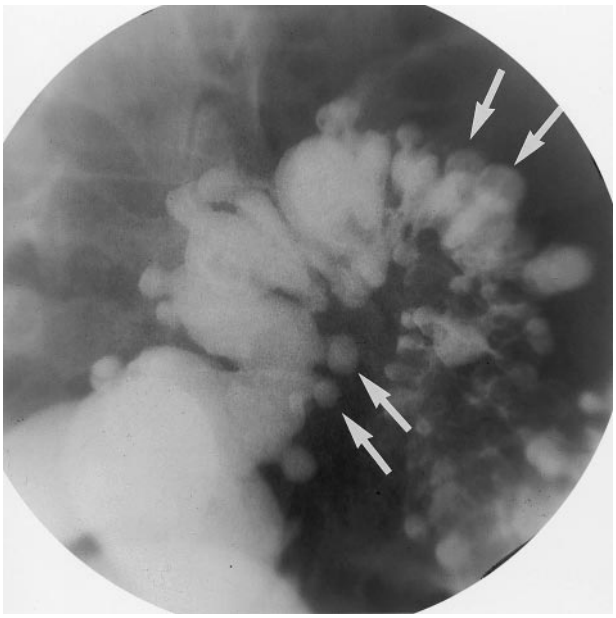

FIGURE 16 Spot radiograph shows extensive sigmoid and descending colonic diverticulosis (arrows).

Technique

As with most portions of the gastrointestinal tract, radiographic examination of the colon can be performed with a single- or double-contrast technique. In single contrast studies, the entire colon is filled with a relatively low-density barium suspension, with the filling monitored by fluoroscopic observation and the use of extensive palpation and compression of the colon during filling. Fluoroscopic spot films and overhead radiographs are performed with both techniques. In double-contrast examinations, the colonic mucosa is coated with a smaller volume of high-density barium, and luminal distension is obtained using air insufflation to generate the double-contrast effect.

The double-contrast technique is superior to the single-contrast method for detection of fine mucosal abnormalities such as small polypoid lesions and early inflammatory pathology. In addition, it is preferable for evaluation of the rectum, and of the splenic and hepatic flexures, which are relatively inaccessible to palpation and compression. The single-contrast examination is faster and less expensive and is preferred for

mechanical problems such as obstruction, fistulas, Hirschprung's disease, and diagnosis and reduction of intussusception, and in cases of suspected diverticulitis when there are no signs suggestive of an acute abdomen, which would preclude performance of a barium examination. Patients who are too old and debilitated are usually evaluated with the single-contrast technique, because they are unable to tolerate performance of the double-contrast technique.

Patients with a colostomy can be evaluated, if clinically indicated, through the colostomy, using a single- or double-contrast technique. When perforation of the large bowel is suspected, the examination should be performed with water-soluble contrast materials to avoid spillage of barium into the peritoneal cavity.

FISTULOGRAPHY AND SINUS TRACT EVALUATION

The gastrointestinal radiologist frequently can contribute significantly to the management of a patient with documentation of the presence of, and demonstration of the extent of, an enterocutaneous fistula (Fig. 17). In addition, a cutaneous sinus tract connected to an abscess cavity can be demonstrated. The sites of communication of a fistula or sinus tract may be demonstrated by catheterizing a cutaneous fistula or sinus tract and injecting the fistula or sinus tract with water-soluble contrast.

gut manometry Evaluation of gut motility by measuring intraluminal pressures.

gut tone Tonic, i.e., sustained, muscular contraction of the gut wall.

tensostat Computerized pump that applies fixed tension levels to the wall of hollow viscera.

The barostat is an air pump that maintains a constant, predetermined pressure level within a flaccid bag introduced into a hollow muscular organ. Hence, the barostat is a pressure clamp that can be used either to measure muscular activity as volume variation at a low and constant pressure level or to distend the organ by increasing the intraluminal pressure. Distension in turn can be applied to measure the local distensibility of the organ (compliance) or to stimulate afferent pathways and measure either reflex responses (reflexes) or conscious perception (sensitivity).

INTRODUCTION

Some hollow muscular organs, such as the stomach, may exert phasic (i.e., brief) or tonic (i.e., sustained) muscular contractions. There is no strict definition to distinguish between phasic and tonic activity, but by convention, contractions lasting more than 1 min have been considered tonic. The tonic muscular activity of hollow organs is also called tone. In the gastrointestinal tract, phasic contractions produce intraluminal pressure changes that can be readily measured by manometry, a technique that has been available since the 1970s. However, tonic contractions outside sphincteric regions generally do not produce recordable pressure changes, probably because the changes are too small and are obliterated by respiratory movements and other artifacts. The barostat was developed in the early 1980s initially for the purpose of measuring gastric tone, but was later applied to measure tonic contraction of other hollow muscular organs.

The barostat is a feedback system that consists of a pressure sensor linked by either an electronic or a computerized relay to an air pump. When the organ relaxes, the barostat injects air to prevent a pressure drop, and when the organ contracts, air is aspirated to prevent a pressure rise.

TECHNICAL SPECIFICATIONS

The bag of the barostat should be flaccid and oversized, so that it does not interfere with the measurements. For reservoir organs, such as the stomach and the rectum, spheroidal bags can be used, and for tubular segments, such as the small intestine, cylindrical bags that are of a fixed length and radially oversized, compartmentalize the segment under study. The bag should be connected by a double-lumen tube to the pressure sensor and the air pump of the barostat. Otherwise, a single lumen tube damps the responsiveness of the system. In each barostat

the speed of air flow and the pressure window for reaction should be determined (approximately 40 ml/s flow rate and 0.5 mm Hg window are appropriate). The compressibility of air and the deformation of the pump with pressure increments introduce an error in intraluminal volume measurements. This compression factor, which is usually linear, should be determined and carefully corrected for.

UTILITIES

Constant Pressure Studies

At a low constant pressure, the barostat measures tonic contraction as volume changes without disturbing the physiological activity of the gut or inducing perception. Measurements of tone may be applied to study (1) physiological events, such as fasting and postprandial changes, (2) reflex responses of the organ induced by distant stimuli, and (3) changes produced by pharmacological manipulations.

Intraluminal Pressure Manipulations

The barostat can be used to manipulate intraluminal pressure and produce distension. The local response to distension, measured as intraluminal volumes at different pressure levels, i.e., compliance, reflects both the capacity (size) of the organ and the distensibility of its walls; the distensibility, in turn, depends on the level of the muscular contraction in the walls. Distension stimulates receptors in the gut wall linked to reflex and sensory pathways that may induce various reflexes and conscious perception, respectively. These responses are stimulus-related, and since wall receptors operate as tension receptors, rather than as pressure or volume receptors, a modification of the barostat concept, the computerized tensostat, probably provides a better standardization of the stimuli under different experimental conditions. The tensostat is a computerized pump that maintains a fixed tension level within the gut wall; based on intraluminal pressure and volume, the system calculates wall tension by applying La Place's law and drives the pump to maintain the desired tension level.

APPLICATIONS

The barostat has been extensively used in both animal and human research. By contrast, its clinical applications are still limited, with very precise indications and restricted use in experienced laboratories. The barostat may provide useful information particularly on gastric and rectal function, specifically to evaluate compliance, pharmacological responses, and sensitivity, whereas the study of reflexes may be still more experimental. The barostat is particularly useful in the evaluation of some patients with severe postprandial symptoms. During ingestion, the stomach relaxes to accommodate the meal and subsequently the stomach progressively recontracts to produce gastric emptying. The barostat may elucidate whether symptoms after a meal are produced by poor accommodation due to defective gastric relaxation or by delayed emptying due to impaired contraction. Clinical symptoms for these two conditions may be the same, whereas therapeutic approaches used to correct defective gastric relaxation differ from the treatments used for delayed gastric emptying.

Barrett's esophagus is defined as the replacement of squamous tissue with columnar mucosa in the form of specialized intestinal metaplasia within the tubular esophagus. The critical ingredient in this process is the presence of goblet cells, the *sine qua non* of intestinal metaplasia, which can be confirmed only by endoscopic biopsy from the esophagus.

CLINICAL RELEVANCE

Barrett's esophagus (BE), as a complication of chronic gastroesophageal reflux disease (GERD), is the single best predictor for the development of adenocarcinoma of the esophagus. Esophageal adenocarcinoma is rising in incidence more rapidly than any other carcinoma in humans, although the cause of this rise is unknown.

EPIDEMIOLOGY

Rising Incidence

Despite the rising rate of adenocarcinoma of the esophagus, the absolute risk is low. There are approximately 12,000 carcinomas of the esophagus diagnosed annually in the United States, about half of which are adenocarcinomas. For a patient with Barrett's esophagus, the risk of developing carcinoma is estimated to be between 0.3 and 0.5% per year.

Risk Factors

GERD, Caucasian or Hispanic race, and male gender are the three strongest risk factors for developing BE. Well-controlled clinical studies have demonstrated that patients with long-standing, frequent, and severe GERD are at markedly increased risk of adenocarcinoma of the esophagus, presumably with BE as an intermediate step. The reason for the predominance among Caucasian or Hispanic males is unclear, although obesity and the declining prevalence of *Helicobacter* infection may play a role.

Role of *Helicobacter pylori*

There is increasing evidence that *H. pylori* may have a protective role against BE and carcinoma of the esophagus. The incidence of adenocarcinoma of the esophagus shows an inverse relationship with the decreasing prevalence of *H. pylori*. Chronic *H. pylori* infection leads to gastric atrophy and loss of acid production (achlorhydria) with decreased acid reflux. Patients with BE, especially those with dysplasia or carcinoma, are less likely to harbor *H. pylori* than are those without BE. The management of *H. pylori* is evolving, and it is premature at this time to recommend either eradication of *H. pylori* or leaving it *in situ* based on its potential role in esophageal adenocacinoma. There is little controversy, however, in recommending eradication of *H. pylori* in patients with peptic ulcer disease.

PATHOPHYSIOLOGY

Although BE has been clearly linked to GERD, little is known about the molecular and cellular mechanisms of the development of BE. Cross-sectional population studies suggest that BE develops early in life, with half of the maximum prevalence reached by 40 years of age and relatively little increase in prevalence after age 60. Once established, the length and presence of BE change little. The cell of origin for BE is unknown, with candidates including pluripotent stem cells in the esophagus, subsquamous glandular cells, or heterotopic gastric mucosa. Markers of inflammation, such as up-regulation of cylcooxygenase-2 (COX-2), are present in BE, offering hope that COX-2 inhibitors may blunt the development or progression of BE. It remains unclear if reflux of acid, reflux of bile, or both are required for the development of BE, although the experimental production of this lesion in a canine

model provides strong evidence for the critical role of acid.

DIAGNOSIS

Detection of Goblet Cells

The diagnosis of BE requires endoscopic biopsy of the esophagus and histological examination for the presence of goblet cells, the *sine qua non* of intestinal metaplasia. This seemingly simple criterion is nonetheless widely confused. This is due in large part to the changing definition of BE over time. Early literature defined BE simply as columnar epithelium, usually occupying at least 2–3 cm of esophagus. The modern definition is a functional one, based on the fact that only patients with intestinal metaplasia are at elevated risk of adenocarcinoma, regardless of the length of BE. The most difficult area of definition lies in distinguishing very short irregularities in the normal squamocolumar junction of the esophagus from true BE. Because intestinal metaplasia is present in the gastric cardia in up to 20% of asymptomatic individuals, it is critical to take biopsies from the tubular esophagus, which requires careful attention to anatomic landmarks.

TREATMENT

The treatment of BE should be distinguished from the treatment of GERD. Almost all BE patients have GERD, and these symptoms are usually controlled with acid suppression, surgical fundoplication, or lifestyle modifications. In contrast, no therapy has definitively been shown to alter the likelihood of BE progressing to adenocarcinoma.

Acid Suppression

Acid suppression has been a mainstay for treating patients with BE for two reasons. Acid suppression controls symptoms of GERD and reduces the degree of inflammation in the esophageal epithelium. Although this reduced inflammation has not been shown to reverse BE or change its natural history, it makes the histological interpretation of dysplasia considerably easier because inflammatory changes can be misinterpreted for low-grade dysplasia. Recent studies suggest that long-term, high-dose acid suppression with a proton pump inhibitor (titrated by pH monitoring) may cause a small reduction in the area of columnar epithelium, although there may be hidden columnar epithelium underneath new squamous cell islands. To date, it is unknown whether the overall risk of carcinoma is changed by this therapy.

Antireflux Surgery

Surgery offers the theoretical advantage of sustained reduction of both acid and bile reflux. However, surgical studies have not shown any significant effect on either the length of Barrett's or, more importantly, the likelihood of developing adenocarcinoma. A randomized controlled trial has compared surgery to medical therapy (histamine-2 receptor antagonists) with long-term outcomes. This Veteran's Administration (VA) cooperative study showed no significant difference in the development of Barrett's or adenocarcinoma, or change in the length of Barrett's. In fact, long-term mortality was lower in the medical therapy group, largely due to a higher cardiac death rate in the surgical group for unknown reasons. Long-term followup of BE patients after surgery suggests no overall effect on the likelihood of developing adenocarcinoma or dysplasia, likely due to ongoing low rates of acid and bile reflux.

Ablation of Barrett's Epithelium

Several investigators have evaluated methods to ablate the metaplastic epithelium of patients with BE either with or without dysplasia. Almost all methods employed (heat coagulation, laser therapy, cyrotherapy, and photodynamic therapy, all in conjunction with high-dose acid suppression) result in substantial replacement of the BE with squamous epithelium. Unfortunately, 20–30% of patients develop squamous epithelium overlying intestinal metaplasia, presenting a difficult clinical dilemma for surveillance and an unclear effect on long-term risk of carcinoma. At this point, attempts to ablate BE should be considered experimental, especially for nondysplastic BE.

ENDOSCOPIC SURVEILLANCE

Endoscopic surveillance of BE has been the cornerstone of management. Multiple uncontrolled observations have demonstrated that under surveillance, patients are more likely to be diagnosed with early-stage tumors or dysplasia, and have better survival compared to patients not under surveillance. No prospective controlled trial data are available to prove the effectiveness of BE surveillance. Decision analysis models have suggested that surveillance is cost effective compared to other commonly accepted medical practices, such as mammography and colon cancer screening. The most cost-effective interval for surveillance is every 5

years, although organizational recommendations have been more conservative, recommending surveillance every 2–3 years for patients without dysplasia, and every 6 months for the first year, then yearly for those with low-grade dysplasia. Surgical esophagectomy remains the standard of care for treatment of high-grade dysplasia, although photodynamic therapy is emerging as a possible alternative. In addition, several recent studies suggest that patients with focal high-grade dysplasia and those with normal DNA ploidy (as opposed to aneuploid) have a low risk of progression and can be followed by close surveillance (every 3–6 months). Newer techniques for optical detection of dysplasia, such as light-scattering spectroscopy and fluorescence spectroscopy, are promising tools in development, but remain experimental at this time.

CONCLUSIONS

Barrett's esophagus is the single most significant risk factor for adenocarcinoma of the esophagus. Patients with long-standing symptoms of GERD should undergo screening to detect Barrett's, and should be considered for regular surveillance to detect the early development of dysplasia or cancer. Areas of active investigation are identification of the cellular and molecular mechanisms for development of BE, better markers of risk among patients with BE, and nonsurgical therapies to eradicate BE once it has developed.

absorption The movement of nutrients and fluid from the intestinal lumen into the lymphatics or bloodstream. This comprises two steps, uptake from the intestinal lumen and transfer from the cytosol of the enterocyte into the lymphatics or portal circulation.

adaptation The process by which the morphology and/or absorptive function of the intestine changes in response to stimuli such as a change in the composition of the diet, the development of diabetes, or a loss of a portion of the intestine.

basolateral membrane The portion of the cell lining of the enterocyte that communicates with the submucosal tissue.

brush border membrane The membrane of the intestinal absorptive cell, the enterocyte, which faces the intestinal lumen.

enterocyte The major cell lining the intestinal villus that is responsible for the absorption of nutrients.

intravillous space The space between the long villi. Nutrients must diffuse into this space in order to be taken across the brush border membrane in portions of the villus away from the villus tip and toward the crypt.

lipid-binding proteins Proteins in the brush border membrane and the enterocyte cytosol that bind lipids. Their physiological role is unknown; they may influence or modify intestinal absorption, bind lipids as they move from the brush border membrane to microsomes, or possibly play a role in the handling of adaptation.

unstirred water layer Consists of a series of lamellae of water, progressively less and less stirred as one moves from the bulk phase in the intestinal lumen to the brush border membrane. The unstirred water layer reduces the concentration radiant between the bulk phase and the brush border membrane and thereby slows the uptake of nutrients.

Lipids represent a major source of calories and are thereby nutritionally important. Some lipids are essential as they are not synthesized in the body and play an important role in a variety of functions, such as integrity of membranes. Most lipids are emulsified in the stomach, digested in the intestinal lumen as the result of enzymes secreted from the pancreas in response to the presence of food in the intestinal lumen, and then solubilized by bile acids secreted by the liver. The long-chain fatty acids and cholesterol are solubilized in bile salt micelles, diffuse across the intestinal unstirred water layer, and then passively permeate the lipophilic brush border membrane (BBM). There are lipid-binding proteins in the BBM as well as in the enterocyte cytosol and these may contribute to the uptake of lipids. Once the lipids are in the enterocyte, they pass to the endoplasmic reticulum, where they are further metabolized before being excreted across the basolateral membrane into intestinal lymphatics or into the portal vein. Although the process of intestinal absorption of lipids has many steps, it is complex and integrated and it is a highly efficient process in which normally more than 95% of lipids in the diet are absorbed.

INTRODUCTION

Lipid absorption involves uptake across the brush border membrane (BBM) into the enterocyte, where the lipids must be transferred intracellularly to sites of metabolism or exit the cell across the basolateral membrane (BLM) into the lymph or portal blood. Fat digestion and absorption constitute a complex process involving insoluble substrates, neutral and amphipathic lipids, and lipases acting in the stomach and small intestine. Intestinal lipid absorption involves several coordinated steps, including digestion and solubilization of the lipid, diffusion across the unstirred water layer (UWL), mediated and nonmediated transport across the BBM, diffusion across the cytosol, intracellular metabolism, binding to lipoproteins, and exit across the basolateral membrane into the lymph or portal blood.

The uptake of lipids into the enterocyte occurs predominantly at the upper third of the villus. Nutrients must cross two barriers in series in order to be taken up by the enterocyte: the intestinal UWL and the BBM. The rate of nutrient uptake is determined by the dimensions and properties of these two barriers, as well as by the activity of protein-mediated components of transport.

LIPID UPTAKE ACROSS THE INTESTINAL BBM

Lipid uptake across the BBM is the rate-limiting step for uptake of short- and medium-chain fatty acids, whereas passive uptake of long-chain fatty acids is rate-limited by passage through the UWL. Three models of passive uptake of long-chain fatty acids (LCFA) and cholesterol have been outlined. The first model proposes that the entire mixed micelle is absorbed by the BBM. However, no experimental evidence supports this model. In the second model, the micelle collides with the BBM, allowing for the uptake of lipids to occur. Evidence for this model is suggested by the linear relationship between lipid uptake and bile acid concentration. In contrast, the third model proposes that the lipids dissociate from the micelle into the aqueous compartment of the UWL before being taken up by the BBM. Support for this model is suggested by the finding that fatty acid uptake decreases with an increase in the number of bile acid micelles, under conditions in which fatty acid concentration is kept constant. The dissociation of lipids from bile acid micelles is under the influence of the acidic microclimate adjacent to the BBM. Under these acidic conditions, the critical micellar concentration increases, the fatty acids become protonated, and this protonation increases their rate of permeation across the BBM. Increase in the fluidity of the BBM also increases the rate of permeation of lipids. Other factors influencing the rate of lipid uptake may be the lumenal lipid composition, lipid-binding proteins, and membrane potential. For example, polyunsaturated fatty acids and phophatidylcholine may inhibit cholesterol absorption, possibly by shifting the partition coefficient of cholesterol away from the cell membrane back to the micelle, thereby preventing the uptake of lipid. There are numerous lipid-binding proteins in the BBM and cytosol of the enterocyte (Table I) and these likely play a role in lipid absorption.

Short-chain fatty acids (SCFA) are produced by bacterial degradation of complex carbohydrates and proteins entering the colon. SCFA are rapidly absorbed. SCFA stimulate electroneutral sodium absorption via activation of the BBM Na^+/H^+ exchanger (NHE), which results from the SCFA changing the intracellular pH gradients. Medium-chain fatty acids are neutral lipids containing fatty acid molecules with chain lengths ranging from 6 to 12 carbon atoms. These fatty acids are more rapidly and completely hydrolyzed than are long-chain triglycerides (LCT), even in the absence of pancreatic lipase. Medium-chain fatty acids are absorbed at the same rate as SCFA in the human rectum. The absorption of medium-chain triglycerides (MCT) is less dependent on the action of bile salts, because MCT are more water soluble than LCT. Although MCT are better absorbed than LCT in the presence of pancreatic insufficiency, pancreatic extracts may increase their absorption. Thus, if patients with pancreatic insufficiency are given pancreatic supplements, there may be little additional benefit to lipid absorption when giving MCT compared with using LCT. The availability of orally administered hydrophilic drugs to the systemic circulation is generally limited by the barrier properties of the intestinal membrane. The sodium salts of medium-chain fatty acids (MCFA) enhance the absorption of hydrophilic drugs across the intestinal mucosa and structurally similar MCFA display differences in their mechanism of action.

The uptake of cholesterol into the intestine occurs by a process of passive permeation across the BBM, after dissociation of cholesterol from the micelle directly into the membrane or into the acidic aqueous phase external to the BBM. Proteins facilitate cholesterol and phosphatidylcholine absorption. Cholesterol esters may also be subject to protein-mediated uptake. Cholesterol absorption is a multistep process that includes hydrolysis of cholesterol esters in the gut lumen, formation of mixed micelles, transport of cholesterol into enterocytes, its reesterification, and then assembly and secretion of chylomicrons as well as nascent high-density lipoproteins. There may be lipid-binding proteins that facilitate cholesterol absorption.

Bile acids are water-soluble end products of cholesterol metabolism that participate in fat digestion in the gastrointestinal tract. Bile acids are synthesized from cholesterol in the liver and are secreted with bile into the small intestine. Lumenal bile acids form micellar structures that solubilize lipids and facilitate their absorption across the brush border membrane. In the terminal ileum, the lumenal bile acids are actively reabsorbed by the enterocytes and are returned to the liver via the portal circulation. This process is known as the enterohepatic circulation. Lipid absorption requires an optimal concentration of bile acids in the intestinal lumen and this concentration is maintained by the balance between ileal excretion and ileal active reabsorption of bile acids. The enterohepatic cycling of bile salts is a major factor in the maintenance of the bile salt pool. Bile salts are absorbed passively in the jejunum and are actively absorbed in the ileum. Bile acids are taken up by passive or protein-mediated processes. The BBM Na^+/bile acid cotransporter has been cloned from rat, hamster, and human ileum and is subject to both translational and posttranslational regulation. A 14 to 15 kDa cytosolic binding protein, the intestinal bile acid-binding protein, belongs to a family of hydrophobic

ligand-binding proteins, the fatty acid-binding proteins. The binding of bile acids to ileal lipid-binding protein (ILBP) increases the affinity of ILBP for bile acids. This may be a substrate-load modification of transport activity and a positive-feedback regulation for active uptake of bile acids in the ileum.

Low-molecular-weight cytosolic bile acid-binding proteins are also involved in the intracellular transport of bile acids and may be subject to transcriptional regulation. Bile acids may provide positive feedback regulation for active bile acid uptake by binding the ileal ILBP.

The Unstirred Water Layer

The passive and carrier-mediated transport processes are described kinetically on the basis of the passive permeability coefficient (P), the incremental Gibbs free energy values ($\delta\Delta F_{w\rightarrow 1}$) associated with the addition of specific substituent groups to a probe molecule, the Michaelis affinity constant (K_m), and the maximal transport rate (V_{max}). These measurements provide critical information about such important characteristics of the BBM as its relative hydrophobicity and permeability and about the number and characteristics of specific transporters in the BBM. Although it has been assumed that uptake is determined by the properties of the BBM, it is critical to correct uptake for potentially serious qualitative and quantitative errors arising from failure to account for the effect of the UWL resistance. Failure to correct for the effect of the UWL may lead to underestimation of passive permeability coefficients, incremental free-energy values and reflection coefficients for carrier-mediated processes, overestimation of Michaelis constants for carrier-mediated processes, or erroneous identification of "transition" temperatures in the membrane. Failure to correct for the UWL may lead to overestimation of the value of V_{max} if the contribution of concurrent passive uptake is not taken into account or if recruitment of the carrier along the intervillus space is not taken into consideration. These potential errors may invalidate the use of Michaelis-Menten kinetics for the analysis of carrier-mediated transport processes.

Adjacent to all biological membranes there is a layer of relatively unstirred water through which solute moves by diffusion. In the intestine, this UWL consists of a series of water lamellae that extends out from the BBM, each layer of which is progressively more stirred until it blends in with the bulk water phase in the intestinal contents. The UWL is an operational term, because the boundary between the bulk water phase and the UWL is not well defined. Therefore, the dimensions

of UWL thickness and surface area give rise to a value of "effective resistance."

The UWL is formed by "hydrated mucus and a series of water lamellae extending outward from the BBM, each progressively more stirred, until the layers blend imperceptibly with the bulk phase." It is unclear whether the UWL is the physical structure of water, mucus, glycocalyx, villi, and microvilli; laminar flow of the lumenal perfusate; or movement of the intervillous space. The thickness of the intestinal UWL has been estimated to be 30 to 1000 μm, depending on the methods used to make the measurement, the use of *in vitro* or *in vivo* tissue preparations to obtain varying degrees of stirring or mixing of the lumenal fluid, the shape of the villi, and the extent of villous motility observed in the different species studied. The thickness of the UWL may be 500 Å in humans, although much lower values have been reported.

The effective resistance of this UWL must be taken into consideration when describing nutrient absorption. The rate of solute diffusion across the UWL is determined by the thickness and surface area of the UWL, the aqueous diffusion constant of the solute, and the concentration of the solute. Lipids diffuse across the intestinal UWL before contacting the BBM. The effect of the resistance of the UWL is to reduce the concentration of the lipid presented to the BBM. Therefore, it is important to correct for the effect of the UWL on absorption, to assess the true permeability coefficient of the BBM. Failure to correct for the effective resistance of the UWL will result in underestimation of the true permeability properties of the BBM. Bile acid micelles greatly enhance the uptake of fatty acids and cholesterol from the small intestine, by helping to overcome the resistance of the UWL and by increasing monomer concentration at the aqueous–membrane interface.

A variety of approaches have been developed to estimate UWL resistance. These include techniques that are based on the following: (1) the morphometric analysis of small bowel dimensions; (2) the rates of carbon monoxide diffusion out of the intestinal lumen; (3) the effects of changes in viscosity of the perfusate on solute absorption; (4) the osmotic gradient technique to determine time required for development of diffusion potentials; (5) the kinetics of entry of macromolecules into the intervillus spaces; and (6) the comparison of the K_m values for solute transport or peptide digestion with the values observed in the intact intestine.

The osmotic transient technique has been used *in vitro* and it assumes the presence of a planar surface. The osmotic transient technique has also been used in intestinal perfusion studies in animals and in humans. UWL thickness estimates of 300 to 800 μm have been obtained from the determination of the half-time of changes in the potential difference in a perfused gut segment when one solution is rapidly substituted for another with a different osmolarity. This method probably does not yield accurate estimates of UWL thickness because the osmolarity of the lumenal bulk solution is achieved slowly. Furthermore, fluid perfused through the rat intestine moves by laminar flow, rather than segregating into a UWL and well-mixed bulk lumenal contents.

Another method used to assess the effective resistance of the UWL is to determine the rate of intestinal uptake of a homologous series of probes, such as saturated fatty acids. The fatty acid partition coefficient increases with its chain length by a factor corresponding to a decrease in the incremental change in free energy moving from an aqueous phase to a lipid phase. Values for the apparent passive permeability coefficient (P) increase with the chain length of the fatty acids, until the value of P becomes proportional to their free diffusion coefficients. This point indicates that uptake was limited by the rate of diffusion across the UWL up to the BBM. From rates of uptake of such diffusion-limited probes, the UWL resistance in rat jejunum *in vivo* may be calculated and closely approximates the value of the UWL resistance calculated from the half-time of change in diffusion potential. The diffusion barrier resistance falls by approximately 45% over a range of perfusion rates observed *in vivo* (1.5–15 ml/min).

In vivo, the magnitude of the UWL thickness varies depending on the method used to access this dimension: in rat jejunum the UWL is 700 to 800 μm thick in a 30 cm segment perfused in the conventional fashion on the abdominal cavity, falling to 200 to 400 μm when the segment is placed in the abdominal wall and falling to 32 to 68 μm with shaking of the intact rat. Values for the effective thickness of the UWL in rat perfusion experiments have been obtained by various methods: 410 to 430 μm by measuring the development of osmotically induced potential difference, 460 to 486 μm by the segmented flow technique, and 212 to 708 μm by changing the flow rate.

Another method used to obtain measures of UWL thickness *in vivo* involves the measurement of the rate of hydrolysis of probes *in vitro* and *in vivo*; from the difference in these rates, the UWL effect is calculated. Such estimates have yielded UWL thickness values of 48 μm in the human jejunum. This method assumes that the K_m of the disaccharides, measured *in vitro*, accurately reflects the K_m of these enzymes in the intact intestine. This is a reasonable assumption, given that the kinetics of these enzymes are not altered by dissociation from the BBM. This method also assumes that all

disaccharide hydrolysis occurs in the BBM rather than in the lumenal contents, again a reasonable assumption.

Measurements of UWL thickness made in the jejunum of conscious dogs by assessing the absorption rate of two rapidly absorbed probes, glucose and [^{14}C] warfarin, gave values of only approximately 35 and 50 μm for perfusion rates of 26 and 5 ml/min, respectively. Measurements of the maximal UWL thickness for the human jejunum calculated from previous studies of glucose absorption yielded a mean value of only 40 μm. These measurements are less than one-tenth of previously reported values obtained using the osmotic transient technique.

The effective resistance of the UWL is determined not just by its thickness, but also by its surface area and by the diffusion coefficient of the probe under consideration. The diffusion coefficient may vary with viscosity of the bulk phase or of the mucus in the UWL. Earlier physiological studies showed that the uptake of most nutrients occurs from the upper portion of the villus. The "recruitment" of additional transporters or membrane surface area available for uptake will depend on the rate of uptake of solute from the enterocytes at the top of the villus, their access to the intervillus space, and the movement of the villi. Thus, the surface area of the BBM used for nutrient uptake is much less than the total membrane surface area.

The viscosity of fluid influences diffusion resistance. Dietary fiber or its components, such as guar gum, may be used to increase the viscosity of the lumenal contents. Such changes in viscosity may reduce absorption by affecting UWL resistance. Fiber may also increase the pressure in the intestinal lumen, distend the bowel, and thereby increase the uptake of some substances such as antipyrine (a weak base, almost completely undissociated). *In vivo*, other aspects of fiber may play a role in nutrient absorption such as a slowing effect on gastric emptying or a prolonged mouth-to-cecum transit time.

There is evidence to suggest that the dimensions of the UWL may be specific to individual experimental conditions and cannot be predicted. Thus, to correct for effective resistance of the UWL and thereby to obtain valid estimates of the kinetic properties of the tissue in question, this resistance factor must be measured. Only in this way will it be possible to establish whether an adaptation in transport that occurs as a result of a dietary, pharmacological, or other experimental manipulation designed to mimic a disease state influences nutrient uptake as a result of alterations in the value of P, K_m, or V_{max}. Once the kinetic mechanism of altered transport is known, then mechanisms responsible for this adaptation can be determined. Thus, the value of the UWL resistance must be measured for each change in experimental design.

Intervillus Space and Villous Motility

Increasing the rate of stirring of the bulk phase enhances the *in vitro* uptake of nutrients. Faster rates of perfusion through the intestine enhance *in vivo* uptake of nutrients by a process that involves a reduction in the thickness of the UWL and an enhancement of mucosal surface area available for uptake. Distension of rat ileum leads to a reduction in villous height and a marked increase in width of the intervillous space (IVS) in both the transverse and the longitudinal dimensions. The net effect of this distension, however, is that there is no absolute change in total mucosal surface area.

Because the proportion of the IVS that is involved in solute uptake will depend on the extent to which cells at the villous tip exceed their capacity to transport the solute, the V_{max} or P may vary depending on the extent of the IVS used for uptake. With increasing recruitment of carriers along the IVS or recruitment of increasing amounts of cell membrane for passive uptake, the estimated value of these kinetic constants may vary.

Because the IVS is only approximately 50 μm wide in dogs and 15 μm in rats, 7 to 25 μm is the maximum UWL that could separate the solute from the absorptive epithelium in this space. The remaining UWL must be confined to the villous tips. Using measurements of maltose hydrolysis in the rat jejunum, hydrolysis was accurately predicted by a model in which the unstirred fluid extended from 20 μm over the villous tips throughout the IVS. In this model, the depth of diffusion into the IVS is inversely proportional to the efficiency of epithelial handling of the solute. As a result, both the aqueous barrier and the functional surface area are variables rather than constants.

If the thickness of the UWL *in vivo* is low, then what will be its impact on nutrient uptake? Levitt and colleagues have estimated for a rapidly absorbed nutrient such as glucose that the ratio of the cross-sectional surface area of the IVS to the lumenal mucosa surface is 1 : 3, that 50% of the glucose will be absorbed within 9 μm of the villous tips, and that this preepithelial diffusion barrier may remain the rate-limiting step for rapidly permeating probes such as glucose. A UWL of 35 μm would still produce approximately 75% of the total resistance to glucose absorption, because the total resistance (UWL plus epithelial cell) to transport of low concentrations of glucose is equivalent to a UWL of 48 μm. As the infusate concentration increases, the carriers at the villous tip become saturated and the probe must diffuse down the IVS.

When uptake occurs largely from cells along the upper portion of the villus, the thickness of the UWL can be approximated by simple laminar flow analysis and for modeling purposes the intestine can then be assumed to be a smooth cylinder. The IVS may become an important site of uptake when flow rate is high or when there is intestinal distension. However, the increase in the absorption rate after distension is smaller than the enlargement of the inner cylindrical surface area, presumably because of a change in supravillous diffusion resistance.

In canine jejunum *in vivo*, substances absorbed into the villus tips must penetrate an unstirred layer of 500 to 1000 μm, and for those substances absorbed into the lateral surfaces of the villi, an additional barrier of as much as 800 μm exists. The fluid in the IVS is poorly stirred and presumably movement of the villi has little impact on mixing of the IVS fluid. Westergaard and Dietschy, in 1974, and Winne, in 1978, also concluded that villus movement produced little stirring of the UWL. When water absorption occurs then penetration of the UWL by the process of solvent drag may enhance absorption into the tip region of the villus. However, because water absorption occurs largely in the uppermost portion of the villi, diffusion is likely the only process for permeation across the BBM of enterocytes further down the villus.

Intestinal villi exhibit spontaneous movement in the living animal. The villous movements are thought to be due to contraction of smooth muscle fibers from the muscularis mucosae that run longitudinally within the villous core. There is a piston-like retraction and extension of the villi, pendular side-to-side movement, and tonic contraction of several or all villi. Local, neural, and hormonal factors modulate villous motility.

A videomicroscopic method has been used to analyze quantitatively villous motility in the dog intestine. The villous retractions are most frequent and of longest duration in the duodenum, followed by the jejunum and the ileum. It is predicted that villi are in the retracted state for approximately 30, 13, and 6% of the time in these three sites, respectively. The frequency of pendular movements is greatest in the jejunum, followed by the ileum and the duodenum. Lumenal pH or the presence of glucose has no effect on villous motility, whereas amino acids and free fatty acids increase villous contraction frequency by 30–50 and 90%, respectively. It is unclear whether these changes in villous contraction are achieved by feeding alone or by specific nutrients. Increasing villous motility by fluid expansion in the intact canine intestine actually decreases absorption of water and lauric acid. Thus, it is unclear whether the villous motility perturbs the UWL sufficiently to actually modify nutrient absorption.

According to the principles of laminar flow, the flow rate of fluid is most rapid and most completely stirred in the center of the intestinal lumen, with progressively slower flow rates and incomplete stirring in fluid near the BBM. Laminar flow occurs in the gut. The two-dimensional laminar flow model is valid for determining kinetic parameters of carrier-mediated transport *in situ* and for predicting absorption rate *in situ* from uptake rate *in vitro*. Thus, in the constantly perfused intestine, fluid moves with laminar flow. This is different from the conventional unstirred water layer model, which proposes a thickness of totally unstirred water adjacent to the lumen with well-mixed contents in the center of the lumen.

The flow rate of fluid through the proximal small intestine varies widely from an average of 2.5 ml/min in fasting subjects to as high as 20 ml/min after meals. Increasing the flow rate increases the absorption of tritiated water and D-glucose and opens the IVS more widely. Increasing the jejunal flow rate from 5 to 20 ml/min decreases the permeability ratio of xylose/urea by approximately 30% and decreases the average calculated pore radius of the diffusion pathway. Presumably there is increased exposure of the lumenal fluid to the less permeable cells in the IVS.

Most studies of perfused bowel *in vivo* have been performed in anesthetized laparotomized rats, where there is little motility and near-perfect laminar flow, just as if the perfused fluid mass was moving through a pipe. In conscious rats, maximal preepithelial resistance is equivalent to an UWL thickness of only approximately 100 μm, with anesthesia doubling this resistance and anesthesia and laparotomy increasing resistance to approximately 600 μm. Clearly, corrections in UWL resistance become even more important under these experimental conditions.

Acid Microclimate

A layer juxtaposed to the mucosal surface where the proton concentration is higher than in the bulk phase of the intestinal lumen is designated the "acid microclimate." The existence of the acid microclimate was postulated on the basis of differences in the steady-state distribution of weak acids and bases from the values predicted by the pH-partition hypothesis. In a theoretical study in 1977, Winne concluded that the absorption of weak electrolytes could be modified by the existence of unstirred layers. The presence of the acid microclimate was demonstrated indirectly on the basis of acidification of the incubation medium by isolated

segments of rat jejunum, as well as by direct measurements using surface microelectrodes or tip microelectrodes on tissue *in vitro* or *in vivo*. Point-by-point determinations using 50 μm tip diameter antimony microelectrodes show that in rat jejunum *in vitro*, the highest proton concentration (24−224 nmol/liter = pH 6.67−6.65) was found 10 to 100 μm below the tip of the villus. No gradient is seen along the villi in the ileum. The thickness of the acid microclimate in rat jejunum *in vitro*, 700 μm, is similar to the thickness of the UWL. Such an acid microclimate has been described in human intestinal biopsy material and may change in disease states such as celiac disease.

Thus, the pH of the UWL is below 6, which is lower than in the bulk phase of the intestinal lumen, and is lowest in the mucus layer immediately adjacent to the BBM. The low pH of this acid microclimate is maintained by activity of the Na^+/H^+ exchanger in the BBM. The NHEs in the intestinal BBM are responsible for acidifying the UWL adjacent to the BBM. This facilitates partitioning of fatty acids out of the bile salt micelles, their protonation, and hence their greater permeation across the BBM. NHE appears to play a more important role when there is a H^+/Na^+ gradient across the BBM, whereas the fatty acid-binding protein in the BBM, FABPm, is important when there is less of such a gradient. Inhibition of NHE or FABPm results in an approximately 30 to 40% decline in the uptake of fatty acids. Mucus glycoproteins may contribute to this pH gradient by inhibiting the diffusion of protons into the bulk phase. The mucus may act as an ampholyte, restricting H^+ movement in its matrix. The acid microclimate is also maintained by physical properties of the mucus that retard diffusion of H^+ from the BBM to the bulk phase in the intestinal lumen. The acid microclimate may alter the proportion of ionized to non-ionized solutes, which may thereby influence the ability of the solutes to be taken up by the BBM. This is particularly important for fatty acids ($pK_a \sim 4.2$), since the majority would exist in the non-ionized form in the acidic microclimate of the UWL and thereby allow these protonated fatty acids to permeate the BBM more readily.

Brush Border Membrane

The second barrier to lipid uptake is the BBM of the enterocyte. The BBM of the enterocyte is polarized in composition and in function. Tight junctions divide the plasma membrane into two domains: the BBM and the BLM. The surface area of the BBM increases the surface area of the villus up to 40-fold and is subject to direct or indirect regulation by food or food substances. The BBM serves as a permeability barrier that separates the enterocyte from the intestinal lumen. Nutrient transport is determined by endocytosis, carrier proteins, and permeability properties of the membrane. Absorbed nutrients exit the enterocyte across the BLM into the portal blood and into the lymph. The BLM is also the entry site of nutrients, hormones, and ions from the blood. Lipids are presumably incorporated in the external lipid monolayer of the BBM; they subsequently diffuse through the BBM and are released from the inner lipid monolayer of the BBM into the cytosol of the enterocyte. The permeability properties of the BBM are subject to adaptation in health and disease.

Alterations in BBM lipid composition may modify physical properties of the membrane, resulting in alterations in activity of membrane-bound proteins. These changes in BBM composition may produce alterations in cell function, including nutrient transport. For example, alterations in BBM lipid composition with aging have been reported for rat intestine and rabbit intestine. The ratio of total phospholipid to cholesterol in the BBM increases with aging, primarily due to an increase in the phospholipid content of the membrane.

Changes in the fatty acid and cholesterol content of the diet result in alterations in BBM lipid composition and nutrient transport. The degree of unsaturation of dietary fatty acids influences lipid composition and function of membranes isolated from many tissues including intestine. In addition, dietary glycosphingolipid such as ganglioside may alter membrane fluidity and permeability. Nutrients also play a significant role in the regulation of gene expression. In a membrane permeability study using enzymatic and fluorescence spectrometry techniques, incorporation of exogenous gangliosides into the phospholipid vesicle was shown to increase the passive membrane permeability.

Fluidity is a property of membranes that describes the freedom of lipid molecules to move in the membrane. Alterations in fluidity are associated with changes in membrane lipid composition and function. Passive and carrier-mediated nutrient transport processes depend on the nature of the fluidity of the BBM and its lipid composition. The lipid content of intestinal BBM changes with fasting. There are decreased ratios of cholesterol/phospholipid, sphingomyelin/phosphatidylcholine, and protein/lipid, decreased oleic and linoleic acids, increased brush border membrane total phospholipid, an increased double-bond index, and an increased percentage of stearic and arachidonic acids. The low fluidity of the BBM reflects a low phospholipid to cholesterol ratio and may be functionally important for efficient nutrient transport. Enterocyte

BBM fluidity is greater in the proximal small intestine than in the distal small intestine, decreases as cells migrate from the crypt to the villus, and is associated with changes in lipid composition. Passive lipid permeability and carrier-mediated glucose uptake are influenced by changes in BBM fluidity.

Once lipids have diffused across the UWL, their uptake is mediated by passive diffusion, although lipid-binding proteins may contribute to uptake.

Lipid-Binding Proteins

There are numerous lipid-binding proteins in the BBM and cytosol of the enterocyte (Table I). The presence of BBM lipid transport proteins raises the possibility that once lipids have partitioned out of the bile acid micelle, their uptake may occur by this carrier-mediated transport as well as by passive diffusion. Lipid-binding proteins in the BBM may serve to transport lipids into the enterocyte, whereas lipid-binding proteins in the cytosol may remove lipids from the BBM and/or bind them in the cytosol, thereby changing the lipid concentration gradient across the BBM and enhancing further uptake by passive permeation.

Caveolin-1 is a 22 kDa integral membrane protein located in detergent-resistant microdomains of the BBM. The caveolins may act as a plasma membrane storage of cholesterol and may play a role in the sterol-sensing component of the BBM. Caveolin-1 also exhibits a binding affinity for long-chain fatty acids. The role of caveolin-1 in the intestine has not been established, but may be involved in the intracellular targeting of lipids.

The scavenger receptor of class B type I (SR-BI) is a 57 kDa integral membrane protein and is located in the BBM. SR-BI may act as a docking receptor for donor particles, such as bile acid micelles, followed by the transfer of lipids to the BBM. SR-BI may also play a role in cholesterol absorption, as well as lipoprotein transport. SR-BI is present on both the apical and basolateral surfaces of the jejunum villus, with little SR-BI being detectable on either apical or basolateral membranes in the ileum.

A 43 kDa protein, known as the plasma membrane fatty acid-binding protein (FABPpm), was identified in the BBM and BLM of intestinal cells. This protein binds LCFA, monoglycerides, and cholesterol. Incubation of rabbit jejunal BBM vesicles with anti-FABPpm antibody results in a reduction in oleic acid uptake. Polyclonal antibody to FABPm inhibits intestinal oleate uptake in a dose-dependent, noncompetitive fashion, with a reduction in the uptake of fatty acids, cholesterol, monoacylgycerol, and lyso-PC but not in the uptake of glucose, alanine, or bile acids.

Fatty acid translocase (FAT) is an 88 kDa transmembrane glycoprotein located in the BBM of enterocytes. Rat FAT is 85% homologous to the human scavenger receptor CD36, which is found in platelets, lactating mammary epithelium, monocytes, and adipocytes. FAT RNA is more abundant in the jejunum than in the ileum and is present in the upper two-thirds of the intestinal villi; the FAT protein is limited to the BBM. Dietary fat rich in polyunsaturated fatty acids up-regulates the expression of intestinal FAT mRNA. FAT is thought to account for approximately 35% of free cholesterol uptake by the BBM.

The fatty acid transport protein (FATP) is a 63 kDa membrane protein. There is a large family of FATPs, but only FATP4 is present in appreciable levels in the intestine. FATP4 mRNA is expressed in the enterocytes of the jejunum and ileum and at lower levels in the duodenum. Expression of FATP4 mRNA is absent from the crypts of the small intestine and from the colon. Fatty acids containing 10–26 carbon atoms are thought to be substrates for FATP4.

The passive absorption of sterols occurs as a result of collision between mixed bile salt micelles and the BBM, but the BBM vesicle transport is reduced following membrane digestion with proteases, suggesting the existence of a transport protein. This "cholesterol transport protein" is an integral membrane protein, with at least one hydrophobic domain. The multidrug resistance protein (MDR; MDR1 in humans) may be involved in the uptake of cholesterol into intestinal epithelial cells. A sterol glycoside derivative specifically binds to the BBM of enterocytes and blocks the absorption of cholesterol. A 145 kDa integral membrane protein in the BBM of rabbit enterocytes has also been identified and may contribute to intestinal cholesterol absorption.

In the cytosol of the enterocyte, fatty acids are bound and transported to their respective sites of metabolism by several cytosolic lipid-binding proteins including two fatty acid-binding proteins (FABPc), the intestinal type (I-FABPc), which is present exclusively in the intestine, and the liver type (L-FABPc), which is present in both liver and intestine. Rat intestinal I-FABPc and L-FABPc genes and human I-FABP have been cloned. I-FABP is localized in mature villus tip cells and is not usually present in the crypt cells, whereas L-FABP is confined to the crypt–villous junction and is not present in villus tip cells. L-FABPc appears in the crypt cells only under the conditions of fasting, likely in order to obtain fatty acids from the blood. I-FABPc binds palmitic, oleic, and arachidonic acid, whereas

L-FABPc binds both saturated and unsaturated fatty acids, monoacylglycerols, lysophospholipids, and bile salts, but not cholesterol. L-FABPc is a 14.1 kDa protein located in the duodenum and jejunum, with maximal expression in the proximal jejunum. I-FABPc is a 15.1 kDa protein that is expressed throughout the small intestine, with maximal expression in the distal ileum. The mRNAs for I-FABPc and L-FABPc are expressed throughout the small intestine and along the length of the villi. I-FABPc is thought to be important for binding lumenally derived fatty acids absorbed across the BBM, whereas L-FABPc binds fatty acids from the bloodstream. I-FABPc is pH-insensitive, which suggests that it binds protonated fatty acids, whereas L-FABPc binds only the unprotonated fatty acids. L-FABPc also binds growth factors, prostaglandins, and leukotrienes, which suggests that L-FABPc plays a role in enterocyte growth and differentiation. These differences in binding specificities and properties may aid in the targeting of lipids to their sites of metabolism.

Peroxisome-proliferator activator receptors (PPAR) may play an obligatory role in up-regulating the expression of L-FABP and I-FABP genes. The livers of mice fed bezafibrate, a PPAR hypolipidemic drug, showed a fourfold increase in L-FABPc protein and mRNA. Bezafibrate increases the mRNA expression of FAT, suggesting a complementary role of FAT and FABP proteins in lipid absorption.

The microsomal triglyceride transport protein (MTP) is an endoplasmic reticulum (ER)-localized cofactor required for the assembly of apolipoprotein B (apoB). MTP is a heterodimer consisting of a 58 kDa subunit of protein disulfide isomerase (a multifunctional ER protein) and a unique 97 kDa subunit. MTP is essential for the transfer of triglyceride and cholesterol esters into the hydrophobic core of apoB. Mansbach and co-workers have suggested that the rate-limiting step in lipid absorption is the trafficking of triacylglycerol from the ER to the Golgi. Specifically, the rate-limiting step may be formation of a prechylomicron vesicle that transports the developing chylomicron from the ER to the Golgi. This rate-limiting step in the complex process from fatty acid and monoacylglycerol entry to triacylglycerol export may involve a protein for the transport of triacylglycerol from the endoplasmic reticulum to the Golgi complex. This transport particle has been isolated and characterized; electron microscopy shows a 200 nm vesicle containing immunoidentifiable apoB48 and apoA-IV, but very little apoA-I. The surface of the chylomicron contains both exchangeable apoA-I, apoA-IV, apoC, and apoE and nonexchangeable apoB48.

Basic Electrical Rhythm

JACKIE D. WOOD

interstitial cells of Cajal Specialized nonneural cells that function as pacemakers for the gastric and intestinal musculature.
myogenic Originating in the musculature of an organ.

Electrodes attached to the serosal surface of the stomach or small and large intestines of mammals detect electrical activity that is continuous and rhythmic. Because of its cyclic periodicity, following its discovery, this electrical activity was called "basic electrical rhythm." The more modern term for the same kind of activity is "electrical slow wave." The time period from the onset of one wave to the onset of the next is designated as one cycle of the rhythm. Quantitative descriptions of the rhythm frequencies in the specialized regions of the gastrointestinal tract are usually expressed as cycles per minute.

INTRODUCTION

The basic electrical rhythm (BER) in the stomach or small and large intestines of mammals is a property of the musculature. The rhythm continues after blockade of all of the innervation of the gut muscles and continues in isolated preparations of stomach or intestine placed in warmed physiologic solutions outside of the body. This is the basis for describing the slow waves as myogenic. Depolarization of the muscle membrane potential accounts for the rising phase of the slow wave and repolarization accounts for the falling phase.

Specialized pacemaker cells determine the frequency at which the slow waves occur. The specialized pacemaker cells are the interstitial cells of Cajal; named after the famous Spanish neuroanatomist, Ramón y Cajal. Interstitial cells of Cajal are electrically coupled to the bulk of the smooth muscle in the stomach and intestine. Electrical slow waves generated by the pacemaker cells spread passively into the bulk musculature. The slow waves do not trigger contractions of the muscle. Invasion of the bulk musculature by the slow waves depolarizes the membrane potential of the muscle cells to the threshold for discharge of action potentials, and the action potentials trigger contraction. Contractions and electrical slow waves occur at the same frequency when action potentials are triggered by each and every slow wave. No contractions occur when the slow waves fail to trigger action potentials in the muscle. The nervous system of the gut determines when the ongoing slow waves trigger action potentials and their accompanying contractions.

BASIC ELECTRICAL RHYTHM OF THE STOMACH

The waveforms (Fig. 1) of the BER, as recorded with intracellular microelectrodes in the stomach and small and large intestines, are similar in shape. Frequencies of occurrence of the BER cycles in the stomach are slower than in the small intestine. The waveform of the gastric BER consists of a sharply rising depolarizing phase, a plateau phase, and a repolarization phase (Fig. 1D). Action potentials may appear on the plateau phase in the distal regions of the stomach (Fig. 1E). A dominant pacemaker located in the midregion of the stomach initiates each slow wave. Once started at the pacemaker site, the slow waves travel rapidly around the gastric circumference and trigger the characteristic ringlike contractions of the distal stomach. The slow waves and associated ringlike contractions then travel more slowly toward the gastroduodenal junction.

Electrical connections between smooth muscle cells account for the propagation of the slow waves from the pacemaker site to the junction with the small intestine. The pacemaker region generates slow waves and contractions at a frequency of 3 cycles/min in humans, 5 cycles/min in dogs, 3–4 cycles/min in cats, 6–7 cycles/min in guinea pigs, and 4–5 cycles/min in rats. The duration of each gastric electrical slow wave in humans is about 10 sec.

BASIC ELECTRICAL RHYTHM OF THE SMALL INTESTINE

Electrical slow waves in the intestine, like the BER in the stomach, occur spontaneously and are always present. Action potentials are triggered at the crests

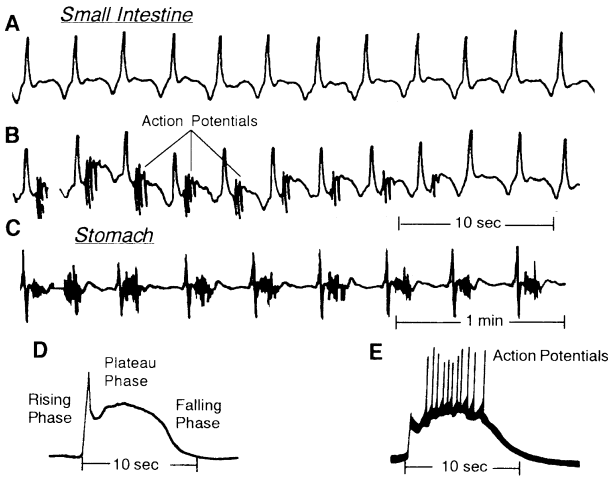

FIGURE 1 Electrical slow waves constitute the basic electrical rhythm in the small intestine and stomach. In the small intestine, the electrical slow waves that constitute the rhythm did not trigger action potentials (A) and exhibit action potentials at the crests of the waves (B). (C) Basic electrical rhythm in distal region of the stomach. (D) Waveform of the slow wave in the midregion of the stomach exhibits a rising phase (depolarization), plateau phase, and falling phase (repolarization). (E) Waveform of the slow wave in a more distal region of the stomach. Action potentials appear in association with the plateau phase. An electrode was attached to the serosal surface of the intestine or stomach for recording of the basic electrical rhythm in A–C. An intracellular microelectrode in a single gastric muscle cell recorded the waveforms in D and E.

of the depolarization phase of the slow wave and are followed by the associated muscle contraction (Fig. 1A). Consequently, the highest frequency of contractions is the same as the frequency of the slow waves. The small intestinal BER frequency in humans is highest in the duodenum, at about 12 cycles/min and progressively decreases more distally, with the ileum having the lowest frequency. Every slow wave may not trigger action potentials and the frequency of contractions in an intestinal segment may not be the same as the BER frequency. When not all slow waves are generating contractions, the intervals between contractions are multiples of the shortest slow-wave interval.

Intestinal slow waves occur synchronously around the circumference of the intestine. They behave as if they either travel very rapidly or are triggered simultaneously at all points around the intestinal segment. At the same time, they appear to travel at much slower velocities in the longitudinal direction along the intestine. The direction of travel is in the caudal direction in the small intestine. Velocity of travel in the duodenum is 5–15 cm/sec, depending on the animal species. Velocity of propagation decreases from the proximal to distal small intestine. Contraction waves tend to travel in the caudal direction with the same velocity as the slow waves because the slow waves trigger the action potentials that trigger contractions.

BASIC ELECTRICAL RHYTHM OF THE LARGE INTESTINE

Specific properties of slow waves in the large intestine are different from the properties of gastric and small intestinal slow waves. The frequency gradient for the large intestinal slow waves is reversed relative to the small intestine. The lowest frequency of slow waves in the large intestine occurs in the proximal colon and is highest in the distal regions of the large bowel.

Behçet's Disease

SALAHUDDIN KAZI
University of Texas Southwestern Medical Center, Dallas

aphthosis Occurrence of numerous mucosal ulcers, or apthae. Commonly occurs as an idiopathic disorder or can occur as a part of disorders such as Behçet's disease or Crohn's disease. In Behçet's disease, the aphthae are typically numerous, large, and deep.

pathergy Excessive inflammatory reaction to tissue trauma. Characteristic of Behçet's disease, but also seen in pyoderma gangrenosum.

uveitis Inflammation of the uveal tract of the eye, which consists of the iris, cyclic body (anteriorly; anterior uveitis, iritis, and iridocyclitis), and the choroid plexus and retinal layers (posteriorly; posterior uveitis). Inflammation of the entire uveal tract is referred to as panuveitis.

Behçet's disease is an idiopathic, intermittent inflammatory clinical syndrome characterized by recurrent genital and oral aphthosis accompanied by other systemic inflammatory manifestations that commonly include arthritis, uveitis, and skin lesions. Loss of vision from recurrent ocular disease is the principal morbidity of this disease.

EPIDEMIOLOGY

Behçet's disease is a worldwide disease but occurs more frequently in countries along the ancient Silk Road, which linked China to the Roman Empire. The highest prevalence is in Turkey (80–370 cases per 100,000). It has intermediate prevalence in Iran, Saudi Arabia, and the Far East and has a much lower prevalence in North America and Northern Europe. The disease is more common in men, and characteristically affects young adults in the third to fifth decades.

ETIOLOGY AND PATHOGENESIS

Like other autoimmune diseases, the precise cause of Behçet's disease is unknown. The increased prevalence of Behçet's disease in geographic regions along the Silk Road correlates with the prevalence of the human leukocyte antigen (HLA)-B51 allele in populations endemic to these regions; HLA-B51 appears to contribute to the risk of Behçet's disease, but the association is much less prominent in Western countries. This allele also appears to affect the severity of disease. The major histocompatibility complex class I chain-related A gene (MICA gene), which is in linkage disequilibrium with the HLA-B51 allele, is also a candidate gene for Behçet's disease. Hypotheses examining the relationship between microbial infection and the development of Behçet's disease have suggested that shared ubiquitous antigens, including the heat-shock proteins of microorganisms, may trigger cross-reactive autoimmune responses in patients with Behçet's disease.

Pathologically, the lesions in Behçet's disease are predominantly seen in the vasculature. Histopathologic analysis reveals a neutrophilic vascular reaction (leukocytoclastic vasculitis). Hypercoagulability, likely secondary to endothelial activation, is also characteristic of Behçet's disease.

CLINICAL FEATURES

Oral and Genital Lesions

Recurrent, painful, aphthous oral ulcers are frequently the first and most persistent manifestation of Behçet's disease. They resemble common oral aphthae, but when they are large, multiple, or seen on the soft palate or pharynx, they should arouse suspicion for Behçet's disease. Recurrent genital ulceration is seen in the majority of patients. In men and women, such ulcers are typically seen, respectively, on the scrotum and on the vulva, but can be seen on any mucosal surface.

Cutaneous Lesions

Common skin lesions include acneiform nodules, pseudofolliculitis, and papulopustular lesions. Occasionally, erythema nodosum and pyoderma gangrenosum occur. A positive pathergy test is considered highly specific for Behçet's disease. A 20-gauge needle is inserted in the skin of the volar surface of the forearm to a depth of 0.5 cm and is then rotated and withdrawn. The appearance of a pustule >2 mm at the puncture site 48 hours later constitutes a positive

pathergy test. Pathergy is distinctly less common in North American and Northern European patients.

Ocular Lesions

The classic ocular lesion seen in Behçet's disease is severe anterior uveitis resulting in visible pus in the anterior chamber (hypopyon). Anterior uveitis is typically relapsing and remitting in character. Posterior uveitis, which involves the posterior uveal tract and retinal vasculitis with its associated complications, is the main cause of permanent visual impairment in Behçet's disease. Ocular inflammation is less common in North American and Northern European patients.

Musculoskeletal

A nondestructive oligoarthritis is the extent of joint involvement in Behçet's disease and is not a dominant feature of this disease, occurring in less than half of the patients. It is often reflective of systemic disease activity. Overlap myositis with proximal muscle weakness occasionally occurs.

Nervous System

Neurological disease occurs in one-third of patients with Behçet's disease, often several years after mucocutaneous manifestations have been present. Aseptic meningitis, stroke syndromes, and cranial neuropathies can occur. Magnetic resonance imaging reveals the predilection for small brain stem vessels and periventricular sites of involvement.

Vascular

Behçet's disease can involve arterial and venous blood vessels of any size. Large-vessel involvement is relatively more common. Clinical syndromes include inferior vena cava obstruction and Budd–Chiari syndrome. Deep venous thrombosis and superficial thrombophebitis occur quite commonly in Behçet's disease.

Gastrointestinal

Ulceration can occur in any part of the gastrointestinal tract but is most frequently seen in the terminal ileum and cecum. Perforation and bowel infarction from mesenteric vasculitis have also been reported in Behçet's disease. The ulcerations can be longitudinal, fissured, or aphthoid. Symptoms include abdominal pain, melena, or hematochezia. The clinical and endoscopic appearance may be indistinguishable from that of Crohn's disease, creating difficulty in differentiating these disorders, because patients with Crohn's disease frequently exhibit oral aphthae as well.

Other

Renal disease is relatively uncommon in Behçet's disease. Amyloidosis has been reported. Epididymitis is also rare. A variety of rare cardiac lesions have been reported. An overlap syndrome with relapsing polychondritis, the "mouth and genital ulcers with inflamed cartilage" (MAGIC) syndrome, can occur.

DIAGNOSIS AND DIFFERENTIATION FROM OTHER CONDITIONS

Recurrent aphthous stomatitis is a common disorder. Ulcers in Behçet's disease are typically larger, deeper, take longer to heal, and may cause scarring. The diagnosis of Behçet's disease should not be assigned unless other clinical features are present. In 1990, the International Study Group for Behçet's disease proposed criteria for the diagnosis of the disease (Table I). Other disorders characterized by recurrent mucocutaneous

TABLE I Criteria for Diagnosis of Behçet's Disease[a]

Criterion	Observation
Primary	
Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulceration observed by physician or patient, recurring at least three times in one 12-month period
Plus two of the following symptoms	
Recurrent genital ulceration	Aphthous ulceration or scarring observed by physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in the vitreous (on slit-lamp examination) or retinal vasculitis observed by ophthalmologist
Skin lesions	Erythema nodosum observed by physician or patient, pseudofolliculitis, or papulopustular lesions; or acneiform nodules observed by physician in postadolescent patients not receiving corticosteroid treatment
Positive pathergy test	Read by physician at 24–48 hours

[a] Modified from International Study Group for Behçet's Disease (1990).

lesions include Crohn's disease, human immunodeficiency virus (HIV) infection, recurrent orogenital aphthosis, herpes simplex infection, and cyclic neutropenia. Differentiation from Crohn's disease may be particularly challenging because many other clinical features are also shared, i.e., anterior uveitis, terminal ileal ulcers, and arthritis. Posterior uveitis is rare in Crohn's disease and bowel histology is often distinctly different.

THERAPY AND PROGNOSIS

Mucocutaneous disease is often treated with topical and intralesional steroids. In refractory cases, systemic steroids are employed. Colchicine may also be effective. Steroid-sparing medications include azathioprine, cyclosporine, methotrexate, and thalidomide. Ocular disease is treated very aggressively, often using topical steroid drops or steroid injections into the episcleral space (subtenon injection); with steroid-resistant disease, cyclosporine or methotrexate is often used. Interferon α is emerging as a useful agent for both mucocutaneous and ocular disease. Small open trials have also shown beneficial effects of antitumor necrosis factor (anti-TNF) therapy.

Behçet's disease is a progressive disease with an undulating course. Morbidity is higher in the young, in males, and in patients from the Middle or Far East. Blindness and vascular disease are the cause of the greatest morbidity in Behçet's disease.

Belching

DANIEL C. BUCKLES AND RICHARD W. MCCALLUM
Kansas University Medical Center

achalasia Disorder in which the lower esophageal sphincter fails to relax properly.
aerophagia Swallowing air.
gastroparesis Disorder in which the muscular contractions of the stomach are lacking and the stomach does not empty its contents.
Helicobacter pylori Gram-negative bacteria that can infect stomach mucosa.
hypochlorhydria Condition of having decreased amounts of stomach acid.
proton pump inhibitor Class of medication that blocks acid production in the stomach.
vagal Pertaining to the vagus nerve of the parasympathetic nervous system.

Belching, also known as eructation or burping, is defined as the involuntary and sometimes noisy regurgitation of air from the stomach and mouth. It is a normal physiological activity that commonly occurs after eating.

PHYSIOLOGY

The sequence of events that lead to belching has become fairly well understood through detailed manometric and fluoroscopic studies. A rise in intragastric pressure will lead to transient lower esophageal sphincter relaxations (TLESRs). These then result in pressure equalizations between the esophageal body and the stomach, and intragastric gas is refluxed into the esophagus. This occurs commonly; during the majority of times, the intraesophageal gas is not perceived by the patient, and the gas is returned to the stomach by secondary esophageal peristalsis. If the volume of intraesophageal gas is sufficient, relaxation of the upper esophageal sphincter is triggered. The intraesophageal air passes out of the oropharyngeal cavity and a belch is produced if the intrathoracic pressure generated is adequate. This sequence is thought to be under vagal control.

CLINICAL SYNDROMES

As a normal physiological event, there is no definition as to what constitutes an abnormal volume or frequency of belching. In general, belching comes to the attention of the clinician only when the patient perceives that it is abnormal or problematic. A number of organic gastrointestinal disorders may give rise to excessive belching. These include esophageal motility disorders, such as achalasia, which may lead to retained esophageal contents. Gastric outlet obstruction and gastroparesis may cause increased gastric pressure resulting in belching. Gastroesophageal reflux disease or a hiatal hernia may also lead to excessive belching. *Helicobacter pylori* infection, in the presence or absence of peptic ulcer disease, may lead to excessive production of ammonia and bicarbonate through urea splitting. Small bowel bacterial overgrowth, seen in patients with surgically altered small intestinal anatomy, motility disorders, and hypochlorhydria from autoimmune causes or chronic proton pump inhibitor use, may lead to excessive hydrogen and methane production. Often such disorders will have accompanying symptoms, such as, pain, vomiting, regurgitation, change in bowel habits, or weight loss, and a detailed history and physical examination can guide further necessary evaluation. Also, for poorly understood reasons, patients may unconsciously attempt to lessen epigastric or thoracic pain not of gastrointestinal origin by purposely swallowing air and belching. This could be part of an anxiety response. It is therefore important to think of angina pectoris in appropriate risk patients who present with the new onset of excessive belching.

After organic conditions that lead to excessive belching have been excluded, the majority of patients will have aerophagia, or air swallowing, as the cause of their complaints. Sometimes easily correctable behavioral causes of aerophagia can be identified. These would include cigarette smoking, sucking hard candy, ill-fitting dentures, or drinking through a straw, for example. Other patients will reflexively swallow air during stressful or anxiety-provoking situations. The remainder will habitually swallow air as part of a functional gastrointestinal syndrome. Aerophagia rarely leads to any significant adverse outcomes except in children or mentally retarded persons, who may swallow such large amounts of air that massive

abdominal distension occurs; a rare case of perforation has been reported in such individuals.

DIAGNOSTIC TESTING

A detailed history will usually guide the need for specific testing. In most situations, a plain film to check the distribution of bowel gas is appropriate. Barium esophagography can assess esophageal diameter and determine whether a hiatal hernia is present. Esophagogastroduodenoscopy (EGD) may be helpful in ruling out peptic ulcer disease, sequelae of reflux, or other structural lesions. Urea breath testing, examination of gastric biopsy, stool antigen tests, and serum antibody detection are all available to identify *H. pylori* infection. Hydrogen breath testing can identify abnormal small bowel bacterial overgrowth through the detection of excess hydrogen production after glucose or lactulose challenge. Finally, cardiac stress testing can help identify those with angina as a cause of excessive belching.

TREATMENT

If a specific organic disorder is identified as the underlying cause of excessive belching, then treatment aimed at alleviating that cause is usually sufficient to correct the complaint. In patients with aerophagia, a number of measures may be tried. Sometimes behavioral modification, such as chewing and eating more slowly, quitting tobacco, and avoiding hard candy and carbonated beverages, may be helpful. In patients with anxiety as an etiology, anxiolytics and antidepressants may be appropriate. Other patients with habitual aerophagia may benefit from referral to a psychologist for behavioral therapy and counseling to help them control the urge to belch. Such patients should be reminded that, although their habit may be personally troubling and socially distasteful, it is generally a benign disorder and the prognosis is excellent.

Pharmacologic treatments aimed at directly modifying belching have been largely disappointing. Simethicone is a defrothicant that acts to coalesce small bubbles of gas. Many simethicone-containing products are available and are widely used, but convincing studies regarding their effectiveness are lacking. Other agents designed to neutralize or suppress acid production, such as proton pump inhibitors, histamine-2 (H2) blockers, or antacids, would not be expected to be useful in the absence of a specific acid-related disorder.

Bezoars

HAGITH NAGAR
Tel Aviv Sourasky Medical Center and Tel Aviv University

bezoar Any of various calculi found chiefly in the gastrointestinal organs and formerly believed to possess magical properties. The prefixes phyto-, tricho-, and lacto- are used to define the major bezoar constituents: vegetable matter, hair, and milk products, respectively.

Bezoars are intralumenal masses consisting of undigested matter that may lodge at any level within the alimentary canal. These objects consist of plant material, hair, dairy products, or foreign bodies. Therapy consists of enzyme dissolution, endoscopic extraction, or surgery.

HISTORY

The word "bezoar" is derived from an Arabic corruption of the Persian word "*panzahar*," meaning "against poison," a reference to curative properties that were formerly ascribed to these objects. Bezoars have been described for more than 3000 years, having been noted in the intestines of sheep and goats. In ancient times, people used bezoars as cameos for good luck, health, and youth. In some cases, the objects were ingested as treatment for dysentery, leprosy, snake poisoning, vertigo, and epilepsy.

Bezoars were highly valued; indeed, Debakey and Ochsner describe one case in which a bezoar was given in exchange for a castle, and it was even possible to "rent" a bezoar. As forgeries became prevalent, tests were developed to examine their authenticity.

The first trichobezoar in a human was described as a postmortem finding in 1779 and the first report of surgical removal of a bezoar was reported by Schonborn in 1883. Diagnosis through palpation of an abdominal mass was reported in 1896 by Stelzner. The first gastroscopic removal of a bezoar was performed by McKechne in 1972.

CLINICAL FEATURES

Bezoars have been reported in patients ranging in age from a few months to 90 years and at all levels of the gastrointestinal tract from the esophagus to the rectum. Areas of physiological or anatomical narrowing, or those that result from surgery or peritoneal adhesion, are particularly common sites. Although they can occur at any portion of the gastrointestinal tract, most are found in the stomach. A single bezoar may completely fill the stomach and even extend into the small bowel (Figs. 1 and 2).

Bezoars are classified into four types, depending on their contents. Phytobezoars consist of undigested portions of fruits or vegetables, trichobezoars consist of hair, and lactobezoars consist of congealed milk products. The fourth category may contain any of a wide range of foreign objects, such as coins, gallstones, and ingested medications ("pharmacobezoar").

Trichobezoar usually presents as a gastric mass, occasionally extending into the duodenum and even into the jejunum. As many as 90% of trichobezoars are diagnosed in adolescent girls. Often, underlying stress is present and the patient suffers from trichophagia and trichotillomania. Cases in which the hair mass continued as far as the cecum have been referred to as "Rapunzel syndrome," after the famed fairy tale character who used her long hair to escape from a castle. The clinical presentation of trichobezoar depends on the location and size of the mass and may include vomiting due to partial or complete obstruction, weight loss, or an abdominal mass that may be thought to be malignancy. addition to mechanical obstruction, bezoars may be complicated by anemia, gastrointestinal ulcers, or perforation.

Lactobezoar consists of a compact mass of undigested milk concretions located within the gastrointestinal tract. Most are reported in infants, in particular preterm infants on caloric-dense formulas. Lactobezoars may precipitate gastric outlet obstruction, which mimics a variety of medical and surgical conditions.

The diagnosis of bezoar is confirmed using ultrasonography (US), computerized tomography (CT), or barium swallow. Endoscopy may be useful in both the diagnosis and the management of gastric bezoar. CT is considered more accurate than ultrasonography and has been used to diagnose bezoars at all levels of the gastrointestinal tract. Findings on US consist of hyperechoic band-like lesions and acoustic shadows, whereas CT demonstrates a mass that contains air pouches, without postcontrast enhancement.

Therapeutic options include medical dissolution, endoscopy extraction, or surgery. Gastroscopic extraction is the treatment of choice for gastric phytobezoars. Endoscopic suction removal of gastric phytobezoars using a large-channel endoscope is efficacious and safe. Endoscopically guided electrohydraulic lithotripsy has been advocated as a safe and effective modality for gastric bezoars. Alternative endoscopic methods have included the use of a water jet, forceps, or snare and basket. Lactobezoars may be removed in this way or dissolved using oral enzymes. Surgery is the treatment of choice for trichobezoar, with removal of the entire mass, including the "tail," via gastrotomy.

Esophageal bezoars are rare and tend to occur in patients with structural or functional abnormalities of the esophagus. Additionally, enteric feeding formulas that include sucralfate and casein have also been implicated in the formation of esophageal bezoars, particularly in the setting of decreased esophageal pH.

ABC transporters ATP-stimulated membrane transporters that are responsible for transporting molecules "uphill" (against their concentration gradient); such molecules have an ATP-binding cassette, hence the designation "ABC."

amphipathic Denoting molecules that have hydrophobic and hydrophilic domains such that they are surface active and often self-associate to form aggregates (micelles).

bile acids Molecules that are present in high concentrations in bile and are responsible for its physiological properties. Chemically, bile acids are compounds having the cholane or cholestane nucleus with an acidic group on the terminal carbon of the side chain. One to three hydroxyl groups are present on the nucleus, and there may be an additional hydroxyl group on the side chain. Bile acids are formed in hepatocytes from cholesterol. They occur in bile conjugated in an amide linkage with glycine or taurine.

bile alcohols Molecules that are present in high concentrations in bile in certain species (cartilaginous fish, herbivorous fish, ancient mammals). Chemically, they are compounds with a cholestane nucleus, having a hydroxyl group on the terminal carbon of the side chain. One to three hydroxyl groups are present on the nucleus, and there may be one to three additional hydroxyl groups on the side chain.

bile salts Collective term denoting both bile acids and bile salts.

bilirubin Tetrapyrrole (brown in color); the major bile pigment present in the bile of most mammals; the end product of heme metabolism. When bilirubin is oxidized, it becomes biliverdin.

biliverdin Oxidized bilirubin (green in color); the major bile pigment in the bile of some fish and mammals. When biliverdin is reduced, it becomes bilirubin.

canaliculus Space formed between the apical membranes of hepatocytes, into which canalicular bile is secreted; the smallest unit of the biliary tract.

cholesterol Sterol that is present in cell membranes. Cholesterol is white and insoluble in water. It has the cholestene nucleus with a double bond at C_5-C_6 nucleus and a hydroxy group on the third carbon atom.

cholic acid Primary bile acid; very common in many mammals. Chemically, it is a C_{24} bile acid with hydroxyl groups at carbons 3, 7, and 12.

conjugation In metabolism, the addition of a molecule that renders a lipophilic molecule more hydrophilic and usually makes it more water soluble. Molecules commonly used for conjugation include sulfate, glucuronic acid, glutathione, glycine, and taurine.

enterohepatic circulation Movement of molecules from the liver, to the biliary tract, to the intestine, to the portal venous system, and to the liver. The only molecules that are known to have an efficient enterohepatic circulation are bile salts.

flavinoid Collective term for a variety of polycyclic compounds that are present in vegetables, especially soy products. Many of the molecules have antiestrogen properties (these are termed "phytoestrogens").

flippase Transporter that "flips" a molecule in the membrane from one side to the other. In the canaliculus, mdr2 flips phosphatidylcholine from the cytosolic side to the luminal side.

gallstones Concretions formed in the biliary tract; composed of molecules that are insoluble in water, usually cholesterol and/or calcium bilirubinate.

Gibbs–Donnan equilibrium Distribution of anions and cations when an impermeable anion is present on one side of the membrane. Electrostatic effects lead to enrichment of divalent cations on the side of the impermeable anion. In bile, this results in the concentration (activity) of Ca^{2+} ions being higher in gallbladder bile than in plasma.

γ-glutamyl transpeptidase Enzyme located on the luminal face of the canaliculus (in some species) and the bile duct epithelium; cleaves the amide bonds of glutathione to constituent amino acids. The concentration of the enzyme increases in liver disease.

glutathione Tripeptide consisting of glutamic acid, cysteine, and glycine. The sulfhydryl group on the cysteine is used for conjugation of a number of organic anions, especially those containing halogen groups.

immunoglobulins A, M, and G Molecules with potent bacteriostatic properties; IgA is the dominant immunoglobulin of intestinal secretions and is found also in saliva and bile.

micelles Polymolecular aggregates formed by amphipathic molecules, such as detergents and bile salts; their presence above a certain concentration is termed the "critical micellization concentration" (CMC).

mucin Protein that has many carbohydrate molecules covering its surface; the dominant protein of mucous.

phosphatidylcholine Zwitterionic phospholipid present in cell membranes and in bile; chemically, has a glycerol backbone. Fatty acids are esterified to the first two hydroxyl groups; a phosphate group is attached to the third hydroxyl group, yielding phosphatidic acid; the phosphate group is esterified to choline (hence the name, phosphatidylcholine).

primary bile acid Synthesized in the hepatocyte from cholesterol.

saturation, or cholesterol saturation Number, expressed as a fraction or a percentage, describing the cholesterol concentration of a bile sample relative to its equilibrium solubility (at saturation). Mathematically, it is the cholesterol concentration divided by the equilibrium solubility in the sample, or that predicted to hold for a sample based on studies of model systems simulating bile.

secondary bile acid Formed by modification of the hydroxyl groups of a primary bile acid. Common changes involve removal of the hydroxyl group at C-7 (7-dehydroxylation) or oxidation of any hydroxyl group to an oxo group, or epimerization of any hydroxyl group (a change of an α-hydroxyl group to a β-hydroxyl group or vice versa).

solubility product Mathematical product of the concentration of the anion times the concentration of the cation of a salt that has a low solubility in water. When the solubility product of a salt is exceeded, the solution is supersaturated, and the salt can potentially precipitate from solution.

sphincter of Oddi Valve at the end of the biliary tract where the tract empties into the duodenum. In humans, the common bile duct and pancreatic ducts merge at the sphincter of Oddi.

triangular coordinates Method for showing the relative proportions of three constituents that together add up to 1 (or 100%). Because there are only two degrees of freedom (the third is equal to the total minus the first and second), it is possible to represent compositions of such mixtures in two dimensions.

vesicles Lipid aggregates composed of a bilayer of amphipathic lipids. Vesicles may consist of a single bilayer (unilamellar vesicles) or multiple bilayers (multilamellar vesicles). In bile, vesicles are composed mostly of phosphatidylcholine and cholesterol. Bile salt molecules adsorb to vesicles and, if present in sufficiently high concentration, change the vesicles into mixed micelles.

Bile is a digestive and excretory fluid formed by secretion of solutes (and accompanying water) into the biliary tract. Most bile originates from hepatocytes. These secrete bile into the biliary canaliculi, i.e., the spaces between the apical membranes of hepatocytes. Canalicular bile drains into the bile ducts, which merge to form the common bile duct that in turn drains into the small intestine. Bile is modified be secretion and/or absorption as it passes down the bile ductules and ducts or when it is stored in the gallbladder. Biliary constituents are organic or inorganic. The lipid component of the organic fraction consists of three major classes—bile salts (bile acids), phospholipids (mostly phosphatidylcholine), and cholesterol. Three major classes of bile salts are present in the bile of vertebrates—C_{27} bile alcohols (conjugated with sulfate), C_{27} bile acids (conjugated with taurine), and C_{27} bile acids (conjugated with glycine or taurine). In most mammals, bile salts are composed predominantly of C_{24} bile acids.

INTRODUCTION

Bile is an aqueous fluid secreted by the liver into the biliary tract. Bile is distinguished from other digestive secretions by its color—brown or green—and by its high concentration of bile salts. Bile is colored because it contains bile pigments, tetrapyrroles formed from heme. Biliverdin is green; when reduced, it becomes bilirubin, which is brown. Bilirubin is the bile pigment in most vertebrates, but in some species (certain fish and the rabbit), biliverdin is the dominant bile pigment. The emphasis herein is on bile in mammals, because relatively little information is available on bile composition in amphibians, reptiles, fish, and birds.

Bile salts are surface-active molecules formed in the hepatocyte from cholesterol. Bile salts are present in bile as anions that self-associate to form polymolecular aggregates termed "micelles." The presence of such micelles gives bile potent solubilizing properties, and in mammals, the micelles in bile also contain phospholipids and cholesterol. Bile is bitter in taste because of its high concentration of bile salts. Bile is isosmotic and slightly alkaline.

In most vertebrates, the biliary tract contains a globular reservoir, the gallbladder, in which bile is stored and concentrated between meals. When a meal is eaten, the gallbladder contracts and the sphincter at the end of the biliary tract (sphincter of Oddi) relaxes. As a result, bile enters the small intestine, where it promotes the digestion and absorption of dietary lipids.

Bile is also an excretory fluid in that it serves as a vehicle for the excretion of molecules that cannot be eliminated in urine. In contrast to renal excretion, in which the driving force is filtration by the glomerulus, biliary excretion relies on transporters in the canalicular membrane. Biliary excretion serves to eliminate ions or molecules that are bound to plasma proteins. Such substances include a variety of lipophilic organic molecules and polyvalent metal cations. When these molecules enter the intestine via bile, they are poorly absorbed, thereby leading to their elimination from the body in feces.

Historical Aspects

Because the gallbladder is readily detected at autopsy, examination of the appearance of bile for clues to the nature of disease has been practiced since antiquity. Bile was one of the four "humors" proposed by Aristotle; the term "melancholia" was used to suggest that when bile was black, disease was present, causing a state of depression. Because gallbladder bile is readily obtained when livestock are slaughtered for meat, studies on its composition began nearly two centuries ago. Isolation of bile salts—the major constituents of bile—was performed early in the nineteenth century. Pure compounds were isolated and named before any idea of their chemical structure was available. The Greek word *chole* for "bile" gave rise to the name "cholic acid," from which the names of many other bile salts are derived.

Bile contains a greater concentration of cholesterol in humans than in any other vertebrate. When cholesterol molecules crystallize and the crystals aggregate, a gallstone is formed. In the late eighteenth century, gallstones were dissolved in hot alcohol and cholesterol crystals were obtained. The crystals were named "cholesterin" (later changed to cholesterol), the name denoting the solids in bile.

The major bile salts in bovids are the two bile acids, cholic acid and deoxycholic acid. They occur in bile as taurine or glycine conjugates. When bile is heated with alkali, the unconjugated bile acids, cholic acid and deoxycholic acid, are formed. These are readily isolated and have been available as laboratory chemicals in relatively pure form for at least half a century. As a result of their availability, a great deal is known about their properties.

TYPES OF BILE

Bile is formed by secretion of solutes into the canaliculus, a space formed between the apical membranes of adjacent hepatocytes. Such bile, termed canalicular bile, cannot be sampled, because the canaliculus is too small to be sampled by micropuncture techniques. Bile enters the biliary ductules, where it is modified by solute absorption and secretion. The biliary ductules have an arboreal architecture. The ductules progressively anastomose, ultimately forming the right and left hepatic ducts; these in turn merge to form the common hepatic duct. Bile sampled at this point is termed "ductular bile." Ductular bile may either enter the gallbladder or bypass the gallbladder to enter the small intestine. Bile in the gallbladder may be sampled *in vivo* by gallbladder puncture during surgery or *ex vivo* after gallbladder removal; such bile is termed "gallbladder bile." When studies seek to ascertain the composition of gallbladder in the healthy subject, a tube is placed into the duodenum and gallbladder contraction is induced by intravenous injection of a peptide. Such bile that is collected in the duodenum is termed "duodenal bile" because it contains a mixture of gallbladder and hepatic bile as well as pancreatic secretions.

CLASSIFICATION OF BILIARY CONSTITUENTS

Biliary constituents may be divided into two broad classes—organic and inorganic. The organic fraction, in turn, is divided into a lipid fraction and a nonlipid fraction. The lipid fraction is defined as bile salts (or bile acids), phospholipids, and cholesterol. The nonlipid fraction contains other organic molecules, most of which are of endogenous origin. The major organic nonlipid is bile pigment (bilirubin or biliverdin). Other trace constituents include conjugates of steroids, fat-soluble vitamins, and proteins and peptides. Exogenous molecules may also be present in bile (for example, drugs, ingested bile acids, and dietary constituents such as flavinoids). Table I describes a classification of biliary constituents.

Organic molecules that are larger than sucrose can enter bile only by carrier-mediated transport. For a substance to be present in bile, it must be a substrate for one or more of the canalicular transporters. These transporters, which have been cloned in the past decade, have an ATP-binding cassette (ABC).

Hepatic bile is formed by the flow of water and filterable solutes across the paracellular junctions between the hepatocytes. Such flow occurs in response to the osmotic stimulus of molecules that are actively secreted into the canalicular space. In most species, the osmotically active agents are bile salts and probably anions such as bicarbonate and chloride. Glutathione also contributes. Because bile salts and most organic molecules in bile are anions, an equivalent concentration of cations must be present. The dominant cations are those of plasma (Na^+, K^+, Ca^{2+}, and Mg^{2+}) and have concentrations that are similar to those of an ultrafiltrate of plasma. Canalicular secretion of copper, iron, and cations of heavy metals promotes their biliary excretion. A summary of the composition of hepatic and gallbladder bile is given in Table II.

BILIARY LIPIDS

The following descriptions of biliary lipids apply to mammals. In some reptiles and fish, no biliary lipids other than bile salts are present.

Bile Salts

Bile salts are the dominant anion in gallbladder bile. Active secretion of bile salt anions by a canalicular transporter into the canaliculus generates an osmotic force that pulls water and filterable solutes into the canaliculus. Bile salts are derived from cholesterol by a multienzyme process. Three major classes of bile salts are present in vertebrates—bile alcohols with 27 carbon atoms (C_{27} bile alcohols), C_{27} bile acids, and C_{24} bile acids. (In most mammals, bile salts are composed predominantly of bile acids, as distinguished from bile alcohols, and much of the clinical literature uses the term "bile acids").

Bile salts are secreted in conjugated form. The terminal carbon of bile salts contains a functional group—a hydroxy group in bile alcohols and a carboxyl group in bile acids. The functional group serves to couple bile acids to the conjugating moiety. Bile alcohols are esterified with sulfate. The carboxyl group of the C_{27} bile acids is coupled to the amino group of taurine, with the result that such conjugated bile acids are termed "N-acyl amidates" or "N-acyl aminoamidates." The C_{24} bile acids are conjugated with taurine in some species, with glycine in other species, and with both taurine and glycine in some species, including humans. Conjugated bile salts are strong acids and are fully ionized at the pH conditions prevailing in bile and the small intestine. Therefore, conjugation of bile acids increases their aqueous solubility. Conjugation also prevents precipitation by Ca^{2+} ions.

Bile salts are hydroxylated on the nucleus and sometimes on the side chain. All bile salts have a 3-hydroxy group because they are derived from cholesterol, which is a 3β-hydroxy sterol. Cholesterol 7α-hydroxylase is a microsomal enzyme that is rate limiting for bile salt synthesis, and bile salts with hydroxy groups at carbons 3 and 7 can be considered to be the building block on which an additional nuclear hydroxyl group is added. All hydroxyl groups are present on one face (the α face) of the bile acid molecule, causing bile acids to be amphipathic. Trivial names of bile acids are based on the pattern of nuclear substituents as well as on the animal from which the compound was first isolated.

During enterohepatic cycling of bile acids, bacteria in the distal intestine remove the 7-hydroxy group of bile acids, giving rise to one or more 7-deoxy bile acids. The 7-deoxy bile acids are termed "secondary" bile acids because they are formed by bacterial enzymes, and thus should be distinguished from "primary" bile acids that are synthesized in the liver.

Bile salts have a metabolism that differs from that of other biliary lipids. They are efficiently absorbed from the distal small intestine and are returned to the liver in portal venous blood. They are transported efficiently into the hepatocyte and again secreted into bile, thus undergoing an enterohepatic circulation. Efficient intestinal absorption leads to a recycling pool of bile salts, with the result that the transhepatocyte flux of bile acids greatly exceeds bile acid biosynthesis. A small fraction of bile acids is not absorbed in the distal intestine and is

excreted in the feces. Fecal loss of bile salts is balanced by *de novo* biosynthesis.

In humans, biliary bile acids consist of the two primary bile acids, cholic acid and chenodeoxycholic acid, each comprising about 40% of biliary bile acids. The remainder is made up of deoxycholic acid (formed by bacterial dehydroxylation of cholic acid), lithocholic acid (formed by bacterial dehydroxylation of chenodeoxycholic acid), and ursodeoxycholic acid (formed by bacterial epimerization of chenodeoxycholic acid). Each bile acid is conjugated with glycine or taurine.

Phospholipids

In most mammals, bile contains phospholipids that are predominantly phosphatidylcholine (PC). (The term "lecithin" is sometimes used for biliary phospholipids.) The phospholipids in human bile have been analyzed by high-performance liquid chromatography (HPLC) in order to quantify individual PC species. A large number (up to 30) of PC molecules are present in human bile. In general, these tend to have a C_{16} saturated or monounsaturated fatty acid moiety in the first position and a C_{18} mono- or diunsaturated molecule in the second position.

PC is synthesized in the hepatocyte and travels to the canalicular membrane by a phospholipid-binding protein. The canalicular membrane contains the usual variety of membrane phospholipids, and a "flippase" selectively flips PC molecules across the canalicular membrane. The accumulation of phospholipid on the luminal face of the canalicular membrane is evidenced by vesicular evaginations that can be visualized by electron microscopy.

Biliary phospholipid serves to protect the biliary epithelium from the cytotoxic effects of bile salts. In the presence of phospholipids, bile salts form mixed

micelles at a lower concentration than is observed in the absence of phospholipids. Biliary phospholipid also serves to enhance greatly the solubility of cholesterol in bile, a property that is important in humans because the ratio of cholesterol (the solute) to the solvent (bile salts and PC) is much higher than in other mammalian species.

Cholesterol

Cholesterol is present in bile in unesterified form. Cholesterol in bile has no function and its presence in bile indicates that not all cholesterol in the liver was converted to bile acids, or, as a corollary, that cholesterol excretion is mediated by biliary excretion of cholesterol as well as bile acids.

Cholesterol has a low aqueous solubility and is maintained in solution by being incorporated into the mixed bile salt phospholipid micelles present in bile. Because the solubility of cholesterol depends on the concentration of the mixed micelles, it has been common practice to express cholesterol concentration as a mole fraction of either total biliary lipids or bile salts plus PC. It is also common practice to express the relative proportions of the biliary lipids using triangular coordinates. From these proportions and from the equilibrium solubility of cholesterol in model systems composed of the three biliary lipids, it is possible to calculate cholesterol "saturation." Gallbladder bile that is supersaturated in cholesterol is a risk factor for the formation of cholesterol gallstones.

When bile is supersaturated with cholesterol, additional phases besides mixed micelles are present in bile. These include cholesterol-rich vesicles. The vesicular phase may be isolated by centrifugation or exclusion chromatography. Besides cholesterol, bile also contains trace amounts of other sterols. These include endogenous sterols such as oxysterols, which are intermediates in bile acid biosynthesis. Bile also contains plant sterols such as sitosterol, campesterol, and methosterol.

NONLIPID ORGANIC MOLECULES

Bile Pigments

The major biliary nonlipid is bilirubin, which is formed in the hepatocyte by reduction of biliverdin. Bilirubin is classified as a nonlipid because it is present in bile as a glucuronide conjugate, and in this chemical form is not appreciably incorporated into the mixed micelles present in bile.

Bilirubin is formed in the reticuloendothelial cells from heme and enters the hepatocyte by uptake from sinusoidal plasma. In the hepatocyte, bilirubin enters the smooth endoplasmic reticulum, where one or both of its two carboxylic groups are esterified to the C-1 hydroxyl group of glucuronic acid. In humans, bilirubin is present predominantly in the form of the diglucuronide, but in other animals, the monoglucuronide may be the dominant bile pigment. Bilirubin, in contrast to bile acids, does not undergo enterohepatic cycling, so that biliary secretion is approximately equal to synthesis from heme.

Organic Anions Present in Trace Amounts

Other lipophilic molecules are present in bile in trace amounts. These include glucuronides or sulfates of steroid hormones, prostanoids, flavinoids (of dietary origin), and conjugates of fat-soluble vitamins and/or their metabolites. Biliary secretion is not considered to play a major role in the excretion of these compounds and they are not known to have any functional effects on the biliary tract or small intestine. Their presence in bile results from their serving as substrates for the rather nonspecific anion transporters of the canalicular membrane.

Proteins and Peptides

Only three proteins have appreciable concentrations in bile—immunoglobluin A (IgA), mucin, and an anionic polypeptide fraction/Ca^{2+}-binding protein (APF/CPB), which is amphipathic and has phospholipid and Ca^{2+}-binding properties. IgA is secreted into bile from cholangiocytes in humans; in other mammals, it is thought to enter bile from hepatocytes. IgA serves to inhibit bacterial growth in the biliary tract and may also bind to cholesterol crystals, inhibiting deposition of additional cholesterol molecules. Mucin is present in hepatic bile and gallbladder bile. Biliary mucin is predominantly type 3 and 5B. Biliary mucin also enters bile from peribiliary "glands" that secrete mucin into the larger bile ducts. In gallbladder bile, mucin (type 2) originates in part as a secretion by goblet cells that are present in the gallbladder epithelium. The presumed role of mucin is to prevent bacterial adhesion to epithelial cell membranes. The anionic, amphipathic protein(s) APF/CBP bind Ca^{2+} and phospholipids, but their biological functions have not as yet been elucidated.

A variety of plasma proteins are present in bile in trace amounts, including several apoproteins (of lipoproteins), albumin, transferrin, α-2-macroglobulin, fibrinogen, α-1-antitrypsin, and haptoglobin. These proteins are considered to enter bile in part by

exocytosis of vesicles from hepatocytes, cholangiocytes, or cholecystocytes. Other modes of entry of proteins are desorption from the canalicular membrane and leakage across patulous paracellular junctions. IgG is considered to play a role in nucleation of cholesterol gallstones. Antigen–antibody complexes have also been reported to be secreted in bile. Concentrations of some proteins in gallbladder bile are summarized in Table III.

Bile also contains enzymes, presumably arising from desorption of enzymes on the luminal face of the canaliculus, from exocytosis into bile of vesicles from the hepatocyte and the biliary tract epithelium, and from sloughing of biliary tract epithelial cells. Enzymes that have been measured in bile include lactate dehydrogenase, 3-hydroxybutyrate dehydrogenase, malate dehydrogenase, glucose-6-phosphate dehydrogenase, ornithine carbamoyltransferase, aspartate aminotransferase, alanine aminotransferase, creatine kinase, cholinesterase, alkaline phosphatase, lysozyme, β-glucuronidase, aminopeptidase, γ-glutamylpeptidase, and fructose biphosphate adolase. A variety of lysosomal enzymes have also been measured in bile.

The tripeptide, glutathione is secreted into bile, mostly in the form of its disulfide, its oxidation product. During passage along the biliary tract, it is hydrolyzed to its constituent amino acids (glycine, cysteine, and glutamine) which are in part absorbed.

Bile serves as the major excretory route for a number of lipophilic drugs and/or their metabolites. Anionic drugs and their glucuronides or sulfates are secreted into bile by a nonspecific organic anion transporter, the multidrug-resistance-associated protein 2 (Mrp2), and occasionally by a bile acid transporter, the bile salt export pump (BSEP). Cationic and some uncharged drugs are transported by the multidrug-resistance 1 (MDR1) P-glycoprotein. Because these compounds do not have an enterohepatic circulation, their biliary excretion does not exceed the daily dosage, and their concentration is usually quite low when compared to that of bile salts.

The bile acid ursodeoxycholic acid (ursodiol) is used to treat cholestatic liver disease and cholesterol gallstone disease. It is conjugated in the liver and secreted in bile. With continued administration, its pool size increases and it may become the dominant biliary bile acid.

INORGANIC CONSTITUENTS

Cations

As previously noted, biliary cations are those that are present in an ultrafiltrate of plasma. Polyvalent cations are secreted into bile by one (and possibly more) canalicular metal transporter(s). During concentration of bile in the gallbladder, the activity of Ca^{2+} increases because of Gibbs–Donnan equilibrium effects. The result is that precipitation of calcium salts in the gallbladder is not uncommon and may occur whenever the solubility product of a calcium salt is exceeded. Calcium salts of unconjugated bilirubin, carbonate, phosphate, uncommon bile acids, a number of anionic drugs, and oxalate have been observed. The most common calcium salt in gallstones is calcium bilirubinate.

Anions

The concentration of bicarbonate in hepatic bile varies widely between species, and the concentration of chloride varies reciprocally. The guinea pig is unique among mammals in having a bicarbonate concentration of 80 m*M*, and bile flow in this species appears to be driven mainly by bicarbonate secretion. In other species, bicarbonate concentration may exceed plasma concentration because of bicarbonate secretion by cholangiocytes.

CHANGES IN COMPOSITION DURING TRANSIT IN THE BILIARY TRACT

Bile Ducts

Biliary Lipids

The apical sodium dependent bile salt transporter (ASBT), which is a membrane bile salt–sodium cotransporter, is present in cholangiocytes, and some reabsorption of conjugated bile salts is likely to occur; however, this flux is small. No information exists on phospholipid or cholesterol absorption in the bile ducts, but it has been speculated that the low cholesterol content of bile in some species may result from cholesterol absorption in the biliary tract.

Despite the lack of major changes in concentration of biliary lipids, the physical state of bile may change considerably during passage along the bile ducts. During biliary lipid secretion, vesicles are desorbed from the canalicular membrane. Such vesicles may transform to micelles during the flow of bile in the ducts. Such a physicochemical transformation is simply the result of time, and the biliary ductules are unlikely to play a role in this process.

Nonlipid Organic Molecules

Unconjugated bilirubin is transported to only a negligible extent across the canalicular membrane. However, it is likely that if unconjugated bilirubin enters canalicular bile, it will be absorbed partly during transit in the biliary ductules.

Canalicular bile may be hypertonic, and becomes isosmotic during transit through the biliary ductules, because their paracellular junctions are permeable to water. Canalicular bile contains filterable solutes such as short-chain fatty acids, glucose, and amino acids. These are absorbed in part. Glutathione is hydrolyzed to its constituent amino acids by γ-glutamyl transpeptidase, which is located on the apical membrane of cholangiocytes; in humans, it is also present on the outer surface of the canalicular membrane.

Molecules present in conjugated form (glucuronides, sulfates, glutathione conjugates) are not believed to be absorbed in the biliary ductules. In some species, glutathione conjugates of xenobiotics undergo cleavage of the outer amide bonds of glutathione, leaving a cysteine conjugate (termed a "mercapturic acid derivative") of the molecule. If molecules are transported into bile in unconjugated form, and if they are sufficiently lipophilic, they will be absorbed in part in the biliary ductules to undergo a cholehepatic pathway. As noted previously, mucin and IgA are secreted into ductular bile by the biliary epithelium.

Inorganic Constituents

Bile ducts contain the cystic fibrosis transmembrane (chloride) regulator (CFTR) and chloride and possibly bicarbonate are secreted by cholangiocytes in response to the hormone secretin. Chloride undergoes chloride/bicarbonate exchange, resulting in an apparent bicarbonate secretion. Sodium ions and accompanying water molecules enter via the paracellular junctions, with the result that an isotonic solution of sodium bicarbonate is added to ductal bile.

Gallbladder

Biliary Lipids

Bile is concentrated in the gallbladder by removal of chloride, bicarbonate, and accompanying cations. Removal of biliary lipids occurs to a much smaller extent. In humans, with prolonged fasting, bile becomes less saturated in cholesterol, indicating absorption of cholesterol. Phospholipids and bile salts are also absorbed but to a smaller extent. The apical bile salt sodium transporter is present in the gallbladder mucosa. During gallbladder storage, there is little change in the phospholipid/bile salt ratio of gallbladder bile.

Nonlipid Organic Molecules

Conjugated bilirubin is not absorbed by the gallbladder wall. During prolonged storage in the gallbladder, bilirubin glucuronides may undergo spontaneous hydrolysis, leading to the formation of unconjugated bilirubin. This may be absorbed, solubilized in micelles, and/or precipitated as the insoluble calcium salt.

The nonspecific anion transporters MRP2 and MRP3 have been recently identified in gallbladder epithelium, indicating that the gallbladder mucosa might secrete organic anions into bile or absorb organic anions from bile and transport them into blood.

The protein composition and content change during gallbladder storage. In humans, haptoglobin, IgM, and IgA, as well as α1-glycoprotein, are reported to be absorbed by the gallbladder. At the same time, mucin, albumin, and IgG are secreted into bile.

Inorganic Constituents

The major change in gallbladder composition during storage is removal of chloride and bicarbonate anions as well as accompanying cations. Water is removed at the same time, with the result that bile remains isotonic. Removal of electrolytes and water is considered to occur by a double-ion exchange mechanism of the type that is responsible for water removal in the ileum. A Na^+/H^+ antiporter transports hydrogen ions into the

Data were obtained using the rabbit gallbladder *in vitro*, but similar concentration changes are likely to occur during *in vivo* concentration of bile in the human gallbladder. However, hepatic bile bicarbonate concentration is lower in humans (about 25 m*M*) than in the rabbit (in which it is about 60 m*M*. From Moore and Hofmann (1993). lumen, and sodium ions into the cell. At the same time, a chloride/bicarbonate exchanger transports chloride into the cell and bicarbonate into the lumen. In the lumen, the hydrogen ions and bicarbonate ions combine to form carbon dioxide and water, thus destroying osmoles. The sodium and potassium ions that have entered the cell are pumped out at the basolateral membrane, and this efflux of cations in turn pulls water and chloride ions through the paracellular junctions.

During this concentration process, bile is acidified. With prolonged storage, gallbladder pH may decrease from pH 7.5 to pH 5.5. Bile remains isotonic, even though total sodium concentrations and bile salt concentrations may be as high as 300 m*M*. Ca^{2+} increases modestly because of a Gibbs–Donnan equilibrium effect. A schematic depiction of the changes in concentration of the major ions in bile is shown in Fig. 1.

Bile Duct Injuries and Fistulas

MUFTI SAADAT A. FAROOQI

biliary fistula An abnormal passage or communication from the biliary system to another location.
cholangiography Injection of a radiocontrast dye into the biliary system to study the anatomy; it can be performed percutaneously via the liver or endoscopically via the ampulla of Vater, located in the duodenum.
cholecystitis Inflammation of the gallbladder.
cholelithiasis The presence of stones in the bile duct system.

A fistula is defined as an abnormal communication between the lumen of a hollow viscus and another hollow organ or the integument. Abdominal fistulas generally are classified by their sites of origin and termination, by the volume and composition of drainage, and by their etiology. Fistulous connections can occur between the biliary tract and various structures, including the enteric tract, bronchial tree, skin, and blood vessels. They can develop as a complication of chronic cholelithiasis (i.e., biliary enteric fistula) or infection such as liver abscess or hydatid disease (i.e., bronchobiliary, biliary cutaneous, or bilioportal fistulas). They can also result from blunt abdominal or operative trauma (i.e., biliary cutaneous fistulas). Internal fistulas connect the biliary system to other abdominal and thoracic organs and cavities. External fistulas are connections between the biliary tract and the skin.

INTRODUCTION

Biliary fistulas were first mentioned by Bartholini in 1654. Thilesus described the first external biliary fistula in 1670. A thorough analysis of biliary fistula was first presented in 1890 by Courvoisier, who reported a large series of approximately 500 cases, including 131 patients with gallstone ileus and 169 patients with spontaneous external biliary fistula.

Biliary fistulas are usually the result of acute suppurative cholecystitis associated with cholelithiasis. The suppurative process leads to necrosis and perforation. The site of spontaneous perforation and subsequent fistula is in the gastroenteric system, in the thoracic cavity, or more rarely through the abdominal wall. Biliary fistulas are commonly reported as a complication of cholecystectomy, common bile duct exploration, inadvertent operative injury of the bile duct, or penetrating trauma.

ETIOLOGY

Biliary fistulas are incidental findings at cholecystectomy in approximately 5% of patients. Cholecystocutaneous fistulas to the abdominal wall occur but are exceedingly rare. More than 90% of internal biliary fistulas occur as a result of cholelithiasis and acute or chronic cholecystitis. During repeated episodes of inflammation, adhesions form between the gallbladder and adjacent structures, and eventually a stone (or stones) erodes into adjacent viscera. Fistulas to the duodenum account for 70% of gallstone-related internal fistulas and most of the remainder are to the stomach or colon. Although fistulas not associated with stones more often involve the common bile duct rather the gallbladder, the gallbladder may be affected.

With more widespread use of laparoscopic cholecystectomy, the incidence of bile duct injury, including biliary fistulas, has increased (compared to the incidence associated with open cholecystectomy). Bile leakage from the cystic duct remnant is among the most common injuries reported as a complication of laparoscopic cholecystectomy. The most common cause of cystic duct leaks involves imprecise application of clips on the duct or their subsequent dislodgement during the procedure. Other potential mechanisms of injury include trauma from cannulation during cholangiography, inadvertent thermal injury, necrosis of the duct from acute inflammation or dissection, induced devascularization, and ischemia.

Biliary fistulas may also arise from intrahepatic ducts and the common duct. Small anomalous bile ducts (of Luschka), if present, drain directly from the liver bed into the gallbladder. These are severed during cholecystectomy and, if not closed operatively, result in a bile leak into the gallbladder fossa.

CLINICAL PRESENTATION

Internal Biliary Fistulas

Most cholecystoduodenal fistulas are asymptomatic or result in nonspecific digestive complaints. Gallstones may occasionally pass through the fistula tract and cause gallstone ileus. A preoperative diagnosis of an uncomplicated cholecystoduodenal fistula is rarely made.

Patients with spontaneous development of cholecystocholic fistulas present with fever, chills, and abdominal pain due to the influx of bacteria into the biliary tract. Because the ileum, the main site of bile resorption, is bypassed, a choleric enteropathy may develop as a sign of bile acid loss. The patients present with nausea, weight loss, and steatorrhea.

Choledochoduodenal fistulas (due to duodenal ulcer disease or biliary neoplasms) are usually diagnosed incidentally, because they are rarely associated with biliary symptoms. In rare instances, cholangitis, jaundice, and abnormal liver tests may occur as indicators of a concomitant biliary tract infection or obstruction.

The hallmark of thoracobiliary or bronchobiliary fistulas (due to trauma, malignancies, liver abscess, parasitic liver disease, choledocholithiasis, postoperative biliary stenosis, or rare congenital disorders) is the presence of bile pigments in the sputum (biliptysis). Bronchiolitis is usually present. Other symptoms include right upper abdominal and pleuritic chest pain.

Fever, chills, or leukocytosis is seen in only half the cases. A right pleural effusion is almost always present.

External Biliary Fistulas

Spontaneous external biliary fistulas are usually a complication of acute cholacystitis with underlying cholelitiasis. They are now extremely rare due to better diagnosis.

An increase in iatrogenic bile duct injury has been seen with the advent of laparoscopic surgery, especially laparoscopic cholecystectomy. These injuries may become apparent in the immediate postoperative period or may develop over months. Patients may present with jaundice, fever, bile peritonitis, biliary fistula, or abdominal pain.

DIAGNOSIS

Plain Films

Gas in the biliary tree is visible on plain films in most patients with a biliary fistula. Previous surgery (choledochoduodenostomy, cholecystojejunostomy, or sphincterotomy), patulous sphincter of Oddi, and ascending cholangitis with a gas forming organism should be considered in the differential diagnosis.

Barium Contrast Examination

An upper gastrointestinal series or a barium enema is frequently useful in detecting and evaluating the cause of a biliary–enteric fistula when the diagnosis is unclear after clinical exam and a plain film. It may be especially useful in the diagnosis of biliary–enteric fistulas due to peptic ulcer disease, carcinoma, diverticulitis, or Crohn's disease.

Ultrasound

The role of sonography is limited, since the fistula is often too small to be imaged. The disappearance of previously documented gallstones in the appropriate clinical context maybe suggestive of a fistula. Chronic inflammatory changes in the gallbladder and associated mass lesion or biliary tract obstruction may be demonstrated.

CT Scan

CT is most helpful when the diagnosis of pneumobilia is unclear from the plain film or when biliary tract obstruction or a mass lesion is present.

Nuclear Medicine

99mTc-IDA scintigraphy is most useful in delineating bronchobiliary fistulas (congenital or traumatic), postoperative or traumatic fistulas, and biliary–enteric anastomotic leaks, often obviating direct cholangiography.

Cholangiography

Direct cholangiography is often necessary to opacify the fistula, demonstrate obstruction, and delineate the pathologic anatomy precisely. However, small fistulas may not be filled.

TREATMENT

Internal Biliary Fistulas

Biliary–Enteric Fistulas

Surgery is unnecessary in asymptomatic or high-risk patients with cholecystoduodenal fistula. If a cholecystoduodenal fistula is discovered incidentally during abdominal surgery, a cholecystectomy and closure of the duodenal defect are sufficient in low-risk patients.

Patients with cholecystocolic fistulas should undergo immediate surgical treatment, including cholecystectomy and closure of the fistulous communication. A laparoscopic approach has been recently described. Segmental resection of the colon may be necessary. Treatment of uncomplicated choledochoduodenal fistula is usually not indicated. Most authors agree that the therapy is dictated by the symptoms of the underlying peptic ulcer disease and not by presence of the fistula. Closure of the fistula may be achieved by conservative management of the ulcer disease. Surgical treatment of the fistula may be necessary in the presence of severe ulcer disease with perforation, bleeding, or obstruction or upon the onset of acute cholangitis.

Thoracobiliary and Bronchobiliary Fistulas

Surgery is the mainstay of treatment in congenital bronchobiliary fistulas. Excision of the fistula through a right thoracotomy is usually performed. Interventional radiology and endoscopic techniques, including stenting to reduce distal biliary obstruction, may provide a safe treatment of acquired fistulas. Currently, operative approaches should be considered only if percutaneous or endoscopic interventions have failed.

External Biliary Fistulas

Definitive treatment of a spontaneous external biliary fistula requires removal of the gallbladder and excision of the fistulous tract. Alternatively, the fistula may be curetted and left to heal spontaneously. An iatrogenic external biliary fistula is a serious and difficult complication of biliary surgery. Delayed surgical repair with a biliodigestive anastomosis after resolution of the inflammation is often preferable. However, this surgery is associated with a high morbidity. When the fistula is well contained and the patient does not present with any signs of sepsis or bile peritonitis, a nonsurgical treatment can advised. A conservative treatment with endoscopic sphincterotomy, stenting, or placing of a nasobiliary catheter to reduce intraductal pressure can facilitate spontaneous healing.

PROGNOSIS

The prognosis in patients with biliary fistula is generally fair, depending in large part on the specific type of fistula, the clinical presentation, and the presence of comorbid conditions.

Bile Flow

RICHARD M. GREEN
Northwestern University Feinberg School of Medicine

bile Fluid secreted by the liver into the biliary system and subsequently into the gut. Bile is composed of water, organic anionic and cationic substances, electrolytes, and several proteins and lipids. In addition, bile is the route of excretion for many toxic substances. It contains endogenous or exogenous substances that are excreted by the liver, frequently after they undergo hepatic biotransformation.

bile acid Organic acid that is derived from cholesterol and possesses a steroid nucleus ring. Bile acids are amphiphilic substances, with both hydrophilic and hydrophobic regions of the molecule, and can thus serve as detergents to solubilize lipids.

bile canaliculus Domain of polar hepatocytes that connects with the biliary system. It contains many transport proteins that are required for bile formation.

bile salt Organic anion that is the ionized form of a bile acid.

bile salt-dependent bile flow Component of bile flow that is attributed to the osmotic effect of bile salts secreted into the bile canaliculus.

bile salt-independent bile flow Component of bile flow that is not attributed to the osmotic effect of bile salts, and is commonly attributed to the active secretion of electrolytes and other substances.

biliary system Anatomic area communicating from the liver to the gut. It includes small bile ductules, bile ducts, and the gallbladder.

bilirubin Porphyrin molecule that is a chemical breakdown product of heme metabolism. Bilirubin is very hydrophobic (insoluble in water) and must be metabolized into its water-soluble glucuronide form prior to secretion into bile. Bilirubin is yellow, thus, when serum bilirubin levels are elevated, jaundice becomes evident.

choleretic Physiologic increase in bile flow. A choleretic substance will stimulate the formation and secretion of bile.

cholestasis Pathophysiologic state characterized by an impairment of bile flow. This can be caused by a physical obstruction of the biliary system or by an impairment of bile formation.

gallbladder Organ of the biliary system that serves the functions of storing and concentrating bile. When the gallbladder is stimulated, such as following a meal, its contents are emptied into the biliary system and subsequently flow into the gut to enhance the digestive process. However, many animals lack gallbladders and humans usually have no symptoms after removal of the gallbladder.

Bile, composed of water, organic anionic and cationic substances, electrolytes, and several proteins and lipids, is the route of excretion for many toxic substances. It contains endogenous or exogenous substances excreted by the liver, frequently after they undergo hepatic biotransformation. Bile formation is an essential function of the liver. Although other organs such as the kidney and intestines are essential for the absorption and secretion of multiple xenobiotic and endobiotic substances, the liver has an important role in the metabolism of many of these substances prior to their excretion into bile.

INTRODUCTION

Many of the physiologic and molecular mechanisms responsible for bile formation have recently been elucidated, as well as the regulation of these transport proteins in both normal physiologic and pathophysiologic states. The transport function of bile formation by the liver is vectoral, occurring in a unidirectional manner. Substances are taken up from the blood of the portal circulation at the hepatic sinusoidal (basolateral) surface, are transported across the hepatocyte to the bile canaliculus, and are secreted into the canalicular space. Once the bile has left the canaliculus it may be further modified by the cholangiocytes, which are the epithelial cells lining the biliary system. Bile is often stored and concentrated in the gallbladder and is ultimately secreted via the bile ducts into the intestine. It is also important to know that bile salts, which are a major component driving the formation and flow of bile, are reabsorbed in the ileum (the distal portion of the small intestine). *De novo* bile salt synthesis quantitatively accounts for only a small amount of the bile salts that are secreted by the liver each day. The overwhelming majority of bile salts secreted into the bile each day comes from cycling in the enterohepatic circulation, in which the bile salts cycle from the liver via the bile duct into the intestine, are absorbed in the ileum and thus enter the portal circulation, return to the liver, and are taken up by the sinusoidal (basolateral) bile salt transporters. These processes may be significantly altered in many pathophysiologic disease states.

BILE FORMATION

Mechanisms of Bile Formation

The anatomical structure of the liver is unique in many aspects. The liver parenchyma is perfused by two distinct vascular systems, from the portal vein and from the hepatic artery. The ultrastructure of the liver also consists of a periportal and pericentral area where blood flows unidirectionally from the periportal to the pericentral end of the hepatic sinusoid. Bile formation occurs in the liver, and bile flow occurs in the opposite direction, arising in the pericentral area, crossing the midzone, and continuing to the periportal hepatocytes before it enters through the bile ductular system. There is a zonal distribution of many liver-specific proteins, including transport and metabolic proteins, which also occur in this unique anatomical and physiologic distribution.

Hepatocytes are polar epithelial cells, which have basolateral (sinusoidal) and canalicular (apical) domains, separated by tight junctions. The sinusoidal membrane is actively involved in the uptake of numerous substances into the hepatocyte from the portal circulation. Portal blood can flow within the space of Disse (between the endothelium of the portal venule and the sinusoidal membrane), and multiple substances in the blood may be taken up by one of the numerous sinusoidal uptake mechanisms. There have been several putative and definitively defined bile salt uptake mechanisms identified on the basolateral membrane of the hepatocyte. The majority of bile salt uptake is via sodium-dependent bile salt cotransport, and a minority of bile salt uptake occurs via a sodium-independent pathway. The sodium-dependent taurocholate cotransporter peptide (NTCP, in humans; Ntcp, in rodents) is the major bile salt uptake mechanism in humans and rodents. There have been several other putative human bile salt transport proteins defined, including epoxide hydrolase, although this remains controversial. A large class of organic anion transport proteins (OATPs) have also been identified in the basolateral membrane of both rodent and human liver cells; these proteins transport numerous organic anionic substances, including bile salts. In addition, there are several other transport proteins and transport mechanisms for electrolytes, including the Na^+,K^+-ATPase, the Ca^{2+}-ATPase, as well as numerous ion channels.

The Na^+,K^+-ATPase is instrumental in creating the electrochemical sodium gradient that drives sodium-dependent cotransport. Although several other channels and transporters are important in maintaining the transcellular sodium gradient, the Na^+,K^+-ATPase is an ATP-dependent protein complex that creates the electrochemical gradient. Activity of this pump has been correlated with many hepatocellular transport functions, although more recent data have also emphasized the import on bile formation of specific transport proteins that have been identified and cloned over the past decade.

Over the past decade, numerous ATP-binding cassette (ABC) proteins have been identified in the liver canalicular membrane. Members of this transporter family include several P-glycoproteins, including multidrug-resistance (MDR) proteins and MDR-associated proteins (MRPs). In addition, numerous other ABC proteins have been demonstrated to be important for the secretion of phospholipid, glutathione, and other organic anionic and cationic substances. Finally, the liver secretes numerous other organic and inorganic anions and cations as well as water (involving aquaporins or water channels). Many of these transport proteins are highly regulated and are significantly modified by numerous hormones, intracellular second messengers, pharmacologic agents, and in pathophysiologic disease states.

Functions of Bile Formation

Several physiologic functions of bile formation have been identified to be important for normal function. Bile formation provides an essential root of excretion for many xenobiotic and endobiotic substances, including bilirubin. The diminished biliary secretion of bilirubin can cause jaundice, which is often the presenting sign of hepatic disease. Clinical jaundice is often the presenting sign of liver disease because bilirubin is "easily seen" due to its characteristic yellow color. Patients with clinical jaundice also frequently have other concomitant hepatic impairments of metabolism and secretion. The liver, due to its unique microvasculature, is also frequently involved in removing from the circulation large molecules that may be bound to albumin or other transport proteins. Similarly, many protein-bound drugs are cleared from the body via biliary excretion. The liver possesses numerous metabolic pathways that frequently will metabolize substrates in the circulation prior to their hepatobiliary secretion. Many hydrophobic substances, which cannot be cleared by the kidney, are cleared from the body only after hepatic biotransformation into hydrophilic substances, which can be cleared in the bile and/or urine.

A second important function of bile formation and/or bile flow into the intestine is the enhanced absorption of hydrophobic or lipid-soluble substances. These fat-soluble substances include numerous lipids

(e.g., cholesterol) and essential fat-soluble vitamins. Bile salts serve as detergents for the solubilization of lipids and fat-soluble nutrients so they can be absorbed in the small intestine. Many cholestatic conditions cause an impaired ability of the body to absorb fat-soluble vitamins, including vitamin K. Many of the clotting factors produced by the liver are vitamin K dependent, and cholestasis can frequently cause severe coagulopathy due to impaired solubilization and the resultant malabsorption of vitamin K. Thus, bile formation and bile flow are essential for both the excretion of numerous substances from the body and the absorption of lipids and other essential fat-soluble nutrients. An impairment of bile flow from the liver into the intestine may be caused by an anatomic obstruction of the biliary system, as well as by an impairment of bile formation.

Bile Acid-Dependent and Bile-Independent Bile Formation

Because bile acids are the major organic solute in bile, it is not surprising that bile acid secretion is a major driving force for bile flow. Formation of canalicular bile has often been functionally divided into two components: bile acid-dependent bile formation and bile acid-independent bile formation. The bile acid-dependent component of bile formation is typically attributed to the osmotic effect of the bile acids. In support of this, there are data from humans, dogs, rats, and rabbits that there is a linear relationship between canalicular bile flow and bile acid output. In addition, many non-micelle-forming bile acids exhibit a larger and more significant choleretic potency than do many micelle-forming bile acids. The bile acid-independent component of bile formation is likely due to the effects of ion secretion as well as to the secretion of bicarbonate, glutathione, and bilirubin. The bile also contains numerous biliary lipids, organic anions, organic cations, and some biliary proteins.

EXTRAHEPATIC CHOLESTASIS

Extrahepatic obstruction of bile flow may be caused by any benign or malignant condition obstructing the bile ducts or adjacent anatomical structures. The initial management of a jaundiced patient or a patient with evidence of cholestasis typically involves a radiologic evaluation of the biliary system. Ultrasonography can reveal both intrahepatic and extrahepatic biliary dilatation. It is a sensitive imaging modality for the detection of cholelithiasis (gallstones) and is often the initial procedure of choice for imaging jaundiced patients. It may also identify the presence of choledocholithiasis (common bile duct stones), obstructing masses in the head of the pancreas or in the liver, as well as biliary obstruction caused by large perihepatic lymph nodes (which can cause extrinsic compression of the bile ducts).

Abdominal computer tomography (CT) scanning may also be useful for the evaluation of extrahepatic obstruction. Biliary dilatation may be evident, and this imaging modality may be more effective than ultrasonography in identifying and characterizing masses of the liver or pancreas, or lymphadenopathy. Endoscopic retrograde cholangiopancreatography (ERCP) has been the gold standard for the evaluation of biliary dilatation. In addition, it is useful not only diagnostically, but also therapeutically when biliary obstruction must be endoscopically treated. Percutaneous transhepatic cholangiography (PTC), intraoperative, or T-tube cholangiography can also be employed to define the biliary anatomy. Magnetic resonance cholangiography (MRC) is also highly effective in evaluating the anatomy of the biliary system. Recent evidence indicates that it is almost as sensitive as ERCP, and may be more cost effective due to the lower complication rate. However, it does not offer the option of therapeutic intervention at the time of the procedure.

Extrahepatic obstruction of the biliary system may commonly be caused by several benign or malignant conditions. Common bile duct stones (choledocholithiasis), bile duct strictures from malignant or benign causes, and extrahepatic compression of the bile duct from pancreatic or hepatic masses may all cause obstruction. These may include primary adenocarcinomas of the pancreas or hepatocellular or metastatic carcinoma, or may potentially be due to metastases and lymphadenopathy of the porta-hepatis lymph nodes. Lymphadenopathy due to lymphoma, neoplasia, or many infectious diseases may potentially all cause biliary obstruction.

INTRAHEPATIC CHOLESTASIS

An impairment of bile flow can also occur in the absence of an anatomic obstruction of the biliary system. This condition is termed "intrahepatic cholestasis," and is due to an impairment of bile formation and/or impaired biliary secretion, often with resultant pruritis or jaundice. Over the past decade, many of the molecular mechanisms responsible for bile formation have been defined, as well as their regulation in pathophysiologic diseases that result in cholestasis. In addition, many genetic diseases responsible for impaired bile formation

have also been elucidated, which often present in the neonatal or pediatric population.

Intrahepatic cholestasis may be caused by many factors, including medication, toxins, inflammation, hepatic regeneration, or inborn errors of metabolism. As previously discussed, distinct hepatocellular transport systems are responsible for the biliary secretion of the various organic anionic, organic cationic, or nonionic substances secreted into the bile. Many sinusoidal (basolateral) transporters have been identified that are responsible for the uptake of xenobiotics or endobiotics from the portal blood into the hepatocytes. Following the hepatocellular uptake of these substances, they may be biotransformed by one of many metabolic pathways found in the hepatocyte. Many of these pathways are responsible for the conversion of hydrophobic (fat-soluble) substances into hydrophilic (water-soluble) substances, so that they may be secreted into bile. These substances are subsequently transported to the canalicular membranes of the hepatocytes for biliary secretion. Intracellular transport mechanisms of many of these substances remain to be elucidated, but likely involve diffusion, binding to intracellular binding proteins, and potentially membrane-to-membrane transport. These substances are subsequently secreted into the biliary system by distinct canalicular transport proteins. Diminished expression or function of canalicular membrane transporters or other hepatic transporters and/or binding proteins may be responsible for intrahepatic cholestasis.

Medications are a common cause of intrahepatic cholestasis. Although, virtually any drug can cause abnormal liver function, certain medications are more frequently implicated in causing cholestasis. Anabolic steroids, estrogens, protease inhibitors such as indinavir, trimethoprim/sulfamethoxazole, phenothiazines, and many antihypertensive medications are frequent causes of an elevated serum bilirubin or alkaline phosphatase. Total parenteral hyperalimentation (TPN) also often causes cholestasis. Severe inflammation due to infection and sepsis may result in cholestasis, a clinical entity often termed "the jaundice of sepsis." Similarly, "benign postoperative jaundice" is a multifactorial entity due to cholestasis from inflammation and medications, often with concomitant hepatic ischemia and increased bilirubin production due to the breakdown of red blood cells from blood transfusions or hematomas. Other less common causes of intrahepatic cholestasis include the intrahepatic cholestasis of pregnancy or benign recurrent intrahepatic cholestasis (BRIC), which are likely due to mutations of canalicular transport proteins, potentially in combination with hyperestrogenemic or other stressor states.

Finally, acute or chronic liver disease due to hepatitis, primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC), the vanishing bile duct syndromes, or other cholestatic diseases may also present as intrahepatic cholestasis. In addition, cirrhosis due to almost any cause may cause cholestasis. Certain types of hepatitis, such as alcohol-induced liver injury or certain viral infections (hepatitis A, hepatitis B, hepatitis C, Ebstein–Barr virus, cytomegalovirus), may also present with particularly cholestatic forms of hepatitis. The cholestasis caused by these etiologies typically resolves when the inciting agent or acute disease process resolves. However, in certain forms of genetic or acquired diseases that cause progressive liver disease, the cholestasis may continue to worsen and cause significant morbidity and mortality.

SUMMARY

In summary, bile formation, biliary secretion, and the resultant bile flow into the intestine are essential functions of the liver and hepatobiliary system. Recent scientific advances have helped elucidate the mechanisms of bile formation and the pathophysiology in many disease states. Hepatobiliary secretion is an essential route of elimination for many xenobiotic and endobiotic substances, and significant symptoms such as jaundice and pruritis can develop when bile flow is diminished. Extrahepatic obstruction can be caused by intrinsic tumors of the biliary system or by external compression of the bile duct. Intrahepatic cholestasis can be due to a host of pathophysiologic states and is typically characterized by impairment of the molecular mechanisms of bile formation. Elimination of extrahepatic obstruction and treatment of the primary causes of intrahepatic cholestasis will often result in normalization of bile flow, and symptomatic improvement of the patient.

lead to life-threatening complications. Knowledge of the intricacies involved in bile formation and its flow in the enterohepatic circulation is integral to developing therapeutic treatments of hepatobiliary diseases.

WHAT IS BILE?

Bile is a complex fluid; it is isosmotic with plasma and is composed primarily of water, inorganic electrolytes, and organic solutes such as bile acids, phospholipids, cholesterol, and bile pigments. Bile is secreted by the hepatocytes, which transport a wide variety of endogenous and exogenous substances from blood into the bile capillaries. Bile formation begins at the level of hepatocytes by the net movement of water and solutes into the microvilli of the bile capillaries, which are formed by the apposition of the cell membranes of the hepatocytes. The hepatocytes are typically arranged in single-cell-thick plates and are joined via the bile canaliculi, approximately 1 μm in diameter from the basolateral, or sinusoidal, domain. Bile salts, cholesterol, phospholipids, and conjugated bilirubin enter the lumens of the bile capillaries together with water and inorganic electrolytes by a process of active transport. Neighboring canaliculi join together and empty into small terminal ductules (canals of Hering), which in turn convey the bile to larger ductules, the intralobular and interlobular ducts, and eventually to the extrahepatic bile ducts. Bile flows through these extrahepatic bile ducts into the gallbladder (when present), where it is stored, and into the intestine, where cholesterol and the lipids from the phospholipids are absorbed in the jejunum and conjugated bile acids are absorbed in the ileum. In the gallbladder, the sodium, calcium, chloride, and bicarbonate ions and water are reabsorbed, resulting in a 5- to 10-fold concentration of the remaining solid constituents of bile. The daily volume of bile secretion in humans averages 500–800 ml.

After food is ingested and the gastric contents, in particular fat, reach the duodenum, secretin is released from the duodenal mucosa, which stimulates the bile duct epithelium to release water and bicarbonate. Simultaneously, the hormone cholecystokinin is released from the duodenal mucosa, which stimulates the gallbladder to contract and the sphincter of Oddi to relax, with the result that the bile flows into the duodenum. The bile salts are more than 95% reabsorbed in the terminal ileum and return to the liver by a process of enterohepatic cycling, to be excreted again into the bile. With the completion of eating and gastric emptying, the neural and hormonal stimuli cease and the sphincter of Oddi closes so that the gallbladder resumes collecting, concentrating, and storing the bile. The relative proportions of the major organic solutes in hepatic bile are illustrated in Table I.

BILE COMPOSITION

Bile acids or bile salts are the major organic solutes in bile and are derived from the liver as well as the intestine. Primary bile acids (cholic acid and chenodeoxycholic acid, in humans) are synthesized from cholesterol in the liver, and secondary bile acids (deoxycholic acid and lithocholic acid, in humans) are produced from primary bile acids by bacteria during their intestinal transit (Fig. 1). Bile acids and cholesterol have the same steroid skeleton (the cyclopentanophenanthrene nucleus with methyl groups between the rings at positions 18 and 19 and a side chain at C-17). Most bile acids have a C_5 side chain with the terminal carbon as the carboxyl group. However, the major bile acids in alligators, 5β-cholestanoic acids, have a C_8 side chain with the terminal carbon as a carboxyl group (Fig. 1). In addition, bile acids have hydroxyl groups in the nucleus, at C-3, C-7, and/or C-12, and the majority of bile acids contain a cis-A/B ring fusion. After synthesis, bile acids are converted into their glycine and taurine conjugates by hepatic enzymes, forming bile salts that are then secreted into the bile. Conjugated bile acids are more hydrophilic than the free (unconjugated) bile acids and possess lower pK_a values, factors that enhance their water solubility and decrease their ability in the small intestine to traverse cell membranes by passive diffusion . Further, glycine and taurine conjugates of bile acids are resistant to hydrolysis by pancreatic enzymes, so that they can accumulate in the small intestine at a high enough intraluminal concentration to facilitate fat digestion and absorption. Secondary bile acids are formed in the intestinal lumen by bacterial deconjugation and dehydroxylation of primary bile salts and are passively absorbed and account for 20% of the human biliary bile salt pool.

Bile salts are amphiphilic [literally, "loving" (mixing with) both oil and water] because they have both a polar,

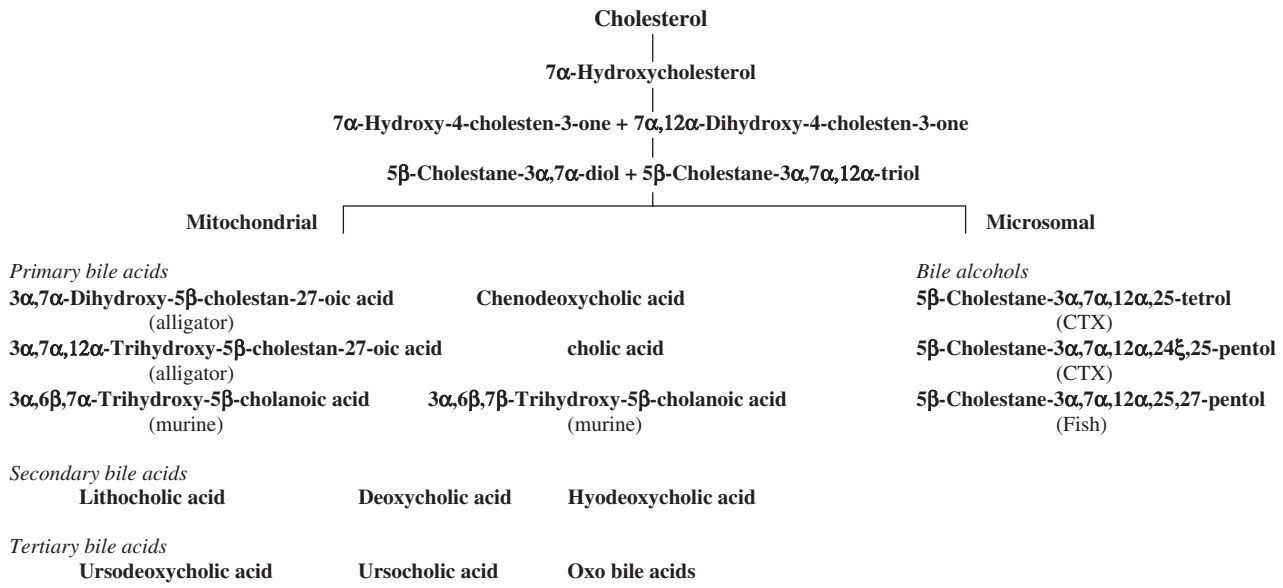

FIGURE 1 Metabolism of cholesterol in humans and animal species. In the classic bile acid synthetic pathway, a series of ring modifications precede side chain oxidation to yield 5β-cholestane-3α,7α-diol and 5β-cholestane-3α,7α,12α-triol, which are then converted into bile acids either via the mitochondrial 27-hydroxylation pathway or via the microsomal 25-hydroxylation pathway. Several bile alcohols play a role in cerebrotendinous xanthomatosis (CTX).

hydrophilic surface and a nonpolar, hydrophobic surface. Above their critical micellar concentrations, bile salts form micelles (colloidal aggregates with molecular weights of 16,000–40,000), with their lipid-soluble (hydrophobic) surfaces facing each other and the hydrophilic polar groups exposed to the water phase. These micelles are able to take up other amphiphilic solutes, such as cholesterol and lecithin, to form mixed micelles. The aggregation of bile salts in micelles reduces their osmotic effectiveness, and the micelles also bind sodium and potassium and thereby remove them from the ionic, osmotically active state. The sodium ion activity in gallbladder bile is measured to be 148–186 nmol/liter, whereas the sodium content is 220–340 mmol/liter. Thus, even though bile is isosmolar with plasma, it contains very high concentrations of bile salts and sodium. The major ionic constituents of bile are listed in Table II.

GALLBLADDER FUNCTION

The primary functions of the gallbladder are collecting, concentrating, and storing bile during interdigestive periods; emptying the bile by smooth muscle contraction in response to cholecystokinin; bile acidification; moderating hydrostatic pressure within the biliary tract; and absorbing lipid-soluble organic components of bile, such as unconjugated dihydroxy bile acids, radiocontrast agents, unsaturated fatty acids, lecithin, lysolecithin, and even free cholesterol. The greatly increased concentration of bile salts and lecithin in the gallbladder bile helps keep relatively large concentrations of cholesterol in solution; this greatly reduces the risk of cholesterol gallstone formation due to cholesterol supersaturation in the gallbladder, where the bile remains stored for hours to days. With the 6- to 10-fold concentration of bile salts in the gallbladder bile during fasting, which accounts for up to 60% of the total bile acid pool, the hepatic bile acid secretory rate and bile salt concentration within the hepatic bile ducts

are markedly reduced. However, the secretion of biliary lecithin and cholesterol is reduced, with the result that lecithin-rich vesicles are formed in the bile acid-depleted bile; these vesicles carry increased amounts of cholesterol that may precipitate.

The concentrated gallbladder bile is largely the result of electroneutral Na^+-coupled Cl^- transport and passive water movement. In addition, HCO_3^- transport also takes place via Cl^-/HCO_3^- exchange and perhaps substitution by short-chain fatty acids, in particular butyrate. The net result is that the gallbladder bile is isotonic to plasma and is composed of high concentrations of Na^+, bile salts, and Ca^{2+} and lower concentrations of chloride and bicarbonate, compared to hepatic bile.

BILE SALT-DEPENDENT AND -INDEPENDENT BILE FORMATION

Bile formation can be considered to be a result of active secretion of electrolytes and bile acids followed by passive water flow. Three different modes of bile acid uptake by the liver have been identified: nonsaturable, Na^+-dependent saturable, and Na^+-independent saturable. The Na^+-dependent transport of bile acids is quantitatively the most common mode of uptake and seems physiologically to be the most important mechanism. The Na^+-independent component has been detected in a few studies and is nonspecific and shared by other organic anions (e.g., sulfobromophthalein). Most studies have shown that there is a Na^+-dependent uptake of conjugated bile acids, in particular taurocholate, and a Na^+-independent uptake of all unconjugated bile acids and certain nonbile acid anions, such as sulfobromophthalein, bilirubin, and many other xenobiotic substrates. The solute uptake is mediated by certain carrier proteins that have been recently characterized by photoaffinity labeling with fluorescent bile salt derivatives and by cloning techniques. The apparent molecular weight of the bilirubin and sulfobromophthalein carrier is 60,000 or 55,000; of the nonesterified fatty acid transporter, 40,000; and of the bile acid transporter, 48,000–50,000. Most of these transport proteins are located in the basolateral membrane of the liver.

Sinusoidal Transport

The sinusoidal uptake of conjugated bile acids, such as taurocholate, is primarily mediated by a secondary active transport process driven by the inwardly directed Na^+ gradient maintained by Na^+,K^+-ATPase located in the basolateral membrane. Studies on hepatocellular membrane vesicles show that Na^+/taurocholate cotransport is responsible for the uptake across the basolateral membrane. The transport rates of cholate and taurocholate are decreased in the absence of extracellular sodium, but are not completely suppressed, suggesting that the inward transport of bile acids is composed of both Na^+-dependent and Na^+-independent components. In contrast to the Na^+-dependent bile salt uptake, the physiological and biochemical properties of the largely nonspecific Na^+-independent hepatocellular bile salt uptake pathways are less well defined. The driving force for the Na^+-independent uptake of bile acids is not known, but most studies suggest the role of a Na^+-dependent bile acid transporter identified as the Na^+/taurocholate cotransporting protein (NTCP).

The amphipathic bile salts and nonbile salt organic anions reach the sinusoidal or basolateral surface of hepatocytes largely as albumin-bound complexes and pass across the fenestrae of sinusoidal endothelial cells. Dissociation of the bile salts, sulfobromophthalein, and fatty acids is facilitated by the microenvironment of the space of Disse or by the sinusoidal plasma membrane. However, the hepatocellular uptake of these organic anions is a saturable function of the unbound ligand concentrations at physiological albumin levels and involves Na^+-dependent and Na^+-independent transport systems.

The *Xenopus laevis* sinusoidal Na^+/taurocholate cotransporting protein (Ntcp) was the first Na^+-dependent hepatocellular cotransporting protein identified and characterized by expression cloning of *X. laevis* oocytes. It is a glycoprotein with 362 amino acids and an apparent molecular weight of 51,000 in isolated basolateral rat liver plasma membranes. The human analogue Ntcp (human NTCP) has also been identified and consists of 349 amino acids with 77% amino acid homology with the rat liver Ntcp. A number of recent studies have shown that Na^+/taurocholate cotransporting protein can account for most, if not all, physiological properties of Na^+-dependent bile acid uptake in intact liver. In addition, expression cloning in *X. laevis* oocytes also identified the rat organic anion-transporting polypeptide 1 (oatp1) from rat liver as well as the human organic anion-transporting polypeptide (OATP) from human liver. Rat oatp1 is a glycoprotein with 670 amino acids and a native molecular weight of approximately 80,000 in sinusoidal plasma membranes isolated from rat liver. Human OATP also consists of 670 amino acids and shows a 67% amino acid homology with the rat liver oatp1, thereby suggesting that both transporters may belong to the same transporter gene family, although significant differences between the two exist on both structural and functional levels. Cloning

Ntcp/NTCP and oatp1/OATP has increased our understanding of the molecular physiology of sinusoidal bile acid, organic anion, and drug uptake into rat and human livers. Both Ntcp and NTCP are physiologically relevant hepatocellular Na^+-dependent bile acid carriers, whereas the cloning of oatp1 and OATP has confirmed the existence of Na^+-independent multispecific bile acid carriers at the basolateral plasma membrane domain of mammalian hepatocytes. The transport properties of oatp1 can account at the same time for the multispecific bile acid carrier, the neutral steroid carrier, and the charge-independent organic cation carrier.

Canalicular Transport

Transport of bile acids across the canalicular membrane of the hepatocyte represents the rate-limiting step in overall transport of bile acids from blood into bile. This canalicular excretion of monoanionic bile acids, which preferentially transports conjugated tri- and dihydroxy bile acids, occurs largely via an ATP-dependent processor. The transporter, the bile salt export pump (BSEP), has been cloned and is a member of the ATP-binding cassette superfamily of proteins. The BSEP is related to the multidrug resistance gene products, or P-glycoproteins, is expressed exclusively in the liver, and has been localized to the canalicular domain of hepatocytes. The expression of this transporter has been shown to be sensitive to bile acid flux through the hepatocyte, possibly at the level of transcription of the BSEP gene. The promoter of the BSEP gene was very recently cloned and was shown to contain an inverted repeat-1 (IR-1) element, which serves as a binding site for the farnesoid X receptor (FXR), a nuclear receptor for bile acids. The FXR heterodimerizes with the retinoid X receptor α (RXRα), and when bound to bile acids, the complex FXR/RXRα regulates the transcription of several genes involved in bile acid homeostasis. These studies demonstrate a critical role of FXR as a physiological bile acid sensor integrating the expression of BSEP in bile acid homeostasis.

ELECTROLYTE TRANSPORT AND BILE FORMATION

Sodium and potassium are the major extra- and intracellular cations in all living cells. The mechanism of the bile salt-independent fraction of canalicular bile flow is considered to involve the Na^+, K^+-activated adenosine triphosphatase sodium pump in the canalicular membrane, whereby three sodium ions are pumped out of the cells for every two potassium ions pumped in, resulting in a net intracellular negative potential that amounts to approximately −35 mV in intact hepatocytes. In cultured hepatocytes, it has been demonstrated that substrate-induced (alanine, taurocholate) sodium influx is associated with a rapid increase in Na^+, K^+-ATPase cation pumping, indicating that pump activity is directly modulated by the intracellular sodium concentration. The basolateral Na^+, K^+-ATPase-mediated electrogenic cation pumping represents a major driving force for both Na^+-coupled solute transport across the sinusoidal membrane and potential dependent anion secretion across the canalicular membrane.

Plasma membrane Na^+/H^+ exchange (or antiport) that involves a sequential uptake of Na^+ by Na^+, K^+-ATPase followed by uptake of protons via Na^+/H^+ exchange is selectively located in the basolateral membrane in the hepatocyte and serves a variety of interrelated metabolic and transport functions, including regulation of intracellular pH and cell volume control. This Na^+/H^+ exchange plays an important role in the generation of bile acid-induced choleresis, e.g., the choleresis induced by physiological bile acids, such as taurocholate and the ursodeoxycholic acid-stimulated bicarbonate secretion. Although a Na^+/Cl^- or a $Na^+/K^+/Cl^-$ cotransport has not been found in rat liver cells, the presence of an electroneutral Cl^-/HCO_3^- antiport is demonstrated at the canalicular membrane and provides an explanation for the role of Na^+/H^+ exchange in the canalicular secretion of bicarbonate stimulated by ursodeoxycholic acid. Also, a Na^+/HCO_3^- cotransport has been demonstrated in the basolateral, but not canalicular, membrane vesicles; it mediates Na^+-coupled HCO_3^- influx into rat hepatocytes under physiological conditions and helps explain the Na^+ dependency of the ursodeoxycholic acid-induced hypercholeresis.

Indirect evidence suggests that transport of glutathione across the canalicular plasma membrane into bile contributes to the formation of the bile acid-independent fraction of bile flow and to an increase in biliary glutathione that is associated with a corresponding increase in bile flow. This tripeptide is secreted into canalicular bile in relatively high concentrations via a specific carrier-mediated mechanism. Quantitative measurements show that bile formation with glutathione is of the same order as that with bile acids when measured at low rates of bile acid excretion, i.e., in the absence of micelles.

ENTEROHEPATIC CIRCULATION

The enterohepatic circulation of bile acids involves hepatic bile acid formation and secretion into the bile, accumulation of bile in the gallbladder, bile emptying into the small intestine, bile acid reabsorption from the

small intestine, and bile acid transport into the liver via the portal blood. The intestinal conservation of bile acids is approximately 95% efficient and reflects both passive and active reabsorption processes. The total bile acid pool in humans is about 3–5 g and cycles 6 to 10 times daily, depending on the number of times food is ingested. In this way, 20–30 g of bile acids enter the proximal small intestine in 24 hours. The daily 0.5-g fecal loss of bile acids is balanced by hepatic *de novo* synthesis of bile acids from cholesterol. The bile acids exert two major actions on bile formation in mammals. First, they stimulate bile flow, primarily as a result of osmotic effects of their active secretion into the biliary canaliculi, and second, they stimulate the biliary secretion of the water-insoluble amphipaths lecithin and cholesterol, with which they form mixed micelles. Based on the observation that biliary bile acid output and bile flow are linearly related in all animal species studied so far, bile acid-stimulated bile flow has been attributed to active secretion of bile acids followed by osmotically driven water flow. However, the choleretic efficiency may vary greatly for the same bile acid given to different animal species, or for different bile acids given to the same animal species, and these differences are not always readily explained by differing micelle-forming properties of the bile acids.

Hypercholeresis and Cholehepatic Shunt

Unconjugated bile acids produce choleresis in excess of that predicted by osmotic action of the secreted bile acid, and it is accompanied by a selective increase in biliary HCO_3^- concentration. This phenomenon is called hypercholeresis, which is bile acid-dependent bile flow that appears to be greater than what can be explained by the osmotic effects of the bile acid recovered in bile. Hypercholeresis is observed on feeding a dose of a bile acid that exceeds the capacity of the liver to conjugate fully the infused bile acid with glycine and taurine; the result is that a proportion of the unconjugated bile acid is secreted into the bile. This phenomenon is also observed with infusion of nor-bile acids (which have four carbon atoms in the side chain, instead of the five carbons in the normal bile acids). The hepatic enzymes are unable to conjugate nor-bile acids. Two mechanisms have been proposed to explain hypercholeresis. In the first, the unconjugated bile acid causes intracellular alkalinization by increasing H^+ excretion across the sinusoidal membrane; the increased intracellular pH then induces HCO_3^- excretion across the canalicular membrane. The second mechanism is explained by what is called the "cholehepatic shunt pathway," according to which the unconjugated bile acid is secreted by the hepatocyte in anionic form, protonated by carbonic acid in the biliary tree via carbonic anhydrase, passively reabsorbed in the protonated form by the biliary ductular cells, and carried back to the hepatocytes via the periductular capillary plexus, thus generating HCO_3^- within the biliary tree. The bile acid is thus available at the sinusoidal membrane for another enterohepatic cycle, which may go on until the bile acid is biotransformed.

Intestinal Absorption

An important component of the enterohepatic circulation is the active reabsorption of conjugated bile acids in the ileum, via the ileal apical sodium-dependent bile acid transporter (ASBT), an integral brush border membrane glycoprotein that cotransports sodium and bile acids to ileocytes. Conjugated trihydroxy bile acids (taurocholate) are preferred over dihydroxy (taurochenodeoxycholate) bile acids, and unconjugated bile acids are passively absorbed throughout the small intestine. Several recent studies suggest that the ASBT is regulated by intraluminal bile acids, and conditions that reduce intestinal bile acid concentrations, such as fasting, biliary diversion, and extrahepatic cholestasis, decrease bile acid transport into brush border membrane vesicles. However, others have found a feedback inhibition of ASBT expression after taurocholate feeding in the rat and guinea pig.

Bile acids are transported across the ileal brush border membrane aided by the ASBT, and the accumulation of bile acids within the enterocyte against its electrochemical gradient is driven by the inwardly directed Na^+ gradient, maintained by a basolateral Na^+, K^+-ATPase. Intracellular transport of bile acids in the enterocyte is mediated by several cytosolic and microsomal proteins. At the basolateral membrane of the ileum, bile acids leave the enterocyte by a Na^+-independent anion exchange process. Absorption of bile acids into the portal blood occurs mainly by way of hydrophobic binding to albumin, although a small fraction is bound to lipoproteins. Bile acid uptake from the portal blood, completing the enterohepatic circulation, is typically expressed as the first-pass extraction (percent bile acid removed during a single passage through the hepatic acinus). The fractional extraction is greater for the hydrophilic bile acids compared to the hydrophobic bile acids (80–90% for taurocholate vs. approximately 50% for unconjugated ursodeoxycholic acid). The small fraction of bile acids that escapes absorption from the small intestine undergoes bacterial modification in the colon: deconjugation, 7-dehydroxylation, epimerization of hydroxyl group(s), and oxidation of

hydroxyl groups to oxo-bile acids. The predominant secondary bile acids formed in the colon are the 7-dehydroxylated bile acids, lithocholic acid and deoxycholic acid, formed by 7α-dehydroxylation of chenodeoxycholic acid and cholic acid, respectively. These secondary bile acids are passively absorbed and brought into enterohepatic circulation.

CLINICAL IMPLICATIONS

Cholestasis

Cholestasis is a functional defect in bile formation at the level of the hepatocyte (i.e., intrahepatic cholestasis, an example of which is primary biliary cirrhosis) or an obstruction to bile flow within the biliary tract (i.e., extrahepatic cholestasis, which includes primary sclerosing cholangitis). Extrahepatic cholestasis may be caused by choledocholithiasis, pancreatic and periampullary carcinoma, biliary strictures, and pancreatitis. On the other hand, several mechanisms may play a role in the pathogenesis of intrahepatic cholestasis, including alterations in sinusoidal membrane function and composition, alterations in cytoskeletal organization and function, alterations in tight junction permeability, and impairment of canalicular membrane structure and function.

Regardless of the mechanism of cholestasis, the net effect is retention of solutes, including bile acids, bilirubin, and cholesterol, which are preferentially excreted into bile under normal conditions. It has been recently shown that the sinusoidal sodium-dependent bile acid cotransporter (NTCP), the canalicular Na^+, K^+-ATP-dependent-bile acid transport activities, and the expression of the multidrug resistance protein 2 (Mrp2), which is responsible for the biliary excretion of amphiphilic anions, are all down-regulated in experimental models of intra- and extrahepatic cholestasis. Hepatic retention of bile acids results in decreased biliary excretion into the intestine, so that intestinal bile acid concentrations are reduced to levels below those required for normal fat digestion and absorption, and steatorrhea and deficiencies of fat-soluble vitamins may result. Reduced hepatic uptake also results in greater systemic spillover, so that serum bile acids increase over normal levels and are generally used as an indicator for liver disease, including cholestasis. Jaundice results from retention of bilirubin. Defective cholesterol excretion leads to the formation of xanthelasma, xanthomas, and alteration in the erythrocyte membrane leading to target and spur cell formation. The retained bile acids in the hepatocyte are subject to further enzymatic modification, including 6-hydroxylation, glucuronidation, and sulfation, which can further increase cholestasis, and the renal route of elimination becomes predominant.

Defects in Intestinal Transport and Metabolism

Crohn's disease, ileal resection, and bypass are characterized by defective bile salt absorption and may give rise to cholerrheic or a steatogenic enteropathy. In disorders involving more than 100 cm of ileum, hepatic synthesis of new bile salts cannot compete with intestinal loss to maintain a critical concentration of bile salts in the proximal small intestine for normal fat digestion, and steatorrhea with or without diarrhea occurs. In disorders with lesser degrees of involvement, increased concentrations of bile salts in the colon result in net fluid and electrolyte secretion, and bile acid-induced diarrhea with minimum fat malabsorption occurs.

In steatogenic enteropathy, hydroxy fatty acids formed in the colon by bacterial enzymatic hydroxylation of dietary lipids cause net fluid secretion and diarrhea. Idiopathic bile acid catharsis, a chronic diarrheal illness characterized by bile acid malabsorption, results from a relative lack of ileal bile acid transporter proteins. Disorders that are associated with acidic duodenal pH, such as exocrine pancreatic insufficiency, result in greater passive absorption of bile acids or their intraluminal precipitation. The intraluminal bile acid concentration becomes low, contributing to impaired fat digestion and steatorrhea. In small bowel bacterial overgrowth, bile acids undergo bacterial deconjugation and dehydroxylation to form unconjugated deoxycholic acid and lithocholic acid, which are absorbed passively by nonionic diffusion. Intraluminal bile salt concentration is again compromised and steatorrhea may occur.

Defects in Enterohepatic Circulation Dynamics

The bile acid pool cycles 6–10 times daily through the enterohepatic circulation. This is accomplished by the coordinated action of two physical pumps (the gallbladder and the small intestine), two chemical pumps (the transport systems of the hepatocyte and the terminal ileal erythrocyte), and two sphincters (the sphincter of Oddi and the ileocecal valve). The dynamics of the enterohepatic circulation are influenced by alterations in the gallbladder or the small intestine. Rapid intestinal transit increases cycling frequency whereas delayed intestinal transit decreases cycling frequency. In celiac

disease, reduced release of cholecystokinin in the intestinal mucosa results in impaired gallbladder emptying and stagnation of bile acids in the biliary tree. Cholecystectomy results in increased 7α-dehydroxylation of cholic acid due to increased exposure to colonic bacteria, and an increased deoxycholic acid pool is reported.

Defects in Synthesis

Continuous bile acid synthesis from cholesterol is required to maintain the bile acid pool in the enterohepatic circulation and compensate for intestinal loss. Reduced bile acid synthesis would result in serious complications, e.g., fecal loss will not be replenished, absorption of cholesterol and fat-soluble substances would decrease so that cholesterol excretion would be reduced, and the bile acid-dependent bile flow would stop. In cirrhosis, there is a reduced total bile acid pool, resulting from a reduced microsomal 12α-hydroxylation that results in a reduction of the cholate pool. Intestinal 7α-dehydroxylation of cholic acid is reduced so that the pool of deoxycholic acid is greatly reduced. Further, the increased sulfation/glucuronidation of hepatic bile acids that takes place results in increased renal clearance.

In the rare inherited lipid storage disease, cerebrotendinous xanthomatosis, which is characterized by progressive neurologic disturbances, premature atherosclerosis, cataracts, and tendon xanthomas, mitochondrial 27-hydroxylation is deficient and bile acid synthesis is decreased. Cholesterol synthesis is increased due to loss of feedback inhibition by bile acids, resulting in cholestanol formation. An alternative pathway for cholic acid synthesis becomes active, operating via microsomal bile alcohol formation (see Fig. 1). Large amounts of 5β-cholestane-3α,7α, 12α, 25-tetrols and of 5β-cholestane-3α,7α,12α,24, 25-pentols accumulate in the hepatocyte. The bile alcohols that are secreted in the bile after glucuronidation are poorly absorbed and largely excreted in the stool and urine. Treatment with chenodeoxycholic acid suppresses increased cholesterol synthesis, and in turn, cholestanol and bile alcohol levels, and may improve neurologic symptoms.

Zellweger's syndrome is another rare and fatal autosomal recessive disorder associated with multiple craniofacial dystoses, central nervous system abnormalities, generalized hypotonia, hepatomegaly, and renal cysts. Lack of peroxisomes in the liver and kidney results in defective β-oxidation of long-chain fatty acids and bile acids in this disease, and abnormal C_{27} bile acids accumulate. Smith–Lemly–Opitz syndrome is another devastating, often fatal, autosomal recessive disease characterized by dysmorphic facial features, limb abnormalities, genital disorders, and widespread defects in many endocrine glands and the liver, kidneys, urinary system, heart, lungs, and skeleton. The affected children are mentally retarded, often show severe failure to thrive, and most often die prematurely. Defective 7-dehydrocholesterol-Δ^7-reductase results in highly reduced plasma and tissue cholesterol with concomitant accumulation of the precursor, 7-dehydrocholesterol (5,7-cholestadien-3β-ol), and an isomer, 8-dehydrocholesterol (5,8-cholestadien-3β-ol). Reduced cholesterol levels result in highly reduced circulating bile acid levels, and intestinal fat absorption is impaired. Prenatal diagnosis is possible and supplementation with dietary cholesterol and bile acid seems to show limited promise.

SUMMARY

It is clear that bile flow is a very complex process that involves not only bile acids but also a large number of other components. The Na^+, K^+-ATPase is central to bile formation and current research has shown the involvement of a variety of transport proteins, including NTCP, OATP, and BSEP. The orphan nuclear receptors, liver X receptor α (LXRα), FXR, and RXR, have been shown to be powerful regulators of bile acid synthesis and homeostasis. Identification of novel nuclear receptor ligands and target genes may allow for the design of receptor-specific therapeutic agents to assist in the control of many hepatobiliary diseases.

A biliary stricture is often grouped with gallstones as a frequent cause of biliary duct obstruction. Although strictures caused by malignancy do occur (e.g., in pancreatic cancer or cholangiocarcinoma), the majority of biliary strictures stem from benign processes such as an operative procedure or an inflammatory response (e.g., pancreatitis). Postoperative bile duct strictures tend to be a frustration for surgeons because more than three-quarters of the iatrogenic bile duct injuries go unrecognized at the time of surgery. Strictures located distal to the cystic duct (i.e., closer to the pancreas and duodenum) typify most of the benign postoperative strictures, whereas strictures proximal to the cystic duct tend to be malignant in origin.

ETIOLOGY

Biliary Strictures Due to Operative Trauma

Bile duct injuries have been reported following procedures involving the liver, pancreas, and stomach. (For example, strictures can occur at the site of a biliary–enteric anastomosis done for reconstruction.) More commonly, however, a majority of postoperative biliary strictures occur following cholecystectomy with or without exploration of the common bile duct (CBD) by intraoperative cholangiogram (IOC). The site of bile duct injury is often located within 1 cm of the confluence of the right and left hepatic ducts. Common errors involving excessive cauterization, misplacement of surgical clips, and underrecognition of anatomic variants have been noted as possible reasons for injury in this area. The incidence of postoperative biliary stricture following open cholecystectomy has been reported to be 0.1–0.5% in a large series of patients who underwent laparoscopic cholecystectomy. Bile duct injury as reported from a group at the University of California, Los Angeles, had an incidence of 0.2–0.4%. Many researchers feel that the incidence of injury following

laparoscopic cholecystectomy is initially high because of surgical inexperience.

Biliary Stricture Following Liver Transplantation

Biliary tract complications are a major cause of morbidity following liver transplantation, with several series reporting incidences from 13 to 25%. Strictures have been attributed to hepatic artery or portal vein thrombosis, graft rejection, or tissue ischemia reperfusion injury. In addition, reflux cholangitis secondary to Roux-limb reconstruction and infection by cytomegalovirus (CMV) have been reported as stricture etiologies following liver transplantation.

Biliary Stricture Secondary to Pancreatic Processes

In 1886, Riedel described bile duct obstruction resulting from benign pancreatic disease. Pancreatic processes can often cause distal CBD pathology because that part of the biliary tree runs in a groove on the posterior surface of the pancreas before joining the pancreatic duct in the ampulla and emptying into the duodenum. Tumors, cysts, or extensive edema within the surrounding pancreatic tissue can cause extrinsic compression of the distal CBD. In one study, the prevalence of CBD stenosis approached 100% in the clinical setting of chronic alcoholic pancreatitis, with a corresponding elevated alkaline phosphatase level twice the normal limit for at least 4 weeks. Overall, a prevalence of chronic CBD stenosis caused by chronic alcoholic pancreatitis ranges from 4 to 10%.

Biliary Stricture Associated with Primary Sclerosing Cholangitis

Patients with primary sclerosing cholangitis (PSC) and diffuse ductal disease have been found to have a dominant stricture 15–20% of the time. Severe disease with development of cirrhosis is often treated surgically (e.g., liver transplantation); however, endoscopic stenting has been helpful as a temporizing or palliative measure for those patients who are not surgical candidates. It is important to note that malignancy must be excluded prior to endoscopic treatment. An Amsterdam group has reported successful outcomes after multiple endoscopic stenting of dominant strictures in PSC. In this 10-year retrospective study, endoscopic therapy was technically successful in 84% of patients.

Biliary Stricture Due to Other Causes

Although less common than benign causes, primary malignancy (pancreatic cancer, cholangiocarcinoma) or metastatic disease can cause biliary strictures. In the literature, other benign causes of stricture include parasitic infestation, pericholedochal abscess, choledochal cysts, or vascular rings. External trauma has been reported to cause stricture 1.7% of the time. Tuberculosis and cystic fibrosis are additional processes that have been reported to cause biliary stricture.

CLINICAL PRESENTATION

A majority (80%) of the patients with postoperative biliary stricture present with symptoms within a year after the initial operation (10% within the first week, 70% within first 6 months). Patients may present with jaundice, an elevated alkaline phosphatase, or they may have signs of bile peritonitis (e.g., abdominal pain and fever) secondary to a bile leak or fistula. A clinical diagnosis can be delayed in patients with advanced biliary cirrhosis. They may present with signs and symptoms of portal hypertension, including increased abdominal girth or mass, confusion, or bleeding from varices. Strictures secondary to pancreatic causes can present with elevated transaminases, amylase, lipase or a persistent low-grade hyperbilirubinemia.

DIAGNOSIS

Preliminary imaging studies such as ultrasound and computed tomography (CT) scan are helpful in detecting intrahepatic and extrahepatic ductal dilatation. The most useful diagnostic test is cholangiography by an endoscopic retrograde cholangiopancreatogram (ERCP), percutaneous transhepatic cholangiogram (PTC), and, more recently, a magnetic resonance cholangiopancreatogram (MRCP). PTC may be more effective in patients with proximal strictures because it allows for therapeutic drainage and delineates anatomy. On the other hand, ERCP is advantageous for distal strictures due to pancreatic causes by enabling visualization of the pancreatic ductal system. Prophylactic antibiotic coverage prior to cholangiography is frequently recommended. In cases of bile leakage and recognized postsurgical complications, radionuclide hepatobiliary scintigraphy has been a helpful diagnostic tool. In cases with equivocal results or for patients who are clinically unfit for invasive procedures, MRCP offers improved imaging resolution, which can aid in diagnosis and treatment. The weaknesses of MRCP include

patient claustrophobia, the high cost of the procedure, and the variability of a radiologist's interpretation.

TREATMENT

The management of a stricture is often based on its location. Bismuth, a surgeon, developed a classification of bile duct strictures determined by the anatomic level of involvement. Bismuth I is a type of stricture more than 2 cm from the common hepatic duct (CHD), Bismuth II is a type of stricture less than 2 cm from the CHD, Bismuth III is a high ductal (proximal) stricture where confluence is preserved, Bismuth IV is a high ductal stricture where confluence is destroyed, and Bismuth V is an anomalous right duct. The Bismuth classification continues to be used as a tool in the surgical or medical management of benign biliary stricture.

In the majority of cases in which biliary stricture results from operative trauma, the goal of reoperative surgery is to reestablish bile flow into the proximal small intestine. Possible surgical procedures include choledochojejunostomy, choledochoduodenostomy, or a Roux-en-Y hepaticojeju-nostomy. Most of these surgeries have produced good long-term results with success rates as high as 94%. Recurrent strictures after surgical repair have occurred in up to 10% of cases over a period of 7 months. Biliary stents and endoscopic dilations have been used as adjuncts both before and after reoperative surgery, but this practice is still often debated.

Treatment for biliary strictures resulting from chronic pancreatitis is controversial. If patients present with persistent jaundice and/or cholangitis, surgical decompression is indicated. Sphincteroplasty has been unsuccessful in most series, primarily due to the length of the distal common bile duct stricture. However, the approach to asymptomatic patients with an isolated increase in the level of alkaline phosphatase is debatable. Some clinicians advocate surgical decompression to avoid the possible complications of persistent cholestasis, including secondary biliary cirrhosis. Others advocate a conservative approach, with periodic liver function testing, especially when the alkaline phosphatase is normal or only mildly elevated and the proximal ducts are not dilated.

Because the majority of strictures are in the postoperative setting, most notably cholecystectomy, measures can be taken to help decrease the incidence. According to the surgical literature, there are some main points to remember during surgery: mobilizing the gallbladder by dissecting in a plane next to the surface of a gallbladder, always identify the junction between the common bile duct and the cystic duct; and perform an operative cholangiography, know the major variations of common hepatic duct, and never use cautery or apply clips blindly.

liver segment Portion of the liver defined by an independent blood supply.
sectoral bile duct Bile ducts formed by the merging of segmental bile ducts.
segmental bile duct Bile ducts draining segments of the liver.

The anatomy of the biliary system may be divided into that of the intrahepatic ducts and the extrahepatic ducts. The segmental intrahepatic bile ducts join to form the left and right hepatic ducts. At the hilum of the liver, these two ducts merge to form the common hepatic duct. The common hepatic duct is joined by the cystic duct (that drains the gall bladder) to form the common bile duct. The extrahepatic biliary system is composed of the common hepatic duct, the cystic duct and the common bile duct.

LIVER SEGMENTS

The liver is divided into eight segments based on the fact that the portal venous and hepatic arterial blood supply to and hepatic venous and biliary drainage from these segments are independent of each other and there are no significant anastomoses between segments. This permits segmental resections of the liver. Segment I is the posteriorly located caudate lobe. The primary division of the rest of the liver into left and right lobes is along a line that extends from the center of the gallbladder bed to the left side of the inferior vena cava (Cantlie's line). The left lobe is divided into anterior and posterior sectors. The posterior sector is segment II. The anterior sector consists of segment III and segment IV (the quadrate lobe). In 67% of individuals, the left hepatic duct is formed after the posterior sectoral duct bile ducts (draining segment IV) join the anterior sectoral duct (formed by the merging of the ducts draining segments II and III). In 25% of individuals, the segment IV duct drains into the segment III duct and in 4% there is drainage into both the segment III duct and the right sectoral duct. Drainage of the segment IV duct(s) into the common hepatic duct, into the segment II duct, and into the right sectoral duct occurs in 1% of individuals, for each variation.

SECTORAL DUCTS

The right lobe is divided into four segments. The first division separates the right lobe into antero-medial and postero-lateral sectors, each of which is further subdivided into anterior and posterior segments, i.e., segments V, VI, VII, and VIII. In 91% of individuals, the right anterior sectoral duct drains segments V and VIII and the right posterior sectoral duct drains segments VI and VII. The two sectoral ducts join to form the right hepatic duct. Variations in this anatomy are noted in approximately 10% of individuals. The segment V duct drains directly into the right hepatic duct in 5% of individuals and into the posterior sectoral duct in 4%. The segment VIII bile duct drains into the posterior sectoral duct in 20% of individuals. Variations in segment VI bile duct anatomy include direct drainage into the anterior sectoral duct (10%), the right hepatic duct (2%), and the common hepatic duct (2%). The caudate lobe (segment I) drains into both the left and right biliary systems.

The left and right hepatic ducts join to form the common hepatic duct in 57 to 72% of individuals. Variations in this anatomy primarily involve the right sectoral ducts. They include the right anterior and posterior sectoral ducts separately joining the left hepatic duct in 12% (no right hepatic duct) of individuals. A right sectoral duct drains into the left hepatic duct in 6% of individuals (right anterior sectoral duct in 1% and right posterior sectoral duct in 5%). In 20% of individuals, a right sectoral duct drains directly into the common hepatic duct (the right anterior sectoral duct in 16% and the right posterior sectoral duct in 4%). Finally, all the sectoral ducts may join to form the common hepatic duct without forming the right and left hepatic ducts (3%).

COMMON BILE DUCT

The common bile duct measures approximately 10 cm in length and 0.5 cm in diameter and lies to the right of the hepatic artery and anterior to the portal vein. It descends behind the posterior aspect of the superior duodenum along the free edge of the lesser omentum

and deviates toward the right in a groove on the posterior aspect of the head of the pancreas. Here it lies anterior to the inferior vena cava and enters the descending duodenum on its posterior-medial aspect. The sphincteric muscle of Oddi derived from the duodenal smooth muscle surrounds the common bile duct and the opening of the duct into the duodenal lumen is marked by a mucosal protrusion called the ampulla or papilla of Vater. The pancreatic duct accompanies the common bile duct within the sphincter of Oddi in 70–85% of individuals.

Benign biliary tumors are nonmalignant masses in the biliary tree. These masses may be neoplastic or congenital in origin and they may also result from inflammatory processes. It is necessary to distinguish these tumors from reactions to surgical trauma and from other systemic diseases known to cause strictures in the biliary system, such as sclerosing cholangitis.

INTRODUCTION

Benign biliary tumors are extremely uncommon. They have been reported in 0.1% of all biliary tract surgeries and constitute only 6% of all extrahepatic bile duct

and deviates toward the right in a groove on the posterior aspect of the head of the pancreas. Here it lies anterior to the inferior vena cava and enters the descending duodenum on its posterior-medial aspect. The sphincteric muscle of Oddi derived from the duodenal smooth muscle surrounds the common bile duct and the opening of the duct into the duodenal lumen is marked by a mucosal protrusion called the ampulla or papilla of Vater. The pancreatic duct accompanies the common bile duct within the sphincter of Oddi in 70–85% of individuals.

Benign biliary tumors are nonmalignant masses in the biliary tree. These masses may be neoplastic or congenital in origin and they may also result from inflammatory processes. It is necessary to distinguish these tumors from reactions to surgical trauma and from other systemic diseases known to cause strictures in the biliary system, such as sclerosing cholangitis.

neoplasms. However, in the interest of optimal management, it is important to consider these neoplasms in the differential diagnosis of obstructive jaundice. Benign tumors of the bile ducts, despite their varied origins and histological appearance, are similar in many aspects of their clinical presentation, methods of diagnosis, and treatment. Pathologically, there are at least seven subtypes, as indicated in Table I.

CLINICAL PRESENTATION

Symptomatic benign biliary tumors generally present with obstructive jaundice and/or right upper quadrant pain, most often of long duration. The clinical and radiological presentation of these patients may mimic biliary calculi, cancer, or inflammatory conditions of the bile ducts. Depending on tumor location, it is also possible for patients to be asymptomatic. Very rarely, these patients present with other symptoms, such as bleeding. A single case of death due to hemorrhage from an adenoma has been reported, and biliary papillomatosis has also been associated with hemobilia and may present with anemia. Biliary calculi are reported in only 20% of patients with adenomatous tumors and are not reported in the majority of patients with other types of benign bile duct lesions. The first study usually performed on a jaundiced patient is an ultrasound, which will confirm the diagnosis of obstructive jaundice but will give no indication of the pathology. This is especially true when no biliary calculi are present. In this circumstance, further imaging of the biliary tree is necessary, usually by endoscopic retrograde cholangiopancreatography (ERCP), although magnetic resonance cholangiopancreatography (MRCP) is increasingly being used. Even ERCP is usually not diagnostic of the lesion, although it is helpful in defining tumor location, extension, and size, as well as the status of the intrahepatic ductal system (Fig. 1). These features are useful in operative planning, even if the exact histological diagnosis is most often made postoperatively.

TUMOR SUBTYPES

Epithelial Tumors

Adenoma

The most common benign biliary tumors are those arising from the epithelial tissue lining the ducts. Chu's review of benign biliary neoplasms, published in 1950, found that 26 out of 30 cases reviewed were epithelial tumors. The anatomical distribution of these tumors is illustrated in Fig. 2. Most are found in the ampulla, with the common bile duct being the next most common site. Adenomas vary grossly from a few millimeters to several centimeters, although tumors as large as 15 cm have been reported. Grossly, they are firm, gray–white, and nonencapsulated. Histologically, they are composed of small, round, tubules resembling bile ducts in a fibrous stroma. The ducts may have a tortuous configuration and secrete mucin, but not bile. The epithelial lining consists of cuboidal, lightly basophilic cells that have regular nuclei. The supporting stroma is scanty and variably inflamed and becomes progressively hyalinized with time. It has been suggested that papillary cancers of the extrahepatic ducts may arise from preexisting adenomas, but because of the rarity of these lesions, it is difficult to prove. The origin of biliary duct adenoma is debatable. Plausible hypotheses

include developmental abnormality, hamartoma, a true neoplasm, or a reactive process to a focal injury.

Cystadenomas

Cystadenomas are rare cystic tumors of epithelial origin that arise in the liver, the majority in the right lobe, or less commonly in the extrahepatic biliary system. There are two histological variants, a mucinous type and a serous type. The more common mucinous type histologically resembles the mucinous cystadenoma of the pancreas. The origin of cystadenomas is unclear. They may be derived from embryonic foregut rests or from hamartomas. The cystadenoma (CA) is predominantly a tumor of middle-aged women; females account for 90% of reported cases. In contrast to other benign biliary tumors, abdominal swelling and pain are the most frequent presenting symptoms, although biliary obstruction, hemorrhage, rupture, and vena caval obstruction have been reported. Also, unlike other benign tumors of the bile ducts, imaging studies are reasonably specific and may permit preoperative diagnosis. The classic ultrasound appearance is an anechoic mass with internal septations that are highly echogenic, whereas computer tomography (CT) usually shows a smooth, thick-walled cyst with fine internal septae. The appearance of this tumor on magnetic resonance imagery (MRI) has also been described. Elevated CA 19-9 tumor marker levels have been reported. Grossly, the tumor usually consists of multilocular cysts ranging in diameter from 2.5 to 28 cm and containing a mucinous or gelatinous fluid. The inner surface may be smooth or trabeculated. Microscopically, the tumor is lined by mucin-secreting columnar to cuboidal epithelium with pale eosinophilic cytoplasm and basally oriented nuclei. The tumor is generally single layered but may form small papillary foldings. Focal intestinal metaplasia is occasionally observed. The stromal cells are spindle shaped or rarely oval, resemble ovarian stroma, and are immunoreactive with vimentin, actin, and desmin. Mucinous cystadenoma behaves as a slow-growing tumor but has a tendency to become malignant over a period of years. In one large study series, 6 of 18 cystadenocarcinomas had areas of preexisting benign cystadenoma and 7 of 51 cystadenomas had foci of dysplasia.

The serous variety of cystadenoma histologically resembles serous cystadenoma of the pancreas. It consists of numerous small cystic spaces lined by a single layer of cuboidal cells with clear cytoplasm containing glycogen. The serous cystadenomas rest on a basement membrane but, in contrast to the mucinous variety, are not surrounded by a mesenchymal stroma. Serous cystadenomas are not known to undergo malignant transformation.

Papillomas

Papillomas typically measure a few centimeters, although Leriche, in 1934, reported a case of a papillomatous tumor weighing 750 g in the common bile duct of a 4-year-old child. Grossly, the tumors may be firm, elevated masses or soft, vascular, sessile, or pedunculated growths. Histologically, the tumors are composed of thick or delicate papillae covered by a layer of tall columnar epithelium with a loose connective tissue core.

Biliary papillomatosis is a premalignant disorder consisting of multicentric papillary adenomas in the biliary tract. It is a rare disorder, with only about 50 cases described in the literature. The disease is seen in middle-aged to older men and women at a male : female

ratio of about 2 : 1. Pathologically, the lesion consists of soft, friable, papillary masses filling dilated intrahepatic and extrahepatic ducts. The gallbladder and major pancreatic duct may also be involved. The intervening liver parenchyma may be green or fibrotic. Histologically, the dilated ducts contain multiple papillary adenomas, which are composed of branching papillary fronds covered by mucus-secreting columnar epithelium covering fibrovascular stalks. The epithelial layer is adenomatous, with varying degrees of atypia. Paneth cells and endocrine cells may also be present. A point mutation of the K-*ras* oncogene has been found and may indicate a high probability of progression to carcinoma.

Preoperative diagnosis may be made by cholangiography, although the filling defects seen with this study have been confused in the past with air bubbles or intrabiliary blood clots. MRCP has also been used to image this lesion. Published reports have recommended intraoperative choledochoscopy of all accessible intrahepatic ducts to define the extent of the disease.

Adenomyoma

The majority of adenomyomas are located in the stomach, duodenum, and jejunum, and they also occur with some frequency in the gallbladder. Adenomyoma of the biliary tract is much rarer and was first reported in 1942; a review of world literature conducted in 2000 yielded 25 additional cases. Of these, 84% were located in the common bile duct or ampulla of Vater. A typical example is shown in Fig. 3. Histologically, they consist of a dense mass of intertwined smooth muscle bundles, collagen fibers, and epithelial structures that create distorted lumina.

FIGURE 3 Ampullary adenomyoma.

Granular Cell Tumor

Granular cell tumor is a rare benign tumor occasionally found in the biliary tree, although it is more commonly reported in other locations; the first description of a granular cell tumor in 1926 was in the skin. A granular cell tumor of the biliary tree was first reported in 1952; there have been about 50 reports in the literature since that time. It was originally believed that these tumors originated in muscle, and they were consequently classified as myoblastomas. The currently accepted theory is that they originate from Schwann cells, and can be seen by light microscopy, electron microscopy, and immunohistochemical staining to be very similar to nerve cells. Of the cases so far reported, 62% are in black women with a median age of 31 years. The most common location in which these tumors are found is in the common bile duct, although they have been reported in the gallbladder, cystic duct, and common hepatic and hepatic ducts. In five published reports, biliary granular cell tumors have presented concomitantly with granular cell tumors in other locations, three out of five being in the skin and two in the stomach wall. Grossly, the tumors are yellow–white and usually less than 3 cm (Fig. 4). Microscopically, they consist of polygonal granular eosinophilic cells that react with periodic acid–Schiff staining and have centrally located small vesicular nuclei (Fig. 5). Although preoperative radiological studies are not specific for this lesion, intraoperative frozen section does allow diagnosis. There have been no malignant granular cell tumors reported in the biliary system, although there have been several reported in the skin.

Neural Tumors

Neural tumors of the biliary system are infrequently reported and are thought to arise from the network of neural tissue surrounding the extrahepatic ducts. In 1955, a neurinoma of the common bile duct was reported in a 40-year-old woman who presented with jaundice and pain. The lesion was locally excised, leaving the duct intact, and the patient was reported well 18 months later. Von Recklinghausen's neurofibromatosis has also been recorded in one instance to have caused obstructive jaundice due to a periampullary nodular tumor. There have been several reported cases of paraganglioma of the extrahepatic ducts that presented with jaundice. These tumors, also known as nonchromaffin tumors of the sympathetic nervous system, most commonly occur in the adrenal medulla. Additional locations reported include the mediastinum, small intestine, retroperitoneum, urinary bladder, kidney, stomach, trachea, and tongue, as well as in the gallbladder. Microscopically, paraganglioma is described as nests of large, uniformly polygonal, round cells with abundant finely granular eosinophilic cytoplasm and round nuclei surrounded by a delicate fibrovascular septa. Metastasis has not been reported for biliary paragangliomas but is known to occur for these tumors in other locations. Their malignant potential cannot be predicted on histologic grounds.

Amputation neuroma is not a true neoplasm but a disorganized proliferation of a severed nerve. It most commonly arises after cholecystectomy from the cystic bile duct stump and grows extraluminally, in which location it rarely causes obstructive jaundice. However, it can occur in the main hepatic bile ducts and cause jaundice and pain. This usually follows cholecystectomy, although in one case it occurred in a patient who had a lymph node dissection of the hepatoduodenal ligament for gastric cancer. Amputation neuroma has also been reported as a rare cause of biliary obstruction following liver transplantation.

Leiomyomas

Although leiomyomas are the most common benign tumors of the esophagus, stomach, and small intestine, they are among the rarest in the extrahepatic biliary tree, with only five reported cases. This may be explained by the paucity of smooth muscle fibers in the extrahepatic biliary system. Of the five reported lesions, three were found in the common bile duct, one at the ampulla of Vater, and one at the hepatic duct bifurcation.

Inflammatory Tumors

Inflammatory tumors are nonmalignant lesions that may resemble neoplasms during preoperative investigation and even on gross inspection during laparotomy. One large study series from the Hammersmith Hospital reported 104 patients who had laparotomy for presumed malignant biliary obstruction, seven of which were found to have benign disease. In all seven patients, the obstructing lesion was removed and biliary reconstruction was performed by hepaticojejunostomy. Of these seven patients, six were alive and five were asymptomatic, from 19 to 49 months postoperatively. One patient died of cholangitis with cholangiographic evidence of progression of sclerosing cholangitic lesions.

Histologic examination of these lesions shows an extensive increase of fibrous tissue with subepithelial mucous glandular proliferation. Glandular cells are well differentiated, with elongated to rounded nuclei showing normal polarity. Clumps of lymphocytes are present in both perivascular and perineural locations, but they do not infiltrate the walls of the bile ducts. It is emphasized here that it is important to have tissue diagnosis of bile duct stricture before treating potentially benign disease with a therapy, such as stenting, normally reserved for short-term palliation of malignant disease, because this is associated with a higher complication rate than definitive surgical therapy. Attempts have been made to use mutation analysis of oncogenes such as K-*ras* to distinguish benign from malignant biliary strictures preoperatively, but this is not yet practical with current technology.

Heterotopic Tissue

Symptomatic heterotopic tissue arising in the biliary tree has been rarely reported. Whitaker *et al*. first observed heterotopic gastric mucosa arising in a cystic duct that had obstructed the gallbladder. Gastric mucosa has also been reported in the common bile duct, the common hepatic duct, and the ampulla of Vater. There are two hypotheses for development of this tissue: metaplasia with heterotopic differentiation and congenital development from multipotential endodermal tissue. Seven cases of heterotopic pancreatic tissue have also been reported in the common bile duct and ampulla of Vater.

TREATMENT AND PROGNOSIS

Treatment for benign bile duct tumors depends more on location of the tumor than on specific tumor type. Because of the rarity of these lesions, there is no consensus on standard of care, and only general principles can be advanced. These patients should be carefully investigated preoperatively. If the patient goes to surgery without a definitive diagnosis, it is advisable to obtain an intraoperative frozen section, because histological diagnosis permits better planning of the extent of surgical excision. Operations reported in the literature have included local excision, transduodenal papillotomy, curettage, local duct resection with reconstruction, hepatectomy, and occasionally a Whipple operation for periampullary tumors originally thought to be malignant. Tumors such as cystadenoma and granular cell tumor are known to recur following incomplete excision, although complete resection is usually curative.

Treatment of biliary papillomatosis deserves special note in that it is more complex, and patients for the most part have a less favorable course compared to other benign diseases of the biliary tree. In the past, many patients were treated with palliative techniques, such as cholecystectomy, curettage, and internal or external drainage. These treatments may relieve obstruction temporarily but are usually followed by recurrence. If the lesions are limited to one liver lobe, hepatectomy should be performed, although even with this treatment the disease may recur. In the five reported cases in which hepatectomy was performed, two patients appeared to be cured at the 6-month and 4-year followup exams. One patient died 6 years after resection and had diffuse malignant tumors of the right lobe of the liver, and two patients had recurrences 6 months and 3 years after left hepatic lobectomy. Hepatic transplantation has recently been proposed as an alternative therapy. The role of chemotherapy is unproved because of the rarity of the disease.

SUMMARY

Benign biliary tumors, although rare, are important considerations in the differential diagnosis of obstructive jaundice. These tumors vary considerably in their natural history and malignant potential, although their clinical presentations are similar and also mimic the presentation of cholelithiasis and cholangiocarcinoma, which are much more common. With many of these tumors, it is difficult to arrive at the correct diagnosis preoperatively, although there are a few, such as cystadenoma and intrahepatic biliary papillomatosis, that can be identified using cholangiography. In many cases, correct diagnosis can be accomplished only by intraoperative frozen section. This becomes important in cases in which more radical surgery is being contemplated than may be required, such as a pancreaticoduodenectomy. It is also important not to consign the patient to palliative therapy, such as insertion of a stent, when the patient may be cured by surgical excision. It may be possible that future advances in molecular biology will permit more precise preoperative diagnoses and treatment planning.

biliary tract Branching tubular network draining bile from the liver into the intestine.
duodenum Proximal small intestine into which biliary tract drains.
hepatocytes Individual cells constituting the liver.

The biliary tract consists of the organs and ducts that produce, transport, store, and secrete bile into the duodenum in digestive processes. The biliary system includes the liver, gallbladder, and bile ducts.

FETAL ORIGIN

The biliary tract and the liver arise from the endoderm of the distal foregut. On day 22 of gestation, a thickening called the hepatic plate develops in the ventral wall of the duodenum. This plate continues to proliferate, forming the hepatic diverticulum or liver bud that grows into the septum transversum (the plate of mesenchyme that divides the coelomic space into the thoracic and abdominal cavities and subsequently becomes the diaphragm). Within the septum transversum, the hepatic diverticulum proliferates into hepatic cords that give rise to the hepatocytes, biliary canaliculi, and intrahepatic bile ducts. Simultaneously, blood lakes form between these hepatic cords, followed by the development of capillaries and portal and hepatic veins. This vasculature is derived from the vitelline and umbilical blood vessels that traverse the septum transversum. Though the hepatocytes are intimately related to the sinusoids, they are separated from the portal vein radicals by connective tissue derived from the septum transversum.

DEVELOPMENT

Formation of intrahepatic bile ducts begins at approximately 9–10 weeks of gestation. The first ducts to appear are the left and right hepatic ducts at the hilum of the liver, and development progresses centrifugally toward the periphery of the liver. Biliary epithelium is derived from the hepatocytes immediately adjacent to the mesenchyme surrounding the portal veins. These hepatocytes change their phenotype to form the ductal plate. In contrast to the larger hepatocytes, the ductal plate cells have a low cuboidal shape and acquire cytokeratin 19 and 7 expression that is not present in the hepatocytes. Partial reduplication of the ductal plate occurs and the initial bile ducts are formed by fusion of these two layers at the portal mesenchymal interface. Between 12 and 14 weeks of gestation, these ducts migrate into the portal mesenchyme that now separates them from hepatocytes. Throughout the gestational period, this process extends more peripherally and development of the smallest bile ducts continues in the first couple of months after birth. The extrahepatic biliary system, which includes the common hepatic, cystic and common bile ducts, develops from the portion of the hepatic diverticulum between the duodenum and the septum transversum. On day 26, 4 days after the initiation of the hepatic diverticulum, another diverticulum develops from the ventral duodenal wall; this is destined to develop into the cystic duct and gall bladder. The tissues at the junction of the hepatic and cystic duct diverticuli proliferate to form the common bile duct, which elongates as the duodenum grows away from the septum transversum and undergoes rotation.

Even though studies in rodent models demonstrate the relevance of hepatocyte growth factor (HGF) in mesenchymal epithelial interactions that may be relevant to biliary epithelial proliferation, there is evidence to suggest that direct hepatocyte–biliary epithelial interactions are involved in orderly bile ductal development in the human.

Developmental anomalies of the biliary tract are common causes of obstructive jaundice in infants and children. In most cases, these disorders appear to be due to a defect in biliary embryogenesis or to acquired obliteration of the biliary ductal system. Although some of these disorders are amenable to surgical correction, many will continue to impart some degree of impaired bile flow and subsequent development of hepatic fibrosis or cirrhosis. The diagnostic and therapeutic challenge for the clinician is to identify, as rapidly as possible, those patients for whom surgical correction is beneficial. For the remainder of the patients for whom there are no surgical options, treatment is aimed at the prevention and treatment of the complications of cholestasis.

for physiologic jaundice) should be evaluated by a fractionated bilirubin assay. If the conjugated fraction of bilirubin is elevated, further evaluation should be performed. Although a large number of genetic, metabolic, and infectious disorders may produce neonatal cholestasis, extrahepatic biliary atresia remains among the most common etiologies. Other developmental anomalies of the biliary tract, although less common, represent important potentially correctable causes of infantile cholestasis.

NORMAL DEVELOPMENT OF THE BILIARY TRACT

In the human fetus, the liver begins formation in the third to fourth week of gestation. Immature liver cells begin as outgrowths of the foregut endodermal epithelium; the outgrowths merge with a mesodermal region called the septum transversum. As the endodermal cells proliferate, the liver parenchyma and intrahepatic bile ducts are formed. The liver cells grow in thick sheets with surrounding vasculature, which become the hepatic sinusoids. The sinusoids become the template for the architectural pattern that is assumed by the mature liver.

The bile duct forms as a connection between the fetal liver and the duodenum. The gallbladder and cystic duct connecting the gallbladder to the hepatic duct are formed as outgrowths of the common bile duct. Both are initially hollow, then become solid and once again recanalized by week 12 of gestation, when bile is formed and drains into the gastrointestinal tract. It is the presence of bile that gives the meconium its characteristic dark color. Subsequently, the duodenum rotates and the bile duct assumes its final location, entering the duodenum posteriorly.

The Kupffer cells, connective tissue cells, and hematopoietic cells arise from the mesoderm. The hematopoietic cells reside in the liver until the last 2 months of gestation, when the source of precursor cells is shifted to the bone marrow. At birth, only small regions of hematopoietic cells remain in the liver.

Normal development of the liver and the biliary tract requires a highly coordinated combination of cell proliferation and apoptosis. Developmental anomalies of the liver are presumably related to a defect in this interaction. As a result, there is a large spectrum of abnormalities, including malformation of the entire liver or one of its lobes, positional anomalies (situs inversus viscerum), and hepatic vascular malformations. The most common neonatal anomaly of the biliary tract is extrahepatic biliary atresia.

EXTRAHEPATIC BILIARY ATRESIA

Extrahepatic biliary atresia (EHBA), or bile duct obstruction, is a result of an idiopathic inflammatory process that results in the destruction of the common bile duct, at any point between the porta hepatis and the duodenum. A fibrous cord replaces the normal bile duct and the outflow tract of the liver is therefore obstructed. When persistent obstruction occurs, biliary cirrhosis and its sequelae ensue. EHBA is the most common structural abnormality causing chronic cholestasis in infancy and is the most frequent indication for liver transplantation in the pediatric age group. Although this disease usually presents in the first 2 months of life, in most cases it is unlikely to be a true congenital malformation but is more likely acquired in late pregnancy or after birth.

Characteristics of Extrahepatic Biliary Atresia

EHBA occurs worldwide with an incidence ranging from 1 in 8000 to 1 in 25,000 live births. The female: male ratio is 1.4 : 1 and, in the United States, the incidence is higher in African-Americans and Asians compared to Caucasians. Caucasians have significantly lower survival rates compared to African-Americans, Hispanics, and Asians, but the reasons for this remain unknown. There is no known genetic basis for this disorder.

Kasai has classified extrahepatic biliary atresia into three types. Type I, occurring in 10–15% of cases, consists of an obstruction at the common bile duct and is considered "correctable." Type II is obstruction of the common hepatic duct and includes both correctable and uncorrectable forms. Type III is an "uncorrectable" obstruction of the hepatic ducts at the porta hepatis and occurs in 75–80% of cases.

There are at least two apparent phenotypes of biliary atresia. The embryonic (fetal) type accounts for less than one-third of the cases, and these children have onset of cholestasis immediately after birth. These cases are often associated with other anomalies, including polysplenia, congenital heart disease, situs inversus viscerum, intestinal malrotation and atresias, bilobed right lung, preduodenal portal vein, and azygous continuation of the inferior vena cava. Therefore, the embryonic type is thought to occur early in fetal life and represents a true congenital anomaly. The second type is the perinatal type, in which there is a jaundice-free period followed by later onset of jaundice. This insult most likely occurs after birth, because bile duct remnants are present in the porta hepatis. Landing has suggested that neonatal hepatitis, biliary atresia, and choledochal cyst

represent a spectrum of disorders initiated by a perinatal insult. A perinatal viral infection has been suggested as the most likely initiating event. Other studies have also suggested an association between viral infections and biliary atresia. Potential etiologic agents include cytomegalovirus, rotavirus (groups A and C), and reovirus type 3.

Diagnosis of Extrahepatic Biliary Atresia

Because EHBA presents similarly to other causes of neonatal cholestasis, differentiating the etiology can be difficult (Table II). The clinical presentation of biliary atresia usually consists of a term infant with the onset of jaundice between 2 and 5 weeks of age. Stools without pigmentation (acholic) are common. On physical examination, the jaundiced infant has an enlarged and firm liver and may have splenomegaly. Laboratory studies reveal mildly to moderately elevated total serum bilirubin levels (usually less than 8 mg/dl, with a conjugated fraction greater than 2 mg/dl, or more than 20% of the total), normal to mildly elevated alanine and aspartate transaminases (ALT and AST), and markedly elevated alkaline phosphatase and γ-glutamyl transpeptidase (GGT). As the disease progresses, biliary cirrhosis develops, with resultant portal hypertension.

The two radiologic studies that are helpful in the diagnosis of biliary atresia are hepatobiliary ultrasound and nuclear scintigraphy. The ultrasound can identify a choledochal cyst, or other etiologies of extrahepatic obstruction, as well as associated anomalies, such as polysplenia, situs inversus viscerum, preduodenal portal vein, and discontinuous inferior vena cava. The gallbladder is often absent or small, even after fasting. Biliary dilatation is not usually visualized. Intravenous technetium-99 m-labeled iminodiacetic acid (IDA) is normally taken up by hepatocytes and excreted into the biliary system. In the case of biliary atresia, the uptake is normal, or delayed in the presence of hepatic dysfunction, and excretion into the duodenum is not visualized. The sensitivity of the test is 97−100%, although the specificity ranges from 43 to 97%. Phenobarbital improves sensitivity by increasing the excretion of the imaging agent. The recommended dose of phenobarbital is 5 mg/kg/day for 3 to 5 days prior to the hepatobiliary scan. Computer tomography (CT) and magnetic resonance imaging (MRI) add little additional diagnostic information.

Evaluation of hepatic histopathology is the most reliable method for diagnosing EHBA. Percutaneous liver biopsy is often obtained for tissue diagnosis prior to surgical exploration. The histologic features of biliary atresia are those of extrahepatic obstruction. There are variable degrees of bile stasis, and bile plugs within the portal ducts. Although specific for biliary obstruction, these findings are present in less than half of the cases. Bile duct proliferation is present with or without lymphocytic inflammation in the portal tracts. Additionally, giant cell transformation of the hepatocytes may be present. The portal triads are enlarged with variable degrees of fibrosis (Fig. 1). With continued cholestasis, portal and periportal fibrosis may progress to bridging fibrosis and cirrhosis.

If the diagnosis in EHBA is suspected, an intraoperative cholangiogram is recommended. The

usual approach, through the gallbladder, may be difficult due to the smallness of the gallbladder. Meticulous evaluation of the entire biliary tree is necessary because intrahepatic bile duct paucity can be mistaken for EHBA and is not amenable to surgery.

Extrahepatic Complications of EHBA

Extrahepatic complications of biliary atresia include nutritional deficiencies. Poor weight gain and wasting of the extremities are common and are due to the combination of cachexia and fat malabsorption. Intestinal absorption of fat-soluble vitamins is dependent on bile salts, and when bile flow is reduced, as in the case of biliary atresia, vitamin deficiencies can occur. The most common problem is vitamin D deficiency, resulting in rickets or osteopenia. Vitamin E deficiency can lead to progressive neuromuscular symptoms and can be diagnosed early by the loss of deep tendon reflexes. Vitamin A deficiency can lead to retinopathy. Additionally, vitamin K is important for synthesis of clotting factors and can be monitored with a serum prothrombin time. Oral supplementation is recommended at two to four times the recommended daily requirement (Table III). Vitamin D can be supplemented with cholecalciferol (D_3) or ergocalciferol (D_2). Vitamin E is available in two forms, but the micellized form, D-α-tocopherol polyethylene glycol succinate (TPGS), is recommended. Fat malabsorption from the diet also occurs. Medium-chain triglycerides (MCTs) are absorbed by the intestine without need for lipolysis. Therefore, diets containing MCTs are recommended in the form of MCT-containing formulas or as a dietary supplement. However, even those infants that consume adequate calories often suffer from protein-calorie malnutrition, as evidenced by wasting of their extremities.

The most life threatening complication of biliary atresia is portal hypertension. Despite surgical relief of the biliary obstruction, the intrahepatic disease often progresses. One-fifth to one-third of children will not have significant excretion of bile after portoenterostomy and up to three-fourths of children who initially had good bile flow will develop chronic liver disease. This often progresses to biliary cirrhosis and resultant portal hypertension. Almost half of children who survive for 5 or more years after operation have hepatomegaly and/or splenomegaly. Therefore, they are at risk for complications of cirrhosis, including jaundice, hypersplenism, ascites, and bleeding from esophageal varices. Ascites is managed by sodium restriction and diuretics (spironolactone). Persistent ascites despite sodium restriction and oral diuretics may require intravenous colloid, such as albumin, followed by diuretics or paracentesis if the child is having symptoms of respiratory distress or feeding difficulties due to compression of the stomach. Aggressive management is important because ascites increases the risk for spontaneous bacterial peritonitis and is an indicator of progressive hepatic decompensation.

The presence of significant esophageal varices is bimodal in the presence of successful surgical intervention. The first peak occurs in young survivors, between 9 and 23 months, and the second peak occurs in those over 5 years. The larger and more numerous the varices, the higher the risk of bleeding. Varices will develop in about half of those children with splenomegaly. Of

those, half will develop variceal bleeding. Endoscopic therapy with sclerotherapy or band ligation is the initial treatment of choice.

Treatment of EHBA

Timely diagnosis of biliary atresia is important because early surgical intervention is associated with improved outcome. The Kasai portoenterostomy has altered the outcome of infants with "uncorrectable" biliary atresia, a previously uniformly fatal disease. If the atresia is in the distal common bile duct (type I), the proximal portion can be directly connected to the intestine via Roux-en-Y anastomosis. However, if the proximal common hepatic ducts demonstrate atresia throughout the porta hepatis, the primary therapy is the Kasai portoenterostomy. The gallbladder and extrahepatic biliary tree are excised. Subsequently, the porta is extensively dissected to the surface of the liver, and a segment of jejunum is anastomosed around the small intrahepatic bile ducts. Due to this alteration of the anatomy, the most common complication of the portoenterostomy is ascending cholangitis. Prognosis is directly related to establishing bile flow and resolution of jaundice.

In 82% of Kasai's patients, surgical correction within the first 60 days of life produced satisfactory bile excretion. If the surgery was performed after 90 days of age, the success rate declined to less than 38%. The prognosis of the portoenterostomy depends upon the initial success of the surgery, the extent of the fibrosis, and postoperative complications. In the event of abrupt reduction in bile outflow after previously satisfactory bile excretion, suggesting scar tissue within the porta hepatis, reoperation to reestablish bile flow may be recommended. However, reoperation due to poor initial bile drainage has little advantage at establishing bile flow.

After satisfactory bile flow has been surgically established, laboratory values do not always completely return to normal. Serum bilirubin falls to normal early postoperatively, but ALT and GGT fluctuate between normal to moderately elevated. Alkaline phosphatase often remains elevated but may return to normal over time. Despite normal bilirubin levels, some patients have progressive liver disease. By age 5 years, 40–80% have esophageal varices at endoscopy. Figure 2 summarizes the prognosis in children with EHBA undergoing Kasai portoenterostomy.

Ascending cholangitis is the most significant postoperative complication following portoenterostomy, initially described in 68% of patients. Therefore, surgical modifications of the intestinal anastomosis have

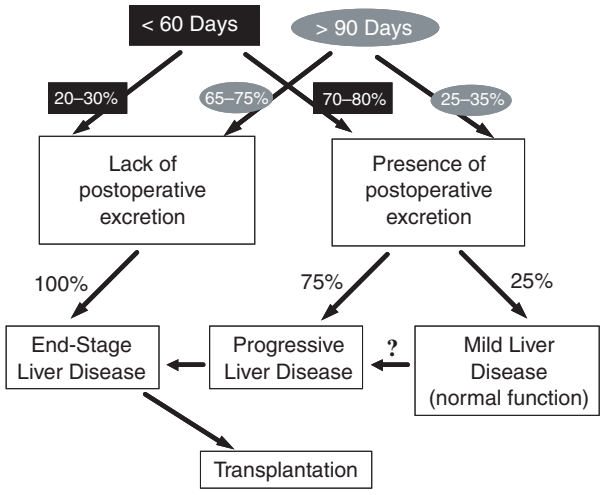

FIGURE 2 Prognosis following Kasai portoenterostomy for extrahepatic biliary atresia. Modified from Sinatra (2001).

been performed and the incidence of cholangitis has been reduced. The symptoms of cholangitis include fever (greater than 38 °C), elevated white blood cell count and erythrocyte sedimentation rate, positive bacterial culture or evidence of sepsis, and simultaneous reduction in bile drainage as evidenced by elevated total and conjugated bilirubin. Bacterial cholangitis prior to the age of 2 years can cause obstruction of the previously patent biliary tree. This complication is almost always limited to children who have established good bile flow, suggesting the direct ascension of intestinal bacteria into the biliary system from the intestinal limb. Treatment includes intravenous antibiotics with both anaerobic and gram-negative coverage. Aggressive management is imperative because cholangitis is associated with progressive fibrosis of the intrahepatic biliary tree. Prophylactic antibiotics remain controversial but many medical centers use a sulfamethoxazole–trimethoprim combination (Septa, Bactrim) for up to 1 year postoperatively.

Prior to the introduction of the Kasai portoenterostomy, the mean life expectancy of an infant with extrahepatic biliary atresia was 11 months. According to Kasai's series, the 10-year survival rate postoperatively was 33% and currently has increased to 54%, with those undergoing surgery prior to 2 months of age having a better prognosis than those undergoing surgery after 3 months of age. Over 50% of pediatric liver transplantations are performed for biliary atresia, and approximately 80% of children undergoing portoenterostomy for biliary atresia will require liver transplantation sometime during their lifetime. The patient survival after liver transplantation is high, 87% at 1 year and 84% at 3 years, with graft survival of 77% at 1 year

and 69% at 3 years, according to the United Network for Organ Sharing.

CHOLEDOCHAL CYST

A congenital segmental cystic dilatation of the biliary system, or choledochal cyst, can be located in any portion of the extrahepatic biliary tract. Symptoms may occur at any age and choledochal cyst must be included in the differential diagnosis of a neonate with cholestasis. Choledochal cysts are 2 to 4 times more common in females, have the highest incidence in Asia, and occur in 1 in 13,000 to 1 in 2,000,000 live births. There is an uncommon association with other abnormalities of the biliary tract, such as biliary atresia, double common duct, double gallbladder, and polycystic or hypoplastic kidneys. The classic clinical presentation includes a triad of pain, abdominal mass, and jaundice, but occurs in only 15% of patients. Neonates usually present with persistent or intermittent jaundice. Other symptoms include fever and vomiting. The laboratory results are nonspecific and demonstrate an elevation of conjugated bilirubin and amino-transferases.

The diagnosis is usually made by pre- or postnatal ultrasound examination that demonstrates extrahepatic and/or intrahepatic bile duct dilatation. Magnetic resonance cholangiopancreatography is another diagnostic tool to evaluate the biliary tree. Todani has classified congenital bile duct cysts into five types, based on location. Type I consists of a fusiform, cystic dilatation of the common bile duct (Fig. 3). Type II is a single outpouching of the common bile duct and/or the gallbladder. Type III is a cystic lesion at the entry into the duodenum, also known as a choledochocoele. In type IV there are multiple cysts in the extrahepatic bile ducts, with or without involvement of the intrahepatic bile ducts. Type V consists of intrahepatic dilatations, similar to those seen in Caroli's disease.

The diagnosis requires an exploratory laparotomy with operative cholangiogram, endoscopic retrograde cholangiography, or transhepatic cholangiography to visualize the entire biliary tree. Once the diagnosis has been confirmed, excision of the entire cyst(s) and gallbladder, followed by Roux-en-Y choledochojejunostomy, is recommended. If untreated, obstructive biliary disease may occur, including bile stasis, cholelithiasis, and pancreatitis, with ultimate development of biliary cirrhosis and portal hypertension. Additionally, there is a high rate (20-fold) of malignant transformation in the residual tissue. The most common malignancy is adenocarcinoma, located in the bile duct, gallbladder, liver, or pancreas. Even after resection, an increased incidence of biliary malignancy exists.

INTRAHEPATIC BILE DUCT PAUCITY

Bile duct paucity is defined as absence or reduction of normal intralobular hepatic bile ducts, usually less than 0.5 bile ducts per portal triad. The normal number of bile ducts in term infants and adults is 0.9–1.8 bile ducts per portal triad. The pathogenesis of bile duct paucity is unclear but may be the result of congenital absence, partial absence, atrophy, or response to injury.

The most common condition associated with intrahepatic bile duct hypoplasia in infants and children is arteriohepatic dysplasia or syndromic paucity of intrahepatic bile ducts (Alagille's syndrome). Described by Daniel Alagille in 1975, this group of patients has a variable combination of hepatic ductular hypoplasia and characteristic facies, vertebral malformations, eye findings, and cardiac anomalies. The extrahepatic biliary tree is patent but may be hypoplastic.

Alagille's syndrome occurs worldwide with an incidence of approximately 1 in 100,000. Genetic studies have demonstrated an autosomal dominant inheritance pattern with variable penetrance and expression. Deletion or translocation within the region of chromosome 20p12 has been linked to Alagille's syndrome. This region has been mapped to the human *Jagged 1* gene, which encodes a ligand for the Notch receptor that mediates cell–cell interaction. Further studies are

underway to evaluate how this genetic deletion results in paucity of intrahepatic bile ducts in addition to the other features of this syndrome.

Persistent jaundice is usually the first sign in infants and is often followed by the onset of intense pruritus. Laboratory findings include elevation of conjugated bilirubin, alkaline phosphatase, GGT, cholesterol, triglycerides, and serum bile acids. On physical examination, the children have a recognizable facial pattern, including broad forehead and pointed chin which produce the triangular shape, in addition to mid-face hypoplasia, deeply set eyes and an elongated nose with a flattened tip. Hepatomegaly is usually present. A cardiac murmur can suggest peripheral pulmonic stenosis (in approximately 90% of patients), tetralogy of Fallot, ventricular or atrial septal defects, aortic stenosis, or coarctation. The vertebral anomalies include butterfly vertebrae (hemivertebrae) in the thoracic area, and the ophthalmologic exam may demonstrate the presence of posterior embryotoxon, a prominence of Schwalbe's line within the anterior chamber of the eye. Posterior embryotoxon occurs in up to 15% of the normal population and can result in glaucoma. Short stature and delayed pubertal development are also common. Cutaneous xanthomas are noted in the presence of extreme elevations of serum phospholipids, with serum cholesterol concentrations often in excess of 500 mg/dl. Other affected organs include the kidneys, pancreas, and vasculature of the central nervous system.

Pruritus and vitamin deficiencies are common complications of prolonged cholestasis. Initial speculation suggested that pruritus was due to the elevation of serum bile acids, but the cause is currently unknown. Oral therapies include ursodeoxycholic acid, cholestyramine, phenobarbital, and rifampin. However, when these are ineffective, phototherapy, partial external biliary diversion, and plasmapheresis have been suggested. Fat-soluble vitamins should be monitored, and supplementation as needed should be provided.

In conjunction with associated features, hepatic histopathology provides the most reliable information in diagnosing intrahepatic biliary duct paucity. However, in young infants, liver biopsy specimens may not demonstrate absence or paucity of intrahepatic interlobular ducts, even in the presence of cholestasis. In fact, bile duct proliferation and giant cell transformation with reduced portal tract size and number may be present in the first months of life. Therefore, the importance of a cholangiogram when EHBA is suspected cannot be emphasized enough, because intrahepatic bile duct disease may be exacerbated by performance of a portoenterostomy and is associated with higher mortality when performed. As a child ages, there is a progressive loss of intrahepatic bile ducts with a variable progression to fibrosis or cirrhosis.

The prognosis of Alagille's syndrome is generally good and is directly related to the severity of liver and/or cardiac involvement. The severity of liver disease does not correlate with the severity of extrahepatic manifestations. The morbidity due to pruritus, hyperlipidemia, and vitamin deficiencies may be significant, and treatment is directed at these complications. Patients with Alagille's syndrome may develop hepatic malignancy, most commonly hepatocellular carcinoma. Approximately 15–20% of patients will develop progressive liver disease and require liver transplantation. Transplantation is also indicated to improve the child's quality of life, usually when associated with intractable pruritus, in the absence of cirrhosis.

Other causes of intrahepatic bile duct paucity include progressive familial intrahepatic cholestasis, α1-antitrypsin deficiency, hypopituitarism, Down's syndrome, congenital infections, graft-versus-host disease, and organ rejection.

INFANTILE POLYCYSTIC DISEASE/ CONGENITAL HEPATIC FIBROSIS

The intrahepatic biliary ducts are formed by immature hepatocytes and branches of the portal vein, which comprise, in the ductal plate, a double-walled tube with a narrow lumen. Remodeling of this plate by cell proliferation in combination with apoptosis is important for development of the mature biliary tract. Lack of remodeling of these immature structures results in ductal plate malformations (Fig. 4). This appears to be the basic

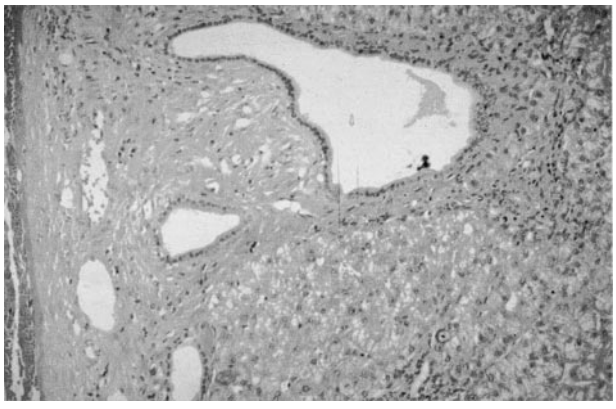

FIGURE 4 Ductal plate malformation in congenital hepatic fibrosis. The portal tract has abnormal and dilated intrahepatic bile duct structures with significant amounts of portal fibrosis (hematoxylin and eosin stain, original magnification ×40).

mechanism in the development of congenital diseases of the intrahepatic bile ducts. Ductal plate malformations appear to be associated with destruction of intrahepatic bile ducts by an inflammatory process. The cysts may be diffuse or localized, causing variable amounts of biliary dilatation and increased fibrous tissue. Multiple syndromes of childhood have been associated with cystic lesions of the liver.

The presence of multiple hepatic ductal cysts is associated with cystic lesions in other organs, especially the kidneys. Cystic disease in the kidney affects the tubular structures of the nephron or collecting ducts. Autosomal recessive polycystic kidney disease (ARPKD) is a rare disorder with an incidence of 1 in 6000 to 1 in 40,000 live births. Genetic studies have revealed an autosomal recessive inheritance pattern, and the gene has been mapped to chromosome 6p. The liver is usually enlarged but liver function is normal. Cystic dilatation of the ductules at the periphery of the portal zone and portal fibrosis are often seen only microscopically. These findings often increase with age. These cystic bile ducts are in communication with the rest of the biliary system and increase the risk of cholangitis, lithiasis, and neoplasm.

Autosomal dominant polycystic kidney disease (ADPKD) is more common, with an incidence of 1 in l000 live births, and the genes have been mapped to chromosomes 16p (85% of cases) and 4q (15% of cases). This disorder is often diagnosed in the adult, not during childhood, because the intrahepatic cystic dilatations may not communicate with the biliary tree and are usually asymptomatic.

Congenital hepatic fibrosis (CHF) is an autosomal recessive disease in which presinusoidal fibrosis is associated with distorted bile duct structures that do not communicate with the biliary tree. The hepatocytes are preserved but portal hypertension develops. Treatment of CHF is directed at controlling variceal bleeding. CHF may occur alone but is also associated with cystic changes of the larger biliary ducts, as in Caroli's syndrome, and 20% of cases have associated renal abnormalities, most commonly ARPKD (less commonly, ADPKD). Other associations include vascular abnormalities, including congenital heart disease and aneurysms, and malformation syndromes such as trisomies 9 and 13.

CYSTIC DILATATION OF INTRAHEPATIC DUCTS (CAROLI'S DISEASE)

Cystic dilatation of the larger, segmental intrahepatic bile ducts, or Caroli's disease, involves multiple segments of the biliary tract. These macroscopic, nonobstructive saccular dilatations alternate with areas of stenosis and are contiguous with the unaffected biliary tract. There is an absence of other histologic abnormalities. These ductal abnormalities are associated with an increased risk of repetitive attacks of cholangitis, intrahepatic lithiasis, and progression to cirrhosis, hepatic failure, and cholangiocarcinoma. Renal abnormalities, most commonly ARPKD, are associated with Caroli's disease.

Bilirubin (from the Latin "*bilis*," meaning bile, and "*rubor*," meaning red) is a bile pigment formed during the catabolism of heme-containing compounds, primarily hemoglobin. Excessive accumulation of bilirubin, as a result of enhanced production or impaired elimination, results in yellow discoloration of the skin, sclera, and mucus membranes, which is termed jaundice.

CHEMICAL PROPERTIES OF BILIRUBIN

Bilirubin is a nearly symmetric tetrapyrrole consisting of two rigid planar dipyrrole units joined by a methylene bridge, which is stabilized in a ridge-tile conformation by two trios of internal hydrogen bonds (Fig. 1). Bilirubin exhibits poor aqueous solubility because it is predominantly in the un-ionized diacid form at physiologic pH. For this reason, plasma bilirubin is bound primarily to albumin and, to a much lesser degree, high-density lipoproteins, with only a trivial fraction present as the free monomer.

BILIRUBIN PRODUCTION AND ELIMINATION

Eighty percent of daily bilirubin production (250–400 mg) is derived from erythrocyte hemoglobin, with the remaining 20% resulting from the degradation of other hemoproteins (e.g., cytochromes, myoglobin, catalases). Bilirubin is generated by the sequential activity of heme oxygenase and biliverdin reductase enzymes, which are present at high levels in

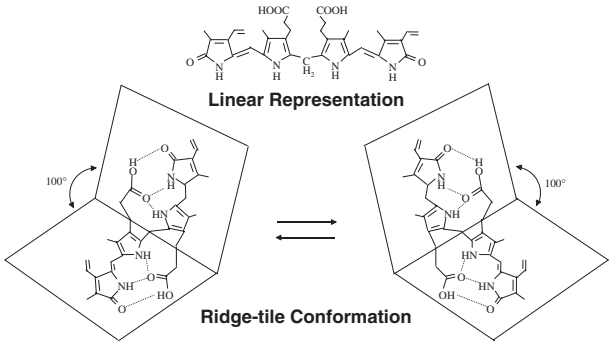

FIGURE 1 The chemical structure of bilirubin. The bilirubin molecule consists of two slightly asymmetrical, rigid, planar dipyrrinones connected by a central CH_2 bridge. The bottom panel depicts the two optical enantiomers of bilirubin in their folded, ridge-tile conformation that is stabilized by intramolecular hydrogen bonds (dotted lines).

reticuloendothelial cells of the spleen, Kupffer cells of the liver, macrophages, and intestinal epithelium. Heme oxygenase is an NADPH-dependent enzyme that initiates the opening of the porphyrin ring by catalyzing the oxidation of the α-carbon bridge of heme, leading to the release of iron and the formation of carbon monoxide and the green pigment, biliverdin. Biliverdin reductase subsequently mediates the reduction of biliverdin to bilirubin, also via an NADPH-dependent mechanism. Bilirubin is cleared from the systemic circulation almost exclusively by the liver. Hepatocellular uptake of bilirubin occurs both by passive diffusion and by a facilitated transport mechanism. In the hepatocyte, bilirubin is conjugated with glucuronic acid to form water-soluble bilirubin mono- and diglucuronides. This reaction is catalyzed by the microsomal enzyme UDP-glucuronosyltransferase (UGT). To date, 15 human UGT isoforms have been identified, each with distinctive substrate specificity. Of these, 8 are encoded by the UGT1A locus, including the bilirubin-specific isoform (UGT1A1). Bilirubin conjugates are actively secreted across the canalicular membrane of the hepatocyte into bile by multidrug-resistance-associated protein 2 (MRP2). Less than 4% of bilirubin in normal human bile is in the unconjugated form.

ENTEROHEPATIC CYCLING OF BILIRUBIN

In the colon, bilirubin conjugates are hydrolyzed by bacterial β-glucuronidases. The resultant unconjugated bilirubin either precipitates as insoluble calcium salts or is further reduced by colonic bacteria to a series of molecules termed urobilinogens, which undergo enterohepatic recycling and are eventually excreted into the urine and feces. Under conditions in which bile salt malabsorption occurs (e.g., ileal resection), unconjugated bilirubin is solublized in the intestinal lumen and passively diffuses across the mucosal epithelium, resulting in enhanced bilirubin flux and increased rates of pigment gallstone formation.

BILIRUBIN TOXICITY

Bilirubin is neurotoxic at high concentrations, a phenomenon known as kernicterus (bilirubin encephalopathy). Infants are at particularly high risk for kernicterus when serum bilirubin levels exceed 20–25 mg/dl (340–425 μ*M*). The most affected regions of the brain include the basal ganglia and the brainstem nuclei for oculomotor and auditory function. Phototherapy can reduce serum bilirubin levels by inducing geometric and structural isomerization, thereby enhancing excretion into bile.

JAUNDICE

Jaundice can be observed clinically when hyperbilirubinemia reaches levels that exceed 3 mg/dl (50 μ*M*), approximately three times the upper limit of normal. Hyperbilirubinemia can be classified into two main categories: (1) unconjugated hyperbilirubinemia as a result of bilirubin overproduction or impaired bilirubin conjugation and (2) conjugated hyperbilirubinemia due to impaired canalicular excretion or biliary obstruction (Table I).

TABLE I Classification of Hyperbilirubinemia

- **Unconjugated hyperbilirubinemias**
  - **Bilirubin overproduction**
    - Hemolysis (e.g., sickle cell disease, glucose-6-phosphate dehydrogenase deficiency)
    - Ineffective erythropoiesis (e.g., thalassemia, megaloblastic anemia)
    - Hematoma
  - **Impaired hepatic conjugation**
    - Inherited disorders
      - Crigler–Najjar syndrome
      - Gilbert's syndrome
    - Drugs (e.g., chlorpromazine, rifampin, irinotecan, HIV protease inhibitors)
  - **Multifactorial**
    - Neonatal (physiologic) jaundice
    - Chronic hepatic congestion (e.g., congestive heart failure)
    - Jaundice of sepsis
    - Portosystemic shunts
    - Wilson's disease
    - Zieve's syndrome (associated with alcoholic hepatitis)
- **Conjugated hyperbilirubinemias**
  - **Intrahepatic cholestasis**
    - Inherited disorders
      - Dubin–Johnson syndrome
      - Rotor syndrome
      - Progressive familiar intrahepatic cholestasis
    - Primary biliary cirrhosis
    - Primary sclerosing cholangitis
    - Drugs and toxins (e.g., arsenic, sulfonylureas)
    - Infiltrative process (e.g., sarcoidosis, amyloidosis)
    - Total parental nutrition
    - Cholestasis of pregnancy
    - Liver transplant rejection
    - Hepatocellular injury (e.g., hepatitis A, fibrosing cholestatic hepatitis)
    - Paraneoplastic syndrome (e.g., lymphoma)
  - **Extrahepatic cholestasis (biliary obstruction)**
    - Choledocholithiasis
    - Malignancy
      - Intrinsic (e.g., cholangiocarcinoma, ampullary carcinoma)
      - Extrinsic (e.g., pancreatic carcinoma, hepatocellular carcinoma, metastatic disease)
    - Biliary stricture (e.g., postsurgical, sclerosing cholangitis)
    - Parasitic infections (e.g., *Ascaris lumbricoides*, liver flukes)

Unconjugated Hyperbilirubinemias

Bilirubin Overproduction

Extravascular hemolysis, intravascular hemolysis, ineffective erythropoiesis, or large hematomas may cause increased bilirubin production through enhanced heme catabolism. Because hepatic bilirubin clearance is extremely efficient and the bone marrow cannot increase erythrocyte production more than eightfold, ongoing steady-state hemolysis generally does not produce plasma unconjugated hyperbilirubinemia beyond 4–5 mg/dl. Bilirubin concentrations that exceed this level are indicative of coincident hepatic dysfunction.

Crigler–Najjar Syndrome

Crigler–Najjar syndrome is a rare, autosomal recessive disorder of bilirubin metabolism. It has been classified into two distinct forms (types I and II) based upon the severity of disease. Crigler–Najjar type I manifests as extreme jaundice and kernicterus as a result of absent hepatic UGT1A1 activity and is nearly always fatal unless liver transplantation is performed. In contrast, type II disease, which is caused by small point mutations that

reduce but do not abrogate enzyme activity, is associated with lower serum bilirubin concentrations and affected individuals typically survive into adulthood without neurologic impairment. Patients with Crigler–Najjar type II frequently respond to phenobarbital treatment, which reduces serum bilirubin levels by approximately 25%.

Gilbert's Syndrome

Gilbert's syndrome is the most common inherited disorder of bilirubin glucuronidation. Affected individuals exhibit isolated unconjugated hyperbilirubinemia, with levels as high as 6 mg/dl occurring in the setting of fasting, febrile illness, or physical stress. This benign condition is caused by a polymorphism in the promoter TATA element of the gene encoding UGT1A1, leading to a TA insertion into the wild-type $A(TA)_6TAA$ sequence. Liver homogenates from individuals homozygous for the Gilbert's $A(TA)_7TAA$ genotype exhibit a 50% reduction in bilirubin-conjugating activity. Approximately 9% of the general population is homozygous and 30% heterozygous for the Gilbert's polymorphism.

"Physiologic Jaundice" of the Neonate

Mild unconjugated hyperbilirubinemia ($\leq$6 mg/dl) is commonly observed in the neonatal period, generally peaking at 3 to 4 days of age. This condition arises from the combination of increased production, decreased conjugation, and enhanced enterohepatic cycling of bilirubin. Bilirubin production is two to three times higher in neonates than in adults due to increased turnover of erythrocytes. Furthermore, bilirubin UGT1A1 activity is very low at birth, rising to adult levels over the initial 2 weeks of life. Newborns also have a relative paucity of enteric flora, resulting in decreased conversion of bilirubin to urobilinogen and high intestinal activity of β-glucuronidase, leading to enhanced deconjugation of bilirubin, which is then absorbed across the intestinal mucosa.

Conjugated Hyperbilirubinemias

Conjugated hyperbilirubinemia results either from impaired canalicular secretion of conjugated bilirubin into bile (intrahepatic) or from obstruction of the biliary system (extrahepatic).

Dubin–Johnson Syndrome

Dubin–Johnson syndrome is a rare, benign, autosomal recessive disorder of the liver characterized by chronic conjugated hyperbilirubinemia. It is caused by mutations in the MRP2 gene. MRP2 is responsible for the canalicular secretion of non-bile-acid organic anions, such as conjugated bilirubin and other glucuronide- or glutathione-conjugated compounds. The liver is histologically normal except for the presence of dense pigment within hepatocytes (lysosomes containing polymers of epinephrine metabolites), which produces a grossly black appearance.

Rotor Syndrome

Individuals with the autosomal recessive Rotor syndrome also exhibit chronic conjugated hyperbilirubinemia. However, in contrast to Dubin–Johnson syndrome, in which total urinary coproporphyrin excretion is normal with 80% excreted as coproporphyrin I, Rotor syndrome patients exhibit elevated levels of urinary coproporphyrins with approximately 65% coproporphyrin I. The liver exhibits a normal appearance and the underlying molecular defect remains to be elucidated.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis is a heterogeneous group of disorders, characterized by defective secretion of biliary components. Mutations in several canalicular transport proteins have been described, including the aminophospholipid transferase (FIC1), the bile salt export pump (BSEP), and the multidrug resistance protein 3 P-glycoprotein (MDR3), which serves as a phosphatidylcholine flipase. These disorders typically present in infancy or childhood and are associated with growth retardation and progressive liver failure.

Cholestasis

Any process that impairs canalicular secretion of biliary conjugates or obstructs the flow of bile can cause cholestasis and concomitant conjugated hyperbilirubinemia. As canalicular transport processes are typically impaired earlier in the course of liver disease than is hepatic conjugation, hepatocellular injury tends to manifest as conjugated hyperbilirubinemia. In extrahepatic cholestasis (biliary obstruction), conjugated bile pigments and other components of bile, such as bile salts and alkaline phosphatase, spill over into the blood.

Boerhaave's Syndrome

MAKAU LEE
University of Mississippi Medical Center, Jackson

Boerhaave's syndrome Spontaneous, transmural tear of the esophagus, with free perforation.
Hamman sign Mediastinal crunching sound with heartbeat.
mediastinitis Infection involving the mediastinum.
odynophagia Pain on swallowing foods or liquids.

Herman Boerhaave, in 1724, described a spontaneous, transmural tear of the esophagus, with free perforation resulting from very forceful retching and vomiting. Boerhaave's syndrome is seen frequently in alcoholism and is highly lethal if diagnosis and treatment are not prompt.

CLINICAL FEATURES

Although most patients report antecedent retching and vomiting, Boerhaave's syndrome can result from any maneuver that causes a sudden increase in intraabdominal pressure. A majority of the esophageal ruptures occur in the distal esophagus on the left side. Boerhaave's syndrome tends to occur outside of the hospital setting and has a high mortality rate from mediastinitis, abscess formation in the mediastinum and pleural space, tissue necrosis, and septicemia, due to a delay in diagnosis. Delays in the diagnosis of Boerhaave's syndrome are common because the initial trauma leading to the perforation frequently occurs during an alcoholic stupor, and the clinical manifestations of this condition are generally nonspecific.

DIAGNOSIS

Clinically, patients with Boerhaave's syndrome may present with chest, neck, and abdominal pain and

odynophagia, dysphagia, hoarseness, aphonia, vomiting, hematemesis, and respiratory distress. Physical examination may reveal subcutaneous crepitation, mediastinal crunching sound with the heartbeat (also called Hamman sign), fever, and shock. Of note, only one-third of patients with Boerhaave's syndrome present with the classic Mackler triad of chest pain, vomiting, and subcutaneous emphysema. Leukocytosis is common. Radiographic findings include pleural effusion, mediastinal widening, hydropneumothorax, and pneumomediastinum. Esophagrams performed with water-soluble contrast medium (such as gastrograffin) are generally diagnostic. The differential diagnosis should include Mallory–Weiss tear, esophageal intramural hematoma, peptic ulcer disease and its complications (such as bleeding and perforation), aortic dissection, myocardial infarction, pericarditis, pulmonary embolism, spontaneous pneumothorax, and pancreatitis.

MANAGEMENT

Boerhaave's syndrome is a highly lethal condition that demands early surgical consultation. Treatment is primarily surgical, involving repair of the perforation, with or without resection of the affected segment of the esophagus. Diagnosed patients should not be managed nonoperatively because diagnosis typically occurs at a time when gross contamination of the surrounding tissues is already advanced and surgical intervention is required.

Borborygmus

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

borborygmi Sounds emanating from the digestive tract.
intestinal power propulsion One of the patterns of motility occurring in the small and large intestine.
migrating motor complex One of the patterns of motility in the stomach and small intestine.

Sounds originating from the digestive tract are termed borborygmus in its singular form and borborygmi in the plural. The term was derived from the Latin word for "rumbling." Borborygmi can be heard during physical examination by placing the listening device on the abdominal surface. Exaggerated borborygmi can often be heard without the aid of listening devices by someone positioned within approximately 1 m of the individual. Movements of gas and liquid in the stomach and intestines cause borborygmi. The muscles in the walls of the stomach and intestines contract in a variety of organized patterns that propel the liquid and gaseous contents within the lumen. Rapid propulsion generates turbulence in the mixed medium of liquid and gas bubbles. The passage of turbulence, especially through orifices of reduced diameter, produces sounds of sufficient volume to be heard away from the abdomen. These sounds may be variously described as rumbling, "growling," "bubbling," "gurgling," etc. There are two kinds of bowel sounds. Normal sounds are those associated with the normal digestion of a meal and the clearance of undigested residue after digestion of a meal is complete. Pathologic bowel sounds are those that reflect a disordered condition. Knowledge of the relations of bowel sounds and specific pathologic conditions can be helpful in clinical diagnosis of patient complaints.

NORMAL BOWEL SOUNDS

The stomach, small intestine, and large intestine can generate borborygmi. Each of these specialized organs differs in its normal physiology. Each differs in its patterns of muscle contractions and propulsive motility. The properties of the solid, liquid, and gaseous contents also differ for the three organs. Together, these factors determine the nature of the sounds that can be heard coming from the abdomen.

Stomach

The stomach is divided into two functional compartments. The proximal compartment is for storage. Its musculature relaxes to increase compartmental volume as food is ingested and slowly contracts to decrease the volume as emptying of the stomach proceeds. The distal compartment has powerful musculature and a contractile pattern that are specialized for grinding food into the small-sized particles required for emptying and for propulsion of the contents through the sphincter that separates the stomach from the small intestine. Propulsive contractile waves are ring-like in the distal stomach and occur at a frequency of 3 per minute in humans. They start in the midstomach and travel to the junction of the stomach with the small intestine. The ring-like contractions vary in strength from weak contractions that can barely be seen in the lumen to very strong contractions that obliterate the lumen. Agitation of the contents by the forces of these contractions accounts for the sounds emanating from the stomach.

The sounds of the stomach are most audible when the subject is reclining in such a way as to bring the gas bubble into the distal compartment of the stomach. In humans, the sounds may continue in lock-step fashion for 2 h or more after a large meal.

"Growling" sounds from the stomach and the sensation of "hunger pangs" several hours after a meal reflect a pattern of motility termed the migrating motor complex (MMC). The MMC is a specialized pattern of gastrointestinal motility that starts in the stomach and slowly migrates to the small intestine and onward toward the small intestinal junction with the large intestine. The first MMC starts in the stomach when digestion and absorption of a meal have reached completion. A second MMC starts in the stomach as the first one reaches the end of the small intestine. Eighty to 120 min are required for the MMC to travel the length of the small intestine. This cycling of the MMC is repeated at approximately hourly intervals until such time as the next meal is ingested.

Ring-like propulsive contractions in the distal stomach are strongest during the occurrence of an MMC.

 Copyright 2004, Elsevier (USA). All rights reserved.

Secretions and gas bubbles accumulate in the stomach between occurrences of the MMC and their movements during an MMC account for the gastric noises. Hunger pangs are believed to be the sensations an individual experiences while the strong contractions of the MMC are occurring in the distal compartment of the stomach.

Small Intestine—Large Intestine

The rhythmic sounds of the small intestine are different in quality from the sounds of the stomach when monitored with a listening device on the abdominal surface. Walter C. Alvarez, of the Mayo Clinic, described the small intestinal sounds as "either soft crepitations, rattling explosive discharges or sometimes slow rumbles" that differ from the "gushing, explosive sounds of the stomach." The sounds from the small intestine are best heard in the lower left quadrant of the abdomen.

Walter B. Cannon (1871–1945), the much respected physiologist at Harvard University, first reported gurgling sounds that were interpreted to be due to contractions of the colon. After the subject was given an enema, the sounds came at regular intervals and were associated with cramp-like lower abdominal pain.

Contractions of the wall musculature and the movements of the lumenal contents cause the borborygmi that emanate from the small intestine or colon. A specialized pattern of intestinal motility, termed power propulsion, most likely accounts for the exaggerated sounds from the small or large bowel. Power propulsion involves strong, long-lasting contractions that propagate for extended distances along the intestine. The contractions are part of an efficient propulsive mechanism that rapidly strips the lumen clean as it travel at speeds of approximately 1 cm/s over long lengths of intestine. Power propulsion accomplishes mass movement of intralumenal material in normal and disordered states. Its occurrence in disordered states (e.g., stimulant laxatives or intestinal infections) is associated with abdominal cramp-like pain.

PATHOLOGIC BOWEL SOUNDS

Ability to hear increased bowel sounds is among the most common physical findings in mechanical obstruction of the bowel. In suspected cases of intestinal obstruction, auscultation is generally included in the physical examination. Borborygmi are often the earliest physical evidence of obstruction. The sounds are described as loud and bubbling, like those made by the emptying of a bottle of water. They can be heard in large rushes and be succeeded by periods of relative quiescence. Frequently, fine high-pitched metallic-like "tinkles" that are often localized to a small abdominal region are heard.

Borborygmi heard in mechanical obstruction are accentuated during the waves of abdominal pain experienced by the patient. The paroxysms of pain and the rushes of sound occur simultaneously because both are produced by powerful contractions of the intestinal musculature. Increased strength of contraction in this case presumably reflects adjustment by the intestinal nervous system for propulsive forces to overcome the obstruction. Whereas audible borborygmi are useful diagnostic signs of mechanical blockage of passage through the intestine, the absence of bowel sounds is a characteristic feature of paralytic ileus, which is the pathologic absence of intestinal motility.

Brain–Gut Axis

JACKIE D. WOOD
The Ohio State University College of Medicine and Public Health

afferent trafficking Inflow of sensory information from the gut to the brain.
efferent trafficking Outflow of information to the gut from the brain and spinal cord.
homeostasis Maintenance of a constant internal state in an organ or the whole body.

The brain–gut axis is a physiologic system comprising all of the neural centers and the incorporated neurophysiologic mechanisms involved between the head and gut. Two-way trafficking of neural information in the moment-to-moment control of activities in the digestive tract is the rule in the brain–gut axis.

EFFERENT–AFFERENT TRAFFICKING

Efferent trafficking is the outflow of information (i.e., efferent information) to the gut from the brain and spinal cord. Outflow information is generally command information for gut behavior determined by the brain to be necessary for bodily homeostasis at a given instant in time. Afferent trafficking is the inflow of sensory information from the gut to the brain. A steady stream of sensory information informs the brain of the ongoing state of the gut. The integrative microcircuits in the brain require accurate information on the state of the gut in order to issue commands for effective adjustments of state. State adjustments include (1) amount of acid being secreted in the stomach, (2) the size of the stomach reservoir during ingestion of food, (3) rate of emptying of the stomach into the small intestine, and (4) reversal of propulsive motility during vomiting.

Afferent information in the brain–gut axis underlies the sensations that an individual refers to the gut. This aspect of information flow to the brain stands aside from the necessity of afferent information for the functions of the automatic feedback control loops that exist between the central nervous system and gut. Most gut feelings would not be felt without the transmission of afferent information and processing of the information in the brain. A majority of the sensations referred to the gut are unpleasant. Often, when extreme, the sensations are motivation for consultation with a physician. Some well-known examples are heartburn, bloating, cramping abdominal pain, and urgency to defecate.

EMOTIONAL GUT

The underpinnings of the "emotional gut" are centered in the brain part of the brain–gut axis. Connections between the neural networks in the higher centers of the brain (e.g., cerebral cortex) and the gut account for the projections to the digestive tract of emotions such as fright, stress, and anger. Projections to the gut of emotions of psychogenic origin are often profound. A repugnant experience may be repeated as nausea and vomiting either at the thought of or on a repetition of the experience. Recently appreciated psychosocial aspects of functional bowel disorders direct additional attention to the brain–gut axis. The evidence suggests that symptoms of the irritable bowel syndrome may arise later in life as a consequence of physical or emotional abuse in earlier life.

Breath Tests

ALAN F. HOFMANN
University of California, San Diego

alveolar air Expired breath that is representative in composition of the gas present in the alveoli, the smallest divisions of the respiratory tree. Alveolar air is obtained by having the subject expire normally and then having the subject forcefully expire the residual air in his or her lungs.

endolytic breath test A breath test based on metabolism of a substrate labeled with isotopic carbon by tissue enzymes.

stable isotope An isotope containing more or fewer neutrons in the nucleus than those observed in the most abundant form of the element. The stable isotope used in breath tests is ^{13}C, which can be measured by mass spectrometry or infrared spectroscopy.

ureolysis Cleavage of urea to carbon dioxide and ammonia by bacterial enzymes.

xenolytic breath test A breath test based on formation of hydrogen or labeled carbon dioxide from an ingested substrate by bacterial enzymes.

This article summarizes the principles of breath tests and describes their clinical purposes and utility. Breath tests are diagnostic tests in which the concentration of labeled carbon dioxide or hydrogen in breath is measured in order to assess the rate of a physiological or pathophysiological process.

INTRODUCTION

Breath tests may be divided into two types according to what is measured in breath—labeled carbon dioxide or hydrogen. They may also be divided into endolytic tests, in which the rate to be measured is mediated by tissue enzymes, or xenolytic tests, in which the substrate is metabolized by bacterial enzymes. Since tissue enzymes do not form hydrogen, all hydrogen breath tests are xenolytic tests. Labeled carbon dioxide tests may be either endolytic or xenolytic.

Other substances may be measured in breath in the research laboratory to provide metabolic information, but discussion of the use of such substances is beyond the scope of this article. Examples are breath ethane to assess cytochrome P450 function, breath carbon monoxide to assess the rate of bilirubin biosynthesis or airway inflammation, hydrogen peroxide to detect airway inflammation, mercaptans in breath as an indicator of halitosis, or ammonia to detect ureolysis of ingested urea or to infer impaired urea synthesis caused by impaired hepatic function. However, such measurements are not usually considered to be "breath tests." In addition, there are other studies examining specific substrates to detect abnormalities in uncommon diseases. These include measurement of $^{13}CO_2$ excretion after administration of cholesterol-1-[^{13}C]oleate incorporated into chylomicrons or measurement of $^{13}CO_2$ production after administration of [^{13}C]galactose in inborn errors of galactose metabolism.

LABELED CARBON DIOXIDE BREATH TESTS

Overview

Labeled carbon dioxide breath tests use either ^{13}C- or ^{14}C-labeled substrates. ^{13}C is a stable isotope that offers the advantage of avoiding radioactivity exposure to the subject; however, ^{13}C has the disadvantage of being more difficult to measure than ^{14}C as well as being a more costly isotope. ^{14}C is a radioactive isotope of carbon that gives off a weak beta particle. The half-life is several thousand years. Because the mass of breath CO_2 that is collected is large (1–2 mmol) and because of the high efficiency of liquid scintillation spectrometric measurement of ^{14}C, only very small quantities of radioactivity need to be administered (5–10 μCi). The radiation hazard to the patient has been calculated to be negligible and the [^{14}C]urea breath test has been approved for marketing in the United States.

Measurement of Labeled Carbon Dioxide in Breath

^{13}C is a stable isotope that can be measured by using a dedicated mass spectrometer or by infrared spectroscopy. When mass spectroscopy is used, breath is collected in an impermeable bag or in an evacuated test tube and mailed to a mass spectrometry facility for processing. Mass spectrometric measurements have been automated and are rapid, accurate, and precise. Measurement of ^{13}C by infrared spectroscopy has improved

greatly in the past few years, and a tabletop instruments that permit measurements of ^{13}C within minutes have been developed. Such instruments permit ^{13}C breath tests to be performed in the clinic or at the bedside with results available shortly after the test is performed.

Measurement of $^{14}CO_2$ is made in two ways. In the first method, breath CO_2 is trapped in a known volume of organic base. To achieve this, alveolar air is blown into the base that contains an acid–base indicator until the color changes, indicating that the base has been fully consumed by expired carbon dioxide. Radioactivity is determined by liquid scintillation spectroscopy. In the second method, breath is trapped in a base and the content of ^{14}C is determined using a Geiger–Muller radiation detector.

Both of these methods give breath-specific activity, that is, the enrichment of breath CO_2 by the administered isotope. To convert enrichment or specific activity to percentage dose expired per unit time, a certain rate of endogenous CO_2 production is assumed, e.g., 9 μmol CO_2 per kilogram per hour.

Endolytic Labeled Carbon Dioxide Breath Tests

In endolytic breath tests, cleavage of the target bond or availability of the substrate to cleavage is rate-limiting in the conversion of an ingested or injected substrate to CO_2. It is assumed that all of the reactions after cleavage are rapid so that the rate of labeled CO_2 production is directly proportional to the rate of cleavage of the target bond. Octanoate, for example, is an excellent "leaving group," as it is rapidly metabolized to CO_2 in the hepatocyte and is not incorporated into ester lipids.

The endolytic labeled carbon dioxide breath test that appears to have some clinical utility is the [^{14}C]octanoate or [^{13}C]octanoate breath test, which is used to measure the rate of gastric emptying. Octanoate is poorly absorbed from the stomach, rapidly absorbed from the small intestine, and rapidly oxidized to CO_2. Accordingly, the rate of appearance of labeled carbon dioxide in the breath is, in principle, a valid indicator of gastric emptying. The disease to be detected is delayed gastric emptying as occurs, for example, in diabetic neuropathy. At present, the test is investigational. The test is not as sensitive as imaging studies of gastric emptying, but is much easier to conduct.

For measurement of pancreatic function, cholesterol-1-[^{14}C]octanoate has been proposed. The cholesterol ester is a substrate for the nonspecific esterase (bile acid-dependent) present in pancreatic juice. The test is not specific for pancreatic disease. It is also not sensitive when compared to direct (invasive) measurements of pancreatic enzyme secretion. The test is investigational at present.

For assessment of lactase activity, a [^{14}C]lactose test has been described and, in limited studies, was sensitive and specific. However, the hydrogen breath test is equally sensitive and specific, [^{14}C]lactose is not readily available, and the test has had little application.

For assessment of hepatic function, a large number of substrates have been improved. These include substrates for microsomal demethylating enzymes such as aminopyrine, methacetin, and erythromycin. Amino acids containing a labeled carboxyl group have also been proposed; the carboxyl carbon is rapidly converted to CO_2 by mitochondrial enzymes. One limitation of microsomal substrates is that the subsequent metabolism of the liberated methyl group is complex and may be impaired in liver disease.

Most of these tests detect severe liver disease, but they have not proven to have clinical utility when compared to other tests of hepatic function such as plasma levels of bilirubin or albumin or measurement of prothrombin time. However, a number of these tests are under active investigation and it appears premature to dismiss them as lacking clinical utility.

Xenolytic Labeled Carbon Dioxide Breath Tests

During the past decade, the treatment of peptic ulcer disease has undergone a revolution because of the astonishing finding that the majority of peptic ulcer disease is caused by *Helicobacter pylori* colonization of the gastroduodenal mucosa. Recognition that *H. pylori* had urease activity and that urease is lacking in all tissues led to the introduction of the urea-labeled carbon breath test (urea breath test, UBT). In this test, urea labeled with ^{13}C or ^{14}C is administered orally and breath CO_2 is collected during the first half hour or hour. The UBT was approved for marketing using urea labeled with either ^{13}C or ^{14}C and has been used widely throughout the world. Because of its excellent specificity and sensitivity, it has been used to diagnose the presence of *H. pylori* as well as to test efficacy of therapy.

Several substrates tagged with labeled carbon have been used to detect bacterial overgrowth in the small intestine. The [^{13}C]xylose or [^{14}C]xylose breath test is based on the rapid oxidation of xylose by bacteria compared to minimal oxidation by endogenous enzymes. The test is investigational and has not been widely used in part because of the rarity of the clinical condition as well as the limited sensitivity of the test. Moreover, rapid small intestinal transit results in the xylose being transported to the colon where it is rapidly oxidized by bacteria. A combined hydrogen-labeled carbon dioxide

breath test in which a positive test is signaled by the appearance of labeled CO_2 before a hydrogen peak has been proposed.

The cholyl-[^{13}C]glycine or cholyl-[^{14}C]glycine breath test is based on the ability of intestinal bacteria to deconjugate the substrate and the rapid oxidation of the liberated glycine (by bacterial and/or tissue enzymes) to CO_2. Only the first carbon of glycine is tagged with labeled carbon, as conversion of this atom to CO_2 is greater than and incorporation into tissue proteins is less than that for the second carbon atom. The test is investigational and has not been widely used because of the rarity of the clinical condition and because of the incomplete sensitivity of the test. Incomplete sensitivity for the detection of bacterial overgrowth is explained by overgrowth with bacteria lacking the enzymes to deconjugate cholylglycine.

Clinical Utility of Labeled Carbon Dioxide Breath Tests

Adaptation of labeled carbon dioxide breath tests in clinical practice has been slow for multiple reasons. Only the UBT has been widely used. Breath tests other than the UBT require prolonged collection of breath and the taking of multiple samples. For substrates given orally, delayed gastric emptying may give false-negative results. Intravenous injection solves this problem, but transforms a noninvasive procedure into an invasive procedure. In many disease conditions, there are competing diagnostic procedures. The technical problems of analyzing rapid and accurate measurement of $^{13}CO_2$ or $^{14}CO_2$ in breath have been solved, but the complexity of reproducible substrate delivery and the subsequent oxidation of the released moiety remain. It is possible that breath tests could be valuable in veterinary medicine where their noninvasive aspects make them attractive for diagnostic procedures.

HYDROGEN BREATH TESTS

Overview

In the healthy person, hydrogen is formed by anaerobic bacteria in the colon from dietary carbohydrate that escapes absorption in the small intestine. Some individuals do not form hydrogen, presumably because such individuals have a different colonic flora. Hydrogen breath tests measure the interaction of a substrate that generates hydrogen when metabolized by anaerobic bacteria. Rapid hydrogen production occurs under three conditions: (1) a substrate that is normally efficiently absorbed is malabsorbed and passes into the colon, for example, lactose in lactase-deficient individuals; (2) there is overgrowth of anaerobic bacteria in the small intestine; or (3) there is rapid small intestinal transit of a nonabsorbed substance, e.g., lactulose.

Measurement of Hydrogen in Breath

Expired alveolar air is collected in an impermeable bag or into the intake of a measuring device. Breath hydrogen is currently detected by specific hydrogen detectors. These are not expensive and are accurate and precise. They are based on the use of a metallic membrane that is permeable to hydrogen gas. Breath hydrogen may also be determined accurately by gas chromatography. Because dietary carbohydrate is not completely absorbed, there is always some hydrogen present in expired air. What is recorded is a peak of hydrogen above the baseline level.

Types of Hydrogen Breath Tests and Their Clinical Utility

Hydrogen breath tests are used to diagnose lactase deficiency. Increased breath hydrogen after a lactose load is a specific and rather sensitive test for lactase deficiency. Measurement of breath hydrogen after a glucose or xylose load appears to be a useful test as a screening test for overgrowth of anaerobic bacteria in the small intestine. Finally, hydrogen breath tests are used in research studies to measure small intestinal transit time by observing the time for breath hydrogen to appear after an oral load of a nonabsorbed carbohydrate such as lactulose, even though the lactulose itself causes more rapid small intestinal transit.

mesocaval shunt Surgically created shunt promoting flow from the superior mesenteric vein into the inferior vena cava, bypassing an occluded hepatic outflow tract.

side-to-side portacaval shunt Surgically created shunt promoting flow from the portal vein into the inferior vena cava, bypassing an occluded hepatic outflow tract.

transjugular intrahepatic portosystemic shunt Internal jugular vein is used to create communication between the systemic and portal circulations in order to decompress the portal circulation.

venoocclusive disease Occlusion of the terminal hepatic venules caused by nonthrombotic fibroobliterative endophlebitis.

Hepatic venous outflow obstruction may lead to a variety of disorders known as the Budd–Chiari syndrome. In this syndrome, patients present with occlusion of the terminal hepatic venules, major hepatic veins, or the inferior vena cava. Patients may be asymptomatic, or they may present with fulminant hepatic failure or cirrhosis with portal hypertensive complications. Although many options are available to diagnose and treat Budd–Chiari syndrome, patients are typically refractory to medical therapy alone. Interventional radiologic techniques may be appropriate and effective in selected cases. Decompressive surgical shunts are recommended for patients with acute or subacute liver injury, whereas orthotopic liver transplantation is standard care for patients with fulminant hepatic failure or decompensated cirrhosis.

ETIOLOGY

Occlusion of the Inferior Vena Cava and Major Hepatic Veins

Membranous and nonmembranous occlusions of the hepatic veins and inferior vena cava (IVC) are responsible for hepatic outflow obstruction and the Budd–Chiari syndrome. Hematologic disorders and myeloproliferative diseases are the most frequent causes of nonmembranous venous obstruction in the Western world (Table I). Paroxysmal nocturnal hemoglobinuria, antithrombin III deficiency, factor V Leiden mutation, and deficiencies of protein C and protein S are additional causes of Budd–Chiari syndrome.

Solid tumors (primary hepatocellular, renal, adrenal, pulmonary, pancreatic, and gastric carcinomas) and vascular neoplasms arising within the hepatic veins or the vena cava can also produce Budd–Chiari syndrome and hepatic failure. Rare causes of nonmembranous hepatic venous outflow obstruction include infections, collagen vascular diseases, inflammatory bowel disease, and many systemic diseases. Whereas nonmembranous venous occlusion is common in the West, membranous occlusion is more common in the Far East, South Africa, and India (Table I). Membranous obstruction can occur in children, but is more prevalent in adults.

Occlusion of the Terminal Hepatic Venules

Nonthrombotic, fibroobliterative endophlebitis of the terminal hepatic venules within the liver is referred to as venoocclusive disease. As with occlusion of the

major hepatic veins and the IVC, occlusion of these smaller veins may lead to the Budd–Chiari syndrome. Multiple etiologies have been reported (Table II). Patients at risk for developing venoocclusive lesions include recipients of bone marrow and renal allografts. Other conditions associated with small vessel occlusion include cryptogenic cirrhosis or cirrhosis secondary to alcohol or hepatitis B. Patients with alcoholic hepatitis may also exhibit focal obliteration of intrahepatic veins. Vitamin A toxicity, arsenic poisoning, insecticide exposure, 6-thioguanine, intraarterial 5-fluoro-2′-deoxyuridine, oral contraceptives, and thorotrast have rarely been associated with venoocclusive disease.

PATHOLOGY

Pathologically, there are distinct differences between acute and chronic hepatic venous outflow obstruction. Grossly, acute outflow obstruction is associated with an enlarged, smooth, red–purple liver. Histologically, centrilobular congestion and sinusoidal dilatation are appreciated. Atrophy, necrosis, and centrizonal hepatocyte dropout with extension to periportal regions are associated with severe injury (Fig. 1). In chronic Budd–Chiari syndrome, the inferior vena cava receives direct outflow from the caudate lobe of the liver, which compensates for venous outflow obstruction of the major hepatic veins. The result is caudate lobe hypertrophy with atrophy and cirrhosis of the remaining hepatic segments. Histologically, there is complete obliteration of the central veins associated with midzonal and centrilobular fibrosis with or without cirrhosis.

CLINICAL PRESENTATION

The clinical presentation of patients with Budd–Chiari syndrome is highly variable, depending on the extent and rate of outflow obstruction. Patients may present in many ways, ranging from an asymptomatic state to fulminant hepatic failure or cirrhosis with portal hypertensive complications. Hepatomegaly and ascites are present in greater than 85% of patients, whereas esophagogastric varices, splenomegaly, and prominent collaterals are less frequently seen. Right upper quadrant pain, nausea, vomiting, hepatomegaly, and ascites are characteristic of acute obstruction. Jaundice and splenomegaly can be present but are usually mild. Most patients present with a subacute course (less than 6 months) characterized by vague right upper quadrant discomfort, hepatomegaly, mild to moderate ascites, and splenomegaly; jaundice may be either absent or mild. Chronic venous outflow obstruction is likely if symptoms have been present for greater than 6 months and are associated with fatigue, bleeding varices, encephalopathy, coagulopathy, hepatorenal syndrome, and/or malnutrition. Fulminant hepatic failure is a

rare manifestation of Budd–Chiari syndrome and is typically the result of complete occlusion of all major hepatic veins. Without treatment, progressive encephalopathy, coagulopathy, and death are inevitable within 8 weeks of venous outflow obstruction.

DIAGNOSTIC EVALUATION

Laboratory Investigation

Standard laboratory investigation is rarely useful in the assessment of patients with suspected Budd–Chiari syndrome. Aminotransferases are typically normal or mildly abnormal; however, elevated enzyme values are not specific for venous outflow obstruction. Likewise, the serum bilirubin, alkaline phosphatase, and prothrombin time can be either normal or mildly abnormal but are not useful in diagnosing Budd–Chiari syndrome. Ascitic fluid analysis adds little specificity to the diagnosis, although it may be useful in ruling out other causes of abdominal fluid accumulation. The workup for Budd–Chiari syndrome cannot be considered complete without a comprehensive workup for an underlying hypercoagulable state.

Medical Imaging

Abdominal ultrasound is the best screening test for the evaluation of the hepatic veins, vena cava, and portal vein. In experienced hands, the sensitivity of ultrasound approaches 85–95%. Enlarged, stenotic, and tortuous hepatic veins identify acute venous occlusion, whereas the veins of patients with chronic disease may be more difficult to visualize. Ultrasound may reveal caval compression by a hypertrophic caudate lobe, or obstruction by thrombus, tumor, or membranes. Hepatic venous-to-venous "spiderweb" collaterals are highly suggestive of Budd–Chiari syndrome. Doppler technology added to conventional ultrasound greatly increases sensitivity.

Computer tomography (CT) and magnetic resonance imaging (MRI) may reveal nonvisualization of vessels or obstruction by thrombus. In addition, these studies readily detect hepatic parenchymal disease, ascites, and splenomegaly.

Angiography remains the gold standard for the diagnosis of Budd–Chiari syndrome. Thrombi commonly form at the junction of the major hepatic veins with the cava or just distal to the venous orifices. Injection of contrast medium classically reveals intrahepatic collateral vessels or recanalized veins, giving the classic spiderweb appearance. Pressure measurements obtained during angiography provide useful information prior to surgical decompression.

Liver Biopsy

Liver biopsy is useful in establishing the diagnosis of Budd–Chiari syndrome and in evaluating the severity of the disease. Based on the severity, physicians can select the most appropriate therapy for individual patients. Angiography and liver biopsy should be obtained from all patients considered to be surgical candidates. Biopsies should be bilobar, because injury may be variable from one lobe to the other.

MANAGEMENT

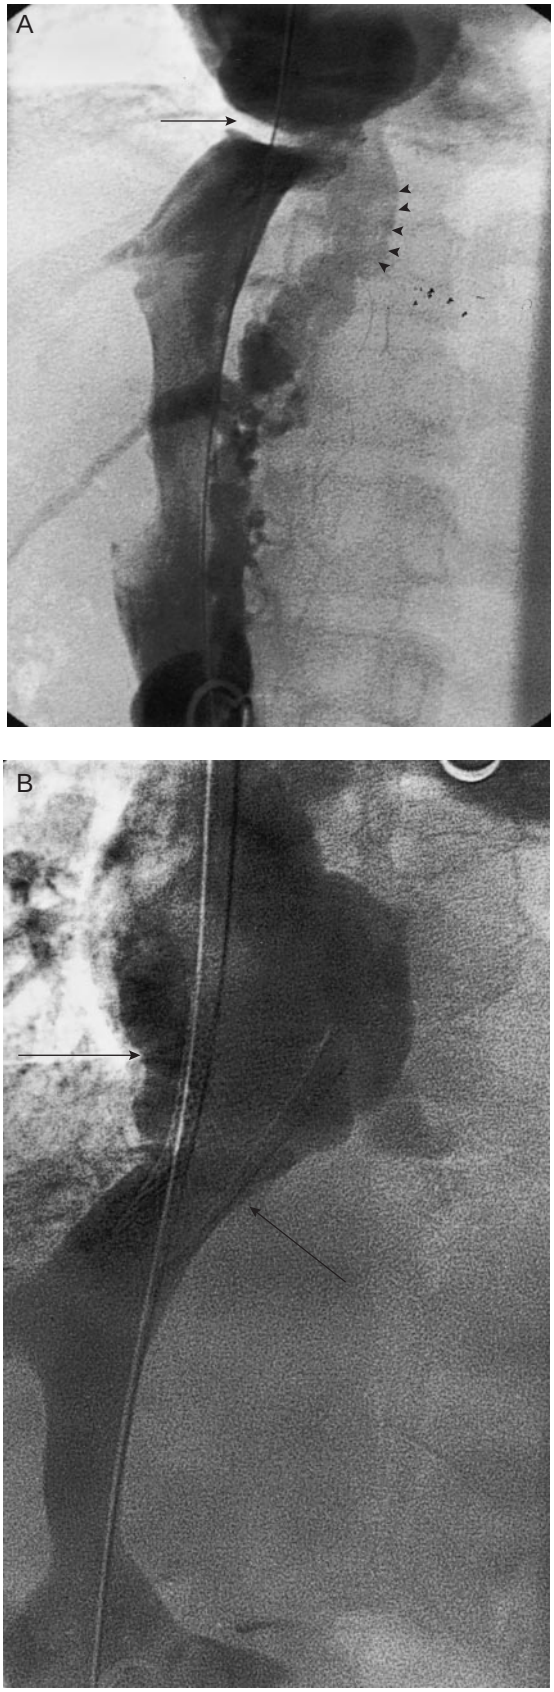
The goals of treatment for patients with Budd–Chiari syndrome include alleviating venous obstruction and preserving hepatic function through eradication of centrilobular congestion. Despite medical therapy and interventional radiologic techniques, the majority of patients will require surgical decompression.

Medical Therapy

Although frequently used in patients with Budd–Chiari syndrome, low-sodium diets, diuretics, and therapeutic paracentesis are generally ineffective because these methods do little to reverse the underlying pathophysiology. The use of anticoagulants and thrombolytics for patients with acute incomplete thrombotic occlusion must be balanced against the typically short window of opportunity to decompress the liver surgically.

Interventional Radiology

Percutaneous transluminal balloon angioplasty is an exciting therapy for hepatic venous outflow obstruction secondary to caval webs or hepatic venous stenoses. Although excellent short-term results are achievable, sustained patency rates have been disappointing. Wire, laser, or needle-assisted angioplasty and intraluminal stenting are emerging techniques (Fig. 2). Transjugular intrahepatic portosystemic shunts (TIPSs) are frequently used as a bridge to transplantation for patients with end-stage liver disease and ascites refractory to medical therapy, or for patients presenting with fulminant hepatic failure. Because patients can develop TIPS thrombosis or pseudointimal hyperplasia after placement, surveillance of TIPS patency with Doppler ultrasonography and/or angiography is recommended. Additional studies will be required before the TIPS can be routinely recommended as treatment for patients with either acute or chronic outflow obstruction.



Surgical Procedures

Surgical options for patients with Budd–Chiari syndrome include decompressive procedures and orthotopic liver transplantation (OLT). A variety of surgical shunts are available for decompression to relieve centrilobular congestion and necrosis. Decompression should be considered the standard of care for patients with acute or subacute venous occlusion. After surgery, long-term anticoagulation is recommended. Prior to surgery, liver biopsy and pressure measurements of the portal vein, IVC, and right atrium should be obtained to determine the best method of decompression. The procedure of choice for patients with either acute or subacute Budd–Chiari syndrome is the creation of a side-to-side portacaval shunt, which converts the portal vein into an effective outflow tract into the IVC. Greater than 85% of patients who receive portacaval shunts enjoy long-term survival, with improvement in hepatosplenomegaly, ascites, liver function tests, and histology; however, decompensation may be observed in patients with marginal hepatic reserve. Mesocaval shunts provide effective portal decompression for patients unable to receive side-to-side shunts. With successfully placed mesocaval shunts, long-term survival is possible for 75–95% of patients. Unfortunately, shunt thrombosis may develop in 20–55% of patients who receive mesocaval shunts. Depending on the venous anatomy, other decompressive shunts may need to be considered. Other surgical techniques can also provide adequate decompression in appropriately selected patients. Surgical reconstruction of the vena cava and hepatic venous ostia, transatrial membranotomy with finger fracture or excision, cavoplasty with autologous pericardial patch, and dorsocranial resection of the liver with hepatoatrial anastamosis have shown efficacy in limited studies.

OLT is the preferred option for patients with Budd–Chiari syndrome and fulminant liver failure or decompensated cirrhosis. Transplantation may also be appropriate for patients with significant liver disease who decompensate after receiving decompressive shunts or for patients with shunt failure. In patients without significant preoperative hemodynamic instability or multiorgan failure, survival after transplantation

is similar to that of decompressive shunts. Survival of patients transplanted for Budd–Chiari syndrome is also comparable to that of patients receiving allografts for other noncholestatic liver diseases, and is better than that of patients receiving transplants for malignancy or chronic hepatitis B. Selected patients, such as those with underlying hypercoagulable states not cured with OLT, require long-term anticoagulation.

SUMMARY

Budd–Chiari syndrome is an uncommon disorder associated with obstruction of the terminal hepatic venules, hepatic veins, IVC, and/or right atrium. Sinusoidal congestion, centrilobular necrosis, hepatic fibrosis, and cirrhosis can develop as a consequence of hepatic venous outflow obstruction. Patients typically present with symptoms and signs of subacute disease or cirrhosis, although an occasional patient may present without any evidence of significant liver injury. Routine laboratory and ascitic fluid analyses are rarely helpful in establishing the diagnosis. Doppler sonography is an excellent screening test, and CT and MRI complement sonography as noninvasive studies. Angiography remains the best technique for the diagnosis of venous occlusion. Pressure measurements at the time of angiography and bilobar liver biopsy are also helpful in guiding the clinician to the most appropriate therapy.

Low-sodium diets, diuretics, and paracentesis are of limited benefit in patients with Budd–Chiari syndrome. Thrombolytic therapy may be useful for early disease associated with fresh thrombosis. Selected patients may also benefit from interventional radiologic techniques such as percutaneous angioplasty with or without stenting. The TIPS can serve as a bridge to transplantation, but additional studies are warranted to assess the impact of TIPS placement on long-term survival. Surgical decompression is appropriate for patients with acute or subacute venous occlusion; alleviation of sinusoidal congestion and hepatic necrosis is possible. OLT is reserved for patients with Budd–Chiari syndrome associated with fulminant hepatic failure, decompensated cirrhosis, or failed surgical shunts. With careful patient selection and improvements in surgical technique, perioperative care, and immunosuppression, long-term patient survival after OLT is expected.

Bulimia Nervosa

JULIE E. B. NOLAN AND THOMAS D. GERACIOTI, JR.
University of Cincinnati and Veterans Affairs Medical Center

arrhythmia Abnormal rhythm of the heartbeat.
binge (binge eating) Consumption in a discrete time frame (usually $\leq$2 h) of an amount of food that is definitely excessive in comparison with the amount of food consumed by most others in similar circumstances. The consumption of large quantities of food at certain celebratory or holiday feasts, for example, is not usually considered to constitute pathological bingeing. A single binge-eating episode may take place at more than one location—such as following dinner at a friend's with eating at home—but day-long snacking is not a binge.
hyperamylasemia Abnormally high concentrations of the digestive enzyme amylase in the blood.
hypokalemia Abnormally low potassium concentrations in the blood.
osteoporosis Diminished mineralization of bone.
ostopenia Reduced bone formation.
parotid gland hypertrophy Enlargement of the salivary glands.
postprandial satiety Sense of satiation or fullness after eating.

The possibility of eating large quantities of food in one feeding episode is contained in the human behavioral repertoire, having developed under prehistorical evolutionary pressure to take advantage of transiently available food during periods of overall food scarcity. In recent decades, binge eating followed by vomiting—or other methods of purging—has been used as a means of body weight control, wherein the gustatory, self-soothing, and orally gratifying aspects of eating can be repeatedly obtained without an increase in body mass. If used routinely by vulnerable individuals, a pattern of binge eating followed by vomiting can become entrained and, in a sense, addictive.

CORE SYMPTOMS OF BULIMIA NERVOSA

The modern syndrome of bulimia nervosa was first described in London by Russell in 1979, in a 30-patient case series, as an eating disorder characterized by recurrent, uncontrolled binge-eating episodes in combination with compensatory behavior aimed at preventing weight gain. Individuals with bulimia nervosa commonly ingest up to 10,000 calories per day. The most common postbinge compensatory behaviors in individuals with bulimia nervosa are self-induced vomiting and laxative, diuretic, or enema misuse. Excessive exercise, fasting, and misuse of medications—including appetite suppressants (for example, amphetamines), cathartics (for example, syrup of ipecac), and metabolism-stimulating agents (for example, thyroid hormone)—are also commonly manifested. A formal diagnosis of bulimia nervosa, according to the American Psychiatric Association, requires that both binge eating and purging (or other compensatory behaviors) occur at least twice per week for at least 3 months (see Table I).

Excessive concern about or preoccupation with body shape, size, or weight is also a hallmark of bulimia nervosa. These individuals are focused upon maintaining or achieving a desirable body weight and shape. Therefore, pathological binge eating that exists in the absence of intense body consciousness (and in the absence of attempts to control body weight or shape) is not bulimia nervosa. Although a substantial minority of individuals with bulimia nervosa have histories of anorexia nervosa, most people with bulimia nervosa have a body weight within the normal range.

Patients with bulimia nervosa show an awareness of having an eating disorder, in contradistinction to patients with anorexia nervosa, in whom denial of an eating problem is intrinsic to the illness. However, individuals with bulimia nervosa are frequently ashamed about their eating pattern and usually—but certainly not always—maintain strict secrecy about it. Since the majority of people with bulimia nervosa are within a normal weight range, or are only slightly under- or overweight, it is difficult to identify someone with bulimia nervosa by sight (whereas, of course, the wasted, skeletal appearance of individuals with anorexia nervosa is quite obvious). Thus, individuals with bulimia nervosa are not frequently recognized by others to have an eating disorder.

TABLE I DSM-IV Criteria for Bulimia Nervosa

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and in similar circumstances.
   2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.

C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Purging type

During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Nonpurging type

During the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

BULIMIA NERVOSA SUBTYPES

Two subtypes of bulimia nervosa have been characterized, the purging type and the nonpurging type. Individuals with bulimia nervosa who purposefully vomit after binging or who misuse laxatives or enemas to expel undigested or incompletely digested food from the gastrointestinal tract have the purging type of bulimia nervosa. Misuse of diuretics is also regarded as a purging behavior. Those individuals with bulimia nervosa who do not purge themselves of undigested food or create a diuresis after binge eating have the nonpurging type of the disorder. Those individuals with the nonpurging type nevertheless engage in behaviors aimed at eliminating the potentially adverse effects of binge eating on body weight and shape by excessive exercise and/or fasting. In many cases, women with bulimia nervosa are intense, obsessive exercisers or "obligatory athletes."

Purging is present in approximately 90% of patients with bulimia nervosa, with forced vomiting present in the overwhelming majority of these individuals. As noted by Russell is his original description of the syndrome in 1979, "with repeated practice, the act of vomiting becomes effortless." Some individuals with bulimia nervosa do not have to stimulate the gag reflex at all in order to vomit; forceful contraction of the abdominal musculature suffices. Laxative abuse is seen in more than half of patients.

VARIANTS OF BULIMIA NERVOSA

In clinical practice, both "subclinical" (low-grade) forms of bulimia nervosa and variants of bulimia nervosa are seen about as frequently as the bulimia nervosa syndrome per se. These variants include, but are not limited to, those that (1) involve binge eating fewer than two times per week; (2) involve binge eating without compensatory, weight-control behavior (so-called binge eating disorder, see below); or (3) involve purging, such as self-induced vomiting, without binge eating. For example, the individual who engages in binge eating followed by self-induced vomiting an average of once per week for months or years has an eating disorder that does not meet the full diagnostic criteria for bulimia nervosa due to a lower frequency of bingeing. The normal-weight or slightly underweight woman who shows overconcern about body weight, intense interest in food, frequently diets, and routinely chews food and spits it out before swallowing it does not meet diagnostic criteria for bulimia nervosa due to the lack of binge eating. Other individuals, again mostly women, induce vomiting after intake of regular or modest amounts of food as a diet strategy; they do not binge eat. In these cases, perhaps one or more meals are digested but most other bouts of eating end in self-induced emesis. These women are at an increased risk of eventually developing full-blown bulimia nervosa. If one of these individuals does not show a compensatory increase in eating, fasts, or vomits after every meal, then she moves on the continuum of disordered eating toward anorexia nervosa, bulimic subtype. The unwieldy, catch-all diagnosis of "eating disorder, not otherwise specified" has been adopted by the American Psychiatric Association to capture these and other eating disorder variants.

Binge eating disorder is a common condition (2–5% in community studies in the United States and 30% among obese patients seeking weight loss) that is

TABLE II DSM-IV Criteria for Binge-Eating Disorder

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances.
   2. A sense of lack of control over eating during the episodes (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. The binge-eating episodes are associated with three (or more) of the following:
   1. eating much more rapidly than normal;
   2. eating until feeling uncomfortably full;
   3. eating large amounts of food when not feeling physically hungry;
   4. eating alone because of being embarrassed by how much one is eating;
   5. feeling disgusted with oneself, depressed, or very guilty after overeating.

C. Marked distress regarding binge eating is present.

D. The binge eating occurs, on average, at least 2 days a week for 6 months.
   Note: The method of determining frequency differs from that used for bulimia nervosa; future research should address whether the preferred method of setting a frequency threshold is counting the number of days on which binges occur or counting the number of episodes of binge eating.

E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, or excessive exercise) and does not occur exclusively during the course of anorexia nervosa or, bulimia nervosa.

characterized by chronic binge eating without compensatory weight-restricting behavior. Given the lack of weight-controlling compensatory behaviors, individuals with binge eating disorder are frequently obese. Binge eating disorder is seen in both men and women across the life span. Although an accepted diagnosis by practicing clinicians, the most recent Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV), published in 1994, proposed binge eating disorder as a new diagnostic entity about which there was insufficient information to include as an official category. It is likely that the diagnosis will be officially recognized by the American Psychiatric Association with the next DSM edition. See Table II for the complete 1994 DSM criteria.

Bulimia nervosa and anorexia nervosa can occur simultaneously, such as constitutes the binge-eating/purging subtype of anorexia nervosa, commonly called bulimarexia. Bulimia nervosa and anorexia nervosa can also occur alternately within the same individual over time.

Yet another eating disorder in which hyperphagia is an essential component is night eating syndrome, described by Stunkard and colleagues in 1955 and consisting of morning anorexia and evening or nighttime hyperphagia with agitation and insomnia. At a minimum, this syndrome appears to reflect phase-delayed circadian rhythms.

EPIDEMIOLOGY

Bulimia nervosa is generally a syndrome seen in young women, afflicting approximately 1–4% of college-aged women in community samples, although it is also seen in older women (mostly with chronic or chronic, intermittent bulimia nervosa that had its onset in youth, but occasionally as a new onset syndrome) and in men. Indeed, the overwhelming majority of people with bulimia nervosa, over 90% in clinical samples, are female. This gender distribution is often regarded to be a result of a societal or cultural premium on feminine beauty that is transmitted to the young woman through either conscious or unconscious channels (most conspicuously via mass media). That eating disorders are more common in industrialized nations and in affluent individuals is consistent with the notion of environmental influences on the development of bulimia nervosa. That white women much more frequently develop bulimia nervosa and anorexia nervosa than black women is also taken to reflect the relatively higher value placed on thinness in the former culture. Black and white women are at roughly equal risk for binge eating disorder—that is, unrestrained eating—but white women are more likely to show compensatory fasting or purging behavior and concerns about body weight and shape. However, if a female—regardless of race—internalizes the view that slender beauty is ideal, body dissatisfaction, severe fasting, and even subsequent binge eating and full-blown bulimia nervosa may develop.

Impaired satiety, secretive eating, binge eating, postprandial vomiting, and other symptoms of abnormal eating are also surprisingly common in preschool children, although much more work is needed to understand and characterize these phenomena and their frequency.

RISK FACTORS, COMORBIDITIES, AND ASSOCIATED FEATURES

Dieting, especially severe and/or repeated dieting, is a major risk factor for development of bulimia nervosa and other eating disorders. Although most individuals who diet do not develop an eating disorder, even moderate dieting by adolescent girls increases the risk of later developing an eating disorder by several-fold. Many bulimic patients have had histories of anorexia nervosa.

Genetic factors are increasingly appreciated as a factor in the development of eating disorders. Studies of the differences in rates of bulimia nervosa between dizygotic and monozygotic twins suggest that approximately 50% of the risk of developing bulimia nervosa is genetic. However, the interplay between inherited vulnerabilities and intrafamilial relationships is hard to definitively tease out. Maternal body dissatisfaction increases the likelihood that an eating disorder will develop in her progeny. The majority of patients with bulimia nervosa have a first-degree relative with a mood disorder, substance abuse disorder (most often alcoholism), or an eating disorder. Indeed, the majority of patients who present for treatment of bulimia nervosa have suffered from another psychiatric syndrome either prior to the onset of the eating disorder or currently with the eating disorder. Most commonly, a mood (affective) disorder, such as major depression, atypical depression, or bipolar affective disorder (manic depression and its low-grade variants), is seen in patients with bulimia nervosa, but a range of other psychiatric syndromes, including anxiety disorders (such as posttraumatic stress disorder, panic disorder, and obsessive–compulsive disorder), substance abuse (especially of tobacco and alcohol), and personality disorders, are also seen.

COMPLICATIONS, PHYSICAL STIGMATA, AND MORBIDITY

Despite the normal or even vigorously healthy appearance of most individuals with bulimia nervosa, physical stigmata do exist as a result of complications from the chronically disordered eating pattern (see Table III). Calluses on the dorsum of the hand or knuckles (Russel's sign) are often seen. These calluses eventually develop after the repeated thrusting of the fingers into the throat in order to induce vomiting, due to the pressure of the teeth on the skin. Loss of enamel from the teeth—even a moth-eaten appearance of the dentition—can be seen following years of very frequent contact with acidic vomitus. Bilateral parotid (salivary) gland hypertrophy (swollen cheeks) can develop from the hyperstimulation of excessive eating and frequent vomiting and confers a characteristic "chipmunk" facies. The breath may be foul from recent or frequent passage of partly digested food during emesis. Rectal prolapse, most likely from forced vomiting-related increases in intra-abdominal pressure or from straining during defecation, has been reported in a number of patients, invariably preceded by complaints of rectal bleeding.

TABLE III Potential Complications of Bulimia Nervosa

Dental
Erosion of dental enamel
Chipped and/or ragged teeth
Frequent caries
Cardiac arrhythmias
Cardiac myopathies
Calluses or scars over knuckles (Russell's sign)
Constipation/delayed gut transit time
Esophageal reflux, spasms, rarely tears
Foul breath odor
Gastric distension (rarely, gastric perforation, rupture)
Hypokalemia
Hyperamylasemia
Hypothermia
Lowered seizure threshold
Osteopenia
Osteoporosis
Parotid gland hypertrophy ("chipmunk" appearance)
Rectal bleeding (rarely, rectal prolapse)

An important, frequently encountered metabolic complication is hypokalemia due to frequent vomiting and/or frequent use of laxatives or enemas; cardiac arrhythmias sometimes follow. Surprisingly, some patients show substantial hypokalemia without cardiac arrhythmia or other apparent adverse effects, perhaps due to long-term organismic adaptations to the situation. For example, a young woman with long-standing bulimia nervosa had a potassium level of 2.1 mEq/L but still performed with great success in a demanding exercise competition. Other patients with similarly low potassium levels have irregular heartbeats and require emergency cardiac monitoring and electrolyte normalization.

Use of syrup of ipecac to induce vomiting can weaken or damage the cardiac myocardium. Circulating pancreas-derived amylase concentrations increase following a binge–purge episode and, clinically, elevated blood amylase levels are a reliable indicator of such behavior.

Despite the numerous complications that can develop (see Table III for a partial list), the morbidity

associated with bulimia nervosa is surprisingly low—certainly much lower than was feared when the first 30 cases were described by Russell in 1979 (although some of those cases would now be classified as "eating disorders not otherwise specified"). As opposed to the situation in anorexia nervosa, wherein growth, genital sexuality, and fertility essentially cease or fail to develop, these parameters are often quite adequate in the person with bulimia nervosa. Moreover, unlike the case with anorexia nervosa, death from a complication of bulimia nervosa is very rare. Gross mortality rates in patients with bulimia nervosa have been found to be at least 0.3%, including deaths from traffic accidents, suicide, malnutrition, and drug interactions. The crude mortality rate in anorexic patients is perhaps 20 times higher.

PATHOPHYSIOLOGY

Patients with bulimia nervosa almost always show prominent impairments in their experience of postprandial satiety. Although the degree of hunger experienced by patients varies—with some showing great ability to suppress hunger and fast between binge eating episodes—once the ingestion of food occurs they are at high risk for uncontrollable food intake. In part, the inability or impaired ability to experience postprandial satiety reflects a general impairment in the communication of peripherally generated satiety signals to the brain. Thus, most patients with bulimia nervosa have impaired postprandial secretion of the satiety-inducing hormone cholecystokinin (CCK) from the proximal intestine. Normally, postprandial CCK-mediated signals promote closure of the gastric pylorus (increasing the feeling of fullness) and travel via the vagus nerve to brainstem and hypothalamic feeding centers that mediate the satiety response. Abnormalities in this signaling system could be genetic and/or acquired (perhaps as a result of frequent binge eating). Part of the mechanism of antidepressant drug treatment of bulimia nervosa involves increasing the postprandial elaboration of CCK.

Abnormally low integrated function of the indoleamine serotonin has also been identified in patients with bulimia nervosa. In this regard, serotonin in intestinal enterochromaffin cells has been found to be necessary for the contractile effect of CCK. Serotonin also appears to have a satiety-inducing effect in the central nervous system. Low brain serotonin function also underlies obsessive–compulsive disorder, elements of which are routinely encountered in patients with bulimia nervosa, and other eating disorders, in whom seemingly nonsensical behaviors are irresistible (such as the eating of 5000 calories within an hour in a person who is trying to remain trim). High doses of pharmacologic agents that increase the whole-body availability of serotonin are efficacious in both bulimia nervosa and obsessive–compulsive disorder.

If patients with bulimia nervosa maintain a normal weight, the hypothalamic–pituitary–thyroid, hypothalamic–pituitary–adrenal, and hypothalamic–pituitary–gonadal neuroendocrine axes remain surprisingly normal.

NATURAL HISTORY AND TREATMENT

The natural history of bulimia nervosa is highly variable, with perhaps 50% undergoing spontaneous remission without treatment after an active, syndromic period of months to years. Other individuals—whether eaters of normal quantities of food, overeaters, or binge eaters—immediately give up on self-induced emesis as a method of weight control after attempting it. However, a substantial minority of those who develop bulimia nervosa, up to 20%, go on to chronically demonstrate the full-blown syndrome at 10-year follow-up, whereas others continue to show subsyndromal elements over the long term. Treatment studies show significantly higher rates of short-term remission than naturalistic follow-up studies, but the long-term benefits of treatment interventions have not been established. Approximately 30% of well-improved patients eventually experience a bulimic relapse. Thus, although bulimia nervosa is generally much more benign than anorexia nervosa, some individuals suffer from chronic bulimia nervosa, lasting even decades. Little is known regarding the risks for developing chronic bulimia nervosa, although the comorbid presence of severe borderline personality disorder is a negative prognostic sign.

The standard approach to the treatment of bulimic patients is a combination of antidepressant medication and psychotherapy. Usually, treatment is instituted and accomplished on an outpatient basis, as opposed to the situation in anorexia nervosa or bulimarexia where inpatient correction of malnutrition and severe wasting is usually necessary. Brief inpatient admissions are reserved for the emergency control of severe electrolyte imbalances and other severe bulimia-related complications (including severe depression and acute suicidality).

A variety of antidepressants, including selective serotonin reuptake inhibitors (usually in high

doses), monoamine oxidase inhibitors, and tricyclic antidepressants, are successful in ameliorating or reducing bulimic behavior in the majority of patients. However, antidepressant treatment alone is inadequate in most cases; complementary intensive psychotherapy is also indicated.

The most well-studied psychotherapy for bulimia nervosa is cognitive-behavioral psychotherapy, with results suggesting that this intervention is efficacious. Cognitive therapy focuses upon the morbid fears of obesity and worries about body size and shape, with cognitive and behavioral exercises aimed at correcting cognitive distortions and low self-esteem and at reducing perfectionism and the hyperfocus on the body. However, intensive, exploratory, psychodynamic psychotherapy with an experienced clinician—in combination with antidepressant medication—is also helpful in most cases and has the advantage of not focusing strictly on eating disorder symptoms (and other superficial, behavioral manifestations of the psyche), but also provides the context for the uncovering of occult or unconscious psychological problems or conflicts.

Psychologically, patients with bulimia nervosa often, but not always, show substantial impulsivity and a great deal of interpersonal neediness and object hunger (hunger for caring and empathic relatedness with others), for which oral gratification often substitutes. Analogous impairments to feeding-related satiety are often seen clinically in the form of seemingly insatiable desire for close contact or merger with another person. The stable presence of a caring, empathically attuned psychotherapist is in itself highly therapeutic for such patients. Nevertheless, long-established binge–purge (or binge–fasting) cycles can become deeply and organismically entrained, and pointed interventions, such as antidepressant medications and nutritional oversight, aimed at normalizing the appetitive and satiety signal processing mechanisms (optimally together with exploratory psychotherapy) are sometimes therapeutically necessary.

SUMMARY

In fewer than 25 years, major strides have occurred in the understanding of the clinical course, pathophysiology, psychopathology, and treatment of bulimia nervosa. Currently, the efficacy of both psychotherapy and psychopharmacologic interventions in the treatment of this common eating disorder has been well established. Ideally, these treatment modalities should be combined.

Calcitonin Gene-Related Peptide (CGRP)

PETER HOLZER
University of Graz, Austria

calcitonin gene-related peptide First neuropeptide discovered by molecular analysis of the calcitonin gene, in the absence of any information about its functional role.

calcitonin receptor-like receptor One of the three proteins that form the calcitonin gene-related peptide receptor complex (the other two proteins are the receptor-associated membrane protein-1 and the receptor component protein). The calcitonin receptor-like receptor consists of seven transmembrane domains, is coupled to G proteins, and serves as the receptor protein that recognizes calcitonin gene-related peptide as ligand.

extrinsic afferent nerve fibers Originate from the nodose ganglia (vagal afferents) and dorsal root ganglia (spinal afferents) and connect the gut with the brain stem and spinal cord, respectively.

intrinsic enteric neurons Originate from the myenteric and submucosal nerve plexuses within the wall of the gastrointestinal tract and supply all effector tissues of the gut.

mucosal homeostasis Complex array of protective mechanisms coordinated by neural and other control systems to ensure that the mucosa survives undamaged the onslaughts that occur during digestion; the gastrointestinal mucosa is endangered by toxic, antigenic, and pathogenic food ingredients as well as by potentially harmful secretory products such as pepsin and acid.

neuropeptide Oligo- or polypeptide that is expressed by specific neurons and serves as an extracellular messenger of those neurons.

receptor-associated membrane protein-1 Single-membrane-spanning protein (also termed receptor activity-modifying protein); required to guide the intracellular trafficking of calcitonin receptor-like receptor to the cell membrane and to endow calcitonin receptor-like receptor with high affinity for calcitonin gene-related peptide. Association of calcitonin receptor-like receptor with receptor-associated membrane protein-1 is a prerequisite for the formation of functional calcitonin gene-related peptide receptors.

receptor component protein Intracellular peptide important for coupling calcitonin receptor-like receptor to the G protein G_s/adenylate cyclase signal transduction pathway.

Calcitonin gene-related peptide is a 37-amino-acid neuropeptide; within the gastrointestinal tract, this peptide occurs primarily in extrinsic afferent nerve fibers and intrinsic enteric neurons. Following its release, calcitonin gene-related peptide acts on specific receptors that are expressed by enteric neurons and gastrointestinal effector systems in a tissue-specific manner. In so doing, the peptide plays a role in the regulation of blood flow, exocrine and endocrine secretory activity, mucosal homeostasis, motor activity, and nociception. It appears that the peptide-specific receptors represent a significant target for therapeutic intervention in various gastroenterological disease entities. Although the molecular pharmacology of calcitonin gene-related peptide actions is not yet completely understood, new information on receptor structure and function suggests that it may be feasible to design selective ligands for the calcitonin gene-related peptide receptor and to evaluate their utility as therapeutics.

INTRODUCTION

Calcitonin gene-related peptide (CGRP) was the first biologically active peptide to be discovered by recombinant DNA technology, instead of the traditional approach of tissue extraction, purification, and bioassay. In 1983, M. G. Rosenfeld and co-workers discovered not only this neuropeptide but also a new regulatory mechanism of cell-specific gene expression. Expression of calcitonin gene-related peptide results from the alternative splicing of RNA transcribed from the calcitonin gene. Primary RNA transcripts are processed to messenger RNA (mRNA) for calcitonin in the thyroid C cells, whereas the mRNA for CGRP is formed predominantly in neurons of the central and peripheral nervous system.

Since the publication of Rosenfeld's work, CGRP has been localized to distinct neurons as well as some endocrine and immune cells in the gastrointestinal (GI) tract. The complex structure of CGRP receptors has only recently been disclosed; functional CGRP receptors are now known to consist of three proteins, calcitonin receptor-like receptor (CRLR), receptor-associated membrane protein-1 (RAMP-1), and receptor component protein (RCP). The cell-selective expression of CGRP receptors on GI effector systems and the peptide's biological actions in the gut suggest

that CGRP plays multiple roles in the neural control of digestive activity. These functions include mucosal-blood flow, mucosal homeostasis, exocrine and endocrine secretory processes, motor activity, and GI nociception. Experimental work indicates that a disturbance of the CGRP system may contribute to a number of GI disorders and that a correction of these perturbations may be of therapeutic potential.

THE CGRP FAMILY

CGRP-α (CGRP-I) is encoded by the calcitonin/CGRP-α gene on chromosome 11 of the human genome and represents a 37-amino-acid polypeptide, the sequence of which varies slightly among different vertebrate species (Fig. 1), although mouse and rat CGRP-α are identical. Common to all of the CGRPs is a disulfide bridge between Cys-2 and Cys-7 and an amidated C terminus. Mouse, rat, and human tissues contain an additional peptide, CGRP-β (CGRP-II), which has a high sequence homology to CGRP-α (Fig. 1). Importantly, though, the gene from which CGRP-β is derived does not encode calcitonin. Because the biological activities of CGRP-α and CGRP-β are generally similar, it is thought that both CGRP homologues act on a similar receptor population.

CGRP belongs to a family of bioactive peptides, often termed the calcitonin peptide family, which comprise calcitonin, CGRP-α, CGRP-β, amylin (islet amyloid polypeptide), and adrenomedullin (Fig. 1). The sequence homologies range from 20 to 30% between CGRP and adrenomedullin as well as CGRP and calcitonin, to 40 to 50% between CGRP and amylin. Encoded by separate genes, amylin, like CGRP, is a 37-amino-acid polypeptide, whereas adrenomedullin is made of 52 amino acids. Although CGRP, amylin, and adrenomedullin share some biological effects, there is now good evidence that they act via different CGRP, amylin, and adrenomedullin receptors (which, however, are related to each other).

CGRP RECEPTORS

The biological effects of CGRP are brought about by interaction with specific membrane receptors. Pharmacologically, two CGRP receptor subtypes, termed $CGRP_1$ and $CGRP_2$ receptors, have been proposed to exist because certain CGRP analogues differ in their potencies in various bioassays. Characteristic of the $CGRP_1$ receptors is their sensitivity to the antagonistic effect of the human $CGRP_{8-37}$ fragment. Although known to be receptors that are coupled to G proteins and linked to adenylate cyclase, functional CGRP receptors have long resisted molecular identification because they are assembled from three different proteins (Fig. 2), CRLR, RAMP-1, and RCP. Despite the fact that CRLR is the CGRP-recognizing protein, the CGRP receptor becomes functional only if the seven-transmembrane domain-containing CRLR is associated with the single-membrane-spanning RAMP-1. This chaperone protein is important for the intracellular translocation of CRLR and its insertion into the plasma membrane and is essential for conferring a CGRP ($CGRP_1$) receptor-like binding profile on CRLR. In addition, RAMP-1 may also play a role in receptor desensitization by modulating the activation of protein kinase A. The intracellular RCP is required for efficient coupling of the receptor to the G_s/adenylate cyclase signaling pathway (Fig. 2). Following activation by an agonist, the CRLR/RAMP-1 complex is phosphorylated and internalized in a dynamin- and β-arrestin-dependent manner. The putative heterogeneity of CGRP receptors inferred from pharmacological studies has not yet been disclosed at the molecular level.

CRLR can associate not only with RAMP-1 and RCP to produce a CGRP ($CGRP_1$) receptor, but also with RAMP-2 or RAMP-3, two other chaperone proteins sharing an approximately 30% sequence homology with RAMP-1. Interestingly enough, these RAMPs dictate the pharmacological profile of CRLR because they

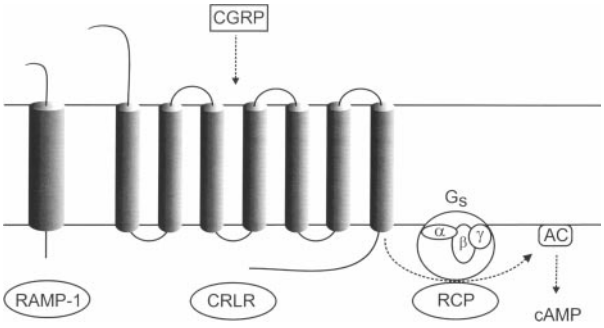

FIGURE 2 Diagram of the calcitonin gene-related peptide (CGRP) receptor complex consisting of the calcitonin receptor-like receptor (CRLR), the receptor activity-modifying protein-1 (RAMP-1), and the receptor component protein (RCP). Association of CRLR with RAMP-1 forms a high-affinity CGRP receptor that, through RCP, is effectively coupled to the G protein G_s/adenylate cyclase (AC)/cyclic adenosine monophosphate (cAMP) signaling pathway.

transfer a unique agonist selectivity profile to the receptor complex. Thus, CRLR associated with RAMP-2 behaves as an adrenomedullin receptor at which adrenomedullin-like peptides have a much greater affinity than do CGRP-like peptides. If the human calcitonin receptor isotype 2 (hCTR2) is assembled with RAMP-1 or RAMP-3, hCTR2 loses its affinity for human calcitonin but acquires high affinity for amylin, thus behaving like an amylin receptor.

Owing to the difficulties in the molecular receptor characterization, the pharmacology of CGRP receptors is still poorly understood. For a long time, $CGRP_{8-37}$ was the sole CGRP receptor antagonist available, and only recently has the first nonpeptide antagonist of CGRP receptors, BIBN4096BS, been published. This compound exhibits extremely high affinity for the human CGRP ($CGRP_1$) receptor, its K_i in the picomolar range being more than 1000-fold lower than that of human $CGRP_{8-37}$. As seen with nonpeptide antagonists for other neuropeptide receptors, the activity of BIBN4096BS is species specific, given that its potency at the rat CGRP ($CGRP_1$) receptor is 100-fold less than at the human counterpart. This variation in potency appears to be determined by species differences in the amino acid sequence of RAMP-1, notably at position 74.

EXPRESSION AND RELEASE OF CGRP IN THE GI TRACT

The principal sources of CGRP in the digestive system are extrinsic primary afferent nerve fibers and intrinsic enteric neurons (Fig. 3). These two neuronal systems contain different molecular forms of the peptide, because most of the CGRP expressed in extrinsic afferents of the rat is CGRP-α, whereas the only form of CGRP in enteric neurons is CGRP-β. The density of the GI innervation by CGRP-immunoreactive neurons varies greatly among different regions of the gut and different mammalian species, as does the relative contribution of extrinsic afferent and intrinsic enteric neurons to the overall CGRP content of the gut. Most of the CGRP found in the esophagus and stomach of small rodents is derived from extrinsic afferent neurons whereas the small and large intestine contains a sizable number of intrinsic enteric neurons expressing CGRP. The CGRP-immunoreactive neurons of the myenteric and submucosal plexus in the guinea pig intestine project primarily into the mucosa whereas those in the rat intestine issue oral and caudal projections within the plexuses as well as to the muscle layers and the mucosa.

Most of the CGRP-expressing extrinsic afferent neurons in the rodent gut originate from cell bodies in the dorsal root ganglia and reach the gut via sympathetic (splanchnic, colonic, and hypogastric) and sacral parasympathetic (pelvic) nerves while passing through prevertebral ganglia and forming collateral synapses with sympathetic ganglion cells. Within the wall of the GI tract, they supply primarily arteries and arterioles but also project to the lamina propria of the mucosa, to the submucosal and myenteric nerve plexuses, and to the circular and longitudinal muscle layers (Fig. 3). It is a characteristic of many spinal afferents in the rat, guinea pig, and canine gut that CGRP is coexpressed with the tachykinin substance P, whereas CGRP and tachykinins do not coexist in enteric neurons of these species. CGRP-positive vagal afferents originating from the nodose ganglion supply the esophagus and proximal part

of the stomach but make a relatively small contribution to the content of CGRP in the gastric corpus, antrum, and intestine, given that a vast majority (80–90%) of the CGRP-containing nerve fibers in the rat stomach are derived from dorsal root ganglia.

As is expected for substances with a vesicular localization, CGRP is released from extrinsic afferent or intrinsic enteric neurons of the GI tract in a calcium-dependent manner if these cells are depolarized. CGRP release from extrinsic spinal afferents within the gut can be elicited by the vanilloid capsaicin because these nerve cells express functional vanilloid receptors of type 1. With the use of capsaicin, it has also been found that CGRP in the general circulation represents primarily an overspill of CGRP released from peri- and paravascular afferent nerve fibers. It is particularly worth noting that acidification of the mucosal tissue releases CGRP from extrinsic afferents in the stomach and duodenum.

Apart from neurons, CGRP is also found in endocrine cells of the human GI mucosa and rat pancreas and in blood-derived or resident immune cells within the lamina propria of the rat gastric mucosa. However, the quantitative and functional significance of these sources is still little known.

EFFECTS, PHYSIOLOGICAL ROLES, AND PATHOLOGICAL IMPLICATIONS OF CGRP IN THE GI TRACT

Motor Activity

The most prominent motor action of CGRP in the active gut is muscle relaxation via $CGRP_{8-37}$-sensitive CGRP receptors. This effect arises in most instances from a direct action on the muscle and leads to retardation of gastric emptying and to attenuation of motility throughout the digestive tract. However, CGRP is also able to excite enteric cholinergic motor pathways, which is in keeping with the peptide's ability to depolarize intrinsic primary afferent neurons of the myenteric plexus, to enhance the release of acetylcholine from enteric neurons, and, via $CGRP_{8-37}$-insensitive CGRP receptors on enteric neurons, to cause contraction of the resting muscle.

There is still scarce information as to whether CGRP released from intrinsic or extrinsic neurons of the gut plays a physiological role in the neural control of GI motility. The claim that CGRP released from sensory neurons contributes to distension-induced peristalsis is not universally accepted. There is, however, increasing evidence to infer that CGRP released from extrinsic afferent nerve fibers contributes to pathological disturbances of GI motility. Thus, experimental data attribute to CGRP a role in the pathological shutdown of GI motility that is associated with postoperative or peritonitis-induced ileus. This is consistent with the observation that CGRP acting via $CGRP_{8-37}$-sensitive CGRP receptors contributes to the inhibition of intestinal peristalsis that ensues after sensory neuron stimulation.

Secretory Processes

The actions of CGRP on GI ion, enzyme, mucus, and fluid secretion vary with the region and species under study and in some instances appear to depend on the experimental conditions. For instance, CGRP is able to inhibit secretagogue-evoked secretion of enzyme, bicarbonate, and fluid from the pancreas of the dog and rat *in vivo*, an effect that to a large extent is mediated by CGRP-induced release of somatostatin. In contrast, amylase secretion from isolated acini of the rat and guinea pig pancreas is enhanced by the peptide.

Electrolyte and fluid secretion in the small intestine of the dog and in the colon of the guinea pig and rat is stimulated by CGRP. Although the secretory effect of CGRP in the rat colon arises from a direct action on enterocytes, as is the case with human epithelial cell lines, the secretory action of CGRP in the guinea pig colon is mediated by enteric neurons. It remains to be shown whether CGRP plays a physiological role in the control of intestinal ion and fluid secretion. Pathologically, it appears as if the peptide contributes to the fluid secretion in the rat ileum that is evoked by *Clostridium difficile* toxin A.

There is good evidence to implicate CGRP as a transmitter by which extrinsic afferent nerve fibers contribute to the homeostatic regulation of endocrine and exocrine secretory processes in the gastroduodenal region. CGRP is highly potent in depressing basal and secretagogue-evoked output of acid and pepsin in the stomach of humans, dogs, rabbits, and rats, an action that is brought about by $CGRP_{8-37}$-sensitive CGRP receptors, that depends on somatostatin as an essential mediator, and that goes along with a depression of the release of acetylcholine, gastrin, and histamine (Fig. 4). It is of note in this context that CGRP regulates not only the release of somatostatin and gastrin but also the transcription of their genes. The physiological relevance of these effects is highlighted by the ability of the CGRP receptor antagonist $CGRP_{8-37}$ to augment basal and stimulated acid output and by the ability of acid accumulation in the gastric lumen to release CGRP from extrinsic afferent nerve fibers. By way of its effects on the release of somatostatin, gastrin,

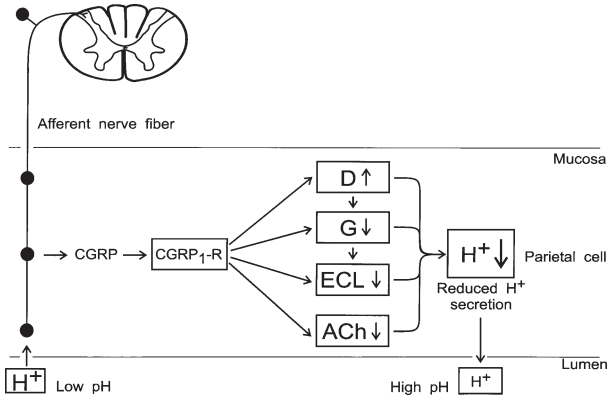

FIGURE 4 Diagram illustrating the role of calcitonin gene-related peptide (CGRP)-releasing afferent nerve fibers in the feedback control of gastric acid secretion in the rat stomach. When the acidity in the lumen rises, afferent nerve fibers release CGRP, which, via activation of $CGRP_{8-37}$-sensitive CGRP ($CGRP_1$) receptors, stimulates the release of somatostatin and inhibits the release of gastrin, histamine, and acetylcholine. histamine, and acetylcholine, CGRP halts further secretion of acid and thus represents an essential transmitter in the feedback inhibition of gastric acid output (Fig. 4). The protection of the gastroduodenal mucosa from any deleterious influence of acid is supported by the peptide's ability to stimulate bicarbonate and mucus secretion.

Vascular Functions

The arteries and submucosal arterioles of the GI tract receive the densest innervation by extrinsic afferents containing CGRP. This localization of CGRP, the expression of CGRP receptors on the endothelium and smooth muscle of arteries and arterioles, and the peptide's high potency in causing vasodilatation point to a vasoregulatory function of CGRP. There is ample evidence to conclude that nonadrenergic noncholinergic dilation of the rat superior mesenteric artery is mediated by capsaicin-sensitive afferent nerve fibers releasing CGRP. In contrast, the physiological significance of CGRP in the microcirculation of the small and large intestine is little known. CGRP is able to dilate submucosal arterioles in the guinea-pig ileum, in which this neuropeptide mediates the vasodilator reaction to afferent neuron stimulation with capsaicin, whereas mucosal blood flow in the rat small and large intestine is not altered by CGRP.

The situation is different in the rat stomach, where CGRP potently enhances blood flow through the mucosa, an action that is brought about by $CGRP_{8-37}$-sensitive CGRP receptors. This CGRP-induced hyperemia arises from dilation of submucosal arterioles, but the diameter of venules remains unchanged. The dilator action of low doses of CGRP is mediated by a mechanism that involves nitric oxide; high doses of the peptide increase blood flow independently of nitric oxide. Although CGRP mediates the nitric oxide-dependent vasodilatation that afferent neuron stimulation by intragastric capsaicin elicits in the rat stomach, there is little evidence that this neuropeptide participates directly in the physiological regulation of gastric blood flow. However, pharmacological and CGRP-α gene knockout studies suggest that endogenous CGRP influences vascular function indirectly through inhibitory modulation of sympathetic nerve activity.

CGRP comes prominently into play under pathological conditions, a role that is best exemplified by the hyperemic response that ensues when the gastric mucosal barrier is disrupted by ethanol or bile salts, allowing acid to enter the tissue and damage the gastric mucosa. This acid-evoked rise of gastric mucosal blood flow involves CGRP released from extrinsic afferent nerve fibers and nitric oxide as the major vasodilator messengers (Fig. 5). The rise of gastric mucosal blood flow in response to acid influx serves a homeostatic and protective role in the gastric mucosa because it helps to neutralize and wash away intruding acid and delivers bicarbonate and other factors to defend and repair the mucosa (Fig. 5). Another example relates to the *C. difficile* toxin A-evoked inflammation in the rat ileum, which involves CGRP as a proinflammatory mediator.

Mucosal Homeostasis

There are several lines of evidence to indicate that GI mucosal integrity and repair are under the control of extrinsic afferent neurons releasing CGRP. The first hint at such a role came from the ability of CGRP to protect the mucosa in a number of experimental models of gastric injury and colonic inflammation. The action of CGRP to reduce ethanol-induced damage in the gastric mucosa is mediated by $CGRP_{8-37}$-sensitive CGRP receptors and involves both nitric oxide and K_{ATP} channels, whereas prostaglandins do not participate.

The activity of CGRP to strengthen mucosal defense appears to be of pathophysiological significance, given that the peptide mediates the gastroprotective effect of primary afferent neuron excitation by capsaicin and many other factors and drugs. Thus, blockade of CGRP receptors with $CGRP_{8-37}$ prevents the ability

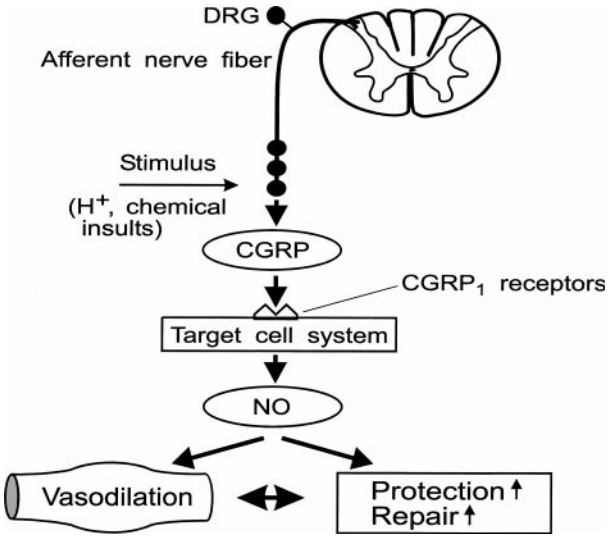

FIGURE 5 Diagram illustrating the homeostatic role of calcitonin gene-related peptide (CGRP)-releasing afferent nerve fibers in the rat gastric mucosa. Influx of acid into the mucosa through a disrupted mucosal barrier or challenge by other chemical insults stimulates these nerve fibers to release CGRP, which then activates $CGRP_{8-37}$-sensitive CGRP ($CGRP_1$) receptors to initiate local mechanisms of defense and repair. NO, nitric oxide.

of intragastric capsaicin to attenuate experimentally imposed injury, as does immunoneutralization of CGRP with polyclonal and monoclonal antibodies to the peptide. This implication of CGRP in gastric mucosal homeostasis is corroborated by the observations that $CGRP_{8-37}$ as well as active immunization of rats against CGRP exacerbates experimental injury in the stomach.

As has been pointed out by P. Holzer, CGRP released from sensory nerve fibers strengthens gastric mucosal defense by mechanisms that involve vasodilatation and hyperemia-dependent and hyperemia-independent processes. Hyperemia supports a number of gastroprotective mechanisms, including appropriate delivery of bicarbonate to the surface mucus layer, and facilitates the rapid restitution and repair of the wounded mucosa. In addition, CGRP is per se able to enhance the secretion of bicarbonate and mucus in the rat stomach and duodenum. Because CGRP-releasing afferent nerve fibers are not tonically active, it seems that they operate as a neural alarm system that, when stimulated by mucosal insults, activates mechanisms of acute defense and supports processes that aid the repair of the injured mucosa (Fig. 5). Complementary evidence for such a homeostatic role of CGRP-releasing afferent nerve fibers in the GI mucosa comes from the observation that sensory neuropathies weaken the resistance of the tissue to injury. This applies not only to the stomach, but also to the esophagus, small intestine, and colon, in which experimentally induced inflammation and damage are aggravated.

GI Sensitivity and Nociception

CGRP is a transmitter of spinal afferent neurons innervating the gut, and there is experimental evidence that CGRP can mediate GI pain and inflammatory hyperalgesia. Intraperitoneal administration of exogenous CGRP or acetic acid-induced release of endogenous CGRP triggers abdominal muscle contractions, a reaction that is indicative of pain. Of particular importance is the finding that $CGRP_{8-37}$ is able to prevent inflammation-induced hypersensitivity to colonic distension. In this respect, intrathecal $CGRP_{8-37}$ is more potent than intravenous $CGRP_{8-37}$, thus J. M. Gschossmann, E. A. Mayer, and co-workers have concluded that the site of CGRP-mediated hyperalgesia is primarily in the spinal cord.

SUMMARY

Experimental evidence indicates that, in the GI tract, CGRP is a transmitter candidate of intrinsic enteric neurons and extrinsic afferent nerve fibers. As such, this neuropeptide seems to be involved in the neural regulation of various digestive functions as deduced from the distribution of CGRP-releasing nerve fibers and CGRP receptors in the gut and the pharmacological effects of exogenous CGRP on GI motility, exocrine and endocrine secretory activity, blood flow, mucosal homeostasis, and abdominal pain. However, the physiological and pathophysiological implications of CGRP in gut function have not yet been fully characterized because potent nonpeptide CGRP receptor antagonists have not been available until recently. It would nevertheless appear, if the situation encountered in small rodents can be extrapolated to humans, that CGRP-immunoreactive afferent nerve fibers act to halt GI motility, increase gastric blood flow, inhibit gastric acid secretion, enforce GI mucosal resistance to injury, and contribute to inflammation-induced GI hyperalgesia. If so, the CGRP system in the digestive tract represents a regulatory system with considerable potential for therapeutic intervention.

Apart from acting within the gut and signaling noxious information to the spinal cord, CGRP may also play a role in the central regulation of digestive functions along the brain–gut axis. As first discovered by Y. Taché, intracerebral administration of CGRP inhibits

gastric acid secretion, ulcer formation, and motility, mostly by increasing the sympathoadrenal outflow.

osteomalacia Defective mineralization of the organic matrix, resulting in excessive accumulation of osteoid in the bone tissue and increased propensity of the bones to bow or fracture under the weight of the body.

osteopenia Condition of decreased bone mass, defined as a bone mineral density between −1.0 and −2.5 standard deviations relative to the ideal peak bone mass (World Health Organization definition).

osteoporosis A skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fractures. According to the World Health Organization, it is defined as a bone mineral level lower than −2.5 standard deviations from the ideal peak bone mass.

rickets A disease caused by vitamin D or phosphate deficiency during childhood; it is characterized by lack of growth plate fusion and bowing of the long bones, with defective bone matrix mineralization.

vitamin D metabolites Cholecalciferol (vitamin D_3) and ergocalciferol (vitamin D_2) are ingested with food, although ergocalciferol can also be synthesized in the skin. They both undergo two subsequent hydroxylation steps to 25-hydroxyvitamin D in the liver, and 1α,25-dihydroxyvitamin D the kidney. The former metabolite represents the storage form of the vitamin, which decreases under deficiency conditions; the latter is the hormonal form, is under the control of parathyroid hormone, and regulates intestinal calcium absorption.

In terrestrial vertebrates, mineral homeostasis involves intestine, kidney, and bone and is regulated primarily by parathyroid hormone (PTH) and 1α,25$(OH)_2$D, the biologically active, hormonal form of vitamin D. The concentration of calcium ions in the circulation is maintained within a narrow range; increased absorption of Ca^{2+} in the intestine and decreased excretion of Ca^{2+} by the kidney are usually sufficient to maintain calcium balance; however, under conditions of severe calcium deficiency, Ca^{2+} is mobilized from bone. The concentration of serum magnesium is regulated primarily by the kidney and magnesium is involved in the synthesis of PTH.

INTRODUCTION

The evolution from marine to terrestrial life required a major change in the way live organisms utilized minerals from the environment. Such a shift led to the evolution of a most exquisite biological homeostatic system that allowed organisms to absorb minerals (primarily calcium) and maintain their content in the body fluids within a narrow range. This homeostatic system, which involves intestine, kidney, and bone, is maintained primarily by two key hormones, parathyroid hormone (PTH) and 1α,25$(OH)_2$D, the hormonal form of vitamin D. Vitamin D dates back at least half a billion years. It was originally produced in ocean-dwelling phytoplankton by exposure to sunlight, probably acting as a sunscreen. With the evolution of terrestrial vertebrates, this "vitamin," which can be produced by ultraviolet (UV) irradiation of precursors in most organisms, gradually assumed its current role in the development and maintenance of the ossified skeleton.

The first priority of the integrated system that regulates mineral homeostasis is to maintain the concentration of circulating ionized calcium (Ca^{2+}) within a narrow range. Even modest deviations from the normal range must be controlled. In most cases, increased intestinal absorption and decreased renal excretion are adaptive mechanisms that are sufficient to maintain extracellular Ca^{2+} concentration within the normal range without the need to mobilize calcium from bone. However, under conditions of severe calcium deficiency and hypocalcemia, skeletal Ca^{2+} stores must be accessed to maintain circulating Ca^{2+}. This homeostatic response occurs even to the point of potentially compromising the structural integrity of the skeleton. Parathyroid hormone directs fast responses to changes in circulating calcium, whereas the vitamin D system represents a slower adaptive mechanism that maintains calcium balance, regulating primarily its input through intestinal absorption. The actions of PTH and 1α,25$(OH)_2$D are coordinated and each hormone influences the production of the other.

Magnesium, the fourth most abundant cation in the body and the major intracellular divalent cation, is not as tightly regulated as calcium, but it is directly involved in the synthesis of PTH.

CALCIUM

Calcium Balance

Calcium is an essential element for survival. It provides the structural integrity of the skeleton and controls vital physiologic processes, i.e., nerve excitability, muscle contraction, and blood coagulation. An adult human body contains approximately 1000 g of calcium, 99% of which is in the skeleton in the form of hydroxyapatite [$Ca_{10}(PO_4)(OH)_2$] and 1% in the extracellular fluids and soft tissues.

There are three fractions of calcium in serum: ionized (or free) calcium (~47%), protein-bound calcium (~46%), and calcium complexed to small ions, such as bicarbonate, citrate, and phosphate (~5–10%). Ionized and complexed calcium constitute the filterable calcium, but only the former is metabolically active. Albumin binds almost 90% of the protein-bound calcium, with the remainder bound to various globulins. Alterations of serum albumin concentration result in changes of total serum calcium with only minor or no changes in ionized calcium. Binding of calcium to serum proteins is pH dependent; acidosis decreases binding and increases ionized calcium, whereas alkalosis increases binding with a consequent decrease in ionized calcium. Reduced ionized calcium increases sodium permeability and enhances tissue excitability, whereas an increase in ionized calcium has the opposite effect. An example of this mechanism is the respiratory alkalosis produced in states of hyperventilation. Increased calcium binding to serum proteins causes a relative decrease of ionized calcium with consequent neuromuscular symptoms.

It is the extracellular ionized fraction of calcium that is physiologically important and it is rigidly maintained by the combined effects of PTH and $1\alpha,25(OH)_2D$. The parathyroid cells are able to sense extracellular calcium concentration via a calcium-sensing receptor and can thus respond to hypocalcemia with increased PTH secretion. As noted above, the integrated actions of PTH on distal tubular calcium reabsorption, osteoclastic bone resorption, and $1\alpha,25(OH)_2D$-mediated intestinal calcium absorption are responsible for the fine regulation of the serum calcium concentration. The sensitivity and accuracy of this integrated control allows fluctuation of ionized calcium to stay within 0.1 mg/dl in either direction from its normal setpoint. Slight decrements in the ionized calcium level elicit a prompt (within seconds) increase in the rate of PTH secretion. The increased circulating levels of PTH stimulate reabsorption of calcium from the distal kidney tubules, thus raising serum calcium. In parallel, phosphaturia is stimulated along with conversion of 25(OH)D to $1\alpha,25(OH)_2D$. The latter is responsible for a slower adaptive response that augments intestinal absorption of calcium and phosphate. If necessary, PTH and $1\alpha,25(OH)_2D$ also promote the net release of calcium and phosphate from bone. The combined calcium efflux into the extracellular fluid from the intestine and bone and the increased calcium reclamation in the distal tubules restore ionized calcium to normal, thereby inhibiting PTH secretion and closing the negative feedback loop. The most rapid changes in calcium handling in response to PTH come from the kidneys and the skeleton. Changes in renal tubular reabsorption are observed within minutes, whereas release of calcium from the skeleton occurs within 1–3 h. On the other hand, adjustments to the rate of calcium absorption in the intestine via the PTH–$1\alpha,25(OH)_2D$ axis require 24–48 h to become fully operative, so that this system does not contribute to rapid adaptive responses. Thus, only minor increases in $1\alpha,25(OH)_2D$ occur within the first few hours of a low calcium challenge, whereas prolonged hypocalcemia results in higher levels of $1\alpha,25(OH)_2D$ in the circulation. With time, an increased number of new osteoclasts appear in bone.

Calcium Deficiency

Although calcium deficiency is highly prevalent in Western societies and in many other ethnic groups, it seldom leads to clinically evident hypocalcemia. The homeostatic mechanisms described above effectively compensate for shortages of calcium intakes in mild or transitory deficiency conditions. Overt hypocalcemia develops with prolonged and severe calcium deficiency or when additional causative factors intervene to either prevent absorption or increase excretion. Therefore, hypocalcemia presents in most circumstances as an asymptomatic condition detected on routine screening and only rarely as a life-threatening medical emergency. Ionized calcium rather than total serum calcium is the primary determinant of symptoms in patients with hypocalcemia.

Perhaps the most relevant example or the metabolic consequences of subtle, but chronic calcium deficiency is represented by age-dependent (type II) osteoporosis. Aging is associated with decreased intestinal calcium absorption, decreased skin production of vitamin D, and deficient dietary intake of calcium and vitamin D. As a compensatory mechanism, PTH secretion increases, leading to increased urinary calcium reclamation and stimulation of $1\alpha,25(OH)_2D$ synthesis, but also to increased bone resorption to enhance calcium efflux from bone to the circulation. The defective calcium

intake occurs in the backdrop of an age-dependent decline in intestinal ability to adapt to a low-calcium diet. It is estimated that after the age of 40, calcium absorption decreases at a rate of 0.21% per year, and in women, an additional ~2% decline occurs after menopause. Thus, the combined effects of menopause and age lead to a 20–25% decrease in absorption efficiency in women between the ages of 40 and 60. If calcium deficiency continues for a substantial period of time, the mild secondary hyperparathyroidism developing with age may cause continued bone loss, thus effecting one of the pathophysiologic mechanisms of age-dependent osteoporosis.

The causes of calcium deficiency can be classified into three major categories, i.e., dietary deficiency, calcium malabsorption, and vitamin D-dependent deficiency (reviewed in Section IV). Although milk and other dairy products are the best source of calcium, calcium-containing supplements currently represent the preferred method of calcium intake in Western countries, especially in elderly individuals. Despite the growing evidence that an adequate calcium intake is critical not only to achieve an optimal peak bone mass but also to minimize age-dependent bone loss, a large number of Americans still fail to meet the currently recommended dietary calcium intake. The inadequacy of standard diets to provide sufficient calcium remains a problem of national relevance in most Western countries, despite food fortification. Clearly, this measure is insufficient to effectively correct the deficiency, and calcium supplementation is commonly required, especially for subjects at risk for bone loss and for elderly individuals. According to a consensus panel convened by the National Institutes of Health in 1994, the optimal daily calcium intake is 800 mg until age 10, between 1200 and 1500 mg/day for young adults, and 1000 mg for individuals in the fertile period. After menopause or in individuals older than 65, a daily intake of at least 1500 mg is required, unless estrogen replacement therapy is instituted.

As noted, most dietary calcium comes from dairy products, grains, and bony fish. Other common food constituents, such as pasta, bread, fruits, vegetables, and juices, contain much smaller amounts of calcium. They also contain large amounts of fibers, the consumption of which has increased because of their putative therapeutic role in the control of serum lipids and bowel motility, particularly in elderly people. Unfortunately, the very mechanism by which indigestible fibers facilitate intestinal transit also reduces the time for calcium absorption in the duodenum. Other mechanisms contribute to the low bioavailability of calcium in leafy green vegetables, including the relatively high content of oxalic acid in spinach and phytate in whole wheat products and other cereals, leading to the formation of insoluble and unabsorbable oxalate or phytate calcium complexes. On the other hand, the most common calcium supplement currently used is calcium carbonate, the salt with the highest concentration of calcium by weight (40%). Preparations containing calcium citrate are also very popular, as they may cause less constipation than calcium carbonate although they tend to be more difficult to ingest.

Aside from fibers, a number of food products or additives may alter calcium absorption from food. Certain dietary sugars, such as lactose, xylitol, and sorbitol, enhance intestinal calcium absorption through various mechanisms, but the potential benefits of lactose are often offset by lactose intolerance in older patients. Ethanol has negative effects on calcium balance. It decreases calcium transport and absorption in the intestinal epithelium and it can indirectly affect calcium transport through its negative effects on other organs, such as the pancreas and the liver. Likewise, there is an inverse correlation between caffeine intake and calcium balance. Caffeine, acting as mild diuretic, transiently increases the urine output of sodium that in turn drives the calcium loss. However, these changes are in most part compensated for by homeostatic responses, and an adequate calcium intake (>1200 mg) protects against any harmful effects that caffeine may have on calcium metabolism and bone mass.

Reduction of the absorptive surface area is responsible for calcium malabsorption in gastrointestinal conditions, such as Crohn's disease and celiac disease, as well as in subjects with short bowel syndrome. Malabsorption of vitamin D and loss of bile salts add to the inadequate calcium input. At the skeletal level, this results in osteopenia sometimes associated with osteomalacia, depending on whether the vitamin D or the calcium deficit prevails. Celiac disease represents a good paradigm for the combined calcium and vitamin D malabsorption in certain intestinal disorders. In celiac disease, serum levels of 25(OH)D are lower than normal, whereas $1\alpha,25(OH)_2D$ is either normal or even increased. Thus, the increase of $1\alpha,25(OH)_2D$, driven by a secondary rise of PTH, is not able to compensate for the absorption inefficiency. Correction of the malabsorption with a gluten-free diet corrects the vitamin D deficiency and prevents osteopenia or osteoporosis characteristic of untreated celiac disease.

Long-term use of anticonvulsant medications, especially phenobarbital and phenytoin, can lead to chronic, subclinical calcium deficiency with biochemical evidence of secondary hyperparathyroidism, more severe in nonambulatory or institutionalized subjects.

The most consistent abnormality is a decreased serum 25(OH)D, reduced calcium absorption, increased fecal calcium excretion with normal or even elevated concentration of circulating $1\alpha,25(OH)_2D$. Colchicine produces a dose-dependent inhibition of calcium uptake and accumulation by duodenal cells. Cytotoxic chemotherapeutic agents can also induce profound malabsorption of calcium by damaging the intestinal epithelium, which is extremely sensitive to these agents owing to the rapid turnover of the intestinal mucosa epithelium.

MAGNESIUM

Magnesium Balance

Although much less abundant than calcium, magnesium is essential in many cellular functions, especially for certain enzymatic activities. Approximately 30% of the total magnesium is protein bound (mostly to albumin), whereas 55% is ionized and 15% is complexed in salts. The kidney is primarily responsible for the regulation of the serum magnesium concentration. Approximately 5–15% of filtered magnesium is reabsorbed in the proximal convoluted tubule and at least 50% is reabsorbed in the thick ascending limb of the loop of Henle. Magnesium reabsorption follows that of sodium and water via a passive paracellular process, including solvent drag, and depends on lumenal magnesium concentration. Tubular reabsorption is normally close to saturation and any increased distal delivery of magnesium results in increased urine magnesium.

Magnesium is rather ubiquitous in food products, especially in vegetables, meats, and dairy products. As for calcium, lactose in milk can substantially enhance intestinal magnesium absorption. Since food of cellular origin is a good source of magnesium, the average dietary magnesium intake in developed countries is higher than the RDA, except in certain conditions, such as during pregnancy and lactation, as well as during chronic use of loop diuretics or after extensive burns, when the magnesium requirement is far higher than the RDA. Magnesium can be absorbed along the entire gastrointestinal tract, with the highest level of efficiency in the jejunum and ileum. Unlike calcium, net intestinal magnesium absorption is directly proportional to dietary magnesium intake, with a fractional absorption of approximately 30–40%. Although magnesium absorption is primarily passive, vitamin D may indirectly affect intestinal magnesium absorption through changes in phosphate and/or calcium absorption, as it occurs when dietary calcium is very low (200 mg/day). In such cases, the homeostatic increases in PTH and $1\alpha,25(OH)_2D$ drive active magnesium absorption, adding to the passive transport mechanism.

Magnesium Deficiency

Because magnesium is found in virtually all foods, dietary deprivation is an infrequent cause of hypomagnesemia in individuals with normal caloric intake. Magnesium deficiency is more commonly caused by excessive losses from either the gastrointestinal tract or the kidney. However, since magnesium absorption is strictly dependent on the lumenal concentration of the element, any chronic dietary restriction or deficiency results in reduced absorption. Hypomagnesemia is not uncommon in hospitalized patients in whom many factors may contribute to magnesium loss, including acidosis, continuous use of diuretics, intravenous administration of sodium-containing fluids, and drugs that increase urinary excretion of magnesium. It is estimated that up to 10% of hospitalized patients have low serum magnesium and the prevalence can be even higher in intensive care patients.

A number of dietary constituents may interfere with magnesium and decrease its bioavailability at sites of absorption. Zinc interferes with magnesium absorption probably by competing for the same absorptive sites along the intestine. Diets with high zinc content can decrease magnesium absorption as much as 10%, resulting in negative magnesium balance if dietary magnesium is low. Although the evidence that dietary calcium can interfere with magnesium absorption is tenuous at best, of more concern for the possible development of magnesium deficiency is the interference of magnesium with anions and in particular phosphate and oxalate. As occurs for calcium, insoluble magnesium phosphate or oxalate salts can form in the intestinal lumen, thus preventing the absorption of either ion. The high level of phosphate in milk formulas used to feed very-low-birth-weight babies, under the assumption that the high level of phosphate may facilitate their skeletal development, exemplifies this premise. Unfortunately, when phosphate is increased to a calcium : phosphate ratio lower than 2 : 1, fractional intestinal magnesium absorption decreases and hypomagnesemia may occur in these small babies. Leafy green vegetables are an important source of magnesium, but calcium absorbability is reduced by the presence of oxalic acid. Food processing can also modify the bioavailability of magnesium. For example, raw spinach has a poorer magnesium bioavailability than boiled or fried spinach, whereas boiling or frying does not improve spinach calcium bioavailability. Phytate, contained in many vegetables, negatively affects

magnesium absorption, as it does with calcium. A case in point is soybean, which contains large amounts of phytate, thus making diets based exclusively on soybean inadequate to provide the daily requirements of minerals.

Primary intestinal diseases associated with decreased transit time (resection or bypass of the ileum for obesity, stomach resection, chronic diarrhea/steatorrhea such as regional enteritis, or ulcerative colitis), loss of absorptive surface from intestinal mucosal damage (short bowel syndrome, nontropical sprue, radiation injury, or intestinal lymphectasia), or insufficient bile secretion (biliary fistula or atresia) can cause a magnesium deficit. It is questionable whether the vitamin D deficiency that develops in hepatobiliary disorders as a consequence of fat malabsorption has any contribution to the decreased magnesium absorption, which is largely a vitamin D-independent process. Massive large bowel resection affects magnesium kinetics more than calcium, leading to decreased magnesium absorption. Abuse of laxatives may also cause hypomagnesemia secondary to decreased transit time, whereas vomiting or nasogastric suction may contribute to magnesium depletion because of loss of the upper intestinal tract fluid, which is rich in magnesium.

Renal magnesium transport is influenced by the filtered sodium and calcium load, and administration of excessive sodium in parenteral fluids is a common factor for hypomagnesemia in hospitalized patients. Excessive urinary magnesium loss is the cause of hypomagnesemia that may occur after treatment with a wide spectrum of medications, including loop diuretics, aminoglycosides, cisplatin, cyclosporine A, amphotericin B, and pentamidine, as well as in alcoholism. Likewise, the mechanism for hypomagnesemia in poorly controlled diabetes mellitus is probably related to both increased urinary magnesium loss and dietary restrictions of grains and nuts. Intestinal magnesium absorption is also reduced in patients with hypoparathyroidism or pseudo-hypoparathyroidism, likely as a consequence of decreased serum $1\alpha,25(OH)_2D$, since magnesium deficiency corrects after therapy with vitamin D metabolites.

VITAMIN D

Vitamin D Balance

Vitamin D is a fat-soluble steroid and exists as two forms, vitamin D_2 (ergocalciferol), found in plants, and vitamin D_3 (cholecalciferol), found primarily in fatty fish. Only the latter can be synthesized in the skin from the precursor 7-dehydrocholesterol and this endogenous production can account for up to 80% of total body vitamin D. In fact, cutaneous production is the main source of vitamin D in humans worldwide. In the circulation, vitamin D is bound to vitamin D-binding protein and is taken up by the liver, where a first hydroxylation on C-25 takes place to produce 25(OH)D. This form of vitamin D is bioactive only at high concentrations, as it occurs in vitamin D intoxication. The physiologically active form is produced by further hydroxylation on C-1, which occurs in the kidney. Because of its very tightly regulated circulating levels, the presence of specific receptors in target tissues, and specific biologic actions, $1,25(OH)_2D$ is a bone fide hormone. The most important regulator is PTH, which stimulates the 1α-hydroxylase. The resulting increased $1,25(OH)_2D$ concentration represents the slow-response feedback loop that increases serum calcium by stimulating its intestinal absorption, thus correcting hypocalcemic conditions. Experimental data also suggest that phosphorus may stimulate 1α-hydroxylase activity independent of PTH, a mechanism operative in renal failure. Both 25(OH)D and $1,25(OH)_2D$ undergo hydroxylation on C-24. Although some physiologic functions have been proposed for $24,25(OH)_2D$, 24-hydroxylation renders the molecule susceptible to inactivation by side chain cleavage and oxidation.

Unlike calcium and magnesium, vitamin D is rare in food. Natural sources of appreciable amounts of vitamin D are fatty fish, such as salmon and mackerel, and in particular their livers, which account for the efficacy of cod liver oil as a cure for rickets. As for calcium, several food products, in particular cereals, bread products, and milk, are frequently fortified with vitamin D and account for a substantial share of vitamin D intake in Western populations. In the United States, federal regulations stipulate that 10 μg (400 IU) of vitamin D be added to every quart of milk. Multivitamin preparations also typically contain 10 μg. Although these doses would meet the recommended dietary allowance of vitamin D, it has been estimated that the true vitamin D requirement in the absence of sunlight exposure could be as much as 600 IU per day.

Vitamin D Deficiency

Despite the widespread use of calcium supplements containing vitamin D and food fortification, the prevalence of relative vitamin D deficiency in the Western hemisphere remains surprisingly elevated. Subclinical vitamin D deficiency, defined biochemically as low 25(OH)D with low-normal serum calcium and phosphate, increased alkaline phosphates, and

mildsecondary hyperparathyroidism, was found in approximately 10% of ambulatory women living in the midwestern United States, referred for evaluation of osteoporosis. Moreover, almost 50% of homebound, community-dwelling, elderly persons may suffer from vitamin D deficiency. Thus, the possibility of subclinical deficiency of vitamin D and calcium malabsorption should be considered in elderly subjects with poor nutrition, who spend most of their time indoors.

A variety of factors can alter the cutaneous production of vitamin D. The skin pigment melanin competes with 7-dehydrocholesterol, the precursor of vitamin D_3, for absorption of UV light. Thus, people with darker skin color require longer exposure to sunlight to produce the same amount of vitamin D_3 as those with lighter skin color. Similarly, sunscreens with a sun protection factor of 8 and above substantially reduce endogenous vitamin D synthesis. Aging significantly decreases the production of vitamin D because of lower abundance of 7-dehydrocholestrol in the aging epidermis. A person older than 70 years produces 30–35% less vitamin D_2 than a young adult, under the same sunlight exposure. Regional meteorological conditions, latitude, and seasons affect dermal vitamin D production because of the different degree of sunlight irradiation, although an average outdoor exposure during normal daily living is adequate to provide with vitamin D requirements in most circumstances.

Once vitamin D is ingested, it is incorporated into the chylomicron fraction and absorbed through the lymphatic system. Biliary cirrhosis and other chronic cholestatic syndromes with impairment of bile salt secretion result in marked reduction of serum 25(OH)D levels and calcium absorption. Excess intralumenal unabsorbed fat not only binds calcium and limits its accessibility to the transport site, it also impairs the absorption of vitamin D. On the other hand, patients with cirrhosis and marked hepatocyte loss have only modestly reduced serum 25(OH)D levels, in the absence of cholestasis, as the enzymatic reserve for 25-hydroxylation of vitamin D is adequately maintained by a relatively small number of hepatocytes. Among the many drugs that are known to interfere with the hepatic P-450 enzyme system, barbiturates are very effective at increasing catabolic hydroxylation of $1\alpha,25(OH)_2D$ and 25(OH)D to biologically inactive metabolites, leading to vitamin D deficiency and osteomalacia in the most severe cases. Intestinal malabsorption syndromes, such as Crohn's disease, cystic fibrosis, and Wipple's disease, can lead to vitamin D malabsorption, whereas diseases that affect the more distal small intestine and large intestine appear to have little effect on the intestinal absorption of fat-soluble vitamins.

In chronic renal failure, a defective production of $1\alpha,25(OH)_2D$ is the leading cause of calcium malabsorption. However, since passive calcium absorption is essentially intact, uremic patients can absorb sufficient calcium when their dietary intake is augmented to 4–10 g/day, although such doses are usually not well tolerated. Oral administration of $1\alpha,25(OH)_2D$ increases fractional calcium absorption up to 45–50% and is the mainstay of therapy in chronic renal failure. Similarly, vitamin D deficiency, hypocalcemia, and reduced intestinal calcium absorption occur in the nephrotic syndrome. These changes are attributed to hypoalbuminemia and the attendant urine loss of 25(OH)D and $1\alpha,25(OH)_2D$ bound to vitamin D-binding protein (DBP). Urinary excretion of DBP increases proportionally to the degree of proteinuria in nephrotic syndrome, whereas absorption of vitamin D is normal. In more advanced stages, 1α-hydroxylase deficiency also ensues, thus contributing to vitamin D deficiency, calcium malabsorption, hypocalcemia, and secondary hyperparathyroidism.

The most important species are *C. jejuni, C. coli*, and *C. fetus ssp. fetus*. *Campylobacter* are microaerophilic, gram-negative, spirally curved rods, which are rendered highly motile by two polar flagella. The complete genome sequence of the *C. jejuni* reference strain NCTC11168 consists of 1,641,481 bp and is predicted to encode 1654 proteins and 54 RNA species.

EPIDEMIOLOGY

Campylobacter infection is a worldwide anthropozoonosis, with *C. jejuni* probably the most important bacterial causative agent of infectious diarrhea in humans. *C. jejuni* and *C. coli* live predominantly as commensals in a wide range of wild and domestic birds and mammals, including poultry, dairy cows, and domestic pets. Sources of human *Campylobacter* infection therefore are animals and animal products, especially raw milk and poultry meat, as well as untreated water, which is frequently contaminated by birds or farm animals. Water, milk, and poultry have also been involved in community outbreaks. The infectious dose is 500 organisms in milk. *C. jejuni* is an important cause of traveler's diarrhea.

CLINICAL FEATURES AND COMPLICATIONS

Enteritis is the most common illness associated with *Campylobacter* infection. A prodromal period with malaise, headache, back pain, and myalgia is followed by the acute phase, often starting with a short peak of fever up to 40°C, severe abdominal cramps, and

watery stools, sometimes with gross blood. Symptoms usually resolve within a few days, but excretion of bacteria may continue for several weeks. Fatal outcome is rare; case fatality rates range between 0.05 and 0.3 per 1000 infections. Severe colitis is one of the more frequent acute complications, whereas toxic megacolon, appendicitis, pancreatitis, and cholecystitis are rare. Bacteremia may occur in approximately one case per 1000 infections. Septic abortion has been reported occasionally. Neonatal meningitis can be a life-threatening complication in such cases. Reactive arthritis as a late complication can occur 1–2 weeks after onset of bowel symptoms in approximately 1% of patients, especially in human leukocyte antigen B27-positive individuals, and in up to 20% is complicated by urethritis and uveitis (Reiter's syndrome).

Postinfectious Guillain-Barré syndrome (GBS) and Miller–Fisher syndrome (MFS), although rare, are the most important complications following *Campylobacter* enteritis in approximately 1 to 3 per 1000 cases. GBS as the predominant condition is characterized by a bilateral ascending paralysis, which can involve cranial nerves, resulting in respiratory insufficiency with a need for ventilation; MFS occurs with ophthalmoparesis, ataxia, and tendon areflexia. A remarkably high proportion of *Campylobacter*-related GBS patients develop serum antibodies against gangliosides, sialic acid-containing glycosphingolipids that are highly concentrated in the nervous tissues, especially in the myelin sheaths of the nerve axons.

C. fetus ssp. fetus in compromised patients is involved in extraintestinal infections, such as septicemia, endocarditis, thrombophlebitis, meningoencephalitis, and osteomyelitis.

LABORATORY DIAGNOSIS

Primary plating of stool samples on selective medium is the optimal method for recovering *Campylobacter* during the acute stage of enteritis. Identification of *Campylobacter* at the species level can be accomplished by using classical biochemical methods, species-specific polymerase chain reaction, and whole-cell fatty acid gas chromatography.

TREATMENT

Most *Campylobacter* enteritis patients do not require specific treatment other than oral replacement of fluid and electrolytes. Antibiotics are indicated in cases with protracted febrile illness, if infections relapse, and in immunocompromised patients. The drug of choice is erythromycin stearate 500 mg bid. Alternative antibiotics are fluoroqinolones, such as ciprofloxacin 250 mg bid, or amoxicillin 500–1000 mg tid or tetracycline 250 mg tid. All drugs are given for 5–7 days.

apoptosis Form of cell death that follows a characteristic pattern of molecular and cellular events, resulting in nuclear condensation and cell membrane disruption.
carcinogenesis Process in which normal tissue develops into cancer.
DNA caretaker gene Sequence on a gene encoding a product that normally maintains the fidelity of genomic DNA.
epigenetic Genomic code other than the base pair code of the DNA sequence. The epigenetic code consists of DNA methylation and histone modifications. e.g., CpG DNA methylation.
genomic instability Loss of fidelity of DNA in cells, resulting in changes to the genomic DNA code.
neoangiogenesis Growth of new blood vessels in tissues.
oncogene Genetic sequence encoding a product that promotes cell transformation or cancer formation. Oncogenes usually result from gain-of-function mutations of normal genes, called proto-oncogenes.
tumor suppressor gene Genetic sequence encoding a product that normally suppress tumor formation; inactivation by mutation or transcriptional silencing contributes to tumor formation.

Cancer is a pathologic condition that results from the abnormal growth and death of cells. Cancer causes disease because of mass effects from the growth of the primary tumor or from tumor invasion into adjacent tissues and/or tumor metastases. At the biological level, defining features of cancer include (1) unregulated (or autonomous) cell growth, (2) unregulated programmed cell death (apoptosis), (3) immortalization/loss of senescence, (4) genomic instability, (5) neoangiogenesis, and (6) invasive growth and metastatic behavior. All neoplasms, which include benign and malignant neoplasms, display unregulated growth. However, only malignant neoplasms invade tissues and spread to distant sites in the body (metastasize). Malignant neoplasms that originate in epithelial cells are called carcinomas, and cancers of mesenchymal cell origin are called sarcomas.

INTRODUCTION

The complex process of cancer formation is characterized by alterations in the morphology and behavior of normal cells; the alterations occur as a consequence of alterations in the cells' genomic DNA. In light of the myriad abnormalities in cancers, it has taken decades to begin to arrive at an understanding of the fundamental processes that drive cancer formation. The initial aspect of cancer that was understood and characterized was the histologic and anatomic aberrations found in the affected tissues. This original understanding of cancer as a histologic and biologic process has given way to an understanding that cancer is fundamentally a molecular and a genetic disease. Indeed, it is now appreciated that the histologic changes characteristic of cancer are the consequence of fundamental alterations in the biology of cancer cells that in turn result from the accumulation of mutations in genomic DNA. The genetic and epigenetic alterations of genomic DNA, which can broadly be considered mutations, play a key role in cancer formation by altering the behavior of proto-oncogenes or tumor suppressor genes. For a cancer to form, however, mutations, usually of both oncogenes and tumor suppressor genes, must first occur in a clonal cell population. These alterations allow the cells to bypass a complex regulatory system that normally precisely controls cell proliferation and behavior. It takes a critical number of DNA alterations that, in aggregate, supersede these regulatory mechanisms and lead once-normal cells to behave as cancer cells. This process has been termed multistage or multistep carcinogenesis and is considered to be the most common way that cancers form.

FUNDAMENTAL ASPECTS OF CARCINOGENESIS

The adult human is composed of approximately 10^{15} cells, and many of them replicate on a daily basis. These cells undergo regulated proliferation in order to maintain the homeostasis of the tissues in the various organs in the body. Examples of organs in which cell proliferation is occurring at high rates include the intestines, where the epithelium turns over approximately every 7 days, and the bone marrow, which has stem cells that can divide as often as every 24 hours. Those cells that have the capacity to proliferate and replenish the cellular mass in a tissue are called stem cells. It is estimated

 Copyright 2004, Elsevier (USA). All rights reserved.

that there are 10^{12} stem cell divisions every day, which normally maintains the integrity of the organ by replenishing cells that either die or are shed from the organism. In light of the constant proliferation of these cells, there are multiple checks and balances on the system to prevent inappropriate cell growth and also to regulate programmed cell death, which is also called apoptosis. Cell proliferation and apoptosis are regulated by processes such as cell : cell contact growth inhibition, which halts cell division when epithelial cells come into contact with one another; anchorage dependence, which prevents epithelial cells from growing unless they are in contact with extracellular matrix; and growth factor dependence.

As a consequence of the multiple mechanisms that control cell growth regulation, cancers do not arise as the result of a single mutational event. Rather, cancer cells arise from the accumulation of multiple mutations, which in sum total allow a cell to circumvent the multiple regulatory mechanisms that maintain homeostasis in the organ. These mutations occur through a variety of different mechanisms, including (1) inheritance of mutated alleles from parent to child [e.g., familial adenomatous polyposis (FAP) with germ-line mutations in *APC*], (2) exposure to carcinogenic agents, such as ionizing radiation, ultraviolet radiation, or chemical carcinogens, and (3) endogenous processes such as errors in DNA replication and the intrinsic chemical instability of certain DNA bases. Normally, cells can repair these mutations and, in fact, have evolved a variety of overlapping repair mechanisms to be able to do so. However, on occasion, these repair processes do not function correctly and DNA base changes, or mutations, occur and are retained in the genomic DNA of the cell. These mutations can accumulate over time in clonal populations and result in these cells becoming independent of the regulatory mechanisms that normally control their behavior. In fact, in cultured cells, which are already immortalized, it has been shown to take at least two added genetic changes to transform the cells into cells with tumorigenic competence.

MUTAGENESIS

Mutations can occur because DNA is a complex molecule that is susceptible to chemical damage. The damage to DNA can cause base pair changes in the DNA and alter the genomic code of the cell. There are a variety of different types of damage, or mutations, that can occur and result in changes in the proteins that are ultimately encoded for by the DNA. These alterations to DNA include the following events: (1) point mutations, which cause amino acid substitutions (missense mutations), frameshift mutations, or mutations that convert amino acid codons to stop codons and lead to protein truncation (nonsense mutations), (2) chromosomal imbalance or instability, resulting in gene amplification or overexpression of a gene, (3) gene deletions secondary to chromosomal loss or chromosomal breakage and fusion, and (4) epigenetic alterations, such as methylation of cytosines in CpG islands, leading to transcriptional silencing.

The most common proximal causes of these DNA alterations are believed to be exposure to environmental mutagens, such as benzopyrene in tobacco smoke, and spontaneous damage to DNA from reactive molecules that are generated during normal cell metabolism or during DNA replication. Thus, it has been estimated that approximately 70% of cancer in Western populations can be attributed to diet and lifestyle, with tobacco exposure accounting for 30% of this cancer incidence. In addition, dietary deficiencies of certain micronutrients such as folate and selenium are believed to influence DNA mutation rates. Spontaneous DNA damage is also a frequent event because of the inherent instability of the DNA molecule. In fact, depurination from breakage of the N-glycosidic bond connecting purines to deoxyribose occurs at the rate of 10^4 events/cell/day and deamination of cytidine to uridine occurs about 20 times/cell/day. The most dangerous mutagenic event that occurs as a consequence of reaction of DNA with by-products of oxidative metabolism is the production of 8-hydroxydeoxyguanosine, which occurs at a rate of $2 \times 10^4 - 10^5$ lesions/cell/day. The net effect of these mutations is to lead to alterations in oncogenes and tumor suppressor genes that ultimately disrupt signaling pathways and transform cells.

GENERAL CLASSES OF CANCER GENES

The genes that are mutated in cancer promote the tumorigenesis process through a variety of different mechanisms that alter cell behavior. As originally proposed by Bishop and Varmus, the genes involved in tumorigenesis can be classified as oncogenes or tumor suppressor genes. More recently, Vogelstein has proposed two additional categories, DNA caretaker genes and landscaper genes.

Classic oncogenes are genes that can deregulate cell growth through gain-of-function mutations. They are referred to as proto-oncogenes until they are mutated, at which time they are called oncogenes. The activation of these genes can occur through point mutations, gene amplification, or chromosomal rearrangements. A classic example of an oncogene that is commonly mutated in colon cancer is *KRAS*, which encodes a protein that

regulates signal transduction from growth factor receptors; its mutation commonly results in increased signal transduction pathway activity and subsequent cell proliferation (see Fig. 1). Oncogenic mutations in *KRAS* occur in codons 12, 13, and 61 and result in loss of GTPase activity of the protein, which results in it always being in an active conformation.

Tumor suppressor genes, on the contrary, are genes that normally regulate a variety of processes that maintain normal tissue homeostasis and cell growth. The loss of function of tumor suppressor genes is the key event that contributes to tumor formation. Usually, a tumor suppressor gene will show inactivation of both alleles in cancers. This principle is known as Knudson's two-hit hypothesis and postulates that biallelic inactivation of a tumor suppressor gene is necessary to eliminate function of the gene. Mechanisms through which this can occur include genomic DNA deletion, also known as loss of heterozygosity (LOH), biallelic somatic mutations, and aberrant DNA methylation. Examples of tumor suppressor genes include *TP53, CDH1* (the gene for E-cadherin), and *APC*. Each one of these genes regulates normal cell growth in a specific manner. For instance, E-cadherin is a membrane-associated calcium-dependent homophilic protein that regulates cell:cell adhesion and cell polarity. Many tumors, including diffuse gastric cancer and prostate cancer, show mutational inactivation or transcriptional silencing of *CDH1*, which is believed to cause enhanced tumor cell motility and invasiveness.

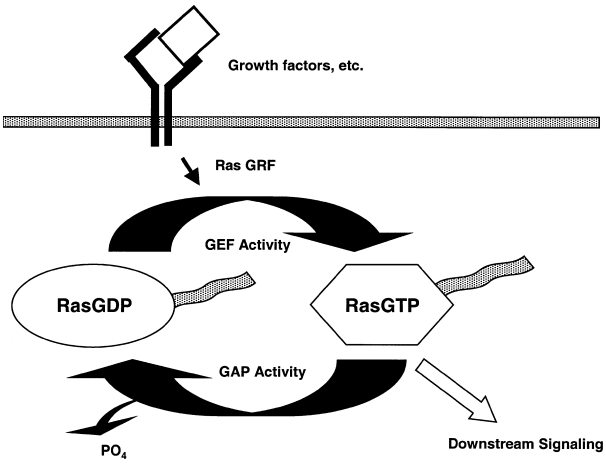

FIGURE 1 Schematic diagram of activation of ras. Ras is activated by phosphorylation of GDP secondary to activation of one of several different pathways, such as the mitogen-activated protein kinase pathway. The phosphorylated ras can then transmit the signal to downstream signaling proteins, which eventually mediate cell proliferation. Ras has endogenous GTPase activity that normally restores it to the inactive state. Mutations in codons 12 and 13, which are the most common type of mutation observed in colon cancer, do not have GTPase activity and result in a constantly activated ras. GRF, GTPase-releasing factor; GEF, guanine nucleotide exchange factor; GAP, GTPase-activating protein.

There is at least one additional category of genes that can be considered to have a discrete role in carcinogenesis. This class of genes includes genes that encode proteins that regulate DNA fidelity, and they have been referred to as DNA caretaker genes. Their inactivation is believed to contribute to the hypermutable state observed in most cancer cells that leads to genomic instability. A classic example of a DNA caretaker gene is the mutation mismatch repair gene, *MLH1*. The product of *MLH1* is one member of a class of proteins called mutation mismatch repair proteins, which correct base–base mismatch and insertion–deletion loop errors that occur during DNA replication. *MLH1* inactivation results in a form of genomic instability called microsatellite instability, increasing the mutation rate up to 1000-fold in expressed sequences. Microsatellite instability results in frameshift mutations in a number of tumor suppressor genes that carry microsatellite sequences in coding regions of the genes, including *TGFBR2, MSH3*, and *IGF2R* (see Fig. 2). Other DNA repair genes that are inactivated in cancers include *MGMT*, which encodes O^6-methylguanine DNA methyltransferase; *ATM*, which causes ataxia–telangiectasia; *FANCA*, which causes Fanconi anemia, *BLM*, which causes Bloom syndrome; and *CKN1, XPA* (causing Cockayne syndrome and xeroderma pigmentosa 1, respectively), and other members of the mutation mismatch repair family, such as *MSH2* and *MSH6*. These genes encode proteins that regulate a variety of DNA repair processes, such as pyrimidine dimer excision (e.g., *XPA*), DNA cross-linking repair (e.g., *FANCA*), and DNA alkylation repair (e.g., *MGMT*).

MULTISTEP MODEL OF CANCER FORMATION

It is well appreciated that cancer cells typically contain hundreds of mutations. In fact, it has been shown that an average cancer may even have up to 11,000 mutations/genome. The carcinogenesis process, though, is initiated by the occurrence of a single mutation in a critical gene in a stem cell. The likelihood of such an event occurring during a cell division at a particular genetic locus is low, approximately 10^{-10}, which means that only 1 cell in 10 billion is mutated per cell division. Thus, it is only as a result of the large number of stem cell divisions that occur every day

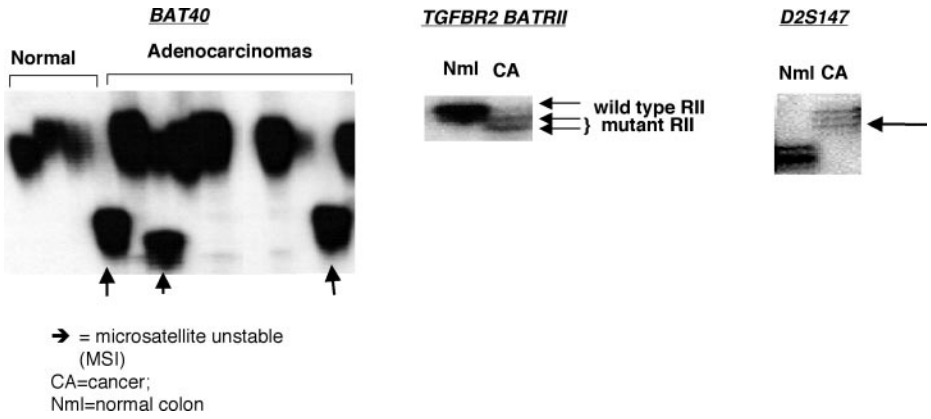

FIGURE 2 Representative example of microsatellite instability analysis at *BAT40*, *TGFBR2 BATRII*, and *D2S147*. Microsatellite instability is most commonly demonstrated by a polymerase chain reaction-based method that generates labeled products amplified from different microsatellite loci, e.g., *BAT40*. The labeled products are subjected to polyacrylamide gel electrophoresis and then visualized. The unstable loci are identified because of their size difference from the normal loci. In this example, the polymerase chain reaction product has been end-labeled with [^{32}P-]ATP and visualized with autoradiography. The microsatellite unstable loci (arrows) are recognized by their size difference from the normal tissue loci.

(approximately 10^{12}/day) that mutations of DNA can have any consequence. Indeed, even though it is estimated that most adult humans have mutated cells inside of them, these people do not have cancers because of the multiple regulatory mechanisms in operation at the cellular level that prevent functional mutations from having a transforming effect on the cells. However, over time, these stem cells can sequentially acquire additional mutations that can eventually overcome these regulatory mechanisms. The exact number of mutations needed to form a cancer cell is not known, but it appears from studies of colon cancer that at least five mutations are needed. Thus, in light of the low rate of DNA mutation and the need for multiple mutations in crucial tumor suppressor genes and oncogenes, it becomes clear that forming a cancer is not a simple process. Furthermore, for a cancer to form, the initial mutations must be coupled to cell proliferation and must promote the clonal expansion of the cells. The clonal expansion is believed to be important in the tumorigenesis process because it creates a cadre of cells that have one mutation in either an oncogene or tumor suppressor gene that can then acquire additional mutations that favor progression to a frank cancer. This process of serial mutations coupled with subsequent waves of clonal growth of the mutant cells is believed to generate a recognizable precancer phase that precedes the appearance of frank carcinomas. For example, in colon cancer, it has been shown that a precancer phase (colon adenoma) usually precedes the cancer phase (colon adenocarcinoma), and that this precancer phase progresses through at least two histological stages before becoming a cancer. Furthermore, this adenoma–carcinoma sequence has easily recognized histologic phases that are accompanied by specific genetic alterations, which presumably drive the cancer formation process (see Figs. 3 and 4). Thus, the carcinogenesis process follows the principles of Darwinian evolution, with cells that acquire mutations that promote their proliferation outcompeting other cells in the precancer. The cancer cells are those cells that show the highest level of reproductive fitness, which at the cellular level is measured by cell proliferation. A dramatic example of this process is the development of cancer cell lines that are used in laboratories around the world. The vast majority of these cell lines, such as HeLa cells, which is a cell line derived from a cervical cancer, or HCT116, a colon cancer cell line, have even outlived the individuals from whom they were derived. Thus, from an evolutionary perspective at the cellular level, these cancer cells have been highly successful.

The concept of multistep carcinogenesis has been most clearly shown in the context of cervical cancer and colon cancer formation, but is likely true of all cancers. Important implications of this model of cancer formation are as follows: (1) there is a precancer phase that may be more amenable to treatment because the cells

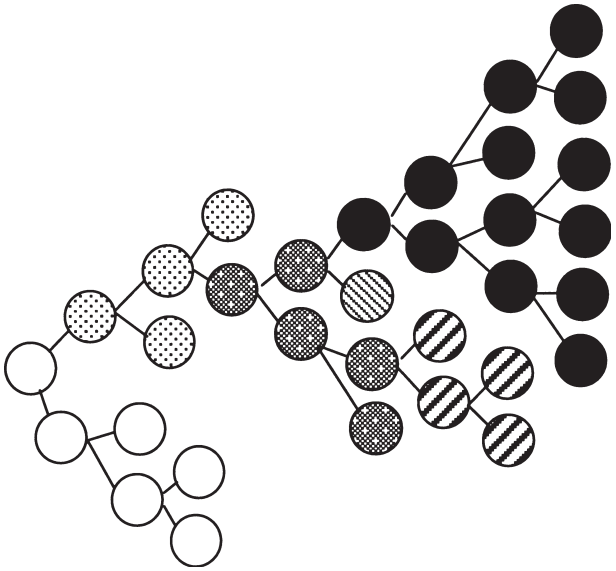

FIGURE 3 Multistep carcinogenesis and Darwinian evolution of cancer. The circles represent cells, and each cell division is shown as two cells to the right of the parent cell, connected to it by lines. The clonal evolution occurring during the cell proliferation is shown by the acquisition of new patterns, representing the acquisition of new genetic makeup or epigenetic alterations that favor tumor cell growth. It can be appreciated that some clones in the cell mass stop proliferating secondary to lethal mutations, whereas others proliferate better than the others do.

have not become as independent of the regulatory mechanisms as they will be when they become frank cancer cells and (2) there may be multiple parallel evolutionary paths for individual cancers as well as for cancer cell clones in a single cancer. Indeed, the phenomenon of intratumoral genetic heterogeneity has been appreciated indirectly by our limited ability to treat most cancers effectively. The polyclonal nature of tumors combined with their Darwinian behavior makes them very effective at acquiring resistance to most chemotherapeutic agents. Furthermore, many cancers, such as Hodgkin lymphoma, have a bimodal age distribution for peak incidences of disease consistent with the idea that there are at least two independent "evolutionary" pathways through which cancers can arise (see Fig. 3). Some of the central biological effects of these mutations of tumor suppressor genes, oncogenes, and DNA caretaker genes on the promotion of tumor formation will be assessed further in the following discussions.

REGULATION OF CELL GROWTH

The mechanisms that control cell division and cell cycle control in dividing cells are highly conserved and are often abnormally regulated in neoplastic cells. Furthermore, a variety of mutations in the genes that govern the cell cycle have been found in many different cancers, providing further evidence that deregulation of cell cycle control contributes to cancer formation. The cell cycle is classically divided into four phases, G_1, S, G_2, and M, and cells not in any one of these phases are in G_0, a resting state. Cells begin dividing by progressing from G_0 to G_1 (gap 1), at which time cell growth occurs, and the cell "determines" if it is ready to initiate DNA synthesis. The cell must transition through a critical point in the cell cycle, called the restriction checkpoint, in order to move from G_1 to the next phase, S. Once the cell passes the restriction checkpoint, DNA synthesis is initiated and the genomic DNA of the cell is replicated. The DNA replication process involves the unfolding of the chromatin and nucleosome complexes and the recruitment of DNA polymerases and primases, DNA helicases, single-strand binding proteins, and topoisomerases to replicate the DNA efficiently at a rate of approximately 50 nucleotides/second. After the DNA is replicated, the cell cycle transitions to G_2 (gap 2), during which the fidelity of the DNA is determined and replication errors are corrected. The cell then must go through a second restriction point, the G_2/M restriction checkpoint, in order to enter M phase and undergo mitosis, which is the process of the replicated chromosomes physically separating into two nuclei and the cytoplasm undergoing cytokinesis. The transitions from G_1 to S and G_2 to M are tightly regulated in order to ensure the orderly proliferation of cells.

The checkpoints are regulated by a family of serine/threonine protein kinases called cyclin-dependent kinases (cdks) and kinase-associated proteins called cyclins. The activation of the cdks is dependent on the cyclins, the levels of which fluctuate throughout the phases of the cell cycle. In addition, proteins that activate the cdks [cdk-activating kinases (CAKs)], phosphatases that remove inhibitory phosphates (cdc25), and cdk inhibitors (p15, p16, p18, p19, p21, p27, and p57) all play essential roles in regulating cell cycle progression and cell division. Finally, the regulation of passage through the G_1/S checkpoint is usually dependent on the phosphorylation status of the nuclear phosphoprotein, retinoblastoma (Rb). Rb binds transcription factors E2F and DP1 in a phosphorylation-specific manner, resulting in their inactivation. The cdk–cyclin complexes can phosphorylate Rb, causing the release of E2F, which can then act as a transcription factor for genes that drive cell cycle progression into S phase. A second pathway regulated by p53 can interact with the Rb pathway to ensure the fidelity of DNA

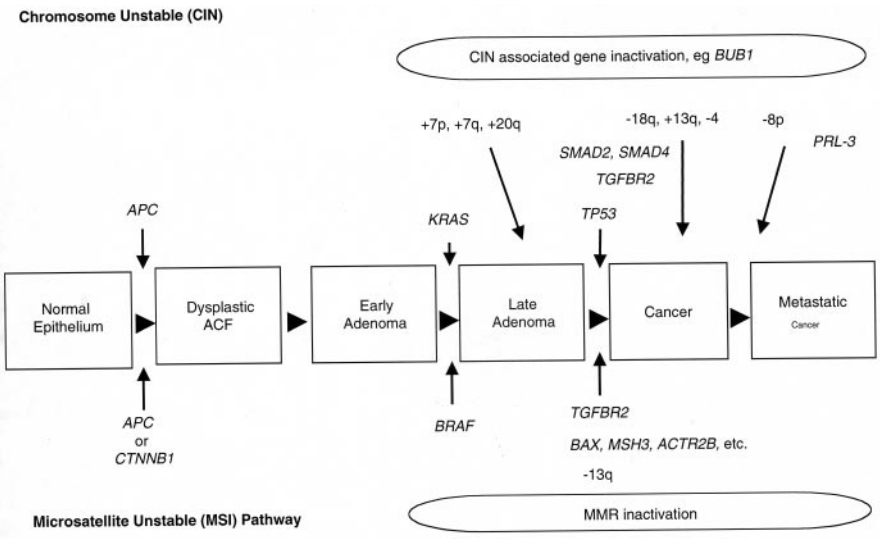

FIGURE 4 An example of multistep carcinogenesis. A schematic representation of the colon adenoma–adenocarcinoma sequence indicates the different stages of colon cancer progression, from the benign neoplasm stage (adenoma) to the malignant neoplasm (cancer). Different patterns of genetic alterations can be identified in colon cancers, depending on whether they display microsatellite instability or chromosome instability (CIN). Microsatellite instability occurs when the mutation mismatch repair (MMR) system is inactivated either through mutations or epigenetic alterations. ACF, Aberrant crypt foci. From Grady (2002). replication by preventing transition through the G_1/S restriction point if DNA damage is present.

Cancers have been found to carry activating mutations in the cdks [e.g., *CDK4* mutations in melanomas, cyclin D1 (*CCND1*) overexpression in B cell chronic lymphocytic leukemia secondary to a t(11;19)(q13;p13) chromosomal translocation], inactivating mutations in the cdk inhibitors (*CDKN2A*/p16 mutations in melanomas), and mutations in *RB1*. In addition, many other genetic alterations in tumor suppressor genes and oncogenes have been shown to directly result in altered expression and function of the cyclin-associated proteins.

REGULATION OF CELL DEATH

In addition to mutations in genes that regulate cell proliferation, cancers also commonly carry mutations in genes that regulate cell death. The deregulation of the mechanisms that regulate cell death is important in cancer formation because the maintenance of homeostasis in tissues not only depends on the regulation of cell proliferation, but also on the regulation of cell death. Programmed cell death, also known as apoptosis, is an important mechanism through which organs maintain an appropriate tissue mass and organization. For example, intestinal epithelial cells undergo apoptosis as they reach the luminal surface and are consequently shed. This process, in conjunction with proliferation, maintains the normal villus/crypt architecture in the epithelial layer. Tumor cells are often resistant to apoptosis, and this evasion of apoptosis appears to play a significant role in the clonal expansion of tumor cells and in the ultimate formation of cancers.

Virtually all normal cells are susceptible to apoptosis and can be induced to undergo this process by a variety of different physiologic signals, including hypoxia and cytokine exposure [e.g., transforming growth factor-β (TGF-β), tumor necrosis factor α (TNFα)]. These signals trigger a series of well-orchestrated events that disrupt cellular membranes, degrade the cytoplasmic and nuclear cytoskeletons, and then degrade chromosomes and fragment the DNA. The proteins involved in mediating apoptosis can be roughly divided into sensors and effectors. The sensors detect alterations in the extracellular environment [e.g., interleukin-3 (IL-3) binding to IL-3R] and/or the intracellular environment, and, if appropriately cued, trigger the effectors, which consist of a family of proteases called caspases as well as proteins that ultimately regulate mitochondrial release of cytochrome c and effect mitochondrial membrane potential states. Proteins that play a role in this process

include members of the Bcl-2 family, including Bax, Bid, Bcl-XL, Bcl-W, and Bim, and APAF1. The evidence to date suggests that there are multiple, redundant regulatory and effector components involved in apoptosis.

Cancer cells acquire resistance to apoptosis through an array of different mechanisms. One of the most frequent means through which the apoptotic machinery is deregulated is through *TP53* mutations, which occurs in approximately 50% of all cancers. p53 normally plays a central role in mediating apoptosis in response to genotoxic stress. Another common mechanism through which cancers deregulate apoptosis is via disruption of the phosphatidylinositol 3-kinase (PI 3-kinase)/Akt pathway, which regulates antiapoptotic survival signals and frequently plays a role in preventing apoptosis in a significant portion of cancers. For example, *PTEN*, a gene that encodes for a protein that inactivates Akt, is commonly mutated in a variety of cancers, causing increased PI 3-kinase/Akt signaling pathway activity. It is likely that virtually all cancers have acquired genetic or epigenetic alterations that mitigate against apoptosis.

GENOMIC INSTABILITY

Although it is now widely appreciated that cancer is a disease that results from genetic alterations that deregulate cell proliferation, apoptosis, and senescence, the mechanisms responsible for the acquisition and accumulation of these gene alterations are less well understood. Another apparently fundamental process in cell behavior that is altered in virtually all cancers is the maintenance of DNA fidelity or genomic stability. The role of genomic instability in the process of cancer formation has been an area of investigation since 1914, when Theodor Boveri postulated that cancer cells might be aneuploid. In 1993, Aaltonen *et al.* identified a form of genomic instability called microsatellite instability (MSI) in colon cancers arising in people with the cancer family syndrome, hereditary nonpolyposis colon cancer (HNPCC); these individuals have germ-line mutations in the mutation mismatch repair (MMR) genes, *MLH1* or *MSH2*, giving further support to the concept that instability of genomic DNA plays an important role in carcinogenesis. This discovery of MSI in HNPCC colon cancers provided evidence for the mutator phenotype hypothesis proposed by Loeb in 1974. This hypothesis argues that for potential tumor cells to acquire the number of mutations needed to attain a malignant state, they must have a higher than normal mutation rate, which would presumably occur through inactivation of the mechanisms that normally regulate DNA fidelity. In fact, if one assumes the known non-germline mutation rate of approximately 10^{-8}, it is impossible for a cell to accumulate enough gene mutations during a human lifetime to acquire a malignant phenotype. However, the role of genomic instability as an integral mechanism in cancer formation is not universally accepted. Others have concluded that the genetic events observed in cancer can occur under normal mutation rates, without the need to invoke genomic instability, as long as the normal mutation rates are coupled with rounds of clonal expansion that select for gene alterations that promote tumor formation. Nonetheless, despite the controversy over the exact role of genomic instability in colon tumorigenesis, a wealth of data generated over the past 6–8 years has provided significant indirect support for the concept that genomic instability is a common mechanism that plays a central role in the formation of most, if not all, cancers, including cancers of the gastrointestinal system. This loss of genomic stability appears to occur very early in the process of cancer formation and to play a central role in generating a hypermutable state that leads to the accumulation of enough mutations to transform a cell.

Several forms of genomic instability can be observed in cancer in general. Lengauer *et al.* proposed four major categories of alterations: (1) subtle sequence changes, including base substitutions, deletions, or insertions, and microsatellite instability, (2) alterations in chromosome number (aneuploidy, also termed chromosomal instability), (3) chromosome translocations, and (4) gene amplification. The first two categories occur commonly in colon and stomach cancers. The genome of colon cancers, like many solid tumors, is often marked by a complex pattern of chromosome translocations that appears nearly random. This form of genomic instability, "translocation instability," is likely mediated by the same mechanisms that cause aneuploidy, but its role in colon tumorigenesis is still being defined. Gene amplification occurs rarely in colon cancer and thus does not appear to be an important process in colon cancer formation.

SIGNALING PATHWAYS AND NETWORKS IN CANCER FORMATION

As the signaling pathways of many of the growth factor-coupled receptors, integrin receptors, etc. have been elucidated, it has become appreciated that the ultimate biological effects of mutations in cancers are not only a result of the deregulation of the function of the single gene products, but also the result of disruption of the signaling pathway in which the gene products operate.

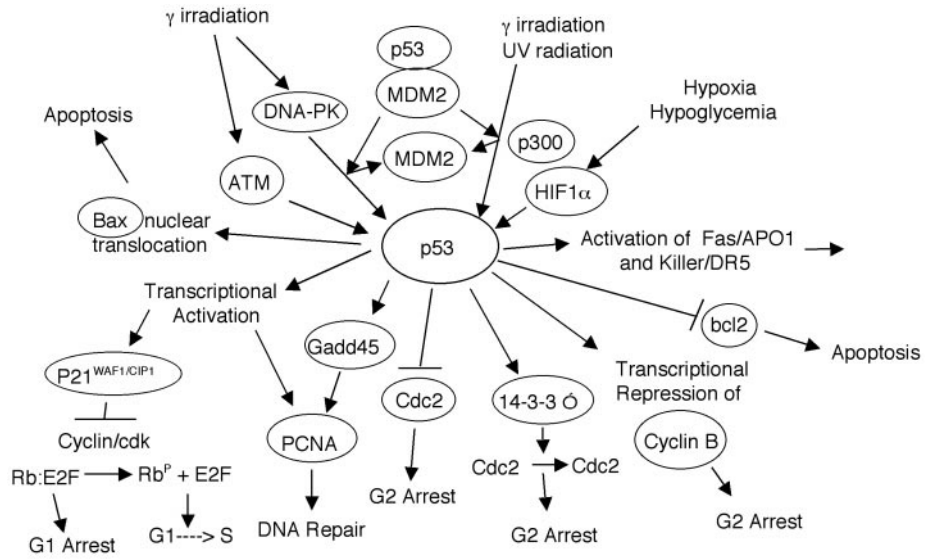

FIGURE 5 Protein network involving p53. p53 interacts with a variety of proteins on exposure of cells to genotoxic events, such as ultraviolet (UV) radiation. These protein–protein interactions result in the phosphorylation and activation of p53, which then either transcriptionally regulates other genes, such as the gene for proliferating cell nuclear agent (PCNA), or directly interacts with the proteins to regulate cell cycle progression or apoptosis. Only a few representative pathways and p53-interacting proteins are shown.

In addition, the multiple mutations in cancers appear to cooperate through effects on these pathways to alter the output of the networks of signaling pathways. Thus, it is now well recognized that cancers result from the mutation of oncogenes and tumor suppressor genes at least in part because these mutations result in the disruption of signaling pathways that regulate cell proliferation and apoptosis. Indeed, it is not uncommon to observe a specific signaling pathway deregulated in a specific cancer type through the inactivation of one of a variety of different members of the signaling path. For instance, in colon cancer, the TGF-β signaling pathway has been shown to be disrupted through mutations of the TGF-β receptor type II (*TGFBR2*), mutations in postreceptor signaling elements (*SMAD2* and *SMAD4*), or up-regulation of pathway inhibitors such as Smad7. Similarly, deregulation of the Wnt signaling pathway can occur through mutations in *APC* or *CTNNB1* (β-catenin), and mutations in one or the other of these genes appear to be nearly universal in colon cancers. Furthermore, the deregulation of these signaling pathways has a multitude of indirect effects, because these pathways also appear to interrelate at multiple levels in the cell, resulting in networks of protein–protein interactions. These networks are often affected in cancers in ways that result in a common effect on target proteins, such as overexpression *CCND1*/cyclin D1. For example, *TP53*, a tumor suppressor gene that is commonly mutated in cancers, interacts with a variety of proteins both in regard to its own regulation and in regard to the regulation of downstream proteins. These effects ultimately regulate cell cycle progression and apoptosis. Consequently, *TP53* mutations have both direct and indirect effects that promote tumorigenesis (see Fig. 5). As our understanding of these signaling pathways and networks improves, our understanding of the global impact of the mutations of different genes on the molecular biology of the cells and cancer formation will improve.

SUMMARY

In general, cancer arises through a complex process of mutagenesis of oncogenes and tumor suppressor genes, followed by clonal expansion of the mutant cells. As a result of the serial acquisition of mutant tumor suppressor genes, oncogenes, and DNA caretaker genes, normal cells transform through a multistep process into malignant cells, resulting in cancer. These gene mutations ultimately lead to cancer formation because they disrupt the regulation of fundamental cellular processes of proliferation, programmed cell death, senescence, and maintenance of DNA fidelity.

Yeast species of genus *Candida* are the most common etiologic agents causing fungal infections of the gastrointestinal tract. Numerous species are reported and, though *Candida albicans* predominates, it is not rare to find Candida parapsilosis and *Candida tropicalis*. Other species are less commonly isolated and can differ in their susceptibility to typical therapeutic antifungals, including the fungistatic azoles, the fungitoxic polyenes, and caspofungin (Table I). Even in species that have been reported as being susceptible, isolates with resistance to azole antifungals, especially fluconazole, are being reported more commonly. Though there are some differences reported in the virulence of *Candida* species (for example, *C. tropicalis* appears to be more invasive than *C. albicans* in neutropenic mice), the diseases produced by the different species are very similar.

GROWTH PATTERNS OF *CANDIDA ALBICANS*

Candida albicans has a variety of morphological forms. It may be found growing as single cells in the form of a budding yeast. It may also grow in a filamentous morphology (Fig. 1). The most invasive form of the fungus has been associated with the filamentous form, but in most situations a mixture of morphological forms is found. Switches between these different morphologies may be necessary to allow both colonization of new epithelial surfaces and release of new cells from colonized epithelium. Indeed, experiments show that epithelial cells tend to bind to the filamentous forms more strongly than to the budding yeasts. The chlamydospore, a morphological form that is produced is culture, is helpful in identifying *C. albicans*. A similar structure has been reported within the intestinal tissues of immunosuppressed mice infected with *C. albicans*. These chlamydospore-like cells show a differential staining similar to that found for chlamydospores produced *in vitro*. Chlamydospores are typically considered to

be "resting spores," or resistant structures; they might allow the fungus to survive during antifungal therapy and to later recolonize the gastrointestinal tract. Almost never reported in humans, this may be because they have been overlooked or because they are formed only under unusual circumstances. For example, chlamydospores have been detected in bronchoalveolar lavage fluid from one AIDS patient.

PREDISPOSITION AND TISSUE DAMAGE

Candidal diseases vary in their presentation and are significantly modified by predisposing factors in the patient. Frank invasion through the gastrointestinal wall, followed by dissemination of *Candida* via the blood and subsequent invasive infection of other areas of the body, such as the kidneys, is typically only seen when the defenses provided by neutrophils are absent or greatly diminished. This can be the situation when the patient has received cytotoxic therapy for certain cancers or in preparation for stem cell or bone marrow transplantation. High doses of steroids or drugs that cause profound neutrophil dysfunction may also predispose invasive disease. In contrast, when there is adequate neutrophil function, any disease is largely restricted to the mucosal tissues of the gastrointestinal tract. Even so, the overgrowth of the yeasts leads to inflammation and significant discomfort and the disease may spread to adjacent regions, including the oropharynx, the edges of the mouth, and the skin surrounding the anus. All these sites become painful and inflamed. This condition is fairly common in patients with diabetes or with T cell dysfunctions, including AIDS, and it can be responsible for severe diaper (nappy) rash in infants. Candidiasis of the oral mucosa was one of the first signs used to define AIDS; the patients may develop such extensive inflammation of the oral mucosa and esophagus that they find it difficult to eat. In some patients with AIDS, there can be perforations in the esophageal wall. In addition to

morphological switching, production of extracellular phospholipase and proteinase appears important for allowing tissue invasion by *C. albicans*. Complement plays an important role in the induction of inflammation; not only does the yeast activate the alternative pathway directly, but, because antibodies to *C. albicans* cell wall mannoproteins are present in all persons, activation via the classical pathway can also occur.

YEAST MICROFLORA IN HUMANS AND ANIMALS

It can be difficult to prove that some *Candida* species are causes of gastrointestinal infections due to their presence on healthy gastrointestinal mucosa. The microbial flora associated with the gastrointestinal tracts of a large number of different mammals, including aquatic mammals, birds, amphibians, and reptiles, includes *C. albicans* and, most likely, its sibling species *Candida dubliniensis* which until recently was not distinguished as a separate entity. Usually frank invasion of tissues needs to be demonstrated via histology before it is certain that *Candida* is the cause of disease (Fig. 1).

OTHER GASTROINTESTINAL DISEASES CAUSED BY FUNGI

In addition to infections, fungus-induced disease of the gastrointestinal system can be a result of exposure to fungal allergens and toxins, including the mycotoxins, ergot, and mushroom toxins. In persons deficient in trehalase, the trehalose disaccharide found in mushrooms can produce symptoms that are similar to those associated with lactose intolerance. Unusually, drunkenness may follow ingestion of food by persons in which a gastrointestinal stenosis has occurred, because yeasts can produce ethanol via fermentation during digestion.

Carbohydrate and Lactose Malabsorption

carbohydrate intolerance Clinical symptoms induced by the ingestion of specific forms of carbohydrate (e.g., lactose intolerance, sucrose intolerance, fructose intolerance) or carbohydrates in general.

carbohydrate malabsorption Poor absorption of any given carbohydrate; detected by specific testing (e.g., lactose absorption test, lactose breath test).

lactase deficiency Very low or absent lactase activity; determined by assay of an intestinal biopsy sample (a similar definition holds for deficiency of sucrase or maltase-glucoamylase)

milk intolerance Clinical symptoms induced by the ingestion of milk; can be due to either lactose intolerance or milk protein allergy.

Carbohydrate digestion reduces complex nutrients into smaller components that are suitable for absorption. Starch digestion is accomplished in two phases—an initial intraluminal phase mediated by salivary and pancreatic amylase and a mucosal phase characterized by surface digestion at the intestinal microvillus membrane. Disaccharides undergo surface hydrolysis followed by uptake of monosaccharides by microvillus membrane carriers. Intolerance to carbohydrates occurs when there is any digestive–absorptive imbalance or when bacterial overgrowth occurs in the small intestine.

PHYSIOLOGY OF CARBOHYDRATE ABSORPTION

Carbohydrate Intake

In infants, carbohydrates account for 35–55% of daily calories ingested, and these are mainly as lactose. As weaning foods are introduced, carbohydrate intake varies and approaches the composition commonly found in adults. The average adult ingests 300 g of carbohydrates per day in approximately the following distribution: 52% of daily calories as starch (mainly cereals and potatoes), 37% as sucrose, 5% as lactose (mainly in milk), and 3% as fructose (in fruit and honey). Glycogen, glucose, and maltose are minor constituents of the diet, and cellulose accounts for approximately 4 g of carbohydrates per day.

Digestion

Salivary amylase initiates starch hydrolysis in the mouth, and this process accounts for not more than 30% of total starch hydrolysis. Because salivary amylase is inactivated by an acid pH, no significant hydrolysis of carbohydrates occurs in the stomach. The intraluminal intestinal phase of starch digestion depends on pancreatic amylase to complete hydrolysis, yielding oligosaccharides of varying lengths. This process is extremely rapid; 75% is completed in the proximal 2.5 feet of jejunum within 10 minutes after passage of starch into the small intestine.

The mucosal phase is characterized by surface digestion of oligosaccharides released by amylase. It also includes hydrolysis of disaccharides (maltose, sucrose, and lactose) by specific disaccharidases (maltase–glucoamylase, sucrase–isomaltase, and lactase). The rates of maltose and sucrose hydrolysis are rapid because these disaccharides are readily cleaved, and the released monosaccharides are rapidly absorbed. Lactose digestion is slower, and hydrolysis is the rate-limiting step for the overall process of absorption. The final uptake of monosaccharides is accomplished by the sodium-dependent glucose transporter (SGLT1).

Colonic Salvage

When carbohydrates are not absorbed by the small bowel, they are passed rapidly into the colon as a consequence of the osmolarity of the intraluminal oligosaccharides, the influx of water, and the increase in motility. In the colon, they are converted to short-chain fatty acids and hydrogen gas by the bacterial flora, producing acetate, butyrate, and propionate. The short-chain fatty acids are absorbed by the colonic mucosa, and this route salvages malabsorbed carbohydrates for energy utilization by colonic epithelial cells. This is a mechanism by which the adult colon salvages

carbohydrate, especially from wheat starch, and the newborn colon salvages lactose. This fermentative process not only conserves nutritionally important carbohydrate, but it also serves as the basis for the breath hydrogen test (discussed later).

CLINICAL PRESENTATION

Symptoms and Signs of Carbohydrate Malabsorption

Considering clinical symptoms induced by the ingestion of carbohydrates, the term "carbohydrate intolerance" is often applied. Symptoms may be induced by the ingestion of carbohydrate (as in cystic fibrosis) or specific sugars (e.g., lactose, sucrose, or fructose). Either nonspecific carbohydrate or specific sugar intolerances (e.g., lactose intolerance) can produce similar symptoms. These include abdominal pain, cramps, or distension; nausea; flatulence; and diarrhea or vomiting. The abdominal pain may be crampy in nature and may be periumbilical or lower quadrant. Borborygmi may be audible. Carbohydrate intolerance generally produces abnormal stools, which are usually bulky, frothy, and watery. In severe cases, mostly in infants, acidosis and dehydration may be a problem. Vomiting after lactose ingestion is often seen in adolescents.

Clinical symptoms may mimic those of the irritable bowel syndrome. Careful clinical history may point to the correct diagnosis; however, this may be established only after appropriate testing.

PATHOPHYSIOLOGY

Several factors account for the variability of symptoms produced by carbohydrate ingestion in people who are intolerant. This pathophysiology is of particular importance in those with lactose intolerance accompanying low lactase activity, but similar mechanisms apply to people with sucrose intolerance and other sugar intolerances, and to those with intraluminal phase defects in carbohydrate digestion. Important factors include the osmolarity and fat content of the food in which the sugar is ingested, the rate of gastric emptying, individual sensitivity to intestinal distension produced by the osmotic load of unhydrolyzed carbohydrate in the upper small bowel, the rate of intestinal transit, and the response of the colon to the carbohydrate load. In general, the higher the osmolarity of gastric contents and the higher the fat content of the diet containing the specific sugar involved, the slower the gastric emptying and the lesser the symptoms induced by the carbohydrate or sugar.

Different individuals appear to have more or less sensitivity to abdominal distension and patients complain differently when ingested carbohydrates stimulate an influx of water into the lumen of the small intestine or the production of gas that leads to distension of the colon. Those with greater tolerance will report fewer symptoms. These subjective responses are difficult to quantify. Intestinal transit is also influenced by the quality of the diet and individual motility patterns. Accordingly, some lactose- or sucrose-intolerant people experience very rapid movement of sugar to the cecum, whereas others have slower motility. Fecal flora are known to adapt to maldigested carbohydrate. Thus, if an offending carbohydrate or sugar (e.g., lactose) is provided slowly over a long period of time in many "intolerant" people, the flora may adapt to the load, and symptoms produced by gas and acid in the colon may be reduced or eliminated. This mechanism of lactose tolerance commonly occurs in people with low lactase levels; this accounts for the discrepancy between measured "lactase deficiency" or "lactose malabsorption" and lactose tolerance.

The term "carbohydrate malabsorption" is generally reserved for those patients for whom the intestinal malabsorption of sugar or complex carbohydrates has been investigated using an appropriate test of absorption (e.g., lactose or sucrose absorption test) or malabsorption (lactose or sucrose breath hydrogen test, or breath hydrogen production after the ingestion of complex carbohydrate). Carbohydrate malabsorption may be due to pancreatic insufficiency with impairment of the intraluminal phase of starch digestion or to disaccharidase deficiency characterized by an absence or very low levels of specific microvillus membrane enzymes (e.g., sucrase or lactase). In very rare circumstances, glucose malabsorption produces clinical symptoms, as in the disorder known as glucose–galactose malabsorption.

DIAGNOSIS OF CARBOHYDRATE MALABSORPTION

Confirmatory Tests

The diagnosis of carbohydrate malabsorption is based on the combination of clinical findings and results of appropriate tests. The presence of low fecal pH or reducing substances indicates carbohydrate malabsorption, but these tests are valid only when carbohydrate has been recently ingested, intestinal transit time is rapid, stools are collected fresh, and assays are performed immediately, and when bacterial metabolism of colonic carbohydrate is incomplete. In general,

carbohydrate malabsorption is best confirmed using more specific tests, especially because sucrose is a nonreducing sugar, will not produce reducing substances, and requires special techniques for detection in stool.

The capacity for sugar absorption can be measured using a lactose or sucrose absorption test. The patient ingests water containing the sugar to be tested and blood glucose is measured before and at 30-minute intervals for 3 hours after a dose of 2 g/kg body weight (maximal dose in adults, 50 g). In adults, the test has a sensitivity of 75% and a specificity of 96%. However, in children, it is cumbersome, invasive, and time consuming, and has largely been replaced by the breath hydrogen test.

The breath hydrogen test really measures carbohydrate (usually lactose or sucrose) nonabsorption (rather than carbohydrate or sugar hydrolysis and monosaccharide uptake). Its sensitivity and specificity are superior compared to absorption tests, and it is simple and noninvasive. The breath hydrogen test can be performed in people of all ages. The dose is customarily 2 g of carbohydrate (or lactose, sucrose, or glucose) per kilogram of body weight (maximum 25 g). Breath hydrogen is sampled prior to the ingestion of sugar and at 30-minute intervals following the ingestion of sugar for 3 hours. It is customary to use a value of $\sim$10 parts per million as normal, comparing samples obtained after carbohydrate ingestion to the baseline value. Values between 10 and 20 parts per million may be indeterminate unless accompanied by symptoms, but values over 20 parts per million are representative of carbohydrate malabsorption. False positive tests are seen with inadequate pretest fasting and when the patient has smoked recently or has swallowed toothpaste just prior to the test. False negative results are obtained when patients have recently used antibiotics or are nonhydrogen producers (approximately 1% of the population). In children less than 5 years of age, an abnormal lactose breath hydrogen test always signifies abnormal intestinal mucosa or bacterial overgrowth, both of which require further definition by appropriate diagnostic tests. A normal breath hydrogen test does not rule out an intestinal mucosal lesion, and it cannot be used to avoid an intestinal biopsy. The glucose breath hydrogen test can be used in the diagnosis of bacterial overgrowth syndromes.

The assay of disaccharidase activity in small bowel biopsy samples establishes the presence of disaccharidase deficiency, and has been used to define populations with low lactase levels and to establish the diagnosis of sucrase-isomaltase deficiency. However, when low lactase activity accompanies intestinal injury, the lesion may be focal or patchy; consequently, intestinal biopsy samples may not yield an abnormal result on disaccharidase assay. Clinical, biochemical, and breath test data must always be compared to obtain the correct diagnosis.

SPECIFIC DISORDERS AND THEIR TREATMENT

Approach to the Patient

Patients who have symptoms and signs of carbohydrate malabsorption should be evaluated in a systematic fashion (Table I). The clinical findings may not immediately suggest a diagnosis of carbohydrate malabsorption, because many patients with this diagnosis actually have a clinical pattern more like that seen in irritable bowel syndrome. Secondary causes for carbohydrate malabsorption must be pursued and appropriate confirmatory tests obtained. When considering lactose malabsorption, especially in infants and young children, the possibility of milk protein allergy must be ruled out.

It is important to remember that lactose malabsorption may occur in patients with other disorders (for example, irritable bowel syndrome or celiac disease). Thus, a lactose breath hydrogen test may be a valuable

Intraluminal Phase Defects

Pancreatic amylase deficiency is seen with hereditary diseases of the exocrine pancreas (particularly cystic fibrosis and Shwachman–Diamond syndrome), pancreatic insufficiency due to alcohol or chronic pancreatitis, and bacterial overgrowth. The majority of patients with cystic fibrosis have absent or low levels of amylase activity; however, their symptoms are usually more attributable to fat than to carbohydrate maldigestion. Shwachman–Diamond syndrome, consisting of exocrine pancreatic insufficiency and hematologic and skeletal abnormalities, is the second most frequent cause of hereditary pancreatic insufficiency in children. Amylase activity is low or absent in such patients, and they have diarrhea and malabsorption. Low amylase levels in adults with pancreatic insufficiency have been well described, and bacterial overgrowth may produce intraluminal fermentation. Amylase deficiency is generally successfully treated by the administration of pancreatic supplements, achieving virtually complete carbohydrate digestion. Elimination of complex carbohydrates from the diet is not acceptable. Bacterial overgrowth syndrome is treated with appropriate antibiotics.

Mucosal Phase Defects

Primary Lactose Intolerance

Primary lactose malabsorption occurs in three clinical settings: (1) genetic lactase decline, (2) developmental lactase deficiency, and (3) congenital lactase deficiency. Genetically controlled lactase decline with lactose malabsorption is the most common form of genetically determined reductions of lactase activity. This clinical finding has been termed "lactase deficiency," although this term is really a misnomer, because a majority of the world's populations develop low intestinal lactase levels during midchildhood (approximately age 5 years). This finding is most prominent in Asian, African, and indigenous populations (Table II). The exact molecular basis of this pattern is unknown, but it has been shown that lactase mRNA content and lactase activity are both extremely low, strongly suggesting that the genetic regulation is at the level of transcription. In striking contrast, peoples of Scandinavian or Caucasian genetic background have a genetically regulated preservation of intestinal lactase activity and a high degree of lactose tolerance as adults. The molecular basis of this phenotype is also unknown. No matter what the genetic background, normal lactase activity is found in all children until about 5 years of age. Lactase deficiency or lactose intolerance detected in children before this age usually indicates an underlying mucosal lesion or bacterial overgrowth syndrome. Recently, genetic polymorphisms in the introns of a gene lying 5′ to the lactase gene on chromosome 2q22 have been associated with lactase persistence or nonpersistence. Similar associations have been found among polymorphisms in the lactase coding region and proximal 5′ untranslated region. The functional significance of these polymorphisms is at present unknown.

There is no evidence that lactase deficiency or lactose malabsorption is a normal part of the aging process. Thus, in the mixed population of Caucasian extraction, the normal aging process does not lead to lactase deficiency. However, alterations in motility, secondary lactase reduction due to medications or to other disorders, or intestinal injury may produce lactose intolerance.

Developmental lactase deficiency is a consequence of gestational age. During fetal development, lactase activity rises late in gestation so that 28- to 32-week premature infants have reduced lactase activity. If they are otherwise healthy, the colon can salvage unabsorbed carbohydrate so that these infants are not nutritionally compromised and do not have diarrhea.

Primary lactase deficiency is characterized by the absence of lactase activity in the small intestine, by normal histology, and by normal levels of other disaccharidases. The disorder has been described mainly in

Finnish populations and is associated with a genetic abnormality in the DNA adjacent to the extended lactase gene, but not in the coding region. This very rare syndrome is associated with diarrhea accompanying lactose ingestion from birth in affected infants. The use of other sugars (e.g., sucrose, fructose) in infant formula leads to elimination of symptoms.

Treatment of Lactose Malabsorption

The treatment of lactose malabsorption includes four general principles: (1) reduction or restriction of dietary lactose, (2) substitution of alternative nutrient sources to avoid reductions in energy and protein intake, (3) regulation of calcium intake, and (4) the use of a commercially available enzyme substitute. When lactose restriction is necessary, the patient must be instructed to read labels of commercially prepared foods, because hidden lactose may be difficult to identify. Table III summarizes the lactose content of selected foods. Complete restriction of lactose-containing foods should be necessary for only a limited period to ascertain the specificity of the diagnosis. Because some patients can tolerate graded increases in lactose intake, small quantities of lactose may subsequently be reintroduced into the diet, careful attention being paid to associated symptoms. Because of its high sugar and fat content, ice cream may be a good way to introduce lactose into the diet. Carefully controlled studies of lactose intolerance have shown that when people complaining of lactose intolerance ingest milk or a control milk containing hydrolyzed lactose, without knowing which sample they ingest, their symptom scores are identical. This indicates an important "anticipatory" component to the symptoms in many people.

Calcium is supplemented in the form of calcium carbonate; tablets such as Tums (Norcliff Thayer, Inc., Tarrytown, NY) or Viactiv (McNeil Nutritionals, Fort Washington, PA) are popular and effective. Standard preparations contain 500 mg of calcium carbonate equivalent to 200 mg of elemental calcium, which is 20% of the United States Recommended Dietary Allowance (RDA) for adults. In infants and young children, liquid calcium gluconate is readily tolerated and available. When complete lactose restriction is recommended, the RDA for calcium should be provided as a supplement. Prolonged lactose restriction predisposes to reduced calcium intake and increases the risk for long-term bone mineral depletion.

Cow milk	9–13 g per 8 oz
Milk sherbet	4 g per 8 oz
Cottage cheese	5–6 g per 8 oz

Commercially available "lactase" preparations are actually bacterial or yeast β-galactosidases. When added to lactose-containing food or when ingested with meals containing lactose, these are effective in reducing symptoms and breath hydrogen values in many people who have low lactase levels and complaints of lactose intolerance. However, these products are not capable of completely hydrolyzing all dietary lactose, and the results achieved in individual patients are variable. Some of the commercial "lactase" preparations are listed in Table IV. LactAid liquid (LactAid, Inc., Pleasantville, NJ) may be added to milk (14 drops/quart), which is then refrigerated overnight before use. The resulting hydrolysis of lactose (which is approximately 90% effective) produces a sweeter taste compared to milk containing lactose. Commercial LactAid products are also sold in most markets in the United States. Lactrase (Kremers-Urban Company, Milwaukee, WI) capsules may be taken orally with lactose-containing foods, as can the other products listed in Table IV, but the individual dose required and responses to individual products must be tested in each patient. It should be noted that "acidophilus milk" is not sufficiently lactose depleted. Live-culture yogurt, which contains endogenous β-galactosidase, is a useful alternative source for calcium and calories, and may be well tolerated by a number of lactose-intolerant patients. However, yogurts that contain milk products added back after fermentation may produce symptoms. Although consumption of yogurt alone by individuals with low lactase activity and lactose intolerance reduces symptoms, consumption of yogurt together with additional lactose does not lead to reduced symptoms.

Sucrose Intolerance

Sucrase–isomaltase deficiency is an uncommon autosomal recessive disorder characterized by very low levels of this microvillus membrane enzyme. The genetic basis appears to be mutations in the gene that lead to alterations in the posttranscriptional processing of the enzyme. Sucrose intolerance presents at different ages. In infants, symptoms may appear when sucrose is introduced into the diet; in younger children, chronic diarrhea may occur, alternating with constipation and confusing the diagnosis. Occasionally, the first manifestations appear in adulthood with complaints

of carbohydrate malabsorption or may mimic irritable bowel syndrome. The diagnosis is most easily achieved by means of the sucrose breath hydrogen test. Treatment is accomplished by restriction of dietary sucrose. Some studies suggest that provision of exogenous sucrase activity ("sacrosidase") using viable yeast cells (*Saccharomyces cerevisiae*) may assist in sucrose tolerance.

Glucose–Galactose Malabsorption

Glucose–galactose malabsorption is a rare, autosomal recessive disorder detected in neonates who develop diarrhea; their stools are acidic and contain fecal reducing substances usually after the first feeding of glucose water (e.g., Pedialyte or similar preparations). The diagnosis in these patients can be confirmed with a flat glucose and a normal fructose tolerance test. Confirmation of the diagnosis can be achieved *in vitro* by measurement of glucose transport in small bowel biopsy or by intraluminal perfusion. Treatment is based on the elimination of glucose and galactose and the use of fructose-containing formula.

Fructose Malabsorption

Fructose malabsorption is an uncommon cause of serious disease. However, the ingestion of large amounts of fructose (particularly in the form of fruit juices) in infants and young children may lead to diarrhea and symptoms of carbohydrate malabsorption because of an ingested load of fructose in excess of the capacity of the small intestine to absorb the sugar. Fruit juice ingestion in infants and young children may produce the syndrome of "chronic nonspecific diarrhea" or "toddler's diarrhea." This can be rapidly reversed by reducing dietary fructose. Fructose content of foods varies, but considerable quantities can be found in figs (31 g/100 g edible portion), dates (24 g), prunes (15 g), and soft drinks containing high-fructose corn syrup (37.5 g/18 oz of soda).

The sugar alcohol of fructose (sorbitol) is not well tolerated by some people. It is poorly absorbed in the small intestine and its transport to the colon may be associated with symptoms of carbohydrate malabsorption. Sorbitol can be found in "diet" products, such as chewing gums (1.3–2.2 g/piece), and "low-sugar" fruits (pears, 4.6 g/100 g dry weight), fruit juices (apple juice 0.5 g/100 g), and carbonated beverages. In the appropriate clinical setting, a search for sorbitol-containing foods in the diet and elimination of offending substances may lead to resolution of symptoms of carbohydrate malabsorption.

Secondary Carbohydrate Malabsorption

Bacterial overgrowth or stasis syndromes may be associated with increased fermentation of dietary carbohydrates in the small bowel. Clinical symptoms of carbohydrate intolerance are often found. The diagnosis may be suspected when a very early peak of breath hydrogen is detected during a lactose, sucrose, or glucose breath test.

Carbohydrate malabsorption frequently occurs after gastrointestinal tract mucosal injury involving villus flattening or damage to the intestinal epithelium. Disorders that often produce this lesion are listed in Table I. When the mucosa is damaged, lactase is usually the first affected disaccharidase, presumably because of its distal location on the villus. Treatment of the primary disorder is mandatory for the return of lactase activity, which often lags behind the return of normal intestinal morphology. Prolonged lactose intolerance, which may persist for months after healing starts, is unique to this disaccharidase, and its biochemical basis is unexplained.

Secondary sucrase-isomaltase deficiency is usually of less clinical significance compared to secondary lactase deficiency. Enzyme activity is not totally lost and usually does not reach the low levels of primary sucrase-isomaltase deficiency; thus, patients tend to tolerate some sucrose intake. Maltase-glucoamylase deficiency is related to the severity of the mucosal lesion and is usually of minimal clinical significance in most patients.

The principles of treatment in carbohydrate malabsorption in patients with secondary disorders are identical to those for the primary disorders, in addition to the treatment of the underlying problem.

Miscellaneous Observations

Patients demonstrating symptoms compatible with the diagnosis of carbohydrate malabsorption, but for whom specific testing fails to reveal an abnormality, may have symptoms related to fiber ingestion. The custom of eating extremely high-fiber foods may predispose some people to symptomatic carbohydrate malabsorption. Flatulence associated with the ingestion of a variety of beans and other vegetables considered to be

"gas producing" is a common complaint. When dried beans are used in food preparation, they can be soaked for 12–24 hours prior to cooking to eliminate sugars not absorbed in the small intestine. This often reduces "gas"-related symptoms.

Patients whose main complaints are increased flatulence may or may not have carbohydrate malabsorption, but they should have this possibility ruled out by appropriate testing. It should be remembered that swallowed air may lead to flatulence as well. However, air swallowing is more often accompanied by excessive belching. The ingestion of large quantities of air may be due to psychogenic factors, to crying in infants, to gum chewing, or to the consumption of carbonated drinks. Appropriate dietary recommendations may lead to resolution of symptoms.

glycosidic linkage Covalent chemical bond between the monosaccharide units of disaccharides, oligosaccharides, and polysaccharides formed by the removal of a molecule of water. The bond is normally formed between the C-1 on one sugar and the C-4 on the other. An α-glycosidic bond is formed when the OH group on C-1 is below the plane of the glucose ring and a β-glycosidic bond is formed when it is above the plane.

oligosaccharide Carbohydrate compound in which monosaccharide units are joined by glycosidic linkages. The term "oligosaccharide" is commonly used to refer to defined structures having three to nine monosaccharide units.

polysaccharide Macromolecule carbohydrate consisting of more than nine monosaccharide residues joined to each other by glycosidic linkages.

Carbohydrates consumed in the diet must be digested and absorbed in the gastrointestinal tract prior to utilization as nutrient energy sources. The processes of carbohydrate digestion and absorption are accomplished by the action of digestive enzymes and carrier proteins with specialized functions and specificities.

INTRODUCTION

Carbohydrates account for 40–60% of the average caloric energy intake in humans. The primary carbohydrates in the human diet are starches, sucrose, and lactose. Starches and complex polysaccharides comprise 60% of the digestible carbohydrates in the average adult Western diet. Sucrose and lactose comprise 30 and 10%, respectively, of carbohydrates in the adult diet. The various carbohydrates must be digested to their monosaccharide components prior to transport across the surface membrane of the absorptive intestinal epithelial cells, enterocytes. The process of carbohydrate digestion (in the case of starches) is initiated by salivary and pancreatic amylase in the lumen of the gut. Digestion is completed by the action of carbohydrate-specific hydrolases bound to the brush border membrane of the absorptive enterocytes lining the villi of the small intestine. The digestive and absorptive pathways for the three major nutrient carbohydrate sources in the human diet (starches, sucrose, and lactose) are described in the following discussions.

Significant amounts of nondigestible carbohydrates are also consumed in the human diet. These carbohydrates consist of nondigestible starches, largely in the form of plant fiber; nondigestible sugars such as stachyose and raffinose present in legumes; and sugar alcohols such as sorbitol and mannitol used as sweeteners. Humans lack digestive enzymes capable of efficiently hydrolyzing these carbohydrates. Thus, these dietary fibers and nondigestible sugars pass through the gastrointestinal tract undigested or are partially digested by enzymes produced by intestinal bacterial flora to yield short-chain fatty acids, hydrogen, carbon dioxide, and methane.

DIGESTION OF STARCHES

Luminal Hydrolysis by α-Amylases

The two major starch polysaccharides in the human diet are amylose and amylopectin. Amylose is a linear chain of glucose molecules linked by α-1,4 glycosidic bonds and accounts for 20% of dietary starch. Amylopectin is a branching chain of α-1,4-linked glucose molecules with an α-1,6 linkage occurring approximately every 20 glucose molecules. Amylopectin accounts for 80% of dietary starch. Glycogen is a polysaccharide found in animal tissues and has a structure similar to that of amylopectin. In order for these complex carbohydrates to be utilized as a nutrient source they must be digested to smaller oligosaccharides and then ultimately must be hydrolyzed to individual monosaccharides. Food starches are present in association with hydrophobic proteins that limit access to enzymes responsible for starch hydrolysis. Prior to consumption, methods of food preparation, such as cracking grains, milling, and cooking, facilitate starch utilization. The process of enzymatic starch digestion is initiated in the lumen of the gastrointestinal tract by the action of α-amylases secreted by the salivary gland and the pancreas. Human salivary amylase (94% identical to pancreatic amylase) tends to be degraded at acidic pH and thus contributes minimally to starch digestion in

the small intestine. Pancreatic amylase is secreted into the intestinal lumen in the duodenum and is the major enzyme of intraluminal starch digestion in adults. In neonates with decreased pancreatic secretion, however, salivary amylase supports a significant amount of starch digestion.

Amylase functions to cleave the internal α-1,4 glycosidic bonds of amylose and amylopectin but is inactive against the α-1,6 linkages in amylopectin and glycogen. The products of luminal starch digestion by amylase are maltose (a glucose−glucose disaccharide), maltotriose (a glucose trisaccharide), and α-limit dextrins. The enzymatic action of the α-amylases on starches is shown in Fig. 1.

Brush Border Membrane Hydrolysis by Oligosaccharidases

The oligosaccharide products of luminal starch digestion are hydrolyzed to glucose monomers by the membrane-bound brush-border digestive enzymes, maltase-glucoamylase, sucrase, and isomaltase (also called α-dextrinase). Maltase-glucoamylase removes single glucose residues from the α-1,4 chains of oligosaccharides, and from maltotriose and maltose. Sucrase-isomaltase is initially synthesized in the enterocyte as a single glycoprotein chain. After insertion in the brush-border membrane, it is cleaved into sucrase and isomaltase units that reassociate noncovalently. Sucrase is capable of hydrolyzing the α-1,4 glycosidic bonds of short oligosaccharides, including maltose and maltotriose. Isomaltase is the only enzyme capable of hydrolyzing the α-1,6 glycosidic linkage in the α-limit dextrins. The free glucose products of oligosaccharidase hydrolysis are transported into the enterocyte as described in the following sections. The pathway for starch digestion is summarized in Fig. 2.

DIGESTION OF DISACCHARIDES

Sucrose and lactose are the major disaccharides in the human diet. These sugars, along with maltose and other disaccharides consumed in minimal amounts, cannot be absorbed across the enterocyte surface membrane intact. Unlike starch digestion, there is no luminal digestion of disaccharides. Rather, they are hydrolyzed to their monosaccharide components by specific brush border membrane hydrolases expressed in the small intestine. Maltase catalyzes the enzymatic hydrolysis of maltose as previously described. Trehalase is a brush border enzyme that specifically hydrolyzes trehalose, a disaccharide found predominantly in mushrooms. The brush border membrane hydrolysis of sucrose and lactose is described in the following section and is summarized in Fig. 2.

Sucrose Digestion

Sucrose, the major carbohydrate in most fruits, is a disaccharide composed of a glucose molecule linked via an α-glycosidic linkage to a fructose molecule. As with the other oligosaccharides, sucrose must be digested to its constituent glucose and fructose monosaccharides prior to absorption across the absorptive intestinal cell membrane. The enzymatic hydrolysis of the

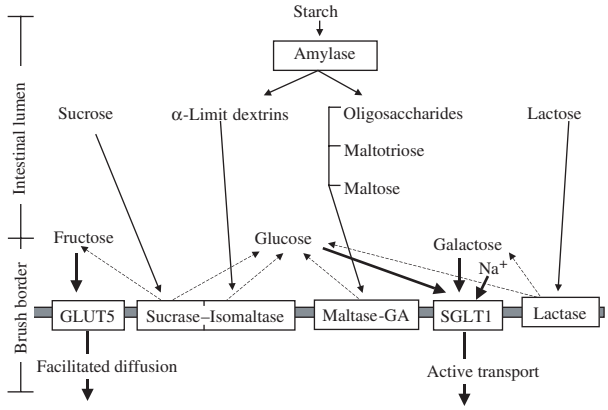

FIGURE 2 Major pathways for digestion and absorption of dietary carbohydrates. GA, glucoamylase. Adapted from Gray (1975).

α-glycosidic bond in sucrose is mediated by the intestinal epithelial cell surface membrane-bound enzyme, sucrase. Sucrase is a membrane-bound glycoprotein associated with the digestive enzyme isomaltase. In most mammalian species, the expression of sucrase-isomaltase is minimal at birth and then is induced dramatically at the time of weaning. In humans, however, sucrase-isomaltase expression is induced prenatally (10–14 weeks of gestation) and is maximal at birth. Such a precocious expression pattern in humans allows for the digestion and absorption of solid sugars prior to weaning in human infants.

Clinical deficiency of sucrase-isomaltase is a rare autosomal recessive condition that results in the inability to digest and absorb dietary sucrose. The condition becomes manifest during infancy on the introduction of sucrose in fruits and juices. The inability to digest the sugars results in signs and symptoms of malabsorption, including diarrhea, increased gas production, and abdominal distension. Treatment for congenital sucrase-isomaltase deficiency consists of avoidance of sucrose in the diet.

Lactose Digestion

Lactose is the predominant carbohydrate in breast milk. The lactose disaccharide consists of a glucose and a galactose molecule linked by a β-1,4 glycosidic bond. The digestive enzyme lactase-phlorizin hydrolase (β-galactosidase) catalyzes the hydrolysis of lactose to yield glucose and galactose, which can then be absorbed across the intestinal mucosa membrane. Lactase-phlorizin hydrolase, lactase, is a brush border membrane protein with enzymatic activity against glycolipids as well as lactose. The lactase-phorizin hydrolase gene is specifically expressed by the small intestinal enterocytes of most mammals. Lactase enzyme activity is maximal in preweaned mammals and declines markedly during maturation. The maturational decline in lactase activity renders most of the world's adult human population intolerant of milk and other dairy products. Lactose present in dairy products cannot be digested in the small intestine, due to the reduced lactase level, and instead is fermented by bacteria in the distal ileum and colon. The fermentative products result in symptoms of diarrhea, gas bloat, flatulence, and abdominal pain. Treatment consists primarily of avoiding lactose-containing foods. Lactase enzyme supplements may be helpful. In a minority of adults, high levels of lactase activity persist in adulthood. This hereditary persistence of lactase is common primarily in people of northern European descent and is attributed to inheritance of an unidentified autosomal-dominant mutation that prevents the normal maturational decline in lactase expression. Linkage disequilibrium and haplotype analyses in humans have recently allowed for identification of two genetic variants located upstream of the human lactase gene that are associated with hereditary lactase persistence.

MONOSACCHARIDE ABSORPTION

Glucose and Galactose Transport

The products of luminal and membrane-bound hydrolysis of starches and sugars are the constituent monosaccharides, glucose, galactose, and fructose. These monosaccharides, present at the enterocyte brush border membrane, must be transported across both the apical and basolateral enterocyte membranes and into the portal circulation. The apical membrane absorption of glucose and galactose is carried out predominantly by a Na^+-dependent active transport mechanism in which each monosaccharide is transported along with two Na^+ molecules (see Fig. 2). The sodium/glucose cotransporter, SGLT1, has been characterized. SGLT1 is a 664-amino-acid transmembrane protein expressed on the apical surface of intestinal epithelial cells. The protein has 12 membrane-spanning domains. Sodium molecules enter the enterocyte via an electrochemical gradient that is maintained by Na^+, K^+-ATPase (the sodium pump) that extrudes sodium molecules out the basolateral surface. By coupling transport to the sodium gradient, the glucose and galactose molecules are able to be transported actively into the cell. Glucose and galactose are transported out of the enterocyte into the portal circulation by the Na^+-independent glucose transporter, GLUT2, located on the basolateral membrane.

Congenital defects of the SGLT1 protein resulting from missense and nonsense mutations have been reported as rare clinical causes of severe glucose–galactose malabsorption in infancy. Such children present in the neonatal period with severe, watery, acidic diarrhea while consuming breast milk or standard infant formulas. The symptoms of diarrhea and dehydration are life threatening. Treatment consists of rehydration and initiation of a glucose- and galactose-free diet. Because fructose is tolerated, most of the carbohydrate initially can be given as fructose.

Fructose Transport

The fructose monosaccharide is transported across the intestinal brush border membrane via a Na^+-independent facilitated diffusion mechanism. GLUT5 is a 501-amino-acid transmembrane protein that transports fructose and glucose molecules. Fructose

is transported from the enterocyte into the portal circulation via the basolateral membrane GLUT2 transporter. Fructose is not as well absorbed as is glucose. Consequently, ingestion of high levels of fructose in the diet can lead to carbohydrate intolerance. In children, drinking excessive amounts of juices high in fructose may result in nonspecific diarrhea and recurrent abdominal pain. In adults, fructose malabsorption has been associated with irritable bowel syndrome.

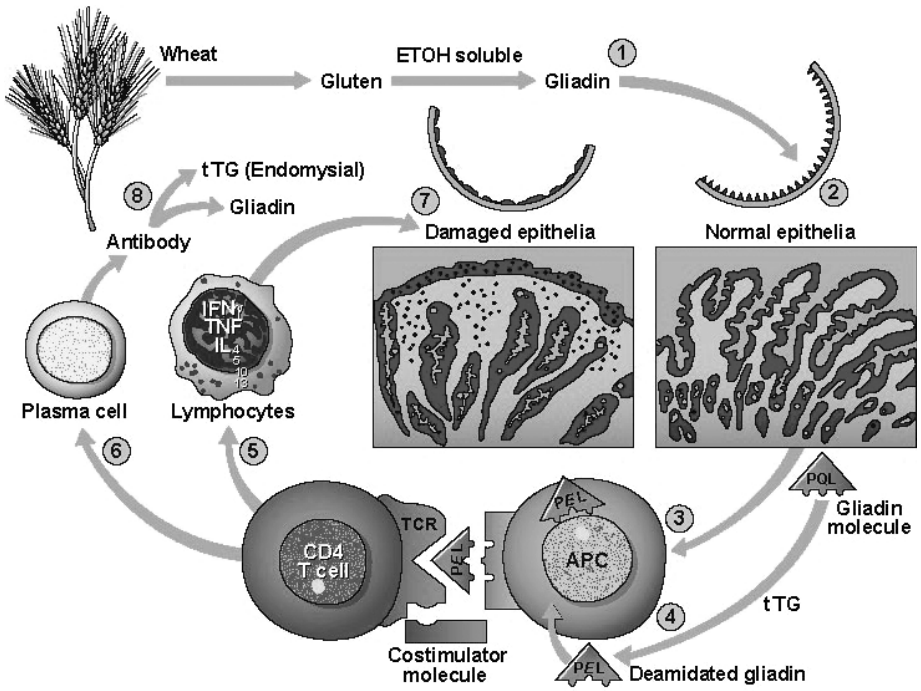

FIGURE 1 The alcohol-soluble gliadin (1) fraction of wheat is highly antigenic. After gliadin peptides are absorbed (2), they are taken up by an antigen-presenting cell (3). The antigen-presenting cell (APC) processes the peptides and presents the gliadin fragments, in conjunction with human leukocyte antigen DQ2 or DQ8, to a T cell expressing T cell receptors (3). Deamidation of the gliadin peptide ligand (PL), which is mediated by tissue transglutaminase (tTG), makes the binding of the ligand to DQ2 or DQ8 stronger by converting the glutamine (Q) in the ligand (PQL) to glutamic acid (E; PEL), inducing a stronger T cell response (4). Activation of T cells leads to activation of lymphocytes (5), which produce a variety of damaging cytokines, and activation of plasma cells (6), which are responsible for the production of antibodies. These actions result in a cascade of effects and ultimately in mucosal damage (7) and antibody production (8). IFN, Interferon ; TNF, tumor necrosis factor; IL, interleukin. methods and better awareness of the disease and its complications.

EPIDEMIOLOGY

Currently, the precise prevalence of CD is hard to predict. CD in the United States is more prevalent than what was initially thought. It was thought that the prevalence of clinically diagnosed CD was 1:300–4500 in parts of Europe and 1:10,000 in the United States. On the other hand, the prevalence in more recent population screening studies ranges between 1:100–500 in Europe and 1:100–200 in the United States. The prevalence of CD is higher in first-degree relatives of patients with CD (close to 10%).

PATHOGENESIS

In genetically susceptible individuals, ingested gluten peptides are presented by the antigen-presenting cells in association with human leukocyte antigen (HLA) DQ2 or DQ8 (Fig. 1). The gluten antigen is presented to T cells expressing α/β T cell receptors, initiating activation and production of lymphocytes, which are responsible for releasing cytokines (e.g., interferon γ and tumor necrosis factor α). Cytokines are thought to be the factors that damage the small intestinal epithelia. The damaged mucosa triggers the release of tissue transglutaminase (tTG), a cytosolic enzyme that deamidates gluten and catalyzes deamidation between gluten–gluten and possibly gluten–tTG; the cross-linking in turn augments the gluten presentation by HLA DQ2 or DQ8. In addition, released cytokines increase the expression of HLA DQ2 on small intestine epithelia, allowing increased antigen presentation to sensitized lymphocytes.

All alcohol-soluble protein components of wheat gluten (gliadins), barley (secalins), and rye (hordeins) are damaging in patients with CD. Rice, corn, and soybean flours are nontoxic. Oats are thought to be safe in most patients.

CLINICAL FEATURES

Children

Symptoms in children usually start after introduction of cereals into the diet, usually after the age of 6 months. Symptoms may include failure to thrive, diarrhea, vomiting, muscle wasting, abdominal distension, abdominal pain, and occasionally constipation. In older children, the disease can present with anemia, rickets, short stature, dental enamel defects, poor performance in school, or behavioral disturbances.

Adults

The disease in adulthood may present as adult onset or may be a clinically silent disease that was present since childhood but produced no symptoms. The most common presenting symptoms in adults with CD are chronic diarrhea and iron-deficiency anemia. Diarrhea may be absent in 50% of patients. Severe steatorrhea is less common and indicates more severe disease. Because of better awareness and test protocols, celiac disease is currently being diagnosed more frequently in asymptomatic patients who are found to have iron deficiency anemia, folate deficiency, or osteoporosis. Other less common features of CD are presented in Table I.

Dermatitis herpetiformis is associated with celiac disease, presenting with intestinal lesions of various degrees of severity in most cases and characterized by blistering skin lesions on the elbows, knees, and buttocks. Intestinal symptoms are not always present when CD presents as dermatitis herpetiformis. The skin disease usually responds well to a gluten-free diet (GFD), although initially dapsone might be needed.

ASSOCIATED DISEASES

CD has been associated with a number of medical conditions, many of which occur with a higher frequency in patients with CD than in the general population. A list of such associated diseases is shown in Table II.

DIAGNOSIS

Small Intestinal Biopsy

The gold standard diagnostic test for CD is a small intestinal mucosal biopsy obtained during upper endoscopy, with multiple biopsies taken from the second or third part of the duodenum. Although on occasion they might give a hint for the diagnosis, flattened or scalloped duodenal folds seen at endoscopy are not specific for CD. The characteristic findings on the biopsy include (1) partial or complete villous atrophy, (2) crypt hyperplasia, and (3) increased intraepithelial lymphocytes and plasma cells. In the past, a diagnostic small intestinal biopsy on a gluten-containing diet followed by complete healing on a GFD, then deterioration on gluten challenge, was required for the diagnosis of CD. Currently, the criteria for the diagnosis of CD require a single biopsy with characteristic findings while on gluten-containing diet, and an unequivocal clinical response to a GFD.

Villous atrophy alone can be found in other diseases of the gastrointestinal tract; when not related to CD, villous atrophy requires different diagnostic methods and treatment. Some of the diseases that can be associated with villous atrophy include cow's milk allergy, lymphoma of the small intestine, autoimmune enteropathy, tropical sprue, and graft-versus-host, disease among others.

The small intestinal lesion of CD usually decreases distally from the duodenum to the ileum, with the first part of the small intestine usually healing last following institution of a GFD. The patient classically improves within a period of a few weeks of starting a GFD, with

histological improvement that might take up to 1 year before complete resolution of the characteristic lesions and return to a normal or near-normal architecture. In the case of refractory celiac disease, there is persistence of symptoms or recurrence of symptoms after initial improvement following institution of a GFD, and persistence of histological damage on small intestinal biopsy. This may be associated with ulceration and can progress to lymphoma.

Serological Markers

Antigliadin Antibodies

Gliadins, the alcohol-soluble fraction of gluten, elicit a strong humoral response that originates in the submucosa. Immunoglobulins of two subclasses (IgA and IgG), or antigliadin antibodies (AGAs), are produced in the small intestine and are used as an adjunct for diagnosis. Their lack of specificity in CD and the development of newer tests have rendered them not useful clinically for specific diagnosis. However, they can be used to follow the response to a GFD. The IgG subclass may help identify CD cases that are associated with IgA deficiency, whereby IgA AGAs, IgA antiendomysial antibodies, and antitransglutaminase are absent.

Antiendomysial Antibodies

Endomysium is a connective tissue protein found in the collagenous matrix of human and monkey tissue. IgA antibodies directed against the endomysium have been found in association with CD. These antibodies are highly sensitive and specific for CD, using both human umbilical cord or monkey esophagus as a substrate. The test is based on immunofluorescence findings of reticular staining when antiendomysial antibody binds to the endomysium. Although highly specific when positive, this binding is still subjective because of variations in interpretation from one laboratory to another. Like IgA AGAs, antiendomysial antibodies will be absent in IgA-deficient patients with CD.

Tissue Transglutaminase Antibodies

Tissue transglutaminase is a cytosolic protein that is released during wounding and serves as a cross-linker of different extracellular matrix molecules. It has been recently found by Diederich that tTG is the autoantigen of CD. IgA enzyme-linked immunosorbent assay (ELISA)-based kits are now available for tTG antibodies, using either human red cell or recombinant tTG.

Test Sensitivity/Specificity

The test sensitivities/specificities for immunoglobulin antigliadin antibodies, tissue transglutaminase, and antiendomysial antibodies (AEMAs) are as follows:

- IgA AGAs: 70–90%/85–94%
- IgG AGAs: 69–85%/88–92%
- IgA tTG: 90–98%/94–98%
- IgA AEMAs: 85–98%/98–100%

Hematologic and Biochemical Findings

Anemia in CD may be secondary to iron, folate, and, occasionally, vitamin B_{12} deficiencies. Anemia with iron deficiency is one of the most common presentations of CD. Low calcium and vitamin D levels can lead to osteopenia and osteoporosis. Leukopenia and thrombocytopenia can be secondary to severe folate deficiency, whereas thrombocytosis is usually seen with hyposplenism. Low vitamin K levels can result in increased prothrombin. Severe malabsorption and diarrhea can be associated with low sodium, albumin, potassium, magnesium, and zinc levels. IgA deficiency is seen in 2–10% of patients with CD. Persistent hypertransaminasemia in a patient with no other diagnosed chronic liver disease should raise the suspicion of CD.

Radiographic Findings

The role of radiographic evaluation in the initial diagnosis of celiac disease is limited. The nonspecific findings of thickened mucosal folds, dilatation of the small intestine, straightening of the valvulae conniventes, and excessive secretion of fluid into the small intestine on small intestinal X ray suggest malabsorption rather than CD per se. On the other hand, small intestinal X ray can be used to rule out serious complications of CD (lymphoma, ulcerative jejunitis, or carcinoma) in patients who are on a strict GFD and presenting with abdominal pain, weight loss, anemia, hypoalbuminemia, or symptoms of obstruction.

Computer tomography is also used to rule out lymphomas and adenocarcinomas and may reveal hyposplenism, ascites, or cavitating mesenteric lymphadenopathy that can be associated with CD.

Stool Studies

The 72-hour stool fat collection and D-xylose absorption tests are nonspecific and play only a minor role in the specific diagnosis of CD.

TREATMENT

A GFD is the mainstay of the treatment of CD and it must be a lifelong regimen. No drug therapy has been proved to suppress the disease. Involvement of the patient in the treatment plan is crucial. Physicians caring for patients with CD should educate the patient about celiac disease. They should provide dietary consultation regarding a GFD and changes in lifestyle and must also encourage patients to join support groups. Patients should be encouraged to lead as normal a lifestyle as possible. Other responsibilities of the physician include assessing the patient's nutritional status and response to interventions, screening for other known associated diseases, followup to ensure compliance with the GFD, obtaining baseline bone mineral density, and being on watch for potential complications of CD.

Gluten-Free Diet

A GFD as a treatment for CD was established by Dicke. A few points about the GFD require further clarification:

1. Even small amounts of gluten can result in injury to the intestinal lining.
2. Patient education and motivation are crucial for successful treatment of CD.
3. The diet requires extensive education of patients and their families by both doctors and experienced dietitians.
4. A trial of a GFD as the sole means of diagnosis should be abandoned.
5. Patients need to know that a GFD not only improves their symptoms but may also reverse anemia, infertility, depression, and osteoporosis and may help prevent small intestinal malignancy.

Clinical improvement is evident in most patients within 2–3 weeks of initiating a GFD. Gluten contamination of food in the diet is very common and is the leading reason for persistence of symptoms. Flours allowed in a GFD include rice, soybean, corn, soy, potato, tapioca, arrowroot, bean, sorghum, quinoa, millet, buckwheat, tef, nut, and amaranth flours. Products made from these flours are safe for use by celiac disease patients.

Wheat, barley, rye, malt, triticale (wheat–rye hybrid), couscous, kamut, spelt, and semolina flours are not allowed. Recent studies have clearly demonstrated that oats are nontoxic for patients with celiac disease; however, contamination of oat products with other prohibited flours during harvesting, milling, or processing of oat products is a concern.

Some items that might be overlooked as a source of contamination include broth, breading, ketchup, mustard, candy bars, cheese spreads, chip and dip mixes, flavoring in meat products, soy sauce, hydrolyzed plant protein, hot chocolate mixes or cocoa, imitation bacon or seafood, instant coffee and tea, salad dressing, malt, modified food starch, nondairy creamer, pasta, peanut butter, processed meat, sausage products, sauce and soup bases, stuffings, tomato sauce, vegetable gum, vegetable protein (thickener), and yogurt with fruit. Medications, vitamins, and mineral supplements may also contain gluten as an inactive ingredient.

A GFD may be associated with either weight gain or loss. It may also be associated with constipation, and the patient should be counseled about these side effects. Special attention should be paid to deficiency states and supplementation with specific agents as needed. Also, after improvement of intestinal injury and consequent improved absorption, adjustment in the dose of medications may be needed.

Support groups provide assistance to newly diagnosed celiac disease patients, particularly by providing name and contact information of companies that produce GFD items and of local vendors; support groups are also sources of up-to date information on the disease and on the GFD, in addition to a wide variety of materials, books, and recipes that can be used with physician/dietitian guidance.

COMPLICATIONS

Serious complications of CD may arise because of the severity of malabsorption and steatorrhea; in addition to osteomalacia and osteoporosis, complications include mineral deficiency states. Patients with CD are at increased risk of developing lymphomas (enteropathy-associated T cell lymphoma) and small intestinal adenocarcinoma, though the risk is still very small. Refractory sprue is defined as initial failure of a GFD to improve clinical symptoms and histological abnormalities of the small intestine or secondary failure after initial improvement. This complication is hard to treat and harbors the risk of progressing to lymphoma. Another serious complication is ulcerative jejunitis, which can be associated with duodenal strictures or intestinal perforation.

EPIDEMIOLOGY

In the era before serological screening, the highest prevalence of symptomatic celiac disease was reported from Western Europe, approaching 1 in 300 individuals in Western Ireland. Celiac disease was also recognized in North America and Australia, both of which were sites of European emigration and where wheat remained a staple food. 1 in 2000–3000. The advent of serological testing has permitted screening of larger populations, and recent series of blood donor tests both in Europe and in the United States have demonstrated strikingly higher prevalence rates. Furthermore, these studies have also revealed that a majority of patients are either asymptomatic or have previously unrecognized atypical symptoms of celiac disease. An Italian study of school-age children revealed more than six times as many unexpected cases of celiac disease as established cases. These studies have led to the concept of a celiac disease "iceberg," with classical symptomatic cases being far outnumbered by atypical and silent cases below the "water's" surface (Fig. 1). Currently, the prevalence in Western Europe, estimated to be greater than 1 in 100, and estimates for the United States, at more than 1 in 250, are similar. Furthermore, the prevalence of this disorder has probably been underestimated in certain non-European countries and areas to which Europeans have not emigrated in high numbers, including the northern Sudan and northern India and other parts of Asia.

Early childhood experiences may affect the incidence of celiac disease and its clinical manifestations. The epidemiology of celiac disease has been carefully studied in Sweden, especially in relationship to gluten introduction and breast feeding. The incidence of celiac disease in that country rose rapidly in the period from 1985 to 1987, when infant gluten consumption was increased through the addition of gluten to baby formula, despite the postponement in cereal introduction from 4 to 6 months of age. Starting in 1995, there was a dramatic decline in early childhood celiac disease in Sweden, coincident with national recommendations to promote breast feeding and the introduction of gluten in smaller amounts while babies were still nursing. In London, a similar decline in incidence of celiac disease in the 1980s and 1990s followed recommendations for later introduction of gluten in the infant diet. Experts have speculated that the delayed introduction of large amounts of gluten in the diet may not have actually decreased the overall incidence of celiac disease, but just changed its presentation. Instead of developing classical symptoms of diarrhea and failure to thrive in the first 2 years of life, more at-risk individuals were presenting in later childhood or as adults, often with atypical symptoms. An independent effect of breast feeding on the occurrence of childhood celiac disease is not clear and merits further study.

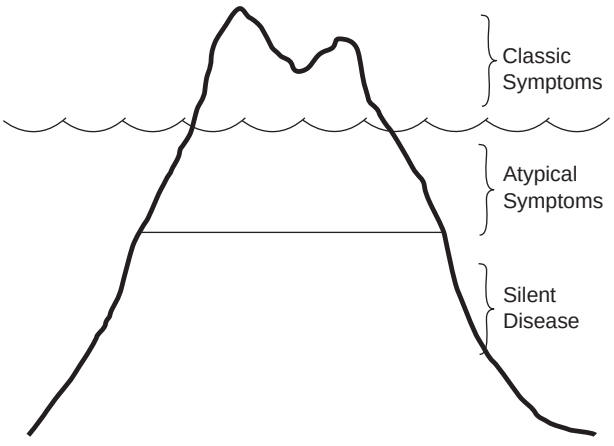

FIGURE 1 The celiac iceberg. Classic symptoms are the tip of the celiac iceberg; most patients have atypical symptoms or silent disease.

Substantial epidemiological evidence of a genetic basis for celiac disease now exists. Approximately 10% of children with celiac disease have a family member who is also affected by the disease and the incidence in monozygotic twins is up to 70% in some series. Histocompatibility genes clearly account for part of this susceptibility; 95% of patients with celiac disease are positive for human leukocyte antigen (HLA) DQ2 or DQ8, as compared to 30% of control patients. The fact that the concordance rate in monozygotic twins is higher than that in HLA identical siblings suggests that other genes may play an important role in the expression of celiac disease.

PATHOPHYSIOLOGY

Major advances have been recently made in understanding the pathogenesis of celiac disease. The toxic components of wheat are proteins, gliadins, which have a rich content of proline and glutamine. These proteins are modified by the enzyme tissue transglutaminase and the resulting peptides are subsequently bound by antigen-presenting cells in the context of the HLA DQ2 molecule. As a consequence, CD4-positive T cells are stimulated to proliferate in a Th1 response. The release of proinflammatory cytokines results in destruction of small intestinal epithelial cells. The unique sequence of the gliadin-derived peptides is required both for the interaction with HLA molecules and for resistance to gastric and intestinal proteolysis.

Abnormal intestinal permeability may also be an important factor in the pathophysiology of celiac disease. One possible mechanism for alteration of permeability is zonulin, a recently discovered protein that can reversibly alter tight junction assembly, thereby increasing permeability via the paracellular pathway. The expression of zonulin has been noted to be increased in intestinal tissues during the acute phase of celiac

disease. Regardless of the exact mechanism, if increased intestinal permeability is an early event in pathogenesis of celiac disease, it might permit exposure of gliadin to the mucosal immune system. Some researchers speculate further that increased permeability of the intestine in celiac disease may permit entry of other luminal factors important in the pathogenesis of associated autoimmune diseases, such as diabetes mellitus.

Despite the elucidation of the key steps in the pathogenesis of celiac disease, many questions remain. The event that triggers the development of celiac disease in a susceptible host is not clear, but presumably could be an infection or other stress resulting in an increase in intestinal permeability to gliadin peptides. Whether the antibody response to tissue transglutaminase observed in active celiac disease plays an important role in the genesis of intestinal injury or is merely an epiphenomenon also remains to be elucidated.

PATHOLOGY

Immune-mediated injury results in the classical histopathologic features of celiac disease, which are subtotal or total villous atrophy, crypt hyperplasia, and an increase in intraepithelial lymphocytes and lamina propria lymphocytes and plasma cells. As cases are diagnosed earlier or in patients with few symptoms, more subtle changes in the intestinal mucosa are being recognized, and some biopsies may demonstrate focal or partial villous atrophy, or only an increase in intraepithelial lymphocytes. In some patients with celiac disease, the immune-mediated injury is not confined to the small intestine and there may be associated lymphocytic gastritis and/or lymphocytic colitis.

CLINICAL MANIFESTATIONS

The typical symptoms of celiac disease follow the introduction of wheat, rye, or barley in to the diet and consist of diarrhea, abdominal pain, and weight loss (or failure to gain weight appropriately). Typically, children between the ages of 9 and 18 months present with frequent, foul-smelling bowel movements, weight loss, poor appetite, a distended abdomen, thin extremities with loss of subcutaneous tissue and sometimes muscle wasting, and irritability (Fig. 2). In severe cases, the child may be pale, listless, and have peripheral edema. In infants younger than 9 months, vomiting may be a prominent symptom. Paradoxically, some children present with constipation, rather than diarrhea, and celiac disease should be considered in the differential diagnosis of intractable constipation.

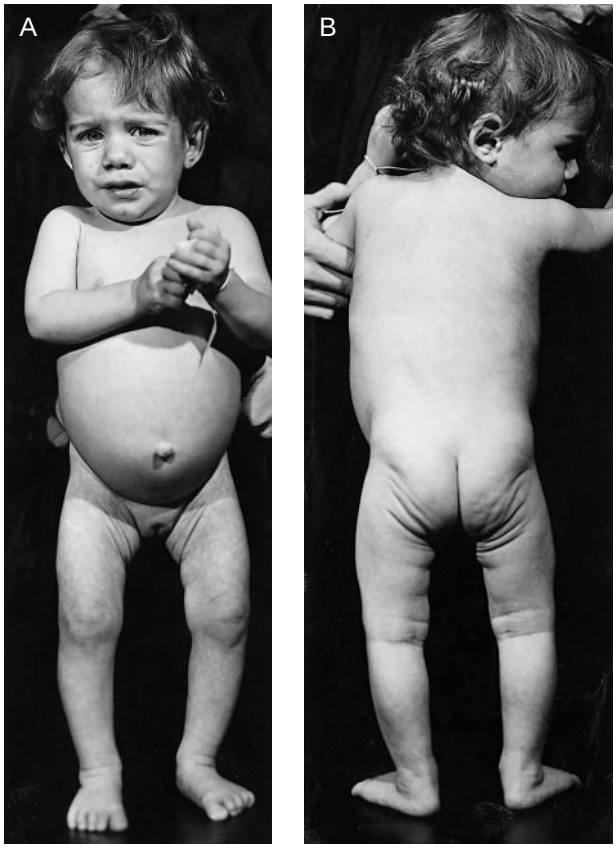

FIGURE 2 An 18-month-old child with celiac disease. Note the anxious look, the distended abdomen, and loss of subcutaneous tissue in the thigh folds and buttocks. Reproduced with permission from H. Shwachman (1954). Mucoviscidosis and the Celiac Syndrome. *Pediatr. Clin. North Am.* **54**.

Although diarrhea and weight loss may occur at any age, older children are more apt to have an atypical presentation. It is extremely important to recognize that isolated short stature, delayed puberty, anemia resistant to iron therapy, osteoporosis, primary amenorrhea, and unexplained elevation of serum transaminase levels may be the presenting complaint of children or adolescents with celiac disease. Other less common signs and symptoms include oral ulcers, behavior problems, dental hypoplasia, and seizures associated with cerebellar calcification.

The intolerance to gluten in celiac disease should be considered permanent, although rare cases of transient gluten intolerance have been reported in childhood. Patients with so-called transient gluten intolerance present with gastrointestinal symptoms and an

abnormal small intestine, and respond to a gluten-free diet. With gluten reintroduction, however, the patient remains free of symptoms and the intestinal biopsy remains normal. Because histopathologic relapse can be delayed after challenge of celiac patients with gluten for months to years, some of these patients have latent celiac disease and will eventually become symptomatic.

A wide range of disorders are associated with celiac disease. Children with Down syndrome have an increased prevalence of celiac disease, estimated at 5%. Other genetic disorders recently associated with celiac disease include Turner syndrome and Williams syndrome. Dermatitis herpetiformis is a pruritic papulovesicular rash that is frequently associated with small intestinal injury reminiscent of celiac disease. This disorder usually responds to a gluten-free diet, although treatment with dapsone is sometimes required. Other autoimmune disorders associated with celiac disease include type 1 diabetes mellitus, autoimmune thyroiditis, rheumatoid arthritis, and possibly others. Up to 8% of patients with diabetes have celiac disease. Since these children often have no gastrointestinal symptoms, the only clue to diagnosis may be difficulty in controlling serum glucose levels. Based on the strong association with celiac disease, however, it would seem advisable to screen all patients newly diagnosed with type 1 diabetes. Immunoglobulin A (IgA) deficiency is also associated with celiac disease and may confound serologic diagnosis.

DIAGNOSIS

The diagnosis of celiac disease should always rest on the finding of histologically abnormal small intestinal mucosa. However, because of the invasive nature of small bowel biopsy, serological tests have been developed and are useful as screening tests. These include assays for antigliadin antibodies (AGAs), antireticulin antibodies (ARAs), antiendomysial antibodies (AEAs), and antitissue transglutaminase antibodies (ATTGs). Patients with celiac disease may have IgA and IgG antibodies in each of these classes, but detection of the IgA class is generally a more specific assay for celiac disease and is the basis for most commercial test kits. The IgG AGA assay has a particularly low specificity and may be elevated in a significant number of control subjects and in patients with other intestinal disorders. Until recently, the best test was the AEA assay, which typically has a sensitivity and specificity of greater than 95%. However, because detection of AEAs is based on an immunofluorescent assay using monkey esophagus or human placental tissue as a substrate, there may be significant variability between different laboratories and the test is quite expensive to perform. The enzyme tissue transglutaminase has recently been identified as a specific target of the AEA assay. This discovery has led to the development of enzyme-linked immunosorbent assays (ELISAs) directed at this enzyme. Initially, the ATTG assays used guinea pig enzyme as the substrate, but the most recent generation assay is based on the human protein. Early studies noted a slightly reduced sensitivity and/or specificity of the ATTG when compared to the AEA assay, but it is likely that the more recently developed assays will not detect significant differences. If the equivalency of these assays is confirmed, it would be most prudent for the clinician to order only the ATTG assay, rather than a panel of different antibodies. Because IgA deficiency can be associated with celiac disease, a total serum IgA should be obtained to ensure that a negative assay is not due to IgA deficiency.

The availability of serological assays has obviated the need for tests of malabsorption and for imaging studies in uncomplicated cases. Standard tests for malabsorption, such as D-xylose absorption assays, breath testing to detect secondary lactose intolerance in young children, and qualitative and quantitative analyses of fecal fat, are too insensitive to be of practical use for the diagnosis of celiac disease in children. Likewise, sugar permeability tests fail to identify most children with active celiac disease. Imaging tests are of limited utility in diagnosing celiac disease and are not indicated unless gastrointestinal complications, such as intussusception, are suspected.

Patients with positive serology and those with negative serology but symptoms suggestive of celiac disease should undergo small bowel biopsy. The first small bowel biopsies were obtained using suction-triggered capsules positioned in the jejunum under fluoroscopic guidance. The advent of small-diameter flexible endoscopes has permitted the performance of endoscopic biopsies, even in infants. Anxious children, particularly those under 5 years of age, may require that the endoscopy be performed under general anesthesia. Patients with celiac disease undergoing endoscopy have been described to have scalloped or otherwise irregular small intestinal folds; however this finding is nonspecific. More recently, a technique of flooding the intestinal lumen to provide a magnified view of the intestinal surface and actual visualization of villi has been developed. Multiple small bowel biopsies should be obtained (at least three), because early intestinal changes may be focal. Biopsies should be obtained as far distally as possible and not in the duodenal bulb, where nonspecific changes of duodenitis may confound biopsy interpretation.

TABLE I Diagnostic Criteria for Celiac Disease

Consistent small bowel biopsy
and at least one of the following responses:
1. Clinical response (resolution of gastrointestinal symptoms) to gluten-free diet
2. Serological response to gluten-free diet
or
Histopathological remission on a gluten-free diet and relapse with gluten challenge (positive gluten challenge)

Traditionally, patients with suspected celiac disease have been subjected to a series of three biopsies to confirm the diagnosis and exclude transient gluten sensitivity or other processes that mimic the clinical and histopathological features. A second biopsy has been performed at least 1 year after the diagnosis to confirm resolution of the mucosal injury. The third biopsy has followed a challenge with dietary gluten to reproduce the histopathological changes of active disease. Current criteria for diagnosis are based on recommendations of the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) and include a small bowel biopsy with compatible histopathological features and a complete clinical response to a gluten-free diet (Table I). Because elevated levels of antiendomysial antibodies in patients with celiac disease decrease to normal levels with adherence to a gluten-free diet, return to normal antibody levels constitutes a complete serological response. It is important to note, however, that it usually takes months for these levels to return to normal.

A gluten challenge should still be considered in certain patients, including those who did not have a biopsy performed before starting on a gluten-free diet or who had atypical biopsies, and those with atypical symptoms and negative serology. In children under 2 years of age, a number of other disorders may result in a flat villous lesion mimicking celiac disease (Table II). Therefore, patients presenting at this age should be considered for gluten challenge, especially if serological studies were not performed or were negative. Also patients, typically teenagers, seeming to tolerate some gluten in their diet and intending to discontinue the gluten-free diet should undergo gluten challenge before the diagnosis of celiac disease is abandoned. The actual challenge can be performed by either reintroducing a standard diet or continuing a gluten-free diet, with the addition of gluten powder added to a food such as applesauce. The latter approach may cause less emotional distress in children who fail the challenge. Repeat serology and biopsy are performed with the recurrence of symptoms or, in the absence of symptoms, after a period of 3 months. Caution should be exercised during the gluten challenge, because patients will occasionally develop severe symptoms (celiac crisis) with reintroduction of dietary gluten.

Given the high incidence of celiac disease in first-degree relatives of children with celiac disease, parents and siblings should be screened with serological testing. Those with positive serology or negative serology but compatible symptoms should undergo small bowel biopsy.

TREATMENT

The treatment of celiac disease is a gluten-free diet, which requires the dietary exclusion of wheat, barley, rye, and other substances that may be contaminated by these grains. The question of whether small amounts of gluten in the diet are harmful has not been adequately answered. Therefore, the goal of the diet should be to eliminate these grains completely. Plant taxonomy can serve as a guide to what other grains should be acceptable in the diet of patients with celiac disease. Grains derived from plants closely related to wheat, such as barley and rye, are toxic, whereas unrelated grains, such as corn and rice, are completely tolerated. Oats, which are a more distant relative to wheat than are rye and barley, have been demonstrated to be safe in both adults and children with celiac disease when ingested in a pure form. The major practical issue is that oats are frequently contaminated by wheat both in the field and in the factory.

Given the ubiquitous occurrence of wheat in the diet, following a gluten-free diet is extremely challenging and requires the assistance of a specially trained dietitian. Determination of whether prepared foods are truly gluten-free demands continual vigilance, because manufacturers do not always explicitly list specific ingredients or may change the source of their ingredients without warning. Organizations and support groups can be very helpful in providing updated information in this regard. Special gluten-free foods are available in specialty food stores and via mail order or the Internet. Baking, however, remains quite difficult, because several unique nongliadin proteins in wheat are responsible for the stickiness critical to the baking

process. Hidden sources of gluten include food additives, emulsifiers, and stabilizers. Importantly, some medications may contain these substances.

Dietary changes other than gluten restriction are generally not necessary. Secondary lactose intolerance is unusual even in recently diagnosed children with celiac disease, although occasional patients may benefit from temporary restriction of lactose. Vitamin and mineral supplements may be recommended, especially if malabsorption or deficiencies of folate, iron, and calcium are suspected.

COMPLICATIONS

Occasionally, patients with celiac disease do not respond to a gluten-free diet alone and require immunosuppressive therapy for so-called refractory celiac disease. In children, such refractory disease is rare. Furthermore, before this diagnosis is made, other complications such as lymphoma need to be excluded. The incidence of enteropathy-associated T cell lymphoma has been documented to be higher in patients with celiac disease than in the general population. Patients with celiac disease also have a greater risk of developing small intestinal, esophageal, and oropharyngeal carcinoma. However, this increased risk of developing certain gastrointestinal cancers may be reduced by strict adherence to a gluten-free diet.

Patients with celiac disease are at increased risk of developing other autoimmune diseases, such as type 1 diabetes mellitus. This risk has been demonstrated to increase with increasing age at diagnosis. Whether the higher risk is the result of a longer period of exposure to gluten or simply the older age of the patient is not clear. Nevertheless, further study may demonstrate that strict adherence to the gluten-free diet may decrease the risk of developing other autoimmune diseases in patients with celiac disease.

PROGNOSIS

Response to a gluten-free diet usually is prompt, with most children demonstrating improvement in symptoms within 1 to 2 weeks. Mucosal healing may be demonstrated in 6–12 weeks. However, complete catch-up growth may take 1 to 2 years. With strict adherence to a gluten-free diet, life expectancy is similar to that of the general population and parents should expect their children with celiac disease to lead productive lives.

proglottid The segment of the tapeworm that, when gravid, contains eggs.
scolex The head of the tapeworm.
strobilation The process by which a tapeworm grows in an anterior to posterior direction.

The adult forms of cestodes share several common characteristics. Mammalian tapeworms have no internal cavity but are flat with a segmented body and a head or scolex. The scolex may have two sucking grooves as in *Diphyllobothrium* or four circular suckers as in *Taenia*. The adult tapeworm grows distally in a process called strobilation, so that the most posterior segments are the most mature. The segments of the tapeworm are named proglottids and contain egg-filled uteri when gravid. Tapeworms are hermaphroditic, with proglottids containing both ovaries and testes. There are four major groups of cestodes, but only those of the orders Pseudophylidea (*Diphyllobothrium latum*) and Cyclophylidea (*Taenia saginata, Taenia solium, Hymenolepis nana*) are significant parasites in humans. Clinical manifestations of tapeworm infection are attributable only to the adult or larval stages. This article will describe cestode infections of the human gastrointestinal tract and hepatobiliary system.

TAENIA SOLIUM

Life Cycle and Biology

Taenia solium infection is common in Mexico, Central and South America, parts of Africa, and Southeast Asia. *T. solium* can cause disease in both its adult and its larval forms. Intestinal tapeworm infection (taeniasis) is acquired by eating undercooked pork containing the larval stages, whereas ingestion of *T. solium* eggs leads to tissue dissemination of larvae and cyst formation (cysticercosis). Neurocysticercosis, or infection of the central nervous system with *T. solium*, is the leading cause of seizures in tapeworm endemic areas. Importantly, adult tapeworm carriers are the primary source of transmission of the larval stages in humans.

The *T. solium* tapeworm (Fig. 1) has a scolex outfitted with four suckers and a double crown of hooks, a narrow neck, and a large body (strobila) that measures between 2 and 4 m and consists of several hundred proglottids. The life cycle begins when human feces contaminated with *Taenia* proglottids are ingested by pigs. The invasive oncospheres in the eggs are liberated by the action of porcine gastric acid and intestinal fluids. The oncospheres then actively cross the bowel wall, enter the bloodstream, and are carried to the muscles and other tissues, where they develop into larval vesicles or cysticerci. Ingestion of undercooked pork containing cysticerci leads to cyst wall breakdown and attachment of the larval scolex to the intestinal wall. Maturation into the adult worm takes 6–8 weeks, at which time the adult sheds up to 10 proglottids per day. Proglottids may contain 50,000 to 100,000 eggs.

Clinical Features

Symptoms of intestinal taeniasis often include vague abdominal pain, nausea, changes in appetite, or diarrhea. However, most cases are asymptomatic until passage of proglottids in feces is noted.

Diagnosis, Treatment, and Prevention

Anti-cysticercal antibodies can be detected in serum, cerebrospinal fluid, and saliva using several assays, including complement fixation, hemagglutination, radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and immunoblot. For those patients with neurologic abnormalities, computed tomography (CT) or magnetic resonance imaging (MRI) of the brain will detect lesions diagnostic of neurocysticercosis. Praziquantel in a single dose (5–10 mg/kg) is the drug of choice for intestinal taeniasis. The role of anthelmintic treatment in the management of uncomplicated neurocysticercosis remains controversial. Infection can be prevented by thorough cooking of pork and sanitary measures taken to avoid spread from tapeworm carriers.

TAENIA SAGINATA

Life Cycle and Biology

Taenia saginata, the beef tapeworm, is highly endemic in Africa and South America, with a prevalence of greater than 90% in certain areas. The initial step in the life cycle is contamination of pastures or animal feed with human feces that contain *Taenia* eggs. The eggs are ingested by the cattle and hatch in the intestine. They travel via the bloodstream and lymphatics and then develop into cysticerci in the tissues. When undercooked beef containing cysticerci is ingested, the larvae are released from the cyst and attach to the intestine via four suckers (no hooks). The worms then grow distally by strobilation, reaching lengths of 10–25 m. Distal proglottids are shed, with each containing up to 80,000 eggs. The proglottids or eggs usually pass through the large intestine and are excreted. The cycle is completed when the eggs or proglottids are ingested by the intermediate host (cattle).

Clinical Features

The incubation period from the time of infection to the passage of proglottids is approximately 10–12 weeks. Infection with a single tapeworm is typical and many patients are asymptomatic unless they note worm parts being passed from the anus. Symptoms associated with *T. saginata* include nausea, postprandial fullness, abdominal pain, and occasionally vomiting or diarrhea. Eosinophilia of up to 1000 mm^3 occurs in approximately half of patients with *T. saginata* infections. Of note, mild eosinophilia is also common in *H. nana, D. latum*, and intestinal *T. solium* tapeworm infections.

Diagnosis, Treatment, and Prevention

Identification of gravid proglottids is the usual method of diagnosing *T. saginata* infection. They should be collected in saline or fixed in formalin. In order to determine the species of tapeworm, proglottids are pressed gently between two microscope slides, India ink is injected into the lateral pore, and the number of uterine branches is counted. *T. saginata* contains more than 15 primary branches on each side of the central core (Fig. 1). Eggs of *T. saginata* and *T. solium* are morphologically similar and are indistinguishable by light microscopy. Coproantigen detection of *Taenia*-specific antigens by ELISA is a sensitive diagnostic tool, although cross-reactivity with other *Taenia* species can occur. Drug therapy is extremely effective at eradicating tapeworm infections in adults and children. The drug of choice for *T. saginata* infection is praziquantel, which can be given orally in a single dose (5–10 mg/kg). Paromomycin is also effective and is considered safe for use during pregnancy. Proglottid segments may pass for several days after treatment is initiated. Follow-up stool examinations should be performed 3 months after treatment to document cure. Re-infection is quite common in endemic areas. The best ways of preventing infection include thorough cooking of meat and sanitary disposal of human feces. Freezing of beef will kill cysticerci. Unfortunately, these measures of public health control are not always feasible in endemic areas.

DIPHYLLOBOTHRIUM LATUM

Life Cycle and Biology

D. latum can measure up to 15 m in length. Its scolex has two deep grooves rather than suckers. An adult worm can release up to 1 million eggs per day. Once an egg reaches fresh water, a coracidium hatches from the embryonated egg, which is then ingested by a small freshwater crustacean (copepod). A procercoid develops within the copepod. When a fish ingests the infected copepod, the procercoid invades the stomach wall and penetrates the host's muscle tissue. The procercoid develops in the muscle of the fish into a plerocercoid. Humans become infected when they eat fish that contains plerocercoid larvae. The larvae then mature into adult tapeworms in the human intestine. Some mammals that ingest fish may also become definitive hosts for *D. latum*.

Clinical Features

Most patients infected with *D. latum* are asymptomatic. Patients may note worm segments in stool. Significant gastrointestinal symptoms occur rarely, although nausea, diarrhea, abdominal pain or distension, and weight loss have been reported. Chronic infection with *D. latum* is associated with macrocytic anemia secondary to vitamin B12 deficiency.

Diagnosis, Treatment, and Prevention

Diagnosis can be established by examination of the stool for proglottids or eggs. Praziquantel is effective treatment (5–10 mg/kg). The greatest risk for acquiring the infection is the ingestion of raw fish. Not surprisingly, the disease is most common in Asia, in northern Europe, and among Native American populations in Alaska and northern Canada. As sushi has become more popular in the United States, an increased number of cases occurring after patients have eaten raw salmon have been reported.

ECHINOCOCCUS SPECIES

Humans can become infected with the larval stages of *Echinococcus granulosus, Echinococcus multilocularis*, and *Echinococcus vogeli*. The adult worm of *E. granulosus* is found in the intestine of dogs or wolves. Humans become an incidental intermediate host when they accidentally ingest infected eggs from canine feces. Infections occur most frequently in areas where sheep or cattle raising are common.

Life Cycle and Biology

The adult *E. granulosus* tapeworm has a scolex with hooks, a neck region, and one immature, one mature, and one gravid proglottid. Adult tapeworms are found in the intestines of canines such as dogs and wolves. The eggs, which are morphologically identical to those of *Taenia* species, are passed in the feces and ingested by an intermediate host such as sheep. The embryos then hatch from the eggs, penetrate the intestinal mucosa of the host, and enter the bloodstream or lymphatics to be carried to various organs. Larvae then develop into fluid-filled unilocular hydatid cysts with an external membrane and an inner germinal layer. Protoscolices, which precede the development of the adult worm scolex, develop from within the inner capsule of the expanding cyst and can accumulate within the cyst as hydatid sand. Daughter cysts can grow from the inner germinal layer as well as cystic structures termed brood capsules. Cysts may rupture, leading to multifocal dissemination of infectious scolices. Adult worms of *E. multilocularis* are morphologically similar to those of *E. granulosus*, but the larval stage grows by external budding. The disease caused by *E. multilocularis* is

termed alveolar hydatid disease. Foxes are usually definitive hosts and rodents are intermediate hosts for *E. multilocularis*.

Clinical Features

Hydatid cysts are capable of developing in nearly any tissue but almost 90% develop in either the liver or the lung. Most patients will have only a single cyst, but they may develop in multiple sites. Symptoms usually develop once the cyst has become large enough to impinge on surrounding tissues. Cysts may grow slowly and can take up to 20 years to become symptomatic. Lung abscesses may develop if a cyst ruptures into a bronchus or the pleural space. Liver cysts may be asymptomatic calcified cysts or may become large enough to cause right upper quadrant discomfort. Biliary obstruction from a large cyst may present with jaundice, abdominal pain, and fever. In 5–15% of infected adults, hepatic cysts rupture into the biliary tract.

Diagnosis, Treatment, and Prevention

A history of exposure to a canine source in an endemic area is suggestive of echinococcosis. Daughter cysts may appear as highly opaque densities on MRI or CT scan. Certain reference laboratories can perform ELISA, immunoblots, or indirect hemoagglutination tests on serum from infected patients. Surgical removal or drainage of cysts in combination with three or more cycles of albendazole (400 mg twice daily for 1 month) is the recommended treatment regimen. The combination of albendazole with praziquantel may be more effective in some patients.

HYMENOLEPIS NANA

Hymenolepis nana, also called the human dwarf tapeworm, is the cestode that most commonly infects humans. Transmission occurs most commonly via the fecal–oral route and commonly affects young children in endemic areas.

Life Cycle and Biology

The life cycle does not require an intermediate host. Once eggs are ingested, they hatch in the small intestine to release a double-membraned oncosphere. The oncosphere then penetrates the intestinal mucosa and develops into a cysticercoid larva within the lymphatics of the intestinal villi. The cysticercoid then migrates back into the lumen of the intestine, attaches by its scolex to the mucosa, and matures into an adult. The adult tapeworm can measure 20 to 40 mm in length. It has four suckers on its scolex and a retractable rostellum that contains up to 25 hooks. Each proglottid contains three testes and one ovary and may contain up to 200 eggs when gravid.

Clinical Features

Most cases are asymptomatic, but heavy infection with *H. nana* can cause significant intestinal inflammation, especially in children. Diarrhea, abdominal pain, anorexia, and pruritus ani have also been described.

Diagnosis, Treatment, and Prevention

Diagnosis is confirmed by identifying the characteristic double-membraned eggs in a patient's stool. Egg output is irregular and multiple stool examinations may need to be performed. ELISA has been used to detect antibodies to *H. nana* in sera, but the test has poor specificity and is not routinely used. The drug of choice is praziquantel in a single oral dose (25 mg/kg). Prevention of disease is by control of fecal–oral contamination and proper hygienic measures.

UNCOMMON TAPEWORM INFECTIONS

Dipylidium caninum is an unusual cause of intestinal disease in humans. It is a common tapeworm of dogs and cats and is found worldwide. Infection usually occurs when young children ingest an intermediate host such as an infected insect or flea containing cysticercoids. Cases are usually asymptomatic but may be associated with diarrhea, abdominal discomfort, or irritability. Praziquantel is the drug of choice (5–10 mg/kg) in a single dose. Infection with *Hymenolepis diminuta*, a tapeworm of rodents, occurs when humans ingest an infected flea or cockroach. Symptoms are similar to those of *H. nana*. Identification of *H. diminuta* eggs in stool is diagnostic. Praziquantel given in a single dose (10 mg/kg) is the recommended treatment.

megacolon Dilation of the colon.
Trypanosoma cruzi The blood-borne protozoan parasite responsible for Chagas' disease.

Intestinal pseudo-obstruction is one of the pathologic conditions that appears in Chagas' disease. Chagas' disease results from infection with the blood-borne, protozoan parasite *Trypanosoma cruzi*. *T. cruzi* multiplies intracellularly until the loaded cell bursts to release the parasites, which are distributed in the blood to invade the cells of different kinds of tissues. While free in the blood, the parasites are exposed to the immune system where stimulation of antibodies to the parasites occurs. The parasite is transmitted by large blood-sucking bugs of the family Reduviidae and affects an estimated 12–15 million people in Latin American countries, in a range that extends from Mexico to northern Argentina.

INTRODUCTION

Heart muscle and nervous tissue are the favorite targets for the blood-borne, protozoan parasite *Trypanosoma cruzi*. Nearly all fatal cases show inflammatory damage to the heart muscle that results in cardiac failure. Extensive neuronal degeneration is a secondary characteristic in chronic stages of the infection. Debilitating degeneration of neurons occurs in the sympathetic, parasympathetic, and enteric divisions of the autonomic nervous system. Neuropathy in the autonomic nervous system in the later stages of Chagas' disease is associated with megaesophagus and megacolon. The clinical picture in the large intestine is reminiscent of Hirschsprung's disease.

Megaesophagus and megacolon in Chagas' disease reflect impaired transit through an obstructed region and accumulation of the lumenal contents proximal to the obstruction. A marked reduction in the numbers of neurons in the enteric nervous system occurs in the affected regions of gut. Prolongation of gastrointestinal transit time is found also in laboratory animals after infection with *T. cruzi* and the degree of transit prolongation is proportional to the decrease in the numbers of neurons in the animal's enteric nervous system. The obstruction is classified as pseudo-obstruction because the lumen of the obstructed segment is patent (i.e., there is no mechanical obstruction). Pseudo-obstruction may occur in the esophagus or the small and large intestine. Partial surgical resection of the affected segment of intestine provides relief in humans; nevertheless, later recurrences commonly occur.

ETIOLOGY

An early assumption was that the parasite invaded cells in the walls of the viscera and destroyed the intramural neurons by the release of a toxin. Later evidence did not support direct invasion by the parasite as the underlying mechanism for the neuropathy. Current evidence

suggests that an autoimmune mechanism is responsible for the destruction of cardiac and neuronal tissue that occurs in Chagas' disease. The explanation given for the autoreactivity is that the cells of the host and the parasite express common antigenic epitopes. As an immune attack is mounted against the parasite, cross-reactivity develops against tissue cells of the host.

Blood from patients with *T. cruzi* infection contains antibodies that recognize components of cardiac muscle and peripheral and central neurons. An antibody raised against mammalian sensory neurons (i.e., dorsal root ganglion neurons) cross-reacts with antigenic epitopes expressed by the parasite. The same antibody that reacts with the parasite also reacts with and labels neurons in the myenteric and submucosal plexuses of the enteric nervous system. This strongly suggests that the autonomic neuropathy associated with Chagas' disease results from development of antibodies against the parasite that later cross-react with neurons of the host. The autoimmune attack results in the ultimate destruction of the enteric nervous system.

PATHOPHYSIOLOGY

The degenerative inflammatory neuropathy associated with Chagas' disease in the gut leads to pseudo-obstruction. Pseudo-obstruction is a failure of propulsive motility that cannot be explained by mechanical blockage. Because propulsive motility is programmed and organized by the enteric nervous system (i.e., the brain-in-the-gut), progressive autoimmune destruction of the neurons in Chagas' disease removes the gut's brain and its control over the motor functions of the digestive tract. Contractile activity of the intestinal musculature remains in the absence of the enteric nervous system due to the myogenic nature of the smooth muscle. Nevertheless, in the absence of neural control, the contractile patterns are not coordinated and fail to achieve functional propulsion.

proton pump inhibitor A drug that blocks acid secretion in the stomach.

Non-cardiac chest pain may be defined as recurrent angina-like or substernal chest pain believed to be unrelated to the heart after a reasonable cardiac evaluation. This condition is also known as unexplained chest pain, as even patients with negative coronary angiograms may experience myocardial ischemia due to microvascular angina.

INTRODUCTION

Recurring substernal chest pain is a common clinical dilemma. Approximately 450,000 new cases are diagnosed annually in the United States. The prognosis for these patients is uniformly excellent with a mortality rate estimated to be less than 1% at 10 years. However, many of these patients continue to have chest pain, which they believe is cardiac in origin. This misunderstanding results in continued health care costs related to emergency room visits, office visits, hospital admissions to exclude myocardial infarction, more diagnostic tests, therapeutic trials, as well as functional impairment in terms of ability to work and quality of life. Thus, the morbidity associated with this condition is quite substantial. The estimated cost of diagnosing and treating these patients approaches two billion dollars annually.

Cardiac and esophageal symptoms may mimic each other. Depending on the criteria used, the esophagus has been implicated as a cause of chest pain in 20 to 60% of these patients.

CLINICAL PRESENTATION

The clinical history does not reliably distinguish between cardiac and non-cardiac causes of chest pain, due in part to the shared innervation of the heart and the esophagus. Both may have the same location (substernal), sensation (squeezing, burning, pressure), and radiation. Furthermore, both may be relieved by nitrates and calcium channel-blocking drugs. Chest pain related to myocardial ischemia typically is related to exertion, whereas esophageal chest pain typically occurs at rest. However, both types of pain may be induced by exercise, because exercise can induce gastroesophageal reflux. Furthermore, both types of pain may also occur at rest. Some features of pain, however, may help to distinguish esophageal from cardiac chest pain. Esophageal causes are more likely to be associated with background esophageal symptoms such as classic heartburn, regurgitation, dysphagia, or odynophagia and respond to antacids or over-the-counter histamine type 2 receptor antagonists. However, these features of esophageal pain are also found in some patients with ischemia-induced chest pain. Similarly, panic attacks, which may include symptoms such as chest pain, dyspnea, and diaphoresis, may be difficult to distinguish from angina-induced chest pain.

MECHANISMS OF NON-CARDIAC CHEST PAIN

The mechanisms underlying non-cardiac chest pain remain incompletely understood. The shared innervation of the esophagus and the heart has focused much of the evaluation on the esophagus as the most common cause of non-cardiac chest pain. Depending on the criteria used, the esophagus has been described as the cause of chest pain in 20 to 60% of these patients. This may be due to hypersensitivity to acid, motility abnormalities, intralumenal distension, or visceral hypersensitivity.

Gastroesophageal reflux disease (GERD) has emerged as perhaps the most common esophageal cause of non-cardiac chest pain. GERD may be present in up to 60% of patients with non-cardiac chest pain. Both acid perfusion studies and prolonged pH monitoring have confirmed that intraesophageal acid may trigger chest pain. Furthermore, anti-secretory therapy is effective in decreasing GERD-associated chest pain. However, the mechanism whereby this occurs remains obscure. It is possible that intraepithelial free nerve endings act as acid-sensitive nociceptors. Patients with gastroesophageal reflux-induced non-cardiac chest pain may also develop hypersensitivity to physiologic amounts of intraesophageal acid.

Patients with well-defined motility abnormalities such as achalasia and diffuse esophageal spasm may experience chest pain. However, these disorders are quite uncommon in patients with non-cardiac chest pain. Instead, abnormalities such as high-amplitude, long-duration contractions ("nutcracker esophagus") or nonspecific motility abnormalities are encountered more commonly in these patients. However, the causal relationship between esophageal motility disorders and chest pain is difficult to prove. Patients rarely have chest pain at the time of diagnostic manometric evaluation, even if a motility abnormality is present. Furthermore, provocation of pain with pharmacologic agents is often not accompanied by motility abnormalities. Studies with 24 h ambulatory esophageal manometry reveal that chest pain is associated with motility abnormalities in only 10 to 20% of cases. Administration of medications that decrease esophageal contraction amplitude does not decrease chest pain in patients with nutcracker esophagus. More recent studies suggest an association between nutcracker esophagus and GERD as well as a lower threshold of perception for intraesophageal balloon distension (visceral hypersensitivity), abnormal psychological profiles (depression, somatization, anxiety), and decreased esophageal wall compliance. As such, nutcracker esophagus may simply be a marker of abnormal brain–gut interactions or gastroesophageal reflux disease in patients with non-cardiac chest pain. A more recent observation is that both spontaneous chest pain and chest pain provoked by injection of edrophonium may be preceded by sustained esophageal contractions detectable only by high-frequency intralumenal ultrasonography. These changes are not accompanied by changes in intralumenal pressure.

Abnormal visceral pain perception (visceral hypersensitivity) may contribute to non-cardiac chest pain. Intraesophageal balloon distension reproduces chest pain in these patients at a lower distension volume compared to control subjects who infrequently develop pain. The etiology of visceral hypersensitivity is unknown, but this abnormality of pain perception may be due to abnormal processing of information in the central nervous system. Psychiatric abnormalities are often encountered in patients with unexplained chest pain. The most common diagnosis include depression, anxiety, somatization disorders, and panic attacks. Panic attacks are encountered in approximately one-third of chest pain patients with normal coronary arteries. Panic attacks consist of a generalized anxiety state characterized by chest pain associated with intense fear, palpitations, diaphoresis, paresthesias, dizziness, or breathlessness. Thus, alterations in sensory afferent input, central nervous system processing, and efferent muscle responses may play a role in disturbed brain–gut interactions in some patients with unexplained chest pain.

DIFFERENTIAL DIAGNOSIS

The most common causes of non-cardiac chest pain are shown in Table I. Typically, the cause of non-cardiac chest pain is gastrointestinal, musculoskeletal, or psychological in etiology. The single most important task is to exclude a cardiac source of chest pain first, because of the potential life-threatening nature of cardiac ischemia.

TABLE I Differential Diagnosis of Unexplained Chest Pain

Common causes of unexplained chest pain	Less common causes of unexplained chest pain
Coronary artery disease	Esophageal motility disorders
Gastroesophageal reflux disease	Peptic ulcer disease
Musculoskeletal disorders	Gallstones
Psychological	Mitral valve prolapse
Brain–gut dysfunction	Microvascular angina
Panic attacks	

Once cardiac causes of chest pain are excluded, attention is typically directed to the esophagus. It is now clear that the most common cause of esophageal chest pain is GERD. GERD may present with chest pain as the major and sometimes sole symptom. However, most patients will report heartburn, regurgitation, or both if closely questioned. Acid reflux may coexist and cause chest pain in patients with known coronary artery disease. Furthermore, drugs commonly used to treat coronary artery disease, such as nitrates and calcium channel antagonists, can decrease lower esophageal sphincter pressure and distal esophageal contraction amplitudes, thereby predisposing these patients to gastroesophageal reflux. Some studies report that up to two-thirds of patients with known coronary artery disease with recurrent episodes of atypical chest pain despite maximal medical and surgical therapy have chest pain related to gastroesophageal reflux events.

Chest pain is a common presenting symptom in patients with esophageal motility disorders, especially the spastic variety. However, the majority of patients with unexplained chest pain have normal esophageal motility studies and the remainder have a variety of generally nonspecific abnormalities of questionable significance. In large studies of patients with unexplained chest pain, no more than approximately one-third will have an esophageal motility disorder. Nutcracker esophagus is the most common motility disorder, followed by nonspecific disorders, diffuse esophageal spasm, hypertensive lower esophageal sphincter, and achalasia.

Chest wall muscles, ribs, and cartilage may all cause unexplained chest pain. These patients have pain and tenderness in the anterior chest wall that may radiate across the chest and increase with inspiration. Pressure applied to the anterior chest on physical examination may reproduce the pain. Radiographic studies typically demonstrate no abnormalities. Symptoms may decrease with nonsteroidal anti-inflammatory drug therapy, with steroid injections into costosternal or costoclavicular joints, or with trigger-point injections.

On occasion, patients with peptic ulcer disease will present with unexplained chest pain. Classic dyspepsia may be absent in these patients. Biliary colic is typically described as severe right upper quadrant pain occurring postprandially. Pain may radiate to the chest or back and substernal pain may sometimes be the only manifestation of biliary disease. An ultrasound of the gallbladder is the simplest way to confirm the diagnosis.

Some patients with chest pain and normal coronary arteries may have cardiac ischemia from microvascular angina. These patients have normal epicardial arteries by angiography, but an abnormal coronary vasodilator reserve in response to atrial pacing and ergonovine as well as reduced left ventricular ejection fractions during exercise. Under these conditions, coronary artery resistance increases instead of decreases, causing chest pain. The physiologic significance of microvascular angina is uncertain because similar studies have not been performed in age-matched normal individuals. Chest pain is commonly reported by patients with mitral valve prolapse. Symptoms may be exertional or nonexertional. The duration of pain is highly variable, lasting from minutes to hours. The cause of chest pain in these patients is unknown, although many different mechanisms have been postulated. Many patients with mitral valve prolapse have concurrent panic disorders, but a cause and effect relationship between the two disorders has not been proven. The diagnosis of mitral valve prolapse is made by the characteristic auscultatory findings of a midsystolic click accompanied by a late or holosystolic murmur. The diagnosis is confirmed by echocardiography. Beta-blocker therapy decreases chest pain in some of these patients.

DIAGNOSTIC APPROACH

Diagnostic testing in patients with chest pain should first focus on excluding a cardiac cause of chest pain. The intensity of the evaluation depends on factors such as patient age and risk factors for coronary artery disease. This should be done preferentially under the supervision of a cardiologist who can then choose the best diagnostic study, be it immediate catheterization, echocardiography, or nuclear perfusion imaging.

Once a cardiac cause of chest pain is excluded, the patient's evaluation should shift to possible esophageal causes of chest pain. There are a number of diagnostic studies that can evaluate the structure and function of the esophagus including barium radiography, esophagogastroduodenoscopy, esophageal manometry, 24 h pH testing, 24 h esophageal manometry, and esophageal provocative tests such as edrophonium injection and intraesophageal acid infusion (Bernstein test). However, the yield of each of these tests is low and current guidelines suggest deferring esophageal diagnostic testing until after an adequate trial of proton pump inhibitor therapy.

A trial of proton pump inhibitor therapy is both sensitive and specific for diagnosing GERD in patients with unexplained chest pain. Furthermore, it results in significant cost savings by decreasing the use of diagnostic tests in these patients. The "omeprazole test" consists of omeprazole given as 40 mg in the morning and 20 mg in the evening for 7 days. Should the patient respond, anti-secretory therapy is continued. Others

suggest a trial of any of the proton pump inhibitors given twice daily for at least 1 month prior to considering additional esophageal testing. Should the patient fail to respond, further esophageal diagnostic studies are indicated.

If a proton pump inhibitor trial is negative, 24 h pH monitoring can be considered. Data collection assesses esophageal acid exposure in the supine, upright, and combined positions, and the relationship between reflux events and chest pain can be determined. If the 24 h pH study is noncontributory, esophageal manometry can be performed to determine whether an esophageal motility disorder is present. However, most patients will have normal manometric studies.

Other gastrointestinal causes of chest pain are best evaluated by a careful history and upper endoscopy. The latter study may identify an unsuspected peptic ulcer, esophageal ulcer, or other evidence of gastroesophageal reflux disease that can be appropriately treated. A gallbladder ultrasound is the best way to evaluate the patient for gallstones. Despite this exhaustive evaluation, many patients will still not have a diagnosis. In these patients, formal psychological testing or an empiric trial of antidepressants should be considered.

The physical examination should entail an assessment of tenderness or pain in the vicinity of the sternum and xiphoid. This is recommended because costochondral causes of chest pain are easily treated and often missed.

TREATMENT

Reassuring the patient that cardiac disease is absent is the first step in managing non-cardiac chest pain. GERD is the most common esophageal cause of non-cardiac chest pain and a number of studies demonstrate excellent results in the treatment of non-cardiac chest pain with proton pump inhibitors. In patients with a good response, treatment can be titrated downward to the lowest dose necessary to control symptoms. Should the above measures fail, supportive reassurance based upon the results of additional esophageal testing that demonstrates an esophageal etiology for pain may alleviate some of the patients' symptoms, enable patients to work, and decrease the need for prescription drugs, physician and emergency room visits, and further hospitalizations. None of the smooth muscle relaxants including hydralazine, anticholinergics, nitrates, and calcium channel blockers is reliably effective in patients with non-cardiac chest pain. More aggressive therapy of esophageal motility disorders with pneumatic dilation or surgical myotomy should be avoided. Uncontrolled trials suggest that botulinum toxin injection (100 units) into either the lower esophageal sphincter or along the entire length of the esophagus may be effective in selected patients with diffuse esophageal spasm or other spastic motility disorders accompanied by intractable symptoms.

Tricyclic antidepressants and selective serotonin reuptake inhibitors may be very helpful in patients with lower pain thresholds or psychiatric diagnoses contributing to their chest pain syndrome. In controlled clinical trials, trazadone (100 to 150 mg daily) imipramine (50 mg at bedtime), and sertraline (50 to 200 mg daily) improve symptoms when compared to placebo. Other effective agents include amitryptiline, desipramine, and nortryptiline at doses of 25 to 75 mg daily. Often, these drugs improve symptoms at lower doses than required for treating psychiatric diseases, suggesting that they are working by improving pain thresholds. Patients with panic attacks will improve with tricyclic antidepressants, selective serotonin reuptake inhibitors, or benzodiazepines such as alprazolam. Controlled clinical trials suggest that cognitive behavioral therapy may also be effective in decreasing chest pain frequency and psychological morbidity and disability in these patients. Musculoskeletal causes of chest pain may be treated by injecting a local anesthetic into painful trigger points.

pepsigogue Agent that stimulates pepsinogen secretion.
pepsinogen Protein precursor of pepsin synthesized and secreted by gastric chief cells.

Gastric chief cells, exocrine cell types localized near the base of gastric glands, synthesize and secrete pepsinogen, the precursor form of the proteolytic enzyme, pepsin.

HISTORICAL OVERVIEW

The Cambridge physiologist John Langley (1852–1925) translated and introduced the term "chief cell" from the "*Hauptzellen*" of the German physiologist Rudolf Heidenhain (1834–1897). Using amphibian peptic cells as a model, Langley elucidated the formation of pepsinogen in chief cell zymogen granules, the secretion of the proenzyme, and the proenzyme conversion to the active acid protease pepsin. Further elucidation of the cellular biology of chief cells has been obtained by using amphibian (bullfrog esophagus) and mammalian (rabbit, rat, and guinea pig) secretory models (isolated gastric glands, dispersed chief cells, and cell culture).

ANATOMY

In mammals, chief cells are located at the base of glands distributed throughout the fundus and corpus of the stomach. It is thought that chief cells derive from mucous neck cells located in the midportion of the glands. The primary function of gastric chief cells is the synthesis and release of the proenzyme pepsinogen, which subsequently, in an acid environment, is converted to the acid protease pepsin. Hence, like other enzyme-secreting cells of the gastrointestinal tract (e.g., pancreatic acinar cells), chief cells contain abundant rough endoplasmic reticulum and apical large dense zymogen-containing granules that occupy more than a third of the cell volume (Fig. 1). The nucleus is located

at the base of the cell, surrounded by mitochondria (Fig. 1). On stimulation, zymogen granules move toward the apical surface, where they fuse with the plasma membrane and release pepsinogen into the lumen of the gastric gland. The major physiologic control of pepsinogen secretion is by the vagal nerve and intrinsic neural reflexes.

CELL BIOLOGY

The orderly and timely progression of zymogen granules toward the apical membrane of chief cells, so that the active acid protease pepsin can be delivered to the gastric lumen to assist in the digestion of ingested protein, requires an efficient and tightly regulated process. Figure 2 represents a simplified scheme illustrating various steps in this process, from ligand binding to basolateral membrane receptors, mediated by activation of guanosine nucleotide binding proteins (G_q, G_s, and G_i), to phosphorylation of currently unidentified protein substrates. Although the identity of these protein substrates remains obscure, their phosphorylation and dephosphorylation are crucial to exocytosis. These proteins may be related to synaptosomal-associated protein receptors (SNAREs) or may be members of the Rab family of guanosine nucleotide binding proteins that are part of the secretory machinery in other cell types. Rab proteins have been identified in chief cells.

Basolateral membrane receptors for acetylcholine (muscarinic receptors) and for cholecystokinin and gastrin (CCK-A receptor) activate a phospholipase C, which results in an increase in cytosolic calcium concentration and the release of diacylglycerol (DAG). DAG activates the serine–threonine kinase protein kinase C (PKC; the α and ζ isoforms have been identified in guinea pig chief cells). Calcium activates a number of kinases and phosphatases, including PKC, calcium/calmodulin kinase II, and protein phosphatase-2B (PP-2B, also referred to as calcineurin).

Membrane receptors for secretin and vasoactive intestinal peptide (VIP) and for cholera toxin (ganglioside GM1 receptor) are linked to activation of adenylyl cyclase, to increases in cellular cyclic adenosine monophosphate (cAMP), and to activation of protein kinase A (PKA). Activation of receptors for peptide YY and neuropeptide Y (PYY and NPY) and for somatostatin reduces the activity of adenylyl cyclase. Recent studies focusing on the integration of these various signals have elucidated the presence of a 150-kDa A-kinase anchoring protein (AKAP150) that serves as the nidus of a complex of signaling molecules, including PKA, PKC-α, and PP-2B, thereby facilitating concurrent or sequential phosphorylation and dephosphorylation of substrates. Attachment of AKAP150 to the actin cytoskeleton also serves an important role in compartmentalization of these signaling cascades within the cell.

Besides the pepsigogues illustrated in Fig. 2, histamine and cytokines (epidermal growth factor and interleukin-1β) have been reported to stimulate pepsinogen secretion. With the exception of acetylcholine, the importance of these *in vitro* pepsigogues to physiological pepsinogen secretion in response to an ingested meal remains to be determined.

Cholangiocarcinoma

bilirubin A bile pigment formed during the catabolism of heme-containing compounds, primarily hemoglobin.
cholecystectomy Surgical removal of the gallbladder.
choledochocyst A congenital segmental cystic dilation of the biliary system located in any portion of the extrahepatic biliary tract.
hepatolithiasis (Oriental cholangiohepatitis) A chronic disease characterized by the formation of primary intrahepatic pigmented stones and sequelae that include recurrent cholangitis, strictures of the intrahepatic bile ducts, hepatic abscesses, portal vein thrombosis, cholangicarcinoma, and sometimes secondary biliary cirrhosis with hepatic failure.
jaundice Excessive accumulation of bilirubin, as a result of enhanced production or impaired elimination, resulting in yellow discoloration of the skin, sclera, and mucous membranes.
sclerosing cholangitis A condition characterized by fibrosis of the biliary tree.
ulcerative colitis Chronic inflammatory condition involving the colon.

Cholangiocarcinoma (CCA) is a rare malignancy that accounts for less than 1% of all cancers. The nomenclature of tumors of the biliary tree has evolved over time. Initially, "cholangiocarcinoma" was intended to define tumors of the intrahepatic biliary tree. In 1965, Gerald Klatskin described tumors of the bifurcation of the extrahepatic ducts, known as "Klatskin" tumors. Currently, CCA includes neoplasms occurring anywhere along the biliary tree and is divided into three groups: (1) those located in the intrahepatic ducts, (2) those located in the perihilar ducts, and (3) those located in the distal extrahepatic ducts. This classification correlates best with the treatment and prognosis. In addition, perihilar tumors have been subclassified further by the Bismuth classification, which identifies the precise location of the tumor.

EPIDEMIOLOGY AND ETIOLOGY

Biliary tract cancers are rare; in the United States, 6800 new cases are estimated to be diagnosed in 2003. Gallbladder cancer accounts for approximately two-thirds of biliary tract cancers and 2000–3000 of these are attributable to cholangiocarcinoma (CCA). The majority of cases occur in patients between the ages of 50 and 70, with a slight male predominance. However, patients with predisposing diseases may present up to two decades earlier. The perihilar and distal extrahepatic bile ducts are the most common sites of involvement. Perihilar tumors account for approximately 70% and distal extrahepatic bile duct tumors for 27% of cases.

The etiology of cholangiocarcinoma in the United States is usually unknown. Genetic predisposition may play a role. It is believed that chronic bile duct inflammation of any etiology may lead to neoplasia of the biliary tree. However, a number of high-risk conditions exist. In the United States, these include patients with chronic inflammation associated with ulcerative colitis with or without primary sclerosing cholangitis (PSC) and chronic intraductal gallstones (hepatolithiasis). Approximately 10–30% of cholangiocarcinomas exist in patients with PSC. Furthermore, congenital and bile duct abnormalities of the biliary tree including choledochocysts, Caroli's disease, bile-duct adenoma, and multiple biliary papillamatosis are associated with cholangiocarcinoma. Caroli's disease consists of numerous intrahepatic cystic dilations of the bile duct with or without stone formation. In Southeast Asia, chronic infections with liver parasites including *Clonorchis sinensis* (in Japan, Korea, and Vietnam) and *Opisthorchis viverrini* (in Laos, Malaysia, and Thailand) are associated with a 25- to 50-fold increased risk of cholangiocarcinoma. Hepatolithiasis (Oriental cholangiohepatitis) is endemic in Southeast Asia and may be associated with congenital ductal abnormalities, chronic infections, and diet. The risk of cholangiocarcinoma in hepatolithiasis is between 1 and 13%. These liver flukes cause chronic inflammation of the intrahepatic bile ducts that leads to stricture and stone formation. In addition, Thorotrast (thorium dioxide) exposure, a radiologic contrast agent used in the 1930s and 1940s, has been associated with the development of cholangiocarcinoma. Environmental factors including multiple chemicals and radionuclides have been recognized as being causal in the development of CCA. Finally, other entertained risk factors may

include tobacco use, asbestos exposure, and prior cholecystectomy and biliary sphincterotomy.

PRESENTATION AND DIAGNOSIS

The clinical presentation of a patient with cholangiocarcinoma is dependent on the tumor's location, its invasiveness, and the degree of biliary obstruction. The patient will become symptomatic when the biliary tree is obstructed. Obstructive symptoms are more prevalent with extrahepatic and hilar disease. These include jaundice, pruritus, abdominal pain, nausea, vomiting, anorexia, and weight loss. The majority of patients will present with painless jaundice. This must be differentiated from other common causes, such as pancreatic and ampullary cancer. The physical examination may reveal only jaundice. Less common findings include hepatomegaly, right upper quadrant pain, and a palpable mass (distended gallbladder or the tumor). Biochemical studies will often show elevations in the bilirubin, transaminases, γ-glutamyl transferase (GGT), alkaline phosphatase (AP), 5′-nucleotidase (5′NT), and prothrombin time.

In contrast, patients with intrahepatic involvement may be asymptomatic early on or have abdominal pain. Biochemical testing will reflect elevations of the biliary ductal epithelial enzymes: GGT, AP, and 5′NT. The bilirubin and other parenchymal enzymes (SGOT, SGPT) will usually be normal until the disease is more invasive, involving the majority of the hepatic parenchyma. As the disease progresses, the prothrombin time will be prolonged. The diagnosis of a pancreatic or hepatico-biliary malignancy is often made from the clinical history and biochemical tests. Further imaging, tumor markers, and tissue acquisition will assist in the final diagnosis, tumor staging, and management decisions. No specific tumor marker exists for cholangiocarcinoma. Serum carcinoembryonic antigen (CEA) and cancer antigen 19−9 may be utilized. However, their sensitivity and specificity have been poor and their levels may normalize once the obstruction is relieved. The α-fetoprotein is usually normal.

Diagnostic imaging modalities include transabdominal ultrasound, computed tomography (CT), cholangiography [via endoscopic retrograde cholangiopancreatography (ERCP) or the percutaneous route], magnetic resonance imaging (MRI), positron emission tomography (PET), endoscopic ultrasound (EUS), and intraductal ultrasound. The primary goal of these tools is to define the local extent of the tumor and the presence of distant metastasis. This information will assist in tumor staging and determining prognosis and management strategies.

The initial evaluation of a patient with the above-listed laboratory test abnormalities will commonly include transabdominal ultrasound (US) and/or CT. US is primarily utilized to identify bile duct dilation. Perihilar CCA may appear as intrahepatic dilation. Intrahepatic tumors may appear as segmental intrahepatic dilation and distal extrahepatic tumors may be represented by both intra- and extrahepatic bile duct dilation. CT and MRI commonly identify the location of the obstructing lesion, evidence of metastasis, and bile duct dilation. Intrahepatic CCA may appear as a hepatic mass with intrahepatic segmental bile duct dilation. Extrahepatic tumors, including Klatskin tumors, may appear as a hilar mass with associated biliary dilation. In some cases, the tumor may not be identified and the site of the lesion may be elucidated by locating where the bile duct dilation begins. In one report of 29 patients with histologically proven hilar CCA, 100% of the tumors were detected using intravenous bolus-enhanced (multiphasic) helical CT. However, resectability was accurately determined in only 60% of the patients. Regional lymph nodes may be detected and assist with local regional staging. However, patients with chronic inflammatory conditions of this anatomic region may be associated with benign lymph nodes.

Cholangiography in the past has been a primary tool used to diagnose CCA. The opacification of the biliary tree allows for localization of the obstructing lesion, tissue acquisition, and stenting for biliary drainage. Cholangiography can be performed by ERCP or by percutaneous transhepatic cholangiography (PTC). ERCP can be difficult in proximal and perihilar tumors that completely obstruct the bile duct. The inability to traverse the stricture after contrast injection may lead to an obstructed contaminated duct and the risk of cholangitis. PTC may be limited in patients with PSC due to the marked stricturing of the intrahepatic biliary tree. Other diseases that may be confused with a CCA-associated stricture are gallbladder cancer, Mirizzi's syndrome, or a benign inflammatory stricture caused by prior instrumentation or stone disease. Tissue acquisition is most easily accomplished via brush cytology, which makes the diagnosis in 20−80% of the patients. Other approaches include forceps biopsy, bile aspirate, and fine-needle aspiration (FNA). A cytologic or histologic diagnosis is not essential if the patient is deemed resectable.

Magnetic resonance cholangiopancreatography (MRCP) is a promising noninvasive modality that displays a three-dimensional image of the biliary tree, hepatic parenchyma, and surrounding vessels. This technique may become the primary imaging tool for local regional preoperative staging.

Additional relatively new modalities are being developed to detect, diagnose, and stage CCA. EUS is a relatively noninvasive endoscopic technique that may be utilized to image the distal extrahepatic bile ducts, perihilar tumors, and surrounding structures. Portal vein invasion has been shown to more accurate with EUS than CT, angiography, and US. EUS-guided FNA may be used to obtain a cytologic diagnosis and is associated with much less risk than ERCP. In one study of 10 patients with suspected hilar CCA, EUS-guided FNA diagnosed 7 patients with CCA and 1 with hepatocellular carcinoma. Intraductal ultrasound has been used to image bile duct strictures and to evaluate for portal vein involvement. However, they have a relatively shallow depth of penetration, limiting visualization of large tumors and surrounding lymph nodes and vessels. PET scanning reflects the high glucose metabolism of neoplasia. One study was able to show high uptake in CCA patients versus those who had PSC. Furthermore, one small study suggests a role for improved preoperative staging by identifying distant metastasis. Other modalities include choledochoscopy, radiolabeled antibody tracing, or ligand imaging.

PATHOLOGY

Cholangiocarcinoma arises from the epithelial cells of the bile duct (cholangiocytes). The most common tumor histologic type is adenocarcinoma (>95%) (Table I).

Papillary carcinoma may have the best prognosis because it typically presents early. These tumors have a strong desmoplastic reaction that leads to difficulty in obtaining sufficient cells for a diagnosis. This likely explains the poor yield from endoscopically obtained tissue. Immunohistochemical stains for CEA, mucin, and cytokeratins may be helpful in making the diagnosis.

CCA usually spreads locally to the adjacent structures, abdominal cavity, and lymph nodes. Regional lymph node involvement occurs in more than 75% of patients. Metastases occur late in the disease, most commonly to the liver, peritoneum, lungs, and bones.

STAGING AND PROGNOSIS

Extrahepatic biliary tract tumors commonly present early. Early small tumors will partially or completely occlude the small-diameter bile duct and lead to obstructive signs. However, tumors of the hilum have a poor prognosis. They are difficult to resect due to their vascular and hepatic parenchymal invasion. CCA is staged according to the tumor−node−metastasis (TNM) system of classification. Extrahepatic tumors confined to the bile duct or beyond are staged as IA and IB. Those tumors invading the liver, gallbladder, pancreas, or unilateral branches of the portal vein or hepatic artery are Stage IIA. Stage IIB is characterized by any of the above with regional lymph node involvement. Stage III includes tumors that invade the other adjacent organs as well as the main portal vein and common hepatic artery. Stage IV is distant metastasis, regardless of the T and N stages. Alternatively, intrahepatic tumors are currently staged the same as hepatocellular carcinomas because of the limited prognostic information.

TREATMENT STRATEGIES

Surgical resection is the only curative treatment modality for cholangiocarcinoma and is the only modality associated with an improved 5-year survival. Overall, the prognosis is poor, with a 5−10% 5-year survival and a 20-month median survival. However, patients with perihilar disease have a median survival of 12−24 months. Patients with distal extrahepatic CCA have 5-year survival rates of 15−25%. Multiple factors determine a patient's candidacy for resection. Anatomical criteria include the absence of distant metastasis, vascular invasion, lymph node involvement, or extensive disease beyond a feasible surgical margin. Common clinical criteria that prohibit surgical resection include poor performance status, significant cardiopulmonary disease, and cirrhosis.

Patients who undergo surgery and are found to have a tumor approaching or involving the resection margins should be considered for adjuvant therapy. Patients that

are unresectable should be offered palliative biliary drainage and adjuvant therapy. This has been shown to improve quality of life and prolong survival.

The surgical approach depends on the location of the tumor. Intrahepatic cholangiocarcinoma is usually treated by hepatic resection. Perihilar tumors are difficult to resect and less than 40% are resectable. The surgical technique depends on the Bismuth classification (location of the tumor). Distal extrahepatic CCA has the highest cure rate and the most common surgery is pancreaticoduodenectomy (Whipple procedure). Liver transplantation has been disappointing and is discouraged given the poor success rates and shortage of livers.

Adjuvant radiation and chemotherapy have not been well studied. Radiation in patients with involved margins may improve survival and quality of life. However, it may be associated with complications of hepatitis and gastroduodenal obstruction. Chemotherapy preoperatively or postoperatively has not been shown to improve survival or quality of life. Chemoradiotherapy may have a role; however, this remains unclear.

Palliative therapy is pursued in the majority of patients with cholangiocarcinoma. Jaundice is the most common ailment palliated and this can be approached surgically via biliary bypass or with endoscopic/percutaneous biliary stenting. The latter technique is less invasive. Metal stents are preferred over plastic because of their longer patency rates. Additional modalities for biliary palliation include photodynamic therapy, Nd-YAG laser, and microwave tissue coagulation.

SUMMARY

Cholangiocarcinoma is a relatively rare malignancy of the biliary tree. The tumor may be located anywhere along the intrahepatic or extrahepatic ducts. Patients generally present with jaundice, pruritus, weight loss, and pain. Associated conditions include liver fluke infestation in Third World countries, congenital biliary cysts, and primary sclerosing cholangitis. A bilirubin level >12 mg/dl in the setting of obstruction indicates malignancy. The cancers arise from the biliary epithelium and are most commonly adenocarcinomas. A tissue diagnosis may be difficult to make because of a marked desmoplastic reaction. Therefore, vigilance must be advocated in seemingly benign inflammatory strictures. The diagnosis is made from the clinical history, laboratory, and imaging studies. Cholangiography, MRCP, helical CT, EUS, intraductal US, and PET scanning can determine the extent of disease and local regional staging. Tissue acquisition is not necessary preoperatively; however, it can be obtained by EUS-guided FNA, ERCP-directed brushings, or biopsies. Treatment entails either surgical resection for attempted cure or the use of endoscopically or percutaneous placed stents for palliative biliary drainage. The role of adjuvant or neoadjuvant therapy is unclear. The prognosis is poor with a 5–10% 5-year survival and a 20-month median survival.

endoscopy Examination of the interior of intestine by an endoscope.
hemobilia Bleeding into the biliary system as a result of trauma, tumor, or infection.
hepaticoenterostomy Establishment of a communication between the hepatic ducts and the duodenum.
jaundice A yellowish staining of the integument, sclera, deeper tissues, and excretions with bile pigments, resulting from increased levels in the plasma.
lobectomy Excision of a lobe of an organ, e.g., liver.
pancreatitis Inflammation of the pancreas.
portal vein thrombosis Thrombus clot within the portal vein.
Roux-en-Y choledochojejunostomy A surgical anastomosis between the common bile duct and the jejunum.
secondary biliary cirrhosis End-stage liver disease due to obstruction of extrahepatic bile ducts, which leads to cholestasis and proliferation of small bile ducts and fibrosis.
sphincter of Oddi Hepatopancreatic ampullae that open to the common bile duct and pancreatic duct.
sphincterotomy An incision or division of the sphincter of Oddi.
stricture A narrowing or stenosis of a hollow structure, usually consisting of cicatricial contracture or deposition of abnormal tissue.

Oriental cholangiohepatitis, more commonly known as recurrent pyogenic cholangitis, is a chronic disease characterized by the formation of primary intrahepatic pigmented stones and sequelae that include recurrent cholangitis, strictures of the intrahepatic bile ducts, hepatic abscesses, portal vein thrombosis, cholangicarcinoma, and sometimes secondary biliary cirrhosis with hepatic failure. Patients often suffer from recurrent attacks of abdominal pain, fever, jaundice due to intrahepatic ductal stone, and strictures. Two theories are proposed as the initiator of the disease process: parasitic infestation with organisms such as *Clonorchi sinensis* and *Ascaris lumbricoides* and malnutrition theory, which suggests nutritional deficiency of an inhibitor(s) of bacterial bilirubin-deconjugating enzyme, resulting in formation of bile duct stones.

INTRODUCTION

Oriental cholangiohepatitis is a syndrome characterized by recurrent attacks of suppurative cholangitis in which the bile ducts are dilated and contain multiple pigment stones. It was first described among the Chinese in Hong Kong in 1930. This condition is also known as Oriental cholangitis, Oriental biliary obstruction syndrome, intrahepatic pigment stone disease, hepatolithiasis, and primary cholangitis and currently is more commonly known as recurrent pyogenic cholangitis (RPC). As these names suggest, the syndrome is endemic to Southeast Asia. It is also encountered mostly in Asian immigrants in the United States and Canada. Sporadic cases have also been reported among natives of Europe, South Africa, India, and South America.

PATHOLOGY

The bile ducts within the liver (intrahepatic) and outside the liver (extrahepatic) are dilated and contain many bile pigment stones. The common bile duct and left hepatic duct are commonly affected. They are surrounded by extensive fibrosis and inflammation. The

papilla of the sphincter of Oddi may be hypertrophied and fibrosed from the repeated passage of stones. As many as 35% of the patients may have biliary strictures. Hilar strictures involving the left hepatic duct are found most frequently, followed by strictures of the common hepatic duct. The stones are composed of bile pigment with color ranging from orange to black and size varies up to 3 cm. However, stones are absent in 20–25% of patients. This may be due to early disease or complete passage of stones.

ETIOLOGY AND PATHOGENESIS

As the name implies, patients often have recurrent pyogenic infection of the biliary system. The common organisms in descending order are *Escherichia coli, Klebsiella, Pseudomonas, Proteus* species, and rarely anaerobes. These enteric organisms are thought to be transported to the biliary system by transient portal bacteremia. Some underlying abnormality, such as ductal epithelial disruption or stasis, promotes seeding of the bacteria and causes infection and secondary pigment stone formation. Stone formation then produces more obstruction and infection and hence the recurrent episode of cholangitis. Two theories are proposed to explain the initiation of the pathogenesis: the parasite theory and the malnutrition theory. The parasite theory proposes that parasitic infestation of the biliary tree results in the epithelial damage. The parasitic debris and ova may act as a nidus. Parasites implicated are liver flukes, such as *Clonorchis sinensis, Opisthorchis viverrini*, and *Opisthorchis felineus*. Infestation with these liver flukes is common in Southeast Asia and up to 45% of patients have evidence of past infestation. *Ascaris lumbricoides* are also associated with RPC found outside of Asia. However, evidence against this theory are the facts that helminthes or ova are recovered from the stools in only 5 to 25% of patients and that RPC is on the decline in some regions that are endemic for *Clonorchis*, such as Japan.

Malnutrition theory suggests that recurrent bacterial gastroenteritis common in lower socioeconomic areas results in portal bacteremia and subsequent seeding of the bacteria in the biliary system. The indigent population often consumes a low-protein diet that may result in deficiency in their bile of glucaro-1:4-lactone, which is an inhibitor of the enzyme β-glucuronidase. Bacterial β-glucuronidase is particularly active at the bile pH and can deconjugate secreted bilirubin, resulting in formation of insoluble calcium bilirubinate and brown pigment stones.

CLINICAL PRESENTATION

RPC is usually seen in patients who are younger than patients with choledocholithiasis in the West. A majority of the patients present in the third to fifth decade. RPC affects men and women equally. Patients most commonly present with Charcot's triad: fever, right upper quadrant pain, and jaundice. The typical clinical course is that of recurrent attacks. Approximately 70–85% of patients have a history of frequent attacks, typically once or twice a year.

COMPLICATIONS

Patients may present with complications such as rupture of the bile duct, causing peritonitis or formation of fistula to nearby organs. Portal vein thrombosis and hemobilia may occur. Systemic sepsis may manifest as brain or lung abscess. Acute pancreatitis occurs in up to 10% of patients. There is an association with an increased risk of cholangiocarcinoma.

DIAGNOSIS

The diagnosis is suggested in patients with the typical history and demographic background. Radiologic studies with ultrasound and computer tomography (CT) are important to make the diagnosis. Ultrasound shows ductal dilation and ductal stone in up to 90% of patients. CT is the best noninvasive diagnostic modality. CT often reveals a characteristic pattern of dilated central intrahepatic ducts with acute tapering of the peripheral ducts. Stones, liver abscesses, and lobar atrophy are best seen on CT scan. Once the patient is stabilized, endoscopic retrograde cholangiopancreatography (ERCP) can be used to demonstrate definitive imaging of the biliary system. The dilation of the intra- and extrahepatic ducts may produce a classic "arrow sign" pattern. However, if the duct was obstructed, cholangiography may be nondiagnostic. ERCP can also assist in sphincterotomy and in stone extraction using balloon and basket and can facilitate bile duct drainage.

MANAGEMENT

The goal of treatment is to treat the acute infection and prevent complications and recurrence. Most patients respond to conservative treatment with broad-spectrum antibiotics. However, up to 20% of patients may require emergent cure surgery. These patients often fail antibiotics with persistent fever, pain, jaundice, or signs

of peritonitis. Emergent surgery often consists of common bile duct exploration, T-tube placement, and cholecystectomy if the gallbladder is also obstructed. ERCP with biliary stent or percutaneous drainage of the intrahepatic duct is also performed in selected patients.

Prevention of future attacks is achieved by removing as many stones and debris as possible and dilating or resecting the stricture. Surgery may be required in patients with gallbladder stones, intrahepatic ductal stones, and disease predominantly localized to the left hepatic ductal system. Surgical techniques include left lobectomy, removal of intrahepatic stone by choledochoscopy and electrohydraulic lithotripsy, and drainage procedures such as choledochoenterostomy or hepaticoenterostomy. In patients with extensive intrahepatic ductal stones requiring frequent endoscopic or radiographic intervention, a Roux-en-Y choledochojejunostomy with the proximal Roux loop attached to the abdominal wall or externalized as a stoma is an increasingly popular approach. Surgical management has a good outcome, with up to 80% of patients remaining symptom-free during a mean follow-up of 7 years. Endoscopic management in one large study reported that 95% of patients were symptom-free during a follow-up period of 2–3 years.

cholangiocarcinoma A malignant transformation of cholangiocytes that carries a poor prognosis.
cholestasis A pathologic process that prohibits the clearance of bile salts from the hepatocyte to the lumen of the gastrointestinal tract.
fibrosis End result of an inflammatory response of an organ or tissue to an insult, resulting in scar formation.
hepatic cirrhosis End-stage condition of the liver recognized histologically by extensive fibrosis and clinically by hepatic cellular dysfunction and portal hypertension.
ischemia Loss of blood supply to the cell, resulting in hypoxia and subsequent cellular injury.
sclerosing cholangitis A condition characterized by fibrosis of the biliary tree.
ulcerative colitis Chronic inflammatory condition involving the colon.

Sclerosing cholangitis (SC) refers to a host of chronic hepatobiliary disorders characterized by an irreversible diffuse fibrosis of the biliary system, leading to the formation of strictures of both the intra- and the extrahepatic biliary trees. The first description of SC is credited to Delbet in 1924. SC used to be discovered at surgery in the course of investigation of a patient with liver disease. It was not until the advent of endoscopic retrograde cholangiopancreatography in the early 1970s that SC became more recognized, which led to improved research and understanding of the disease. The etiology of SC is varied. When the etiology of the biliary fibrosis is known, the SC is referred to as secondary. When the etiology is not known, it is referred to as primary sclerosing cholangitis (PSC). PSC, however, seems to stand as a separate entity, a chronic and progressive fibrosing liver disease with clinical and serologic features suggestive of an underlying autoimmune dysfunction. Most of the published data pertain to PSC.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is part of a spectrum of diseases referred to as sclerosing cholangitis. PSC is characterized by chronic, active, and progressive inflammation affecting the intra- and extra-hepatic bile ducts, leading to an irreversible fibrosis of the biliary tree, stricture formation, and bile duct obliteration and loss; it manifests with cholestasis and eventually leads to liver cirrhosis.

Epidemiology

PSC affects both males and females with a male : female ratio of 2 : 1; most patients present between 25 and 45 years of age. PSC has been reported in patients as early as the neonatal period and as late as the eighth decade. The prevalence of PSC in the United States is estimated to be 1 to 6 cases per 100,000. However, because of the strong association with inflammatory bowel disease (IBD), the prevalence of PSC is higher in populations where IBD is more prevalent, as in the Scandinavian countries.

Etiology/Pathophysiology

The etiology of PSC has not been defined. Many possible mechanisms and associations have been proposed but the evidence is inconclusive. The association between PSC and IBD and other immune system diseases, such as thyroiditis and type I diabetes mellitus, increased levels of serum immunoglobulins, the presence of autoantibodies, and an association with human leukocyte antigen (HLA) haplotypes are strong evidence that immune-mediated malfunction plays a major role in the pathogenesis of PSC. HLA-A1, -B8, and -DR3 as well as -DR52a, -DQ2, and -DQ6 haplotypes have been found to have a strong association with PSC. HLA-A1, -B8, and -DR3 haplotypes seem to confer an risk of developing PSC that is independent of ulcerative colitis (UC) but the risk is increased in its presence. The genetic inheritance pattern favors pleomorphism in the gene of the major histocompatibility complex. However, PSC does not have many of the characteristics of a classic autoimmune disease, such as having a female preponderance and response to immunosuppressive therapy.

Thus far, five different human HLA haplotypes have been associated with PSC: three with an increased risk and two with a reduced risk of the disease. Those that are

associated with an increased risk are MIC-A5.1 and MIC-B24.

Nonimmunogenic mechanisms have been proposed but supportive and reproducible evidence has been lacking. These mechanisms include chronic portal bacteremia, toxic bile acid metabolites produced by enteric flora, toxins produced by enteric bacteria, chronic viral infection, and ischemic vascular damage.

Portal Bacteremia

The association between PSC and UC led investigators to question whether chronic portal bacteremia could constitute a cause for PSC based on findings in animals. Further research failed to find evidence of portal vein phlebitis, a typical feature of portal bacteremia.

Toxic Bile Acid Metabolites

Lithocolic acid is hepatotoxic in animals. It is formed from chenodeoxycholic acid by bacterial 7-α-dehydroxylation in the colon. However, an abnormal concentration of bile acids was not found in the bile and portal blood of patients with PSC. Furthermore, lithocolic acid is rapidly sulfated and rendered nontoxic in humans.

Bacterial Toxins

When *N*-formyl L-methionineL-leucineL-tyrosine, a peptide produced by enteric flora, was introduced in rat colons, it produced a form of colitis and the biliary tree of the rats showed pathological changes similar to those occurring in PSC. Similar changes were also seen when killed *Escherichia coli* and other bacteria cell wall polymers were injected into the portal vein of rabbits. However, the natural history of PSC does not support this hypothesis. Antibiotic treatment was not effective; the course of PSC is distinct from that of UC and not altered even after proctocolectomy.

Viral Infection

Infection with human immunodeficiency virus (HIV) and cytomegalovirus (CMV) can produce changes in the biliary tree similar to those seen in PSC. However, there has been no isolation of CMV or Reovirus3 (a virus that has trophism to the biliary epithelium) from patients with PSC.

Ischemia

The pathology in patients with PSC does not show any involvement of the vasculature of the liver or any ischemic changes in the bile duct as seen in patients with vasculitis or intrahepatic arterial infusion of chemotherapeutic drugs.

Complications and Natural History

What is striking about the natural history of PSC is the variability in its clinical course and progression as well as the dissociation between the cholangiographic appearance of the disease and the clinical symptoms. Some patients might present with cholangitis that resolves spontaneously and does not recur for a long period of time; others, with a marked sclerotic appearance of the bile duct, may be asymptomatic and have only an elevated alkaline phosphatase or have advanced liver disease with cirrhosis. This discrepancy between symptoms and signs makes the formulation of a reliable outcome scoring system hard to achieve. Nevertheless, multiple scoring systems have been developed based on univariate and multivariate predictors to aid in monitoring the clinical course of PSC and the timing of liver transplantation.

The most serious complications that face patients with PSC are the development of liver cirrhosis and the development of cholangiocarcinoma (CC). Also, patients with PSC and concomitant UC seem to have a higher risk of developing colon cancer than patients with UC without PSC. Other complications include the formation of choledocholithiasis, cholangitis, malabsorption, pruritus, fatigue, and chronic pancreatitis.

Hepatic Cirrhosis

In PSC, the development of liver cirrhosis is a consequence of chronic biliary cholestasis. The constant inflammatory process that affects the bile ducts leads to progressive fibrosis of the liver parenchyma and bridging fibrosis. The exact mechanism that leads to this stage is poorly understood. Whether bile retention and copper retention play a role has yet to be elucidated. Once cirrhosis sets in, patients are subject to the usual complications of liver cirrhosis: portal hypertension, ascites, variceal bleeding (esophageal, gastric, or at the anastomotic site in patients with IBD who underwent surgery), peritonitis, encephalopathy, and liver failure; the last complication is the most common cause of death.

Cholangiocarcinoma

The prevalence of CC in patients with PSC ranges between 4 and 20%. The prevalence at autopsy is higher and approximates 40%. In patients undergoing liver transplantation, the prevalence of incidental CC is between 23 and 33%. The tumor is usually multicentric, arises around the proximal main bile duct and its bifurcation, and is less common distally along the duct. Factors such as age at presentation, sex, PSC involvement of the intra- or extrahepatic ducts, or the presence of IBD

do not affect the development of CC. Alcohol consumption is an additional risk factor for developing CC in PSC.

CT scan of the abdomen is valuable in a deteriorating patient to rule out the presence of CC. Ultrasound has low sensitivity in this regard. Positron emission tomography with [^{18}F]fluoro-2-deoxy-D-glucose might be of value in the diagnosis of CC with a sensitivity of 92% and a specificity of 93%.

Patients with tumors that display p53 overexpression and k-Ras mutation have a worse prognosis and shorter survival. However, these markers are not helpful in the diagnosis of CC. For example, k-Ras is found in 30% of patients with PSC without CC. DNA cytometry, a method that detects DNA aneuploidy, was found to be promising in the detection of CC in patients with PSC. Cells of CC showed DNA aneuploidy in 80% of the tissues compared to 12% in tissues of bile ducts of patients with PSC but without CC and 1% in tissues of gallbladders with chronic inflammation.

CA 19-9 and carcinoembryonic antigen (CEA) are not sensitive or specific for the diagnosis of CC. A model using both of these tests (CA 19-9 $-$ CEA $\times$ 40) has yielded 86% accuracy, 66% sensitivity, and 100% specificity in the diagnosis of CC.

Obtaining biopsies and cytology from brushing at the time of endoscopic retrograde cholangiopancreatography (ERCP) has resulted at best in a sensitivity of 80% but the average is approximately 45%. Currently, performing ERCP or any of the tests mentioned above as part of surveillance for CC has not been shown to be beneficial and, in the case of ERCP, is not recommended.

Choledocholithiasis

Cholelithiasis and choledocholithiasis are well described in patients with PSC. Gallstones are usually of the calcium bilirubinate variety. Pigment stones may form in the extra- and intrahepatic ducts, particularly in patients with recurrent attacks of cholangitis. In a retrospective review of 85 patients with sclerosing cholangitis, 20% of patients had biliary stones, 8% had cholelithiasis, 11% had choledocholithiasis, and 7% had both cholelithiasis and choledocholithiasis. The presence of cholelithiasis has no additional clinical significance compared to patients who have cholelithiasis without PSC. The development of cholangitis or a worsening clinical status in a patient with PSC should direct the clinic

Cholangitis

Acute ascending cholangitis can occur in patients with PSC. It occurs mainly in those patients who had endoscopic or surgical manipulation of the biliary system and is less likely in those without endoscopic stenting, dilation, or surgical drainage procedures. In the latter subgroup of patients, a less severe type of cholangitis occurs more frequently (10 to 20%). Usually it is self-limiting but can be recurrent.

Pruritus

Pruritus can be one of the most frustrating complications of cholestasis. Symptoms can become so severe as to interfere with sleep and cause skin abrasions. The pathogenesis of the pruritus is uncertain. The evidence that retention of endogenous bile acids causes cholestatic pruritus is deduced and indirect. Furthermore, recent findings suggest that central events in the brain that lead to an increased opioidergic tone may be implicated.

The view that bile acid retention causes pruritus is old. Varco1 in 1947 noted that biliary drainage reduced pruritus in patients with extrahepatic biliary obstruction and when bile was fed to patients, their pruritus returned. It is known that biliary drainage improved cholestatic pruritus in patients with intrahepatic cholestasis. Processes and medications that bind bile salts, such as the administration of cholestyramine, passage of plasma over charcoal or anion-exchange resins, and extracorporeal albumin dialysis, have been shown to diminish cholestatic pruritus. In all of these procedures, retained substances in addition to bile acids could have been removed at the same time so that cause and effect relationships are uncertain.

Whether peripheral events, such as the accumulation of bile acids in interstitial fluid of the skin, initiate the neural events that mediate this form of pruritus is uncertain. Three lines of evidence support this hypothesis: (1) Opioid receptor ligands with agonist properties (e.g., morphine) mediate pruritus. (2) Endogenous opioid-mediated neurotransmission/neuromodulation in the central nervous system is increased in cholestasis. (3) Opiate antagonists induce amelioration of the behavioral consequence of the pruritus of cholestasis (scratching activity). Serotonergic neurotransmission may also contribute to the pruritus.

Other Complications

Chronic pancreatitis is also associated with PSC. The frequency of this association differs widely in the literature, ranging from 8 to 77%. In general, the pancreatic exocrine function is well preserved and these patients rarely develop steatorrhea secondary to pancreatic insufficiency.

Colonic neoplasia seems to be more prevalent in patients with IBD and concomitant PSC than in patients who have IBD but not PSC.

Clinical Presentation

Symptoms

Patients with PSC usually present in an insidious manner. Most patients suffer from vague symptoms for approximately 2 years before diagnosis. These symptoms can include fatigue, right upper quadrant (RUQ) pain, and eventually jaundice and pruritus. Presentation of a patient with PSC differs between those who have an associated IBD and those who do not. In a Swedish study, 92% of asymptomatic patients had an associated IBD at the time of diagnosis versus 74% of symptomatic patients. This reflects the awareness of the association and therefore the early diagnosis. In all patients, 56% were symptomatic, 37% had RUQ pain, 30% had jaundice, 30% had pruritus, 4% had ascites, and 4% presented with esophageal variceal bleeding. Forty-six percent had histologic stages 1 and 2, 28% were stage 2, and 26% were stage 4. In another study, 10 to 15% had symptoms suggestive of recurrent cholangitis, such as fever, chills, and RUQ pain. Along the course of PSC, symptoms of weight loss or worsening liver test should raise the possibility of CC and, if fever and RUQ pain develop, of cholangitis.

Physical Exam

Early in the course of the disease and when PSC is diagnosed incidentally, physical signs specific for PSC are absent. Patients with advanced liver disease will manifest signs of portal hypertension and cirrhosis, such as spider angiomas, large spleen, muscle wasting, and icterus. Skin scratches secondary to pruritus can be seen. If the patient has cholangitis, abdominal exam reveals tenderness in the RUQ; otherwise, the abdominal exam is normal.

Laboratory Tests

The most common abnormal laboratory value is alkaline phosphatase (AKP). It is seen in more than 90% of patients with PSC. Usually it is elevated 3 to 5 times above the normal range but values as high as 20 times elevated have been reported. Normal values still could be seen in 6 to 8.5% of patients with PSC. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are rarely elevated more than three times their normal levels. Bilirubin is usually normal but is elevated in bouts of cholangitis or intermittent obstruction and in advanced cirrhotic patients. Elevated prothrombin time usually denotes vitamin K deficiency and, less likely, cirrhosis. Albumin is usually normal unless the patient has advanced liver disease.

Blood counts are normal, but eosinophilia can be observed on rare occasions. Serum levels of immunoglobulins are increased. The immunoglobulin M (IgM) level is elevated in 45% of patients followed by an elevation in IgG and IgA. Antinuclear cytoplasmic antibody in a perinuclear pattern is seen in 77 to 88% of patients with PSC. Smooth muscle antibodies are also seen. Anti-mitochondrial antibody is typically absent. Other miscellaneous laboratory findings include elevated levels of cholesterol, lipoprotein X, ceruloplasmin, and copper.

The differential diagnosis of cholestasis is long and is best approached by putting the patient's presentation in the context of his or her past medical history and life events in order to expose predisposing factors. A list of disorders that can present with cholestasis is outlined in Table I.

Diagnosis

The diagnosis of PSC requires a high index of suspicion since patients can be asymptomatic. All patients with IBD should be screened with liver tests. If alkaline phosphatase is elevated, the possibility of PSC should be ruled out. The diagnosis of PSC is established by demonstrating the characteristic changes affecting the biliary tree. The different modalities available to make the diagnosis are discussed below.

TABLE I Differential Diagnosis of Cholestasis

Acute
Biliary obstruction (benign and malignant)
Severe sepsis
Total parenteral nutrition

Imaging

Endoscopic retrograde cholangiopancreatography Because of the lack of specificity of many of the changes seen on liver biopsies, cholangiography is considered the gold standard for the diagnosis of PSC. Although percutaneous transhepatic cholangiography (PTC) is available, because of the nature of the small and attenuated bile ducts and the formation of biliary strictures in PSC, ERCP is the preferred method for diagnosing PSC. In addition to establishing the diagnosis, ERCP can provide a means for therapeutic intervention, such as stricture dilation and obtaining cytological brushing from dominant and suspicious strictures. Also, it can provide information about the pancreatic duct and rule out associated chronic pancreatitis. The classic appearance of affected bile ducts in PSC consists of diminished and attenuated intrahepatic ducts (pruning) with multifocal strictures alternating with areas of normal or mildly dilated segments (cholangiectasia), giving the typical beaded appearance. The finding of webs and diverticula in the biliary tree is not pathognomonic for PSC since it can be seen equally in other conditions. The majority of patients will demonstrate strictures of both intra- and extrahepatic ducts (seen in 67% of patients). Twenty-seven percent have intrahepatic involvement alone and 6% have extrahepatic duct involvement only. The gallbladder and the cystic duct are usually spared.

Adequate visualization of the intrahepatic ducts is needed to delineate the anatomy and exclude other etiologies. Using a balloon and injecting contrast under occlusion are typically used to achieve opacification of the ducts. For example, an underfilled intrahepatic tree in Caroli's disease can give an appearance of PSC. Bile ducts of patients with cirrhosis are attenuated but do not show the beading appearance seen in PSC.

Computed tomography The findings seen on CT scan in patients with PSC are not specific for this disease although they do suggest the diagnosis. However, CT is useful in the follow-up of patients with PSC once the diagnosis has been established. In 16 of 19 patients with involvement of the extrahepatic duct seen on cholangiography, CT demonstrated stenosis of the common bile duct. It also depicted intrahepatic ductal dilation/stenosis in all patients and detected 3 cases of CC. CT is superior to cholangiography in detecting CC with a sensitivity and specificity of 82 and 80%, respectively, compared to 54 and 53% for cholangiography.

Magnetic resonance cholangiography Magnetic resonance cholangiography (MRC) is a rapidly developing imaging modality that is gaining popularity in the diagnostic work-up of patients with hepatobiliary and pancreatic disease. The main advantages it offers over ERCP and PTC are its noninvasive nature and its ability to provide information about the extrabiliary structures. As regards PSC, the current technology of MRC is not yet able to detect the small changes of the intrahepatic ducts seen on cholangiography. Although MRC is not recommended for the diagnosis of PSC, it can be helpful in the work-up of a patient with PSC to rule out CC or as a road map for ERCP.

Ultrasonography For practical purposes, ultrasonography proves to be of little value in the diagnosis and follow-up of patients with PSC. It is of great value in the initial work-up of patients presenting with hepatobiliary symptoms and helps to rule out other etiologies of cholestasis, such as major biliary strictures, postoperative complications, choledocholithiasis, liver cirrhosis, and ischemic insults to the hepatic arteries and veins.

Pathology

Gross specimens of liver from patients with PSC show thickened and hardened bile ducts. Histology reveals evidence of fibrosis involving all layers of the bile ducts from the mucosa to the adventitia. Perfusion studies of livers removed at the time of liver transplantation demonstrated intrahepatic tubular and saccular dilation (cholangiectasia) with transformation of bile ducts into fibrous cords with complete or partial obliteration of the duct lumen. These changes give the typical beading and pruning appearance of the bile ducts seen on cholangiography.

Microscopically, four stages of biliary and hepatic involvement have been established and carry different prognostic values. Early in the course of the disease, the interlobular ducts are infiltrated with small and large lymphocytes, neutrophils, plasma cells, occasional macrophages, and eosinophils. Degeneration of the ductular epithelium is seen. The portal tracts are inflamed and edematous. The ductules show a periductular inflammation and concentric fibrosis representing the described "onion skin" appearance. This finding occurs in less than 50% of liver biopsy specimens. The portal tracts in PSC are typically less inflamed than in primary biliary cirrhosis (PBC). In stage 2, the above-mentioned inflammatory process extends outside the portal tract to involve the periportal hepatocytes. The earlier involved bile ducts start to disappear and bile ductopenia is prominent. There is interference with bile flow and features of cholestasis begin to develop in the hepatocytes adjacent to the portal tract. Accumulation of bile, copper, and copper-associated proteins and formation of Mallory bodies become apparent. Periductular fibrosis is less prominent. In stage 3, bridging fibrosis is seen,

bile ducts disappear, and cholestasis may be prominent, mainly in periportal and periseptal hepatocytes. Stage 4 is frank liver cirrhosis and the histologic feature is similar to what is seen resulting from other etiologies of liver cirrhosis. The parenchyma of the liver displays an increase in copper staining. It is important to note that the pathologic changes seen in PSC, especially in the early stages, vary in severity from one part of the liver to another, which makes staging on the basis of liver biopsy alone difficult.

In less than 5% of patients with IBD and histological changes typical of PSC, the cholangiogram is normal. These patients are thought to have small-duct PSC.

Management

Management of patients with PSC is aimed at addressing two main issues. The first is an attempt to slow the progression of the disease process and subsequent hepatic dysfunction. The second is to treat the complications of PSC.

Treatment of the Disease Process

No treatment has been shown to reverse the inflammatory process. At best there has been improvement in the liver tests and liver biopsy histology but without any proven reproducible evidence of delaying the progression of hepatic dysfunction.

Despite the prevailing concept of the autoimmune basis of PSC, immunosuppressive therapy has been disappointing. Results with oral corticosteroids are inconsistent. However, in a subgroup of patients with PSC with pronounced features of autoimmune disease, corticosteroids may be beneficial. Studies using budesonide had mixed results. AST and alkaline phosphatase (AKP) improved, whereas bilirubin increased. The combination of prednisone and ursodeoxycholic acid (UDCA) showed minimal improvement. Whether adding azathioprine to the latter regimen is beneficial needs further investigation. Cyclosporine A has been used with disappointing results. The use of tacrolimus, methotrexate, pentoxifylline, and cladibrine (a nucleoside analogue with anti-lymphocytic activity) still needs the verification of controlled and larger trials.

Medications that affect bile acid physiology have been used. Cholestyramine (a bile acid-binding resin) has been used with equivocal results. Similar to results obtained in treating PBC, UDCA has resulted in improvement in the laboratory tests (AST, ALT, AKP, and bilirubin) but the effect on histology is less apparent, especially in patients with cirrhosis. The cholangiographic abnormalities do not change and there is no proof that chronic therapy with UDCA alters survival. Cessation of treatment results in an increase in all laboratory values. The beneficial dose was between 15 and 25 mg/kg per day. Higher doses seem to exacerbate pruritus with no added benefit; a lower dosage, e.g., 10 mg/kg, did not have the same beneficial effect.

UDCA is the 7β-epimer of chenodeoxycholic acid and it makes a small fraction of the normal human bile acid pool. The mechanism whereby UDCA induces improvement in liver tests in PSC and other cholestatic diseases is unknown. Potential effects could be related to the following: (1) reduced concentration of the hydrophobic (toxic) bile acid; (2) a hepatoprotective effect; (3) stimulation of choleresis; (4) influence of bile acid transport; or (5) an immunomodulatory effect.

The low side-effects profile of UDCA resulted in its liberal use in PSC. However, long-term benefit from this therapy has not been shown yet. For this reason, and because of the slow progression of PSC, treatment of asymptomatic patients or those with early stage PSC should be carried out as part of a controlled clinical study when possible.

Treatment of Complications of PSC

By the time cirrhosis has developed in patients with PSC, liver transplantation is the only therapy that is associated with improved survival. PSC is the third most common cause of liver transplantation in adults. One-year survival after liver transplantation has been reported to range from 71 to 88%. Studies from the Mayo Clinic and the University of Pittsburgh have shown that the 5-year survival of patients with PSC post-liver transplant was 73% versus 28% for patients without liver transplantation. Unfortunately, the finding of an unsuspected CC in the explant was associated with decreased survival.

Short of liver transplantation, the complications of advanced liver disease and portal hypertension are treated as in any other cirrhosis. The complication of peristomal variceal bleeding occurs to a greater extent in patients with PSC with ileostomy secondary to colectomy from UC. This bleeding can be severe and hard to manage, eventually requiring portosystemic shunts or liver transplantation.

Osteoporosis develops in patients with cholestatic liver disease. Pathogenesis is not fully understood and therapy is not fully satisfying. Exercise, calcium, and vitamin D supplements should be given to all patients with PSC. Therapy with calcitonin and alendronate should be given to those with documented osteopenia or osteoporosis although improvement in bone density has not been consistent.

Steatorrhea usually develops late in the course of PSC. Deficiencies of fat-soluble vitamins, such as

vitamins A and K and, to a lesser extent, vitamins E and D, can occur. A low-grade pancreatic insufficiency can develop and therefore supplementation with pancreatic enzymes, in addition to maintaining a low-fat diet, can be helpful.

Endoscopic Treatment

As yet, there is no controlled study in patients with PSC to show a survival benefit from endoscopic intervention and dilation of the accessible biliary strictures. In addition, once the biliary milieu is violated with instrumentation, the incidence of cholangitis increases and these patients are bound for recurrent intervention. Therefore, ERCP should be reserved for patients who develop complications from PSC, such as cholangitis or dominant biliary strictures. Preliminary data have shown that patients with dominant ductal strictures who underwent scheduled endoscopic dilations had a longer interval before needing liver transplantation than controls.

Outcome Predictor Models

Survival analysis from a large number of asymptomatic patients with PSC showed that most patients have progressive disease. Moreover, their survival is decreased when compared to matched controls in the same geographic area. Data from the Mayo Clinic suggest that 33 to 40% of patients with PSC die within 5 to 7 years after their diagnosis, with an average survival of 11.9 years. Because of the latter finding, risk score models that reflect disease severity and predict survival have been developed. These models, despite their incomplete nature, do provide an objective means of assessing the severity of the disease in patients with PSC and therefore help in their management and in the timing of liver transplantation. The Mayo Clinic PSC model was based on data from 426 patients and was validated. Predictors of survival were as follows: age, serum bilirubin, histologic stage on liver biopsy, and splenomegaly. According to this model, patients who are in the low-risk category had a probability of 92% for 5-year survival. Moderate-risk patients have a 5-year survival of 55% and those in the high-risk category had a 1-year survival of 70% and a 5-year survival of 18%. Still, this model does not correct for the fact that the development of CC does not directly correlate with the duration or the stage of PSC.

Relation to Inflammatory Bowel Disease

It is estimated that 75% of patients with PSC have IBD; 87% of these patients have UC and 13% have Crohn's disease. It is known that 2.5 to 7.5% of patients with UC have or will develop PSC during their illness. It is more common in patients who have diffuse colonic involvement than in those with distal involvement. Patients with IBD tend to be older at the time of diagnosis (44 versus 38 years of age). Sex, pattern of distribution of the biliary strictures, and time to develop CC did not differ between patients with and those without an associated IBD. Several studies have shown that the presence of PSC in patients with UC increases the incidence of colorectal neoplasia. Currently it is suggested that these patients undergo yearly surveillance colonoscopy. Whether the risk of colon cancer increases in these patients after liver transplantation is still controversial.

SECONDARY SCLEROSING CHOLANGITIS

Biliary tract pathology similar to PSC on laboratory and cholangiographic studies can develop secondary to a variety of insults. Injury affecting the vascular supply of the biliary tree (the hepatic artery) can cause ischemic cholangiopathy, and infectious conditions, such as acquired immunodeficiency syndrome (AIDS), can affect the biliary tree. Direct exposure of the biliary tree to different forms of scolecide, such as concentrated sodium chloride solution (30%) or alcohol, during therapy of liver *Echinococcus* cysts (hepatic hydatic disease) can also cause sclerosing cholangitis.

A different form of inflammatory change that affects the biliary tree in a segmental fashion is seen in recurrent pyogenic hepatitis. In this disorder, the intrahepatic ducts show "beading" and dilation with formation of intrahepatic stones of different sizes and number, affecting the left hepatic ducts more frequently than the right.

Ischemic Cholangitis

Ischemic cholangitis is a term used to describe a sclerosing cholangitis that is due to an injury of the hepatic artery, its major branches, and all the way to the level of the microscopic peribiliary plexus. The biliary tree is totally dependent on arterial circulation for its blood supply and any injury to this system can lead to ischemia followed by stricturing and beading of the affected area. Table II lists the causes of ischemic cholangitis.

Clinically, the diagnosis is suspected when patients have the predisposing conditions and present with increased bilirubin and AKP. Cholangiogram shows a picture that is indistinguishable from PSC. On histology, the biliary epithelium of the major ducts displays atrophy and erosion and, when severe, cholangiectasia.

[a] Orthotopic liver transplantation.

The smaller ducts and the intrahepatic ducts show similar findings and sometimes ductopenia. Depending on the etiology of ischemic injury, the surrounding arteries can show evidence of vasculitis, thrombosis, and signs of chronic rejection or they can be normal.

In the setting of liver transplantation, the biliary tree is at risk for serious complications. Anastomotic strictures used to be more common in the early days of transplantation but decreased in frequency with improvements in surgical techniques. However, it is still one of the most common complications in living-related donor liver transplantation. Nonanastomotic strictures can be due to hepatic artery thrombosis or prolonged cold or warm ischemia time during the processes of organ procurement and vascularization, respectively. Complications from hepatic artery thrombosis (HAT) carry high rates of morbidity and mortality (30–40%). HAT usually occurs in 3% of liver transplantation patients but has been reported to occur in as many as 19% of patients. Diagnosis is suspected when patients present with fever, elevated liver tests, or frank cholangitis. Occasionally, patients can be asymptomatic or can present with fulminant hepatic failure. This complication can occur early (less than 4 weeks) or late (more than 4 weeks) posttransplantation. Diagnosis could be established with a Doppler ultrasound study (sensitivity of 53%) but occasionally an angiogram must be performed (sensitivity of 82%). Management is usually by retransplantation (71%). Occasionally, intra-arterial urokinase treatment is effective. If the graft was salvaged, treatment of the biliary stricture proves to be difficult, requiring multiple sessions of endoscopic dilation and stenting, most frequently with hepatico-jejunostomy being the final treatment.

Infusion of different chemotherapeutic materials directly into the hepatic artery has been associated with biliary strictures in 50% of reported series. The most recognized agent is floxuridine. The speculated mechanism for inducing the biliary lesion is direct toxicity and secondary thrombosis to the hilar hepatic arteries used.

Infectious Cholangiopathy

Secondary cholangitis has been seen in association with certain infectious diseases. The best described is AIDS cholangiopathy, seen in patients with advanced AIDS. The prevalence of AIDS cholangiopathy is not well documented. In one study examining patients with AIDS-related diarrhea, cholangiopathy was seen in 30% of these patients. The etiologic factor is believed to be infectious. The most commonly isolated organism is *Cryptosporidium parvum*. Other organisms found include Microsporidia, *Mycobacterium avium* complex, CMV, *Isospora belli*, *Salmonella*, *Enterobacter*, and *Candida albicans* species. Also, the HIV virus itself is known to involve the biliary tree but clinical significance is not proven. In addition to infectious agents, Kaposi's sarcoma and Burkitt's lymphoma can cause similar results in this population.

Patients with AIDS cholangiopathy can be asymptomatic, with the only abnormality being an elevated AKP. Other patients can present with frank cholangitis with RUQ pain, fever, and leukocytosis. Abdominal pain is the most common symptom encountered in AIDS cholangiopathy. Bilirubin is usually less than 3 mg/dl, with higher levels seen in patients with biliary strictures secondary to Kaposi's sarcoma, lymphoma, or extrinsic bile duct compression. AST and ALT can be mildly elevated. AIDS cholangiopathy has been classified into three subgroups: (1) diffuse biliary involvement (37%); (2) combined biliary involvement and papillary stenosis (50–60%); or (3) papillary stenosis alone (6–8%).

Patients with AIDS and elevated AKP should be suspected of having AIDS cholangiopathy. Diagnosis is by demonstrating a cholangiogram with beading and narrowing of the biliary tree or with papillary stenosis. ERCP proves to be the diagnostic modality of choice. It offers diagnosis, a means to collect samples for cultures, and a therapeutic modality in case of the presence of papillary stenosis. The cholangiogram shows the main bile duct to have a rugged and irregular contour. The intrahepatic ducts show a pattern of narrowing and dilation similar to that seen in PSC. Isolated strictures of the main bile duct are usually not present, but if they are present, they are usually related to a malignancy (lymphoma, Kaposi's sarcoma) or due to external compression. However, ERCP should not be performed in asymptomatic patients and should be reserved for those in whom papillary stenosis is suspected. Isolating the culprit organism is not straightforward. Combining the cultures of bile aspirate with biopsies from the biliary tree and from the peripapillary region can increase the yield.

The prognosis of patients with AIDS cholangiopathy is poor. However, the survival of these patients is not different from patients with AIDS with the same opportunistic infections but without cholangiopathy.

Medical therapy for various organisms involved (paromomycin for *Cryptosporidium*, ganciclovir for CMV) has failed to clear the biliary infection, change the course of the cholangiopathy, or affect survival. Patients usually die from AIDS-related complications other than the cholangiopathy. ERCP and endoscopic sphincterotomy do not alter the natural history of AIDS cholangiopathy; however, they do relieve abdominal pain in 75% of patients with associated papillary stenosis.

Secondary sclerosing cholangitis and subsequent cirrhosis were reported in three patients following severe systemic (extrahepatic/extrabiliary) infection. Also, a case of sclerosing cholangitis in association with *Clonorchis sinensis* (a parasite) has been reported.

Other Etiologies

Hypereosinophilic sclerosing cholangitis is a rare disease caused by eosinophilic infiltration of the gallbladder and biliary tract seen in idiopathic hypereosinophilic syndrome. Therapy with steroids has been reported to improve symptoms, biochemical parameters, and cholangiographic parameters. Pathophysiology is not fully known.

Langerhans cell histiocytosis is a rare clonal disorder that consists of single or multiple mass lesions composed of cells with an abnormal Langerhans cell phenotype seen mainly in the pediatric population. Adult patients with this disorder can have involvement of the liver and biliary tree in a picture similar to sclerosing cholangitis.

Sarcoidosis is a multisystem granulomatous disorder of unknown cause that presents most commonly with hilar adenopathy, pulmonary infiltrates, and skin or eye lesions. Liver involvement is seen in more than 90% of these patients, manifesting with cholestasis. Biliary involvement, however, is not common but a case resembling sclerosing cholangitis has been reported. Improvement of the biliary stricture was seen after therapy with prednisone. Finally, tumors affecting the biliary tree can present with a cholangiographic appearance of sclerosing cholangitis and should be ruled out.

In summary, sclerosing cholangitis is a spectrum of disease that affects the intrahepatic and extrahepatic biliary trees. More often than not, it is an irreversible, slow, and progressive fibrosing process that leads to hepatic cirrhosis. Unfortunately, there is no effective therapy short of liver transplantation. Further understanding of the physiology of inflammation and repair of the biliary and hepatic system might lead to improvements in therapy.

cholangiogram Radiograph of the gallbladder and bile ducts; may be performed intraoperatively by either an open or a laparoscopic technique.
cholecystitis Inflammation of the gallbladder.
cholecystostomy Drainage of the gallbladder, usually by percutaneous tube placement, in patients with cholecystitis who are too unstable to tolerate a traditional cholecystectomy.
choledocholithiasis Stones in the common bile duct.
gallstones (cholelithiasis) Stones or pebbles within the gallbladder.
pneumoperitoneum Insufflation of carbon dioxide gas into the abdominal cavity; performed in all laparoscopic procedures to increase the "work space" available inside the abdomen.

Cholecystectomy, defined as surgical removal of the gallbladder, can be performed for a variety of indications. The traditional approach has been through an open incision in the abdomen, but a revolutionary change in the field of general surgery took place with the introduction of the laparoscopic cholecystectomy in the 1980s. Today, laparoscopic cholecystectomy is one of the most common surgical procedures performed worldwide. After intensive retrospective and prospective review, both surgical approaches to cholecystectomy achieve excellent results and a high degree of patient satisfaction.

HISTORICAL BACKGROUND

Although the existence of gallstones was first recognized in the fifth century, the first documented cholecystectomy took place on July 15, 1882, by Carl Langenbuch in Berlin. After extensive anatomical dissection on cadavers and live animals, Langenbuch's first human patient was a 43-year-old male who suffered from longstanding biliary colic so debilitating that he had become a morphine addict. The operation was deemed a success; not only did the patient survive, but his biliary colic was fully relieved and he gained over 10 pounds during his postoperative stay alone. The first successful cholecystectomy in the United States was performed by Justus Ohage in St. Paul, Minnesota, in 1886.

Open cholecystectomy would remain the gold standard for treatment of gallbladder pathology for the next 100 years. In 1987, Mouret performed the first laparoscopic cholecystectomy in France, thereby introducing a revolutionary change in biliary surgery. Over the past decade and a half, the laparoscopic cholecystectomy has become the new gold standard in the treatment of a wide range of gallbladder disease.

INDICATIONS FOR CHOLECYSTECTOMY

The indications for cholecystectomy include cholelithiasis, cholecystitis, biliary dyskinesia, and gallbladder cancer. Most patients with cholelithiasis are asymptomatic, and there is sufficient evidence that prophylactic cholecystectomy for asymptomatic disease is not warranted. Although the annual conversion rate of asymptomatic to symptomatic gallstones is 1–4% per year, a majority of patients develop symptoms for some time before they develop the complications of cholelithiasis, such as cholecystitis or gallstone pancreatitis. Moreover, studies that have followed patients with asymptomatic gallstones over several years have found that less than 20% of these patients will develop biliary symptoms, and the patients with symptoms can be safely treated at the time of presentation. Therefore, the risk of maintaining observation of asymptomatic patients is less than or equal to the risk of prophylactic cholecystectomy, and surgery is not recommended in these patients. One exception to this rule is the pediatric patient with gallstones; a young patient with gallstones will most likely develop symptoms over time. Another important exception is the patient who is undergoing an intraabdominal operation for morbid obesity; a patient with rapid postoperative weight loss is prone to symptomatic cholelithiasis, and data show that open cholecystectomy at the same time as the bariatric surgery is both clinically prudent and cost-effective.

Symptomatic cholelithiasis is the primary indication for cholecystectomy. The operation is performed to avoid recurrent biliary colic and to prevent complications such as choledocholithiasis, cholecystitis, and gallstone pancreatitis. The majority of patients with one episode of biliary colic will suffer from recurrent

pain. In addition, symptomatic patients have a higher risk of complications from their gallstone disease. In one large population-based study, 6.5% of symptomatic patients developed serious complications of gallstone disease that required surgical intervention over a 10-year period.

Acute cholecystitis mandates a surgical procedure on the gallbladder. The natural history of untreated cholecystitis involves gangrenous necrosis of the gallbladder and ultimately life-threatening perforation. In most cases, a laparoscopic or open cholecystectomy is indicated to remove the gallbladder as the primary source of infection. Although in the past many surgeons have treated patients suffering from acute cholecystitis with 4- to 6-week courses of antibiotics before operating, current data show that early operation within 48–72 hours of the onset of symptoms yields the most favorable outcomes. In unstable patients for whom the formal operating room is contraindicated, percutaneous cholecystostomy tube placement and future interval cholecystectomy are indicated.

Acute acalculous cholecystitis also warrants surgical management of the gallbladder. In the stable patient, cholecystectomy is the treatment of choice. However, the patient subset most prone to the acalculous variety of cholecystitis also has a high incidence of hemodynamic instability and severe cardiovascular disease and may be more appropriately treated with cholecystostomy.

Biliary dyskinesis is defined as symptoms of biliary colic with the absence of gallstones and is often associated with abnormal functional emptying of the gallbladder. It is believed that more than 90% of patients with documented biliary dyskinesia (as determined by abnormal gallbladder emptying in response to a fatty meal) have improvement or resolution of their symptoms following cholecystectomy.

Gallbladder cancer is an uncommon indication for cholecystectomy. Most often, cancer of the gallbladder is unsuspected and is found on routine pathologic examination of the gallbladder specimen following cholecystectomy performed for a separate indication. If gallbladder cancer is suspected preoperatively, the operation of choice is open cholecystectomy, given the risks of port site metastasis in laparoscopic cholecystectomy and the need for complete resection of the gallbladder and the adjacent hepatic tissue. For gallbladder cancer confined to the muscular layer of the gallbladder wall (Stage I), simple cholecystectomy is sufficient. For more extensive malignancies, an extended cholecystectomy with resection of portions of the liver around the gallbladder bed is indicated.

OPERATIVE STRATEGY

In preparation for both laparoscopic and open cholecystectomy, all patients should first undergo a thorough history and physical examination. Routine laboratory studies are ordered, including liver function studies; normal liver function confirms that the common bile or hepatic ducts are not obstructed by the patient's gallstone disease. The presence of nonobstructing stones, however, is not ruled out. The risks of the procedure to be discussed in detail with the patient should include infection, bleeding, possibility of bile duct injury, and conversion to open procedure if laparoscopic cholecystectomy is planned. A prophylactic dose of an intravenous first- or second-generation cephalosporin is given preoperatively. All patients are positioned in the supine position on the operating room table, and the entire abdomen is prepped with sterile technique.

Laparoscopic Cholecystectomy

The laparoscopic cholecystectomy involves extensive instrumentation and monitors. In general, a laparoscope, laparoscopic electrocautery and suction devices, and gas flow line are connected at the start of the procedure. Two monitors are placed on either side of the patient, usually toward the head of the bed so that both the operating surgeon and the first assistant have available lines of vision. The operating surgeon stands on the patient's left side. Finally, a nasogastric tube is placed to decompress the stomach.

The first maneuver in a laparoscopic cholecystectomy is the establishment of pneumoperitoneum. This can be done percutaneously with a Veress needle or by an open incision directly into the abdomen. This is performed through a 1-cm incision that holds a 10-mm trocar containing the laparoscope. The incision is often made just below the umbilicus in a transverse fashion but may also be performed vertically above and below the umbilicus. Through this incision, dissection is performed first to the fascia, which is sharply incised, and then to the abdominal cavity. The surgeon can place a finger through the incision and probe into the open abdomen. A 10-mm trocar is placed through this incision, and the gas flow is connected to the trocar to achieve pneumoperitoneum. The laparoscope is then inserted through the trocar when pneumoperitoneum is adequate.

At this point, the surgeon inspects the abdominal cavity. The camera is rotated around the abdomen, looking for adhesions to the anterior abdominal wall as well as additional intraabdominal pathology. Next, two 5-mm incisions are made on the patient's right

anterior abdominal wall, one in the right upper quadrant in the midclavicular line and one laterally in the anterior axillary line at the level of the umbilicus. The 5-mm trocars are placed through these incisions under direct visualization from the laparoscope to avoid injury to the liver or bowel. Grasping forceps are inserted via these trocars. A final incision is made through the midline 3 cm below the xiphoid, and a blunt dissector is inserted.

Using the grasping forceps, the fundus of the gallbladder is retracted toward the diaphragm and tipped posteriorly. This lifts the posterior liver to expose the infundibulum of the gallbladder. Detailed inspection of the gallbladder is carried out; occasionally, due to extensive adhesions around the gallbladder, it is clear at this point that the operation would carry a prohibitively high risk of complications if continued laparoscopically, and an open procedure is then initiated. If the gallbladder appears suitable for laparoscopic removal, the lower grasping forcep is attached to the apex of the gallbladder fundus and is retracted cephalad and held firmly in this position. The remaining grasping forcep is placed on the lateral infundibulum of the gallbladder and is retracted anterolaterally. In this way, the gallbladder is stretched out in both a vertical and transverse axis so that the triangle of Calot is splayed out, isolating and exposing the bile ducts and the vascular structures.

Gently using the blunt dissector, any omental adhesions to the gallbladder infundibulum are lightly grasped and retracted downward. After all adhesions are removed, the peritoneum overlying the gallbladder infundibulum is then dissected downward. These actions serve to expose the region of the cystic duct and artery. Once exposed, the next goal is to dissect around the cystic duct and artery separately, so that both may be individually clipped and ligated. During this portion of the operation, the operating surgeon should carefully trace out the cystic duct as well as the common bile duct. The surgeon should plan on ligating the cystic duct close to the gallbladder so as to avoid any injury to the common bile duct. If this anatomy cannot be readily discerned, a cholangiogram and/or conversion to an open procedure should be strongly considered.

When the cystic duct and/or artery have been fully exposed and dissecting instruments are easily passed around the structure, a clip applicator is inserted through the subxiphoid trocar and placed around the structure. It is recommended to place two clips on the inferior side of the structure and one clip on the superior aspect. The applicator is then removed, and endoscissors are used to divide the duct or artery between the upper and lower clips, maintaining a small stump on the downward side. After one structure has been clipped and ligated, attention turns toward the remaining structure for dissection and ligation.

With the cystic structures ligated, the gallbladder remains attached only to the liver bed. The peritoneum on the lateral and medial sides of the gallbladder is scored with electrocautery and the gallbladder is separated from the liver bed using a combination of anterior retraction and dissection via electrocautery. Any bleeding areas from the liver bed are coagulated with electrocautery as soon as they are visualized, because they often bleed profusely and retract when the gallbladder is fully removed. Once the gallbladder is completely detached from the liver, the camera is placed through the subxiphoid trocar, and a large grasping forceps or specimen bag is inserted through the umbilical port. The assistant then places the gallbladder in the forceps or bag, which is withdrawn via the umbilical port. At this point, the area is inspected for bleeding, and irrigation is performed. The umbilical incision is closed first at the fascia and then all incisions are closed with running subcuticular absorbable sutures.

Open Cholecystectomy

Elective open cholecystectomy is performed when it is decided preoperatively that laparoscopic cholecystectomy would be too difficult or contraindicated. This most often occurs in the patient with multiple previous abdominal surgeries. The procedure is also performed when a laparoscopic cholecystectomy is found to be too difficult and risky to the patient intraoperatively, and the procedure is therefore converted to an open cholecystectomy. Finally, open cholecystectomy may be performed in conjunction with other procedures, such as bariatric surgery or pancreatic and duodenal procedures.

Open cholecystectomy is performed using either the "fundus-down" or the "retrograde" approach to the gallbladder. Both approaches utilize the same incision and exposure of the right upper quadrant of the abdomen. A right subcostal incision is made approximately two fingerbreadths below the costal margin. Alternatively, an upper midline incision may be used if additional abdominal pathology exists or is in question prior to the operation. Once the abdominal cavity has been entered, the gallbladder is palpated to examine for stones in the common bile duct. A clamp is placed on the fundus of the gallbladder and lifted cephalad to expose the gallbladder in full.

In the "fundus-down" approach, the fundus is grabbed securely with the clamp and an incision is

made superficially in the gallbladder serosa around the fundus. This allows for exposure of a plane between the visceral layer of gallbladder serosa and the liver bed. This plane is dissected using electrocautery starting at the tip of the fundus and working down across the back side of the gallbladder toward the body and neck. In this way, a small amount of serosa is left on the liver side of the gallbladder bed and the liver is not dissected. As dissection is continued, the neck of the gallbladder leads to the cystic duct, which is then visualized, palpated for stones, and ultimately clamped with a right angle. If stones are felt in the cystic duct, they are pushed into the gallbladder neck rather than distally into the common bile duct prior to clamping. The cystic duct is then suture ligated using a nonabsorbable suture. The cystic artery is also exposed in this way, clamped, and suture ligated. The exposure usually allows for visualization of the common bile duct; if difficulty exists in defining the cystic and common bile ducts, a cholangiogram is strongly recommended.

In the retrograde approach, following skin incision and exposure of the gallbladder, attention is turned to the region of the porta hepatis, which contains the cystic and common bile ducts as well as the cystic artery. Omental fat or adhesions to these structures are taken down carefully to facilitate exposure. Once the structures are adequately isolated, the cystic duct and artery are dissected and secured with ties but not divided until all other structures have been dissected and identified. This prevents inadvertent division or injury to the common bile duct. At this point, a second clamp can be placed on the body of the gallbladder to help retract the gallbladder away from its liver bed. This exposes the aforementioned avascular plane between the gallbladder and the liver and allows for dissection using electrocautery. This method of dissection is similar to that in the laparoscopic cholecystectomy in that it proceeds from the neck to the fundus of the gallbladder. Although the retrograde approach commonly results in less bleeding because the cystic artery is ligated at the beginning of the dissection, primary exposure of the duct and artery structures can be more difficult. Both approaches have shown equivalent success rates.

Drainage of the gallbladder bed is controversial. Numerous studies have shown that drainage for an uncomplicated procedure does not significantly improve wound infection rate or overall morbidity. Most surgeons agree that drainage is necessary only if the case is complicated by significant bleeding or concern over the integrity of the biliary tree. Placing a drain in complicated procedures allows for a controlled fistula if a bile leak ensues, as well as early recognition of excessive postoperative bleeding.

OUTCOMES OF CHOLECYSTECTOMY

Cholecystectomy has been performed for over 100 years and is a safe operation with a low rate of morbidity and minimal mortality. At the advent of the current laparoscopic era, several studies reviewing tens of thousands of patients confirmed that the open cholecystectomy was indeed the gold standard for the treatment of symptomatic gallstones. The overall mortality rate in these studies averaged less than 0.5%, with one population-based study of 42,474 patients documenting a mortality rate of 0.17%. Patient age was the most consistent single factor associated with operative mortality; other influential factors include comorbid conditions and nature of the biliary disease. In fact, the mortality rate from open cholecystectomy for acute cholecystitis is three times the rate for simple biliary colic but still approximates 0.6%. Cardiovascular disease, including perioperative myocardial infarction, stroke, congestive heart failure, and pulmonary embolism, was the leading cause of postoperative death in this patient group. Technical complications of the procedure account for the minority of all postoperative mortality.

The morbidity rate of open cholecystectomy remains 5–15%, although most complications are nonbiliary in nature and relatively minor. Approximately half of these complications result in no disability and do not prolong the patient's hospital stay, and serious disabling morbidity occurs in only 0.16% of patients. Pulmonary difficulties are common and often secondary to the right subcostal muscle-splitting incision, which makes deep inspiration painful and contributes to risk of perioperative pneumonia. Bile leakage or fistula has been found in 0.3–0.6% of patients. Injury to the common bile duct, which often requires extensive operative reconstruction and increases overall rate of mortality, has been found to occur in only 0.1–0.2% of cases.

Laparoscopic cholecystectomy has proved equal to open cholecystectomy in mortality and morbidity, with the additional advantages of increased patient comfort, shorter hospital stays, and quicker recovery periods. The procedure is frequently done as day surgery—significantly shorter than the typical 3- to 5-day stays following an open cholecystectomy. Studies have shown an average time of 8 days from day of operation to return to work. Overall conversion from a laparoscopic to an open procedure occurs in 2–5% of all laparoscopic cholecystectomies.

Mortality from laparoscopic cholecystectomy is exceedingly low, ranging from 0 to 0.15%. In general, the mortality rate for laparoscopic cholecystectomy is lower than open cholecystectomy. However, of the few deaths

from laparoscopic cholecystectomy, a sizable number are related to technical complications. Complications that increase the risk of mortality include bowel perforations and vascular injuries from percutaneous trocar placement as well as trauma to extrahepatic bile ducts. In some cases, these complications are not observed during the initial procedure, and the delay in the diagnosis results in an unstable and critically ill patient.

The overall risk of complication from laparoscopic cholecystectomy is roughly equal to that of open cholecystectomy. Studies have documented morbidity rates of 2–5%, again with a predominance of minor complications. Wound infection is the most common complication, at 0.3–1%, and is usually found at the umbilical trocar site where the gallbladder is removed from the abdomen. Postoperative hernias, again most common at the umbilical incision, have been found in 0.3–0.5% of patients. Major complications are infrequent but again are often technical in nature. Excessive bleeding (from the gallbladder bed, incision site, or vascular injury) is found in 0.5% of patients, and bowel perforations have been recorded in 0.1–0.3% of patients. Major bile duct injuries have been seen in 0.3–0.7% of patients, slightly higher than in the open cholecystectomy. A majority of patients with major bile duct injuries require laparotomy either at the time of the initial surgery or at a later date for reconstruction. Complications requiring laparotomy are seen in approximately 1% of all patients undergoing a laparoscopic cholecystectomy.

Although laparoscopic cholecystectomy was once thought too risky for patients with acute cholecystitis, the procedure is now used routinely for these patients early in the course of their infection. Initial retrospective reviews revealed that laparoscopic cholecystectomy can be performed in this patient group with acceptable morbidity and no mortality. More structured studies in patients with acute cholecystitis have found that the overall complication rate for laparoscopic cholecystectomy is equivalent to or less than that for open cholecystectomy. Conversion rate, however, is higher in these patients, with a rate of 7–28%, but appears dependent on the timing of the operation. Recent data have shown conclusively that early laparoscopic cholecystectomy (within 48–72 hours of presentation of acute cholecystitis) results in acceptable outcomes, with a lower risk of conversion to an open procedure.

Within 5 years of its inception in the operating room, the laparoscopic cholecystectomy has become the new gold standard for cholecystectomy and continues in that role today. Open cholecystectomy is reserved for patients with difficult anatomy or advanced cholecystitis.

gastrin Gastrointestinal polypeptide hormone produced by G cells of the gastric antrum; stimulates gastric acid secretion.

G-protein-coupled receptor Family of cell surface receptor proteins consisting of seven transmembrane regions. The intracellular region interacts with guanosine triphosphate-binding proteins that, on ligand binding, transduce signals within the cell, leading to a cellular response (e.g., secretion, motility, and growth).

microvilli Fingerlike extensions along the apical surface of intestinal mucosal cells. On enterocytes, microvilli increase the absorptive surface of the cell; on endocrine cells, microvilli allow potential stimuli greater exposure to their targets (e.g., receptors).

myenteric (Auerbach's) plexus System of nerves and ganglia lying within the longitudinal and circular muscle layers of the intestine. The nerves of the system innervate numerous targets, including the myenteric externa, mucosa, and sympathetic prevertebral ganglia.

sphincter of Oddi Muscular region surrounding the distal ends of the common bile duct and pancreatic duct as they enter the duodenum. When constricted, this sphincter prevents flow of bile and pancreatic juice into the duodenum and restricts reflux of duodenal contents back into the bile and pancreatic ducts.

submucosal plexus Network of nerves and small ganglia found in the submucosa of the intestine. It is composed of outer and inner layers and transmits secretomotor and vasodilator stimuli to the mucosa. Primary sensory nerves are contained in this plexus, which also communicates with the myenteric plexus.

Cholecystokinin (CCK), a peptide hormone, is produced and secreted by endocrine cells of the upper small intestine following food ingestion. CCK is the major hormone responsible for stimulating pancreatic enzyme secretion and gallbladder contraction. CCK promotes satiety, delays gastric emptying, potentiates insulin secretion, and may regulate bowel motility; CCK may also play a role in learning and memory, anxiety, analgesia, and thermoregulation.

INTRODUCTION

Cholecystokinin (CCK) was discovered by Ivy and Oldberg in 1928 when they recognized that intestinal extracts could stimulate gallbladder contraction in dogs; they named the substance cholecystokinin ["cholecyst" (gallbladder); "kinin" (to move)], the term now commonly used. In 1943, Harper and Raper noted that a similar extract, which they named "pancreozymin," stimulated pancreatic enzyme secretion. It was not until CCK was purified and its amino acid sequence determined by Mutt in 1968 that it was proved that CCK and pancreozymin were the same hormone, both possessing the ability to stimulate the gallbladder and pancreas.

Over the past three decades, CCK has been found to have many other biological effects. In experimental animals and human volunteers, CCK has been shown to delay gastric emptying, potentiate insulin secretion, and regulate bowel motility. One of the most noteworthy actions of CCK is its ability to induce satiety and reduce food intake. Until the development of reliable assays for measuring blood levels of CCK, the physiological effects of CCK remained controversial. However, it has now been shown in humans that physiological levels of CCK stimulate gallbladder contraction and pancreatic enzyme secretion, inhibit gastric emptying, potentiate insulin secretion, and reduce food intake. Although yet to be proved physiologically, CCK may regulate bowel motility and, in certain species, promote pancreatic growth. Less well-described but fascinating actions of CCK include effects on learning and memory, anxiety, analgesia, and thermoregulation. In the small intestine, CCK is produced by discrete endocrine cells within the mucosa. However, CCK is even more abundant in the brain and is found in peripheral nerves innervating the intestine, where it functions as a neurotransmitter.

MOLECULAR FORMS

The original CCK peptide isolated from the intestine was a tritriacontapeptide (CCK-33). Several larger and smaller molecular forms of CCK have since been found in the intestine, brain, and blood of animals and humans. The biologically active region of CCK resides in its carboxyl terminus and all forms of CCK possesses an identical carboxyl five-amino-acid sequence (-Gly-Trp-Asp-Met-Phe-NH_2) (Fig. 1). This region is

common to gastrin, thus gastrin has some CCK-like activity (albeit weak) and CCK shares some weak gastrin-like activity. The amino acid sequence shared by the two hormones has made developing assays for CCK difficult because antibodies directed against the biologically active region of CCK may cross-react with gastrin. This problem is accentuated by the finding that circulating levels of gastrin are 10- to 100-fold greater than those of CCK.

CCK is produced from a single gene that encodes a 115-amino-acid preprohormone. By posttranslational processing, molecular forms of CCK ranging in size from 4 to 83 amino acids have been identified in tissues and blood. However, the major molecular forms of CCK are CCK-8, CCK-33, and CCK-58. In humans, the CCK gene is located in the 3q12–3pter region of chromosome 3. CCK expression is both tissue specific and developmentally regulated. In the intestine, the CCK gene is expressed prenatally and is regulated after birth primarily by ingestion of foods that stimulate CCK secretion. In the central nervous system, stimuli regulating neuronal CCK gene transcription include growth factors, second messengers such as cyclic AMP, the neurotransmitter dopamine, and hormones such as estrogen.

DISTRIBUTION

Cholecystokinin cells are individual flask-shaped cells that are scattered throughout the mucosa of the small intestine. The concentration of CCK cells is greatest in the proximal small intestine and diminishes in a gradient fashion toward the distal jejunum and ileum. CCK cells arise from progenitor cells in the intestinal crypts and, along with enterocytes, migrate up the villus. Residing in the mucosa, the apical surface of CCK cells is open to the lumen of the intestine. Here cells can actually "sample" luminal contents such as food and releasing factors. These enteroendocrine cells also possess microvilli that increase the exposed surface area, thus allowing greater exposure to potential stimuli.

Like other gastrointestinal hormones, CCK is a "brain–gut" peptide, meaning that the same transmitter is found in both the central nervous system and intestine. In the brain, CCK is highly concentrated in the striatum, hippocampus, and cerebral cortex. CCK-containing neurons may also synthesize dopamine. Such nerves have been shown to extend to the limbic forebrain and ventromedial hypothalamus, where they may participate in controlling food intake. CCK has been demonstrated to modulate dopamine release, dopamine-mediated reward, and receptor binding and function. These actions have implications for a role of CCK in drug abuse and neurologic and psychiatric disease.

CCK is prevalent in peripheral nerves of the gastrointestinal tract. It is most abundant in nerves innervating the colon, with fewer CCK nerves in the ileum. In these locations, CCK is present in myenteric and submucosal plexi, where it innervates ganglionic bodies. CCK is also abundant in the vagus nerve and celiac plexus. In the intestine, CCK stimulates acetylcholine release and causes smooth muscle contraction. Postganglionic CCK-containing neurons also terminate around the islets of Langerhans, where CCK may stimulate islet hormone secretion (e.g., insulin and glucagon release).

CCK RECEPTORS

CCK exerts its biological actions by binding to specific receptors on its target tissues. Gastrointestinal CCK receptors reside on tissues of the pancreas, gallbladder, stomach, lower esophageal sphincter, ileum, and colon. In the nervous system, CCK receptors are abundant in brain and on some peripheral nerves. Two types of CCK receptors have been identified: CCK alimentary (CCK-A) receptors are the primary CCK receptor and mediate most of the effects of CCK in the gastrointestinal tract. The CCK brain (CCK-B) receptor is identical to the gastrin receptor and is the major CCK receptor subtype in the nervous system. It is also abundant in the stomach. Both receptors are G-protein-coupled, seven-membrane-spanning proteins, but arise from different genes. CCK receptor antagonists have been extremely useful in pharmacological and physiological studies to define the physiological role of CCK. The first CCK receptor antagonists useful for *in vitro* studies were cyclic nucleotide analogues (e.g., dibutyryl cyclic guanosine monophosphate). Subsequently, amino acid derivatives (e.g., CR-1409), carboxyl-terminal

CCK analogues, and substituted benzodiazepines (e.g., devazepide) were developed and would be used *in vivo*. Clinical studies have shown CCK receptor antagonists to inhibit CCK- and meal-stimulated gallbladder contraction, accelerate gastric emptying, and induce hunger (i.e., reverse satiety), indicating that CCK has important physiological roles in each of these processes.

CHOLECYSTOKININ RELEASE

CCK is secreted from specialized endocrine cells of the mucosa (known as I cells) into the extracellular space, where it is taken up into the bloodstream. It is by this mechanism that circulating CCK reaches distant target tissues such as the pancreas and gallbladder. Enteric endocrine cells package CCK in secretory granules that are stored along the basolateral surface of the cell, thus allowing CCK to be secreted into the interstitium when the cell is stimulated. *In vivo*, ingested proteins and fat are the major dietary stimulants of CCK release. However, in some species, including humans, and in cell preparations *in vitro*, partially digested nutrients such as amino acids and peptides and fatty acids are potent releasers of CCK, indicating that these components directly interact with the CCK cell.

Circulating blood levels of CCK average approximately 1 p*M* in the fasting state and increase to between 5 and 8 p*M* after eating. Postprandial levels remain elevated for 3–5 hours as food empties from the stomach into the upper small intestine. Gastric distension does not influence CCK release. Although fat and protein are the primary stimulants of CCK, carbohydrate has a modest effect on secretion.

It is well recognized that inactivation of protease activity in the lumen of the small intestine of rodents stimulates CCK release and pancreatic exocrine secretion. This phenomenon is now known as negative feedback control of CCK release. Not only has this principle now been demonstrated in rodents, but it also applies to other species, including humans. Thus, CCK release is controlled in part by the presence or absence of pancreatic enzymes in the intestine. (Fig. 2). This concept indicates that there exist intestinal releasing factors that are secreted into the intestine and stimulate CCK secretion. When pancreatic enzymes are present in the intestine, these CCK releasing factors are inactivated; however, when pancreatic enzymes are inhibited or pancreatic secretion is reduced, these CCK releasing factors are active and stimulate CCK secretion. Similarly, with ingestion of a meal that temporarily binds trypsin and other digestive enzymes, CCK releasing factors are also available to stimulate CCK secretion. To date, a human counterpart of a CCK-specific releasing factor has not been identified.

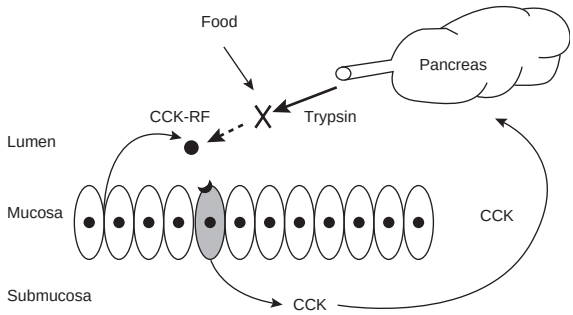

FIGURE 2 Model for regulation of CCK release by an intraluminal releasing factor. One or more CCK releasing factors (CCK-RF) stimulate intestinal CCK secretion. CCK-RF is normally secreted in the intestinal lumen, where it is exposed to pancreatic enzymes. Under basal conditions, CCK-RF is inactivated by even small amounts of enzyme; following a meal, however, food competes for enzyme binding, allowing CCK-RF to interact with CCK cells to stimulate hormone secretion. CCK in the circulation stimulates pancreatic secretion, which, following digestion of food, restores CCK-RF and CCK secretion to basal levels. Modified from Liddle (1995).

BIOLOGICAL ACTIONS OF CCK

CCK is the major hormonal regulator of gallbladder contraction. Coincident with this effect, CCK also relaxes the sphincter of Oddi, which also promotes bile secretion into the intestine. In humans, the predominant CCK receptor type in the pancreas is CCK-B. In most species, however, CCK-A receptors predominate in pancreas, and CCK is a potent stimulant of pancreatic secretion. Therefore, in humans, although CCK stimulates pancreatic secretion, its role may be limited.

At physiological blood concentrations that occur after a meal, CCK delays gastric emptying; this may be important for its ability to reduce food intake and induce satiety. Due to its effects on gallbladder contraction, pancreatic secretion, and gastric emptying, CCK coordinates many digestive processes. Thus, CCK plays an important role in the ingestion and digestion of a meal. Although it has been shown that CCK causes relaxation of the lower esophageal sphincter and promotes intestinal motility, it appears that these effects are neural rather than hormonal. CCK receptors have been found on some gastrointestinal and lung cancers, but it remains unknown whether CCK plays a role in human cancer growth.

CLINICAL USES OF CCK

CCK is used along with secretin as a test of pancreatic function. In patients with pancreatic insufficiency, low levels of pancreatic juice are recovered following intravenous injection of these hormones. CCK can also be used clinically to stimulate gallbladder contraction and is helpful in radiographic testing of gallbladder function. For diagnostic purposes, CCK has facilitated the collection of bile and pancreatic juices for cytological examination.

CCK injections have been administered therapeutically to patients who are unable to eat (e.g., parenteral alimentation) in order to stimulate gallbladder contraction. This therapy has been effective in reducing gallbladder sludge and in preventing gallstone formation.

Low blood levels of CCK have been reported in patients with celiac disease, bulimia nervosa, and in conditions that delay gastric emptying. The defect in celiac disease is likely due to reduced CCK secretion from diseased small intestinal mucosa. The cause of abnormal CCK responses in bulimia is unknown, but may be related to alterations in gastric emptying because normal postprandial CCK release is dependent on delivery of food from the stomach to the small intestine. It is not known whether CCK deficiency contributes to any specific pathological consequences. There are no known diseases of cholecystokinin excess.

acute cholecystitis Acute inflammation of the gallbladder.
biliary pain Symptom due to transient obstruction of the biliary tract, including the gallbladder.
cholangitis Inflammation and infection of the biliary ductal system due to obstruction.
choledocholithiasis Stones in the common bile duct.
gallstone pancreatitis Inflammation due to a gallstone obstructing pancreatic outflow.
gallstones (cholelithiasis) Precipitates (stones or pebbles) within the gallbladder.
ileus (gallstone ileus) Bowel obstruction due to a large stone.
laparoscopic cholecystectomy Removal of the gallbladder via a laparoscopic approach.
microlithiasis (sludge) Microscopic precipitates in bile that can be visualized with ultrasonography or bile microscopy.
Mirizzi syndrome Obstruction of the common hepatic duct due to extrinsic pressure by a stone in the cystic duct or the gallbladder neck.

Gallstones, which occur commonly and usually remain asymptomatic, can result in a variety of symptoms and presentations ranging from mild to extremely severe. The most common symptom from gallstones is abdominal pain, termed biliary pain, which generally occurs in the right upper quadrant of the abdomen. More serious complications include acute cholecystitis, biliary duct obstruction with or without acute cholangitis, and acute pancreatitis. More unusual problems caused by gallstones include gallstone ileus, enteric fistulae, and Mirizzi syndrome.

DIAGNOSIS AND COMPLICATIONS

Ultrasonography is the best method for diagnosing gallbladder stones; its sensitivity in detecting gallbladder stones is about 95%. Although biliary duct stones may sometimes be demonstrated by ultrasonography (about 30–50% sensitivity), these stones are more often diagnosed by the duct obstruction and subsequent duct dilation that they cause. Cholangiography, usually with endoscopic retrograde cholangiopancreatography (ERCP), can directly image ductal obstruction due to stones. ERCP is >90% sensitive and offers the potential for therapeutic intervention. Magnetic resonance cholangiopancreatography (MRCP), however, is being used more often to diagnose bile duct stones.

In selected situations only, percutaneous transhepatic cholangiography (PTC) or intraoperative cholangiography performed during cholecystectomy can be performed to look for ductal stones. Endoscopic ultrasonography (EUS) can visualize ductal stones and sludge or stones in the gallbladder, but is not often used for this purpose. Computer tomography (CT) scanning can often provide more extensive information than ultrasonography about masses and abscesses, but its sensitivity in detecting gallstones is significantly lower.

NATURAL HISTORY

It is now known that a majority of gallstones cause no symptoms after formation. Surveys of large populations using ultrasonography have shown that from 60 to 80% of persons with gallstones are asymptomatic. Only a small proportion of patients with gallstones develop symptoms on a yearly basis on long-term followup. The incidence rate at which asymptomatic patients develop biliary pain is approximately 1–2% annually. The risk of first presenting with a complication rather than just biliary pain is very low. Because of this low rate of development of symptoms, the consensus is that asymptomatic patients with gallstones should not undergo cholecystectomy because many or even most of them will never develop symptoms.

Asymptomatic patients with gallstones may be followed expectantly with surgery or other interventions reserved for those who eventually develop biliary pain. There is still some variation to this approach based on individual physician and patient preference. There is one condition in which there is still uniform agreement that cholecystectomy should be performed as soon after diagnosis as possible, and that is porcelain gallbladder (calcification in the gallbladder wall) because of its risk of developing malignancy, that is, gallbladder cancer.

BILIARY PAIN

The most common complication of gallstones is episodic upper abdominal pain. The term "biliary colic" is still commonly used to describe pain due to gallstones. However, the term "biliary pain" is preferred because the pain due to gallstones is not a true colic, that is, of a waxing and waning nature like intestinal colic. Biliary pain can have somewhat varied features among patients, but the hallmark of true biliary pain is its episodic nature.

The term "chronic cholecystitis" is still sometimes used to describe the condition in which a patient has experienced repeated episodes of biliary pain. Strictly speaking, chronic cholecystitis describes the histologic changes in the gallbladder. There is frequently an inexact correlation between the pathologic changes in the gallbladder and the symptoms the patient has experienced.

Etiology and Pathogenesis

Biliary pain is thought to arise from transient obstruction of the cystic duct by stones or sludge. It may also develop due to microlithiasis or biliary sludge, presumably due to similar mechanisms. Sometimes, patients experience what appears to be biliary pain with no demonstrable gallstones or sludge. The explanation for this is not completely known; in some cases the pain may result from disordered biliary motility at the gallbladder or sphincter of Oddi level, but in other cases, no explanation is found.

Clinical Features of Biliary Pain

Biliary pain is typically characterized by its location in the right upper quadrant or epigastrium and may radiate around to the right subscapular area or midback or occasionally to the right shoulder. Sometimes, the pain may be felt in the middle lower chest or even in the left abdomen. The pain may range from fairly mild to very severe, and may be described, for example, as feeling like a pressure, stabbing, heavy weight, cramping, and so forth. Sometimes, the pain is compared to a toothache or childbirth. Patients often state that they are restless or cannot get comfortable during an attack of biliary pain and often walk around the room or shift position around on the couch or bed waiting for the pain to end. Patients with milder discomfort may only describe it as a pressure or a heavy feeling or a localized bloating and not a "real" pain. Some patients may experience nausea during an episode, but vomiting is uncommon. There are no systemic signs of toxicity such as fever or chills.

Biliary pain usually has a fairly clear onset with no antecedent warning. The pain then reaches a plateau of intensity ranging from quite mild to extremely severe. It may last from 15 to 30 minutes up to typically 3 to 4 hours. Sometimes, the duration may be 6 to 8 hours or more, but over 12 hours is unusual unless acute cholecystitis is developing. After the pain abates, the patient may feel a residual abdominal soreness for a while. In some patients, what appears to be otherwise typical biliary pain may last for 15 minutes or less. Some patients even describe episodes lasting for a few minutes; it is difficult to know whether these brief episodes represent true biliary pain.

Biliary pain is typically episodic in occurrence; the interval between episodes varies from daily to once every few weeks or months. Some patients have only one episode every year or so. The clearly episodic nature of most biliary pain is why it is often described in terms of "attacks" or "bouts." Once a patient experiences the first episode of biliary pain, it is highly likely that subsequent episodes will occur. Approximately 75% of such patients will have at least one further attack within a 2-year period.

Differential Diagnosis of Biliary Pain

In some cases, biliary pain caused by gallbladder stones may not be typical. The pain may vary in one or more features, such as its location, frequency, duration, or character. Because there is no "gold standard" for confirming biliary pain, it is not uncommon to have difficulty in deciding whether the discomfort patients are experiencing is due to gallstones. There are many conditions that need to be considered in the differential diagnosis of right upper quadrant abdominal pain, including: peptic ulcer disease, pancreatitis, gastroesophageal reflux, angina, bowel obstruction, liver disease, rib pain, and irritable bowel syndrome. In such situations, clinical judgment, further diagnostic testing, followup over time, and possible treatment for gastroesophageal reflux or irritable bowel syndrome usually help elucidate the clinical picture. When the relationship between stones and symptoms is not entirely clear, decisions regarding cholecystectomy need to be carefully considered based on the patient's wishes and on surgical consultation.

It has been fairly convincingly shown that symptoms generally categorized as dyspepsia (intolerance to fatty foods, flatulence, bloating, belching, and heartburn) cannot be attributed to gallstones. Cholecystectomy does not have a reliably beneficial effect on such symptoms. The term "postcholecystectomy syndrome" has been used to describe symptoms that remain after

cholecystectomy; most often, such residual symptoms were not due to the stones in the first place.

Management

During an actual episode of biliary pain, analgesics may be used for pain control. Cholecystectomy is the definitive treatment of choice for symptomatic gallstones. Once a patient experiences the first episode of biliary pain, it is very likely that future episodes will occur and it is for symptomatic relief that cholecystectomy is recommended for such patients. Laparoscopic cholecystectomy is usually performed; occasionally, the traditional open approach is used either as a conversion from the laparoscopic approach or as a planned procedure. Cholecystectomy removes the stones and the gallbladder and prevents future episodes of pain.

Oral bile salt therapy with ursodiol is an option that is rarely used now. Extracorporeal shock-wave lithotripsy combined with ursodiol is utilized occasionally outside the United States.

Biliary Pain and the Risk of Developing More Serious Complications

Patients with symptomatic gallstones (that is, patients who have experienced biliary pain at least once) are at risk for developing a major complication, such as acute cholecystitis, cholangitis, or pancreatitis, at any time. The yearly rates at which these complications develop have not been well studied because most symptomatic patients with gallstones undergo definitive treatment and do not enter long-term studies in which no therapy is given. But from the available data, it appears that the yearly risk of developing a serious complication is in the range of 1–3%.

A patient with previously asymptomatic gallstones may present for the first time not just with simple biliary pain, but with a serious complication. However, the annual incidence rate of this type of presentation, although not known with certainty, is much lower than that for with patients with symptomatic gallstones.

ACUTE CHOLECYSTITIS

Acute cholecystitis is the most common acute complication of gallbladder stones. Usually, the diagnosis is straightforward based on a typical clinical scenario and confirmatory radiologic studies. But in some cases, the diagnosis is more difficult because of an atypical clinical presentation. A high index of suspicion for acute cholecystitis is warranted in any patient with upper abdominal pain.

Etiology and Pathogenesis

Cystic duct obstruction is the precipitating event that results in inflammation of the gallbladder by cytokines and other mediators (lysolecithin, prostaglandins) of inflammation. The obstruction is usually caused by a stone, but mucus, sludge, and viscous bile may also play a role. In addition, the normally protective mucus layer over the luminal surface is disrupted, allowing relatively toxic bile salts to come in contact with the mucosa. Secondary bacterial infection may later ensue.

Clinical Features

The majority of patients present with at least moderate pain in right upper quadrant; the pain may radiate to the right shoulder or scapula. The pain usually has been present for at least several hours before the patient presents. Fever may be present, although temperature is usually not above 102°F; higher temperatures suggest bacteremia or an abscess. There is right upper quadrant tenderness and Murphy's sign (accentuated tenderness to palpation during inspiration) is often present. Clinical presentation may vary, however, and can range from deceptively mild to quite severe with sepsis. There may be minimal pain and minimal tenderness, particularly in the elderly or an obtunded patient. Other patients may present in a very toxic manner with high fever, severe abdominal pain and tenderness, bacteremia, and marked leukocytosis, sometimes in shock.

Laboratory studies show a white blood cell (WBC) count of usually 10,000–15,000/ml. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase as well as bilirubin may be normal or just slightly elevated. If the alkaline phosphatase is disproportionately elevated relative to the transaminases, choledocholithiasis should be considered.

With more extensive complications, such as empyema, gangrene, localized or free perforation, peritonitis, or emphysematous cholecystitis (air in the gallbladder wall), the clinical scenario is more severe and represents more of a surgical emergency. Although unusual, the combination of acute cholecystitis and either cholangitis or pancreatitis may occur, thus making the clinical picture more complex.

Diagnosis

The diagnosis of acute cholecystitis is made primarily based on typical clinical findings and secondarily based on radiologic studies. Either ultrasonography or radionuclide hepatobiliary scanning with iminodiacetic acid (HIDA) derivatives may be used. Ultrasonography

is preferred because it is easier to perform and provides additional information regarding the bile ducts and other organs. The typical findings seen are gallstones, dilated gallbladder, thickened gallbladder wall, edema within the gallbladder wall, or pericholecystic fluid; sludge may also be seen. The sensitivity of ultrasonography for acute cholecystitis is approximately 90–95% and specificity is about 80%.

Management

It is common practice to administer antibiotics to patients with acute cholecystitis. Coverage for enterococci and gram-negative aerobic organisms is usually enough. For patients who are extremely toxic, coverage for anaerobic organisms should be added. Patients should be kept at a "nothing per oral" (NPO) status; intravenous fluids should be started and mild analgesia may be necessary for pain.

Cholecystectomy is the treatment for acute cholecystitis and may be performed as soon as the diagnosis is made and the patient is stable enough. Generally, this is within the first 2 to 3 days after admission. In the great majority of cases, laparoscopic cholecystectomy is possible. In those cases in which a complication, such as an abscess, gangrenous wall, or perforation, is suspected or is encountered, an open approach is needed. If the patient has a seriously decompensated medical condition, consideration may be given to either surgical or radiologic-guided cholecystostomy as a temporizing measure.

Acute Acalculous Cholecystitis

Acute cholecystitis may occur without the presence of gallstones in the gallbladder, in which case it is termed acute acalculous cholecystitis (AAC). AAC accounts for $<5\%$ of all cases of acute cholecystitis and is most frequently encountered in patients who are hospitalized and frequently already seriously ill. Cystic duct occlusion is thought to be the principal pathophysiologic event in the development of AAC. The occlusion may be due to sludge or microlithiasis, viscous bile, or mucus. Gallbladder stasis is a major factor in many cases and gallbladder ischemia is also considered to play a significant role. Patients with AIDS are a special subgroup because infectious causes for cholecystitis, especially viral or fungal, may be seen.

The diagnostic approach is similar to that for calculous cholecystitis but is complicated by the fact that many patients with AAC are already seriously ill and may have atypical signs and symptoms. Treatment is with open cholecystectomy, which should be performed expeditiously. In some cases, especially if the patient is septic, an ultrasound-guided percutaneous puncture of the gallbladder can be performed and a catheter can be left in place for drainage. AAC has a high mortality, especially if treatment is delayed, because gangrene, perforation, and abscess formation are more frequent.

CHOLEDOCHOLITHIASIS AND OBSTRUCTIVE JAUNDICE

Choledocholithiasis refers to gallstones in the common bile duct and is present in approximately 10% of patients with cholelithiasis. These stones can cause partial or complete obstruction of the biliary system, causing pain and ductal dilation, obstructive jaundice, favorable conditions for acute bacterial cholangitis, and acute gallstone pancreatitis.

Clinical Features

Clinical manifestations suggestive of choledocholithiasis include biliary pain, nonspecific abdominal pain, obstructive jaundice, cholangitis, or acute biliary pancreatitis. Individuals may also harbor asymptomatic stones that are diagnosed serendipitously. Physical examination may reveal icteric discoloration of the skin and visible mucous membranes and abdominal tenderness in the right upper quadrant on palpation.

Diagnosis

Laboratory Tests

Choledocholithiasis cannot reliably be diagnosed on the basis of the patient's history and physical examination alone. Almost all patients will have an elevated alkaline phosphatase and γ-glutamyl transpeptidase (GGT) level. Bilirubin and aminotransferase levels are elevated in 70–90% of patients at the onset of symptoms. However, normal liver chemistries do not completely exclude the possibility of choledocholithiasis. In patients with biliary obstruction, alkaline phosphatase rises faster and often precedes the elevation of serum level of bilirubin.

Radiologic Imaging

Transcutaneous ultrasound has been the traditional noninvasive test of choice for diagnosing choledocholithiasis. It is very specific but has low sensitivity, thus a negative ultrasound result should be interpreted with caution. Dilation of extra- or intrahepatic ducts can be a useful indirect sign of intraductal stones. In cases with high likelihood of ductal obstruction with stones, ERCP should be the next step after ultrasonography and offers the potential for therapeutic intervention.

However, there is a 3–6% complication rate associated with therapeutic ERCP for stone removal. EUS is very sensitive and specific and, in cases of unsuccessful cannulation of the major duodenal papilla, can be a valuable diagnostic alternative to ERCP. MRCP can also be an alternative to ERCP to screen for possible choledocholithiasis in high-risk patients with complicated medical problems. The reported sensitivity, specificity, and overall accuracy of MRCP is 91.6, 100, and 96.8%, respectively.

Therapy

Patients with common bile duct (CBD) stones complicated by obstructive jaundice or cholangitis need urgent ERCP. Uncomplicated choledocholithiasis requires elective ERCP. For large stones, mechanical or laser lithotripsy may be required. The overall therapeutic success rate of endoscopic treatment is 80–95%. If endoscopic therapy fails, laparoscopic or open surgical CBD exploration should be considered.

ACUTE CHOLANGITIS

Cholangitis is a clinical syndrome consisting of stasis in and infection of the biliary ductal system; gallstones are the cause in 80% of cases. Acute cholangitis can be a serious and life-threatening illness and requires prompt recognition and treatment.

Etiology and Pathogenesis

The most common cause of acute cholangitis in the United States is choledocholithiasis. Bile is usually sterile but biliary obstruction disrupts the host defense mechanisms, allowing infecting microbes to reach the biliary tree, typically by direct spread from the duodenum into the bile duct or hematogenous spread by translocation of organisms through the bowel wall into the portal venous system. The presence of a foreign body, such as a stone or stent, can then act as a nidus for bacterial colonization. Once bacteria colonize bile, biliary stasis favors multiplication. High pressure promotes the migration of bacteria from bile into the systemic circulation, resulting in septicemia. Bile cultures are positive in over 90% of cases, yielding a mixed growth of gram-negative and gram-positive bacteria. *Escherichia coli* is the major gram-negative bacterium isolated (25–50%), followed by *Klebsiella* (15–20%) and *Enterobacter* species (5–10%). The most common gram-positive bacteria are *Enterococcus* species (10–20%). *Pseudomonas* may be found after interventional endoscopy or a surgical procedure. Anaerobes, such as *Bacteroides* and *Clostridia*, are usually present in a mixed infection, but are rarely the sole infecting organisms.

Clinical Features

The hallmark of cholangitis is the classic "Charcot's triad" of fever, right upper quadrant pain, and jaundice, but this is fully present in only 50–75% of cases. Later manifestations include mental obtundation and hypotension, producing "Reynold's pentad," which is associated with significant morbidity and mortality. Hypotension may be the only presenting symptom in elderly patients, and septic shock in severe cases can lead to multiorgan failure.

Diagnosis

Diagnosis can usually be made on clinical grounds alone, with laboratory tests and imaging studies playing a confirmatory role.

Laboratory Tests

Routine laboratory tests typically reveal an elevated WBC count with neutrophil predominance, and a cholestatic pattern of liver function test abnormalities with elevations in serum alkaline phosphatase, GGT, and bilirubin. AST and ALT levels are usually mildly elevated, although a pattern of acute hepatocyte necrosis can occasionally be seen. Mildly increased serum amylase occurs in up to one-third of patients, with 10% also having clinical acute pancreatitis.

Radiologic Imaging

Ultrasonography is usually the first imaging study in patients suspected of having cholangitis to look for CBD dilatation and presence of stones. Ultrasonography should usually be followed by ERCP both to confirm the diagnosis and to intervene therapeutically with sphincterotomy, stone extraction, or stent insertion as needed. If ERCP is not possible, PTC can serve to drain the obstructed biliary system.

Management

General Support

The initial treatment usually includes stopping all oral intake and intravenous fluids, frequent monitoring of vital signs for evidence of sepsis and multiorgan failure, administering parenteral vitamin K to counteract any coagulopathy due to hepatic dysfunction, and treating with antibiotics. Pressor agents may be indicated in severely ill patients. The mainstays of therapy are antibiotics and establishment of biliary drainage.

Antibiotics

Antibiotics for the treatment of acute cholangitis should be given for 7–10 days. A broad-spectrum antibiotic regimen is required (e.g., ampicillin and gentamicin, third-generation cephalosporins, imipenem, or ciprofloxacin). In sick patients, metronidazole is often added to cover anaerobes.

Biliary Drainage

Eighty percent of patients with acute cholangitis will respond to conservative management and antibiotic therapy. Biliary drainage can then be performed on an elective basis. In 15–20% of cases, cholangitis fails to improve over the first 24 hours with conservative therapy alone, requiring urgent biliary decompression. Endoscopic sphincterotomy with stone extraction and/or stent insertion is now the treatment of choice for establishing biliary drainage in acute cholangitis.

Role of Surgery

Emergency surgery for acute cholangitis has largely been replaced by nonoperative biliary drainage. Elective surgery carries a very low morbidity and mortality risk as opposed to emergency surgery. If emergent surgery is needed due to failure of a nonsurgical drainage procedure, choledochotomy with placement of a large-bore T tube carries a lower mortality risk compared to cholecystectomy with CBD exploration.

The rendezvous procedure combines the endoscopic technique with percutaneous cholangiography. It is used when endoscopic cannulation of the papilla is unsuccessful and surgery is indicated, but the risk associated with operation is high. The combined technique increases the success rate of biliary tract cannulation and thus facilitates the diagnosis and treatment of biliary tract disorders.

Prognosis

Reported mortality rates for acute cholangitis vary from 13 to 88%. With effective antibiotics and biliary drainage, the prognosis for mild to moderate cholangitis is much improved. However, the mortality rate remains very high (approximately 50%) for patients with severe cholangitis (Reynold's pentad).

GALLSTONE PANCREATITIS

Gallstone pancreatitis is an episode of acute pancreatitis caused by a gallstone. Gallstones are a common cause of acute pancreatitis, being responsible for 30–75% of all cases. The presence of gallstones increases the relative risk for pancreatitis 12- to 35-fold. Gallstone pancreatitis may sometimes be associated with cholangitis.

Etiology and Pathogenesis

It is now accepted that gallstone-associated pancreatitis results from the passage of stones through the sphincter of Oddi into the duodenum. Many cases of presumed idiopathic pancreatitis are caused by gallstones too small to be visualized. Recent advances in ultrasonography and the wider use of ERCP for diagnosis have demonstrated that in cases that previously would have been classified as "idiopathic," small microcalculi are indeed present in up to 75% of such cases. The pathway by which ductal obstruction by the passage of a stone leads to pancreatitis is still unclear. It is believed that changes of acute pancreatitis are most likely related to an injury from the digestive enzymes secreted from the pancreas; a series of chemical events leads to premature activation of inactive digestive enzymes that are usually activated in the duodenum.

Clinical Features

Patients with acute gallstone pancreatitis present with complaints of severe diffuse epigastric or right upper quadrant abdominal pain that typically radiates to the back. This is usually constant and severe and may last many hours. Severe nausea and vomiting may occur. Patients with severe biliary pancreatitis appear ill with signs of systemic toxicity (tachycardia, hypotension, fever, and tachypnea). Skin and visible mucous membranes may be icteric. Palpation of the abdomen usually shows severe tenderness in the epigastric area and the right upper quadrant, often with guarding and rebound tenderness.

Diagnosis

Laboratory Tests

Blood tests for amylase and lipase are sensitive but not specific for acute pancreatitis. Serum amylase is less specific than lipase. The use of a cutoff level three times the upper limit of normal serum value increases the specificity of amylase and lipase in the diagnosis of acute pancreatitis. The WBC count is usually elevated in patients with acute gallstone pancreatitis. Threefold elevations of serum ALT and AST are highly specific but not very sensitive (only about 50%) for gallstone pancreatitis. Total bilirubin and alkaline phosphatase are elevated in patients with gallstone pancreatitis and obstruction of the extrahepatic bile ducts.

Imaging

Transabdominal ultrasound is recommended for all patients with suspected biliary pancreatitis. Dilation of the biliary and pancreatic duct can be an indirect ultrasonic sign of a stone impacted in the major duodenal papilla. The CT scan is currently the best test available to evaluate the size and structure of the pancreas (edema, necrosis, phlegmon, and development of pseudocyst), the condition of the gallbladder and biliary ducts, and potential intraabdominal complications (intraabdominal or intrapancreatic abscess, retroperitoneal fluid collection, and pancreatic ascites).

ERCP is the best technique to visualize the pancreatic and biliary ducts and can be complemented by therapeutic manipulations to relieve the obstruction and to extract the offending stone(s). ERCP does carry an associated morbidity and should be performed in patients with suspected impacted stones in the distal CBD or duodenal papilla only if therapeutic intervention is envisaged.

Management

General clinical management is the same as for pancreatitis of any other cause. In severe cases and those in which there is any evidence of biliary obstruction, the use of prophylactic antibiotics and the early application of ERCP are warranted.

General Measures

General supportive measures include intravenous fluids, bowel rest, histamine-2 (H2) receptor antagonists or proton pump inhibitors, parenteral analgesia, antiemetic medications, and parenteral nutrition. Systemic antibiotics reduce septic complications and mortality in severe cases. Development of sepsis or other systemic complications requires admission to the intensive care unit. A majority of patients have a relatively mild illness that clinically resolves within 1 week with this conservative management strategy.

The modified Glasgow or acute physiology and chronic health evaluation (APACHE II) scoring systems can be used to predict which patients are likely to follow a severe disease course, to develop systemic complications, and to benefit from more aggressive interventional therapies.

Biliary Decompression

Bile duct decompression is beneficial in patients with predicted severe pancreatitis. The currently recommended treatment for patients with gallstone-associated pancreatitis and either jaundice or cholangitis includes ERCP with endoscopic sphincterotomy (ES) within the first 2–3 days. Three of four published randomized trials have shown a significant reduction in local and systemic complications of severe gallstone-associated pancreatitis by the use of urgent ERCP plus ES. Emergent ERCP is not indicated in patients with predicted mild or moderate gallstone pancreatitis.

On the basis of available information, ERCP is recommended within the first 2 to 3 days of hospitalization for patients with gallstone pancreatitis who have evidence of biliary sepsis or organ failure. Stones that are found in the common bile duct should be removed endoscopically.

Role of Surgery

Elective cholecystectomy is recommended for patients with cholelithiasis after gallstone pancreatitis is resolved to prevent future relapses of pancreatitis. It is advisable for cholecystectomy to be performed during the same hospital admission. Cholangiography should be performed during the cholecystectomy to exclude residual common bile duct stones. The one exception involves patients with severe gallstone pancreatitis who have a prolonged clinical course. Several weeks are allowed to elapse between the hospitalization for acute pancreatitis and readmission for laparoscopic cholecystectomy.

MISCELLANEOUS COMPLICATIONS

Calcification in the gallbladder wall (termed porcelain gallbladder) may develop over many years in gallbladders that contain stones. Gallbladder carcinoma is found in a significant proportion of gallbladders with wall calcification. Prophylactic cholecystectomy is recommended for patients with porcelain gallbladder.

Gallbladder cancer may also be found in stone-containing gallbladders without wall calcification. It does not occur at a high enough frequency to warrant prophylactic cholecystectomy. Mirizzi syndrome is the obstruction of the common hepatic duct as a result of extrinsic pressure by a gallstone in the cystic duct or the gallbladder neck. The clinical scenario is usually that of acute cholangitis. Fistulae between the gallbladder and other organs may develop as a result of gallstone erosion through the gallbladder wall. The most common sites of fistulization are into the duodenum or colon, but other sites may be involved. Occasionally, a fistula may develop between the common bile duct and another organ, usually the duodenum. Cholecysto- or choledochoenteric fistulae may or may not require specific intervention, depending on the patient's symptoms.

Gallstone ileus is a mechanical bowel obstruction resulting from a stone, typically fairly large, eroding into

usually the duodenum and becoming impacted at the ileocecal valve or some other strictured area in the gastrointestinal tract. Gallstone ileus is not rare and most often affects older patients. The diagnosis may be suspected based on the finding of air in the biliary tract in the setting of a bowel obstruction.

SUMMARY

Most gallbladder stones are asymptomatic. When they do become symptomatic, biliary pain is the most common manifestation. The hallmarks of biliary pain are its episodicity and location in the upper abdomen, usually in the right upper quadrant. Because gallstones are fairly common, other conditions may coexist with gallstones and may actually be responsible for the symptoms/signs initially attributed to the stones. The treatment of choice for symptomatic gallbladder stones is laparoscopic cholecystectomy; when this approach is not feasible, open cholecystectomy is the alternative.

Acute cholecystitis is the most common acute syndrome that gallstones may cause. Although cholecystectomy is the treatment of choice, there are often difficult diagnostic and management decisions to be made and consultation between internist/gastroenterologist, surgeon, and radiologist is frequently warranted in order to arrive at the most efficient plan for care. Acute acalculous cholecystitis requires a high index of suspicion for diagnosis; patients are usually quite ill and rapid therapy is usually necessary. When managing acute gallstone complications, whether the patient is improving, stabilizing, or worsening will dictate the pace of the diagnostic evaluation and the number and types of diagnostic studies that may be performed in order to confirm the presumptive diagnosis. The patient's course will also influence the threshold for intervening therapeutically as well as the choice of intervention.

pili Bacterial surface appendages involved in attachment to host cells.
serogroups Categorization of bacteria into groups with similar carbohydrate-based surface antigens. Tests are done by agglutination with defined antisera.

Cholera is among the leading causes of diarrheal disease in developing countries of Africa, Asia, and South America. Despite the recognition of its infectious etiology more than a 100 years ago and the existence of effective control measures, cholera remains a major public health problem due to the lack of adequate water supply and infrastructure, financial resources, and education in many areas of the world.

MICROBIOLOGY

Cholera is caused by infection with toxigenic strains of *Vibrio cholerae*, gram-negative, motile, curved, rod-shaped bacteria of the family Vibrionaceae. Of the 200 recognized O serogroups, only two serogroups, O1 and O139, have been associated with severe disease and pandemics. *Vibrio cholerae* are natural inhabitants of the aquatic ecosystems of rivers and coastal waters, which form a large bacterial reservoir not accessible to exposure control measures. Toxigenic strains differ from nonpathogenic strains by the presence of specific virulence genes, some of which can be transmitted horizontally between different strains. The major virulence genes, which code for toxins and colonization factors, are categorized into two groups. The toxin-coding genes are located in a single-stranded filamentous phage integrated into the bacterial chromosome as prophage DNA, which can be excised and transmitted as a virion to other bacteria. Many of the genes required for bacterial colonization are located in a gene cluster, termed the *Vibrio* pathogenicity island (VPI); the expression of this cluster is tightly controlled by environmental conditions. The entire *V. cholerae* genome comprises two circular chromosomes of 3 and 1.1 megabases, the sequences of which have been determined completely. This provides an important basis for understanding the biology and virulence of these bacteria.

EPIDEMIOLOGY

Transmission is by the fecal–oral route. Infection is initiated by ingestion of contaminated water or, less commonly, food. Contact with contaminated utensils and houseflies and direct person-to-person contact also have been implicated, but are less important routes of transmission. The most common causes of water contamination are insufficient or absent disinfection and breaks in the integrity of water supply systems, leading to mixing of fecally contaminated and fresh water. These modes of transmission point to the primary importance of hygienic measures in preventing infection, both at the personal and the community levels. In addition to environmental exposure, personal risk factors play a role in determining susceptibility. Persons with low gastric acidity due to chronic gastritis, malnutrition, or treatment with gastric acid blockers are at increased risk for cholera infection. Bottle feeding of infants is also associated with increased risk of acquiring infection, whereas breast feeding is protective.

PATHOGENESIS

Vibrio cholerae colonizes the lumen and mucosal surface of the small intestine, but has little capacity to invade the intestinal mucosa. Bacteria attach to the mucous layers and the brush border of the intestinal epithelium via specialized appendages, particularly the toxin coregulated pili (TCP) and bacteria-associated hemagglutinins. Attachment is important for effective bacterial colonization of the small intestine. Intestinal disease is caused mainly by the release of cholera toxin, an AB holotoxin composed of a single A subunit and five B subunits. The B subunits bind to the cell surface of intestinal epithelial cells, whereas the A subunit enters

the cells and exerts enzymatic activity. Cholera toxin is taken up by apical endocytosis and subsequently follows a retrograde trafficking pathway through the Golgi cisternae to the endoplasmic reticulum, after which it enters the cytoplasm and binds to a G protein, $G_{\alpha s}$, at the cell membrane. The toxin ADP-ribosylates and thereby activates $G_{\alpha s}$, which in turn stimulates epithelial adenylyl cyclases, leading to increased production of cyclic AMP from ATP. Cyclic AMP activates protein kinase A, which phosphorylates and controls the functions of multiple target proteins in the cells, particularly those involved in regulated ion transport. The most important effects of elevated cAMP levels are stimulation of active chloride secretion and inhibition of sodium absorption, leading to the loss of electrolytes and secondarily water. In addition to cholera toxin, *V. cholerae* elaborates other toxins, such as zonula occludens toxin (ZOT), that contribute to disease pathogenesis by disrupting the epithelial barrier.

DISEASE AND DIAGNOSIS

The majority of infections (50–95%) with *V. cholerae* are asymptomatic or only mildly symptomatic, with a few episodes of watery stools without mucus or blood, and no significant fluid loss. Severe disease (cholera gravis) is characterized by massive watery diarrhea ("rice water" stools), vomiting, and dehydration, in the absence of abdominal pain and fever. Clinical symptoms first appear 1–3 days after infection, and often progress rapidly, leading to hypovolemic shock and anuria within 24 hours after onset. With sustained fluid loss, severe electrolyte imbalances occur, particularly hypokalemia and acidosis due to loss of potassium and bicarbonate in the stool, respectively. Mortality in untreated patients can be as high as 50%, with a higher risk in children compared to adults. If treated appropriately, disease symptoms subside after 4–6 days.

The symptoms of mild to moderate cholera cannot be clearly distinguished clinically from diarrhea caused by other infectious agents. Cholera should be considered in all cases with severe watery diarrhea and vomiting, particularly those with rapid progression and severe dehydration, and the potential for exposure to *V. cholerae*. Confirmation requires laboratory identification of toxigenic *V. cholerae* strains in stool specimens or rectal swabs of patients with diarrhea. The bacteria are grown on selective semisolid media [e.g., thiosulfate citrate bile sucrose (TCBS) agar], which is sufficient for identification in most cases because bacterial numbers in the stool are often high ($>10^6$/ml). Based on their characteristic tolerance to elevated pH, bacteria can be enriched by initial growth in alkaline peptone water before plating on selective agar media. Colonies are further identified by biochemical assays and agglutination tests with specific antisera. For epidemiological studies, different *V. cholerae* strains can be further characterized by determining the presence and/or sequence of specific genes using polymerase chain reaction (PCR)-based methods. This information can be used to follow the spread of infections with specific strains and to reconstruct the natural history of novel strains.

TREATMENT

The treatment of acute cholera is primarily symptomatic and aimed at rapid and appropriate fluid replacement. The time between the onset of symptoms and initiation of therapy critically determines the outcome of infection. Rehydration therapy can be oral or intravenous, depending on the available medical facilities and supplies. Oral rehydration is based on the fact that glucose-dependent sodium and water absorption remains intact in the presence of cholera toxin. Patients are given an oral rehydration solution (3.5 g sodium chloride, 2.5 g sodium bicarbonate, 1.5 g potassium chloride, and 20 g glucose per liter of water, as recommended by the World Health Organization). The volume is adjusted according to the severity of dehydration (as determined by several clinical signs, such as degree of thirst, mental state, pulse, and skin turgor). In severe cases and when ready access to appropriate clinical facilities is available, intravenous rehydration therapy with a balanced electrolyte solution (e.g., Ringer's lactate) is indicated.

Although rehydration is necessary and sufficient for patient management, antibiotics can reduce the severity of symptoms and the duration of bacterial excretion. Tetracycline and doxycycline are the first choice as antimicrobials, with erythromycin, trimethoprim/sulfamethoxazole, and furazolidone as alternatives for infections with tetracycline-resistant strains. The appropriate antibiotics are given orally when vomiting stops, which usually coincides with the completion of initial rehydration. Injectable antibiotics are not necessary. Antisecretory drugs have little or no benefit in cholera. Antidiarrheal, antiemetic, and antispasmodic drugs and corticosteroid medications are contraindicated in the management of cholera, because they have no beneficial effects and can prolong the disease.

PREVENTION

Prevention is mostly focused on improving hygienic and sanitary conditions. Of foremost importance are measures to provide adequate sewage collection and

disposal, the protection of clean water resources, and effective water disinfection. Although the effectiveness of these measures is well established, many regions throughout the world do not have the resources and infrastructure to institute them. On a personal level, hygienic measures can be taken to reduce the risk of infection. These include hand washing after defecation, proper food preparation and storage, and cleaning and drying of kitchen utensils.

Chemoprophylaxis with antibiotics can be effective under individual circumstances but has not been successful in limiting the spread of cholera at the community level. Several vaccines have been developed and tested, but their efficacy is limited. The development of vaccines that confer effective and long-lasting protection against different *V. cholerae* strains without causing excessive disease on inoculation remains a promising but challenging approach to controlling cholera.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are the most common chronic cholestatic liver diseases in adults. Differential diagnosis of cholestatic diseases in adults also includes drug-induced cholestasis, idiopathic adulthood ductopenia, idiopathic biliary ductopenia, cholestasis of pregnancy, and cystic fibrosis. PBC and PSC represent clinically distinct entities with a presumed autoimmune basis. Both conditions are characterized by progressive destruction of bile ducts leading to chronic cholestasis and consequent complications such as portal hypertension and liver failure. Despite improvements in the management of complications from end-stage liver disease and excellent long-term results from liver transplantation, a continued understanding of the clinicopathologic processes responsible for cholestatic liver disease remains important.

PRIMARY BILIARY CIRRHOSIS

Epidemiology

Primary biliary cirrhosis (PBC) occurs worldwide and predominantly in middle-aged women, with a female to male ratio of 9 : 1. The median onset of disease is 50 years of age, but with a wide range of 21 to 91 years. The true prevalence and incidence of PBC are unclear, because few epidemiological studies have been conducted. disposal, the protection of clean water resources, and effective water disinfection. Although the effectiveness of these measures is well established, many regions throughout the world do not have the resources and infrastructure to institute them. On a personal level, hygienic measures can be taken to reduce the risk of infection. These include hand washing after defecation, proper food preparation and storage, and cleaning and drying of kitchen utensils.

Chemoprophylaxis with antibiotics can be effective under individual circumstances but has not been successful in limiting the spread of cholera at the community level. Several vaccines have been developed and tested, but their efficacy is limited. The development of vaccines that confer effective and long-lasting protection against different *V. cholerae* strains without causing excessive disease on inoculation remains a promising but challenging approach to controlling cholera.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are the most common chronic cholestatic liver diseases in adults. Differential diagnosis of cholestatic diseases in adults also includes drug-induced cholestasis, idiopathic adulthood ductopenia, idiopathic biliary ductopenia, cholestasis of pregnancy, and cystic fibrosis. PBC and PSC represent clinically distinct entities with a presumed autoimmune basis. Both conditions are characterized by progressive destruction of bile ducts leading to chronic cholestasis and consequent complications such as portal hypertension and liver failure. Despite improvements in the management of complications from end-stage liver disease and excellent long-term results from liver transplantation, a continued understanding of the clinicopathologic processes responsible for cholestatic liver disease remains important.

PRIMARY BILIARY CIRRHOSIS

Epidemiology

Primary biliary cirrhosis (PBC) occurs worldwide and predominantly in middle-aged women, with a female to male ratio of 9 : 1. The median onset of disease is 50 years of age, but with a wide range of 21 to 91 years. The true prevalence and incidence of PBC are unclear, because few epidemiological studies have been conducted. The estimates of annual incidence range from 2 to 22 per million individuals. Whether this variation represents a true difference in prevalence or

results from different methodologies being used is unclear. The prevalence of PBC has increased over time, with 18 cases per million individuals in 1976 rising to 240 cases per million individuals in 1997. This rise may reflect an increase in survival time for patients with PBC, as well as increased awareness of the disease, leading to more frequent diagnosis. In families with one affected member, a prevalence rate of up to 4% has been described among first-degree relatives. An increased prevalence of other autoimmune-related disorders among first-degree relatives of PBC patients is also observed despite the absence of a documented strong genetic association.

Pathogenesis

Although the cause of PBC remains unknown, several lines of evidence suggest an autoimmune process. These include the presence of anti-mitochondrial antibodies (AMA), a frequent association with other autoimmune diseases, involvement of T cells in the destruction of the bile ducts, and numerous defects in immunologic regulation. The mechanisms and agent(s) responsible for the inflammation and bile duct destruction are unknown. The disease seems to be triggered by an immune-mediated response to an alloantigen or autoantigen that leads to progressive destruction of bile ducts and eventual development of biliary cirrhosis. Disease progression is characterized by ductular proliferation and necroinflammation leading to fibrous septa formation. Bridging between portal triads results in nodule formation and cirrhosis. The severity of ductopenia in PBC appears to correlate highly with the degree of fibrosis and is unrelated to periportal or lobular inflammation.

Clinical Features

Asymptomatic Disease

PBC is diagnosed at an asymptomatic stage in as many as 30% of patients with this condition. Such patients are found incidentally to have an elevated serum alkaline phosphatase level and AMA during routine health evaluations. Recently, it has been found that most asymptomatic individuals with AMA and normal liver biochemistries have features in the liver biopsies diagnostic of or consistent with PBC; these patients eventually develop symptoms and laboratory abnormalities of chronic cholestasis.

Symptomatic Disease

The patient who is diagnosed with PBC is typically a woman in the fifth or sixth decade of life with complaints of fatigue or pruritus. Other symptoms may include right upper quadrant abdominal pain, jaundice, and anorexia. Fatigue, although relatively nonspecific in PBC, is the most common symptom, found in about two-thirds of patients, and generally becomes worse as PBC progresses. Pruritus can occur at any time during the course of the illness, developing early, or later as the PBC evolves, or intermittently throughout the course of the disease. Pruritus is generally intermittent during the day and most troublesome at night. The development of xanthomas and xanthalesmas from abnormal lipid metabolism is also associated with PBC. Though uncommon, steatorrhea in PBC is usually from bile salt malabsorption, pancreatic exocrine insufficiency, or concomitant celiac disease. Osteopenia resulting in spontaneous bone fractures is often a manifestation of the metabolic bone disease associated with PBC. Jaundice is a symptom that often heralds the onset of advanced histologic disease and is seen in fewer than 20% of cases at initial diagnosis. Typical complications of cirrhosis such as ascites, variceal bleeding, and hepatic encephalopathy occur. Patients with advanced disease may warrant consideration for surveillance endoscopy to exclude esophageal varices at high-risk for bleeding.

Associated Diseases

Eighty percent of individuals with PBC also have coexistent extrahepatic autoimmune diseases. These include a number of rheumatologic diseases such as sicca syndrome, scleroderma, rheumatoid arthritis, dermatomyositis, mixed connective tissue disease, and systemic lupus erythematosus. Autoimmune thyroiditis and renal tubular acidosis have also been described with PBC. There is an increase in malignancy in patients with PBC; hepatocellular carcinoma is uncommon, but PBC patients have a substantially increased risk of developing this disease compared with the general population.

Diagnosis

Biochemical Changes

Liver biochemical tests show a cholestatic picture. Almost all patients have elevations in serum alkaline phosphatase (three to four times normal) and γ-glutamyltranspeptidase. Increased values for alanine aminotransferase and aspartate aminotransferase (AST) of two to three times normal are common; however, marked elevations are unusual and may suggest PBC—autoimmune hepatitis overlap syndrome or coexisting viral hepatitis. Serum total bilirubin levels often rise during the course of disease progression

with levels occasionally reaching 20 mg/dl. With advanced disease, the combination of elevated total bilirubin, decreased albumin, and increased prothrombin time represent poor prognostic markers for outcome. Serum immunoglobulins, especially IgM levels, are increased, as are serum bile acid levels, in particular cholic and chenodeoxycholic acids, as well as serum cholesterol.

Serologic Diagnosis

Up to 95% of patients with PBC test positive for AMA. The M2 antibody, which is directed against the pyruvate dehydrogenase complex of the inner mitochondrial membrane, has a sensitivity of 98% and a specificity of 96% in the diagnosis of PBC. Anti-centromere antibodies seen in the CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, teleangiectasias) syndrome despite absent clinical findings of scleroderma have also been noted. Seventy percent of PBC patients may also exhibit anti-nuclear antibodies (ANA) with or without anti-smooth muscle antibody (ASMA). The terms "AMA-negative PBC" or "autoimmune cholangitis" have been created to describe patients with clinical features and natural history profiles consistent with PBC but without AMA. ANA or ASMA positivity is often observed in the absence of AMA in this patient group.

Liver Biopsy

Although serum AMA will confirm a suspected diagnosis of PBC, a liver biopsy is needed for determining the stage of disease at diagnosis. Prognostic information such as determining the need for surveillance of complications related to cirrhosis or consideration of liver transplant evaluation may also be provided by liver biopsy. Wide variations in histology can exist even with slight elevations in total bilirubin and alkaline phosphatase. The most important and only diagnostic clue in many cases is ductopenia as defined by the absence of interlobular bile ducts in more than 50% of portal tracts. The florid duct lesion, in which the epithelium of the interlobular and segmental bile ducts degenerate segmentally with formation of noncaseating epitheloid granulomas, is nearly diagnostic of PBC, but is found in a relatively small number of cases (<10%) and mainly in early stages. The two most popular classification systems are those presented by Ludwig and Scheuer, which classify the disease in four stages. Both systems describe progressive pathologic changes, initially beginning in the periportal areas surrounding the bile ducts, with the eventual development of cirrhosis.

Natural History

The natural history of PBC has been described in both asymptomatic and symptomatic PBC.

Mitchison *et al*. and Metcalf *et al*. have reported that 83% of patients who were AMA-positive and who had normal liver biochemistries and no symptoms of liver disease had liver histology compatible with PBC. These patients were followed for a median of 17.8 years, and eventually 83% of patients developed abnormal liver biochemistries and 76% developed symptoms consistent with PBC. These studies clearly demonstrated that asymptomatic patients who are AMA-positive have very early PBC.

Several reports have provided evidence regarding the natural history of asymptomatic patients who are AMA-positive, have abnormal liver biochemistries, and have liver histology compatible with PBC. Patients who remain asymptomatic for years may have significantly longer survival than symptomatic patients, but their life expectancy is still less than that of an age- and gender-matched control population.

In contrast, patients with symptomatic PBC show a more rapid progression to end-stage liver disease and its inherent complications and they have a worse prognosis. Several independent predictors of poor prognosis have been identified in this group of patients with PBC, including advanced age, high serum bilirubin levels, poor synthetic function, hepatomegaly, ascites, variceal bleeding, and advanced histological stage. When untreated, PBC may follow a course that extends over a 15- to 20-year period. However, in patients with serum bilirubin levels greater than 10 mg/dl, the average life expectancy is reduced to 2 years. To predict survival in patients with PBC, several prognostic models have been reported. Of these models, the Mayo risk score based on patient age, serum bilirubin, albumin, prothrombin time, and edema has been cross-validated and widely used in predicting survival and guiding physicians in patient referral for liver transplantation.

Treatment

A number of potential treatments for PBC have been evaluated to date with the primary goals of stabilizing or halting disease progression. A variety of treatment options have been tested in patients with primary biliary cirrhosis. Therapies that have been tested and have not been found to be beneficial or had excessive toxicity included penicillamine, cyclosporin, azathioprine, thalidomide, mycophenolic acid, and chlorambucil. Corticosteroids and colchicine as well as methotrexate have had some advocates, although data supporting the use of any of these are

either quite limited or unconvincing. The drug with which there is currently the most experience and the most optimism about is ursodeoxycholic acid. This drug has been approved by the FDA for use in patients with PBC. Ursodeoxycholic acid is a safe, well-tolerated drug that improves liver biochemistries, improves survival free of transplantation, reduces the risk of developing varices, and improves pruritus. Four randomized, placebo-controlled trials using ursodeoxycholic acid (UDCA) have demonstrated histologic benefit and/or a delay in the time to transplantation or death. At a dose of 13 to 15 mg/kg/day, UDCA has also been shown to reduce the risk of developing esophageal varices and cirrhosis in the long term. This is a cost-effective therapy and is expected to have a real impact on the natural history in patients with primary biliary cirrhosis.

Pruritus as a frequent complication of cholestatic liver disease creates difficult management options as significant impairments in quality of life are observed. Cholestyramine (a bile-acid-binding resin) may decrease the intensity of pruritus but rarely leads to complete symptom resolution. Rifampin (300 to 600 mg daily), antihistamines, and UDCA with or without cholestyramine have been tried, usually with good success. Patients should be instructed to take UDCA several hours after cholestyramine administration to prevent the binding of UDCA and its elimination without absorption.

Osteopenia or metabolic bone disease has been associated with an accelerated rate of bone loss among individuals with PBC. Decreased bone formation rather than increased resorption is considered to be an important mechanism of action.

PRIMARY SCLEROSING CHOLANGITIS

Epidemiology

Seventy percent of affected individuals are men with an average age of 40 years at diagnosis. There have been no epidemiologic studies on the prevalence of PSC in any general population group. Most data were derived from epidemiologic studies on inflammatory bowel disease (IBD) patients. The close association between PSC and IBD has been well established, as 70–80% of PSC cases are associated with IBD, usually chronic ulcerative colitis (CUC). Conversely, approximately 5% of patients with CUC develop PSC. From an estimated prevalence rate for CUC of 40 to 225 cases per 100,000 individuals in the United States, the prevalence of PSC is estimated to be between 2 and 7 cases per 100,000 individuals. These figures, however, underestimate the true prevalence of PSC, since the prevalence of PSC in CUC is likely to be higher than estimated.

Pathogenesis

The cause of PSC is unknown. However, a number of factors that might cause recurring damage to the bile ducts and lead to the development of the disease have been proposed. Periductal fibrosis with inflammation, bile duct obliteration, and ductopenia constitute the main histologic findings in PSC. Similar findings may occur in other conditions such as PBC, autoimmune hepatitis (AIH), or chronic extrahepatic bile duct obstruction, which constitute the primary differential diagnoses. In the pathogenesis of PSC, cellular immune factors may play a role, as suggested by the composition of the portal infiltrate, which is made up mainly of $CD4^+$ T lymphocytes. An immune-mediated mechanism also has been suggested by the findings in an experimental model of immune-mediated cholestasis and shared antibodies against colonic and biliary epithelia.

Anti-neutrophil cytoplasmic antibodies (ANCA) originally detected in serum from patients with ulcerative colitis were subsequently identified in a high proportion of patients with PSC. However, ANCA have also been detected in the serum of patients with other autoimmune liver diseases such as autoimmune hepatitis and PBC. The occurrence of PSC in relatives suggests human leukocyte antigen association and genetic predisposition for developing this condition. In fact, the DR4 allele may be a marker of more rapid disease progression. Although major advances in the understanding of PSC have been made in recent years, the cause of the disease still remains to be elucidated.

Clinical Features

Originally, many patients who were recognized as having this disease presented with features of advanced liver disease. Now, increasingly, it appears that more patients are being discovered incidentally, often during evaluation for abnormal liver tests seen in association with inflammatory bowel disease. Asymptomatic elevations in serum liver biochemistries or the development of symptoms such as fatigue (75%) and pruritus (70%) are often observed with the diagnosis of PSC. Jaundice (60%) and weight loss (40%) are less common and should raise the suspicion of advanced disease or a complication related to PSC. Xanthomatous lesions and hyperpigmentation, however, are less common than in patients with PBC. Fever and abdominal pain in a patient with PSC are highly suggestive of bacterial cholangitis, which can manifest at initial presentation. The presence

of jaundice is not required for the diagnosis of bacterial cholangitis. Over the course of time as the disease progresses, most patients will eventually develop one or more of these symptoms. Over the average period of 10–15 years, patients often progress to end-stage liver disease and suffer the consequences of a failing liver or require liver transplantation, although this course can be highly variable, with some patients surviving 25 or more years with nearly asymptomatic PSC.

Radiographic Features

Endoscopic retrograde cholangiopancreatography (ERCP) is the test of choice for visualizing the biliary tract and is considered the gold standard for making the diagnosis of PSC. Segmental fibrosis of both intrahepatic and extrahepatic ducts with subsequent saccular dilation of normal intervening areas results in the characteristic "beads on a string" appearance seen in PSC (Fig. 1). Approximately 20% of patients will have only intrahepatic and hilar involvement with sparing of the remaining extrahepatic duct. The presence of a significant or dominant stricture on ERCP should raise the question of cholangiocarcinoma as a supervening complication of PSC. Cross-sectional imaging studies are of limited value in patients with suspected primary sclerosing cholangitis. Magnetic resonance cholangiography (MRCP) is a noninvasive test that does not require administration of contrast or use of radiation and appears to be promising. MRCP does not allow histological sampling or therapeutic intervention but may be a cost-effective initial step.

FIGURE 1 ERCP in primary sclerosing cholangitis shows beading irregularities (arrow) in the bile ducts.

Diagnosis

Nearly all patients with PSC have significant elevations in serum alkaline phosphatase (three to five times normal) and a milder increase in serum hepatic transaminases. High levels of total bilirubin, which often fluctuate in PSC, are worrisome for advanced disease when persistent elevations occur. No significant differences in serum liver biochemistry profiles have been seen among asymptomatic and symptomatic individuals at diagnosis. In combination with the appropriate clinical and radiographic findings, an initial diagnosis of PSC can be made without the explicit use of hepatic histology. Liver biopsy is useful in histological confirmation and staging of the disease, but, because of the sampling variability, can be troublesome. A recent analysis by Burak *et al*. suggests that a liver biopsy adds little to the diagnosis of PSC. Unlike PBC, no specific autoantibody has been identified to confirm the diagnosis of PSC (see Table I). A total of 70 to 80% of patients will test positive for ANCA though its clinical significance remains unclear because this autoantibody is common in several other liver diseases. An increased prevalence of extrahepatic autoimmune disorders has been observed for PSC but these are much less commonly seen than in PBC, except for inflammatory bowel disease.

Natural History

The natural history of PSC is not as well defined as with other liver diseases, primarily because the entity has been widely recognized only in the past quarter century. In 1970, a review described all cases of PSC reported to that time, which numbered less than 100. With the advent of ERCP in the mid to late 1970s, the diagnosis became much more commonly established so that some major medical centers are seeing over 100 patients a year with PSC. Because the broad recognition of the disease is relatively recent, some may have the sense that the natural history is changing. The median reported survival in patients with PSC is 10 to 12 years from the time of diagnosis. Several variables such as older age, elevated serum levels of bilirubin, AST, low albumin, hepatosplenomegaly, variceal bleeding, presence of IBD, and histologic stage have been identified as independent risk factors indicating poor prognosis. Child–Pugh classification has been evaluated as a

prognostic indicator for survival in PSC. The study showed that the age-adjusted Child–Pugh model predicts survival before transplantation and it has been used in formulating minimal listing criteria. The recently described entity of small duct PSC also seems to follow a course comparable to classic PSC. These patients have similar clinical, biochemical, and histologic features and may make up fewer than 5% of patients with a histologic diagnosis of PSC. These patients are distinguished by normal cholangiograms in the setting of inflammatory bowel disease. Some of these patients may develop cholangiographic features of classic PSC and eventually require liver transplantation. More work is obviously needed to better understand the natural history of this variant.

Treatment

Due to the variable disease progression seen in PSC, the development of randomized clinical trials for the assessment of therapies has been difficult. As a potential consequence, there is no acceptable medical therapy available today for the treatment of PSC. As seen with PBC, the use of pharmacologic agents such as *d*-penicillamine, colchicine, corticosteroids, and immunosuppressive agents has not been shown to impart a significant clinical benefit. UDCA in standard doses (13 to 15 mg/kg/day) appears to cause biochemical improvement but has no significant impact on histology or survival. Recently, it was shown that UDCA at a higher dose (20 mg/kg) looks promising by showing improvement in liver biochemistries and histology after 2 years of treatment compared to placebo.

PSC is one of the more common indications for liver transplantation in the United States. The cumulative 1-year survival rate after liver transplantation is now greater than 85%. Liver transplantation should be considered before the disease is too advanced because PSC patients with low (<4.4) Mayo risk score have a significantly better survival.

Cholangitis in PSC is most commonly associated with a previous history of biliary tree manipulation by surgical or radiologic/endoscopic interventions in select individuals. Once suspected, empiric intravenous antibiotic therapy to cover gram-negative and anaerobic bacteria should be initiated. ERCP should then be considered to exclude biliary obstruction from benign (choledocholithiasis, dominant stricture) or malignant (cholangiocarcinoma) etiologies.

The presence of a dominant stricture (defined as a high-grade, localized narrowing of the biliary tree) is often manifested by a sudden increase in serum alkaline phosphatase and/or bilirubin in the asymptomatic patient. Progressive jaundice and the development of cholangitis from obstruction are also consequences of dominant stricture formation, requiring cholangiography. Balloon dilation of identified strictures by endoscopic or radiologic approaches often provides satisfactory results. Use of endoscopic stents for 3 to 6 months to prevent recurrent stricture formation may be fraught with an increased rate of infectious complications. Pinch biopsies with brushings for histological analysis of all dominant strictures are required to help exclude the presence of cholangiocarcinoma.

Cholangiocarcinoma is the most feared complication of PSC, occurring in 10–15% of cases. Clinical progression of disease in a rapid fashion with jaundice and marked liver biochemistry elevations often alerts the clinician to the possibility of bile duct cancer. Repeated attempts at diagnosis with biopsy and brushings may be required for definitive exclusion. Occasional surgical intervention is required for full-thickness biopsy in special instances. The overall median survival is approximately 5 months from the diagnosis of cholangiocarcinoma, although liver transplantation in highly selected cases was shown to improve survival.

VARIANT CHOLANGIOPATHIES

Recent observations have documented a group of patients with clinical characteristics suggestive of PBC without AMA but with positive ANA or ASMA. The

terms "autoimmune cholangitis" or "AMA-negative PBC" have been used in referring to these individuals. The clinical course and response to UDCA therapy are the same as in patients with AMA-positive PBC.

The presence of features consistent with both AIH and PBC has resulted in a diagnostic category termed the overlap syndrome. Both ANA and AMA are often positive through serologic testing. Piecemeal necrosis and coexistent periductal/portal inflammation with bile duct destruction is commonly seen. This group appears to benefit from immunosuppressive treatment as well as UDCA. Similar overlap also occurs in PSC and AIH in both adult and pediatric populations. The presence of typical biliary stricturing and dilation seen in PSC is often accompanied by histologic lesions seen in AIH and also by high-titer ANA. The overlap of AIH and PSC may warrant the use of immunosuppressive therapy.

Dietary cholesterol absorption is defined as the process by which dietary cholesterol is absorbed through the intestinal tract and transported into the blood circulation. In view of the fact that dietary fat and cholesterol intake are increasing at an alarming pace in industrialized countries, there is an increasing interest among clinicians to understand the mechanism of dietary cholesterol absorption. The goal is to design intervention strategies, either by dietary manipulations or therapeutics, to lower the efficiency of dietary fat and cholesterol absorption, thereby reducing the risk of coronary heart disease, cancer, diabetes, and obesity.

INTRODUCTION

Epidemiological studies have clearly established a direct relationship between cholesterol level in blood plasma and coronary heart disease. Elevated plasma cholesterol level also promotes other debilitating diseases, including certain forms of cancer, diabetes, and obesity. Cholesterol levels in the circulation are dependent on several parameters, including endogenous synthesis, secretion, and catabolism of the various plasma lipoproteins. Another major contributor to the amount of cholesterol in plasma is the exogenous cholesterol ingested in the diet. Depending on different individuals, 10–60% of the cholesterol entering the body each day is derived from the diet. In addition to its effect on total plasma cholesterol level, the amount of dietary cholesterol entering the bloodstream also has a direct impact on the level of low-density lipoproteins (LDLs), the "bad" cholesterol that directly contributes to plaque formation in the arterial wall. It has been estimated that a 90% reduction of cholesterol absorption in subjects with a moderately elevated plasma cholesterol level can reduce plasma cholesterol level by 35%, and that a 62% reduction in plasma cholesterol level can be achieved by 100% inhibition of cholesterol absorption.

Cholesterol exists in the diet mainly in the unesterified form, with only 5–10% of the cholesterol being esterified by fatty acids as cholesteryl esters. The intake of cholesterol is usually associated with fat consumption. The process of absorption begins in the stomach with partial fat digestion by preduodenal lipases and emulsification by peristalsis. The crude emulsions are then delivered to the duodenum, where they are mixed with bile and pancreatic juice. The dietary cholesterol appearing in the lumen of the intestine is usually associated with triglycerides and phospholipids in lipid emulsions, and coexists with cholesterol secreted from the liver into the bile, which is mixed with bile salt in the form of micelles. The lipid emulsions are further digested in the intestinal lumen by enzymes secreted by the pancreas, converting the phospholipids and triglycerides to fatty acids, lysophospholipids, and monoglycerides. Cholesteryl esters are also hydrolyzed to unesterified cholesterol and free fatty acids. The unesterified cholesterol is then distributed to phospholipid vesicles and bile salt mixed micelles, and is transported to the brush border of the intestine, where it is taken up by the mucosal cells. A diagrammatic representation of luminal events involved in cholesterol absorption is shown in Fig. 1.

Once the cholesterol is transported to the intestinal cell surface by phospholipid vesicles and bile salt mixed micelles, it can diffuse through the cell membrane into intracellular compartments. Cholesterol embedded in vesicles and micelles can also be taken up into the cell

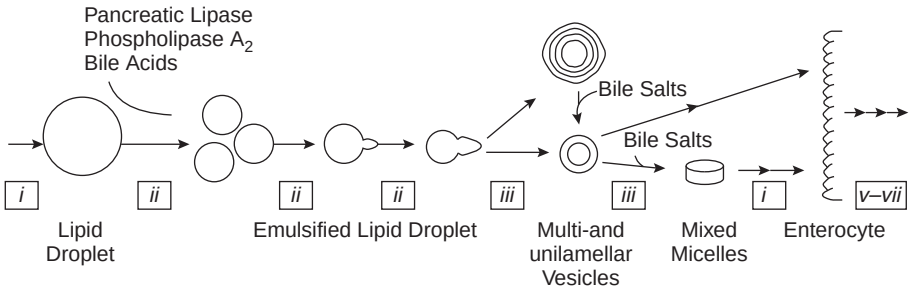

FIGURE 1 Process of dietary lipid absorption in the lumen of the small intestine. Dietary lipid absorption involves a multitude of processes in several different tissues. The processes include (*i*) lipid emulsification in the stomach, (*ii*) lipid digestion within the intestinal lumen by enzymes secreted from the pancreas, (*iii*) micellar solubilization of the lipid components, (*iv*) intestinal uptake, (*v*) intracellular lipid esterification and lipoprotein assembly, (*vi*) enterocyte secretion, and (*vii*) homeostasis of the dietary components in plasma.

interior by an active transport process involving cell surface transporter proteins. The amount of cholesterol entering the enterocytes can also be regulated by specific cell surface transporter proteins, the function of which is to export cholesterol back to the luminal space for excretion out of the body. The cholesterol entering the mucosal cells is rapidly transported to an intracellular compartment, where it is reesterified with fatty acid, packaged into large intestinal lipoproteins called chylomicrons, and then secreted into the lymphatics.

The process of dietary cholesterol absorption, from the point of cholesterol ingestion to its appearance in circulation, thus requires the participation of a number of different proteins. It is not surprising, therefore, that different expression level and/or activity of these proteins can influence the efficiency of cholesterol absorption. Indeed, genetic variations in cholesterol absorption efficiency have been reported in a number of species, including humans. A number of key proteins that participate in the cholesterol absorption process, including those that are required for lipid digestion, cellular uptake and efflux, and intracellular processing of the cholesterol prior to its secretion into the circulation, are the focus of the following discussion. The latest advances indicating genetic regulation and intervention strategies aimed at reducing cholesterol absorption efficiency are also discussed.

LIPID DIGESTION

Cholesterol is ingested in the diet in association with the fatty triglycerides. These lipids are emulsified in the stomach by the action of peristalsis. Some of the dietary triglycerides are partially hydrolyzed by preduodenal lipases into diglycerides and free fatty acids. Depending on the individual species, the preduodenal lipase can be found in the tongue (lingual lipase) or in the stomach (gastric lipase). In humans, the preduodenal lipase is gastric lipase and no lingual lipase is found. Regardless of the tissue source of the preduodenal lipases, these enzymes prefer triglycerides with short- and medium-chain fatty acids and are incapable of hydrolyzing significant amounts of triglycerides with long-chain fatty acids. These lipases are also ineffective in hydrolyzing phospholipids and cholesteryl esters. Thus, these preduodenal lipolytic enzymes do not hydrolyze much of the phospholipid-coated emulsions, and a majority of the dietary fat and cholesterol are transported to the intestinal lumen as large, emulsified lipid droplets.

The lipid emulsions entering the luminal area of the intestine are digested by lipolytic enzymes secreted by the pancreas. The major lipases secreted by the pancreas in response to a meal include the pancreatic triglyceride lipase, a pancreas-specific form of phospholipase A_2, and carboxyl ester lipase. The latter enzyme is also known as cholesterol esterase or as bile salt-stimulated lipase. Two additional proteins, pancreatic lipase-related protein-1 and -2, which are similar in sequence and structure to the pancreatic triglyceride lipase, are also secreted by the pancreas. The important role of pancreatic enzymes in fat and cholesterol absorption is best illustrated by fat and cholesterol malabsorption in cystic fibrosis patients and in patients with other pancreatic diseases, including those with pancreatitis due to chronic alcoholism. These patients suffer steatorrhea and reduced cholesterol absorption and have deficiencies of fat-soluble vitamins and essential fatty acids.

In vitro studies show that pancreatic triglyceride lipase is the primary digestive tract enzyme that hydrolyzes triglycerides in emulsified lipid particles. Its activity is dependent on the presence of its coenzyme,

colipase. The contribution of pancreatic triglyceride lipase/colipase in fat and cholesterol absorption is highlighted by observations that patients with congenital pancreatic triglyceride lipase deficiency or deficiency of colipase suffer from fat and cholesterol malabsorption similar to that seen in patients with pancreatic insufficiency. The mechanism by which pancreatic triglyceride lipase facilitates dietary cholesterol absorption is indirect. *In vitro* cell culture experiments suggest that cholesterol carried by bulky lipid emulsions is not accessible for uptake by intestinal cells and that pancreatic triglyceride lipase hydrolysis of the core triglycerides is required for intestinal uptake of the cholesterol. It is likely that the dietary cholesterol in lipid emulsions needs to be redistributed to smaller phospholipid vesicles and bile salt mixed micelles prior to its transport to the brush border surface, where it can be taken up by the intestinal mucosa. In the absence of pancreatic triglyceride lipase-mediated lipid hydrolysis, the cholesterol is retained in the lipid emulsion, which may be too large for penetration through the unstirred water layer of the brush border membrane.

The remodeling of the cholesterol carrier in the intestinal lumen also requires phospholipase hydrolysis of phospholipids on the surface of emulsions and on lipid vesicles. Thus, phospholipase-mediated hydrolysis of the phospholipid in mixed micelles may also be an important step in the cholesterol absorption process. The role of phospholipase in facilitating cholesterol absorption can be inferred from early *in vitro* organ culture experiments, which showed that increasing phospholipid content of bile salt mixed micelles retarded cholesterol transport to the intestine. Subsequent studies also showed cholesterol output from the lumen to the lymphatics was higher when duodenal infusions were performed with lipid emulsions containing low levels of phosphatidylcholine. In addition, human subjects receiving an intraduodenal infusion of phosphatidylcholine were also found to absorb cholesterol to a lower extent compared with subjects infused with the same amount of cholesterol and safflower oil with a similar level of fatty acids. A direct role of phospholipase A_2 in facilitating cholesterol transport to intestinal cells was suggested by cell culture experiments showing that the addition of the pancreatic Group 1B phospholipase A_2 to the cell incubation medium increased cholesterol uptake by Caco-2 cells. In intact animals, phospholipase A_2 inhibitors effectively reduced cholesterol transport from the intestinal lumen to the lymphatics. Although these experiments clearly demonstrate a role for phospholipase A_2 in mediating cholesterol absorption, the particular type of phospholipase that is involved in this process is less clear. The Group 1B phospholipase A_2 secreted by the pancreas is the predominant phospholipase in the intestinal lumen, but animals lacking this enzyme are not defective in cholesterol absorption under normal dietary conditions. However, under high dietary fat conditions, the phospholipase A_2-deficient mice display reduced fat and cholesterol absorption efficiency. These latter observations suggest that phospholipase A_2 synthesized by the intestine may compensate for the lack of the pancreatic-type phospholipase A_2 in phospholipid digestion in the intestinal lumen and in mediating cholesterol absorption. Thus, the pancreatic phospholipase A_2 is uniquely required among various phospholipases in controlling cholesterol absorption and transport during high dietary fat input, whereas other phospholipases expressed in the intestine may take its place when dietary lipid content is low.

The role of the third lipolytic enzyme secreted by the pancreas, carboxyl ester lipase, in cholesterol absorption has drawn considerable interest over the past three decades because of its ability to influence cholesterol esterification and deesterification directly. This enzyme also catalyzes the hydrolysis of triglycerides and fat-soluble vitamin esters. *In vitro* data reveal that complete hydrolysis of triglycerides to fatty acids and glycerol requires the concerted action of both pancreatic triglyceride lipase and the carboxyl ester lipase. Thus, carboxyl ester lipase works in concert with pancreatic triglyceride lipase in mediating fat digestion. Its direct involvement in the dietary cholesterol absorption process is suggested by early studies that showed that the reduction in cholesterol absorption due to pancreatic diversion can be restored by infusion with pancreatic juice containing the carboxyl ester lipase, but not with juice devoid of this enzyme. The incubation of rat intestinal sacs with cholesterol containing micelles also shows that cholesterol uptake by the intestinal sacs is three- to fivefold higher if carboxyl ester lipase is included in the medium. Specific inhibitors of carboxyl ester lipase, such as the phenoxylphenyl carbamates WAY-121,751 and WAY-121,898, are effective inhibitors of cholesterol absorption in normal and cholesterol-fed animals. Unfortunately, these results have been challenged by more recent studies, which yield contradictory results. It is likely that the carboxyl ester lipase preparations used in the earlier studies contain other lipolytic enzymes that act in concert with carboxyl ester lipase to facilitate cholesterol absorption. The phenoxylphenyl carbamates may also be less specific and may also affect the activity of other pancreatic lipases. The generation of carboxyl ester lipase-deficient mice by the homologous recombination technique conclusively shows that this enzyme plays only a minor role in controlling

the amount of dietary cholesterol absorbed through the intestine. However, carboxyl ester lipase may be more important in dictating the type of lipoproteins being produced by the intestine in response to a fatty meal. Animals lacking a functional carboxyl ester lipase are incapable of secreting the larger sized chylomicrons. Lipoproteins produced in the intestine of these animals are similar in size to the smaller liver-derived very-low-density lipoproteins. It is postulated that carboxyl ester lipase alters intracellular lipid trafficking and/or signaling pathways that are important in transporting exogenous lipids to intracellular compartments where lipoprotein assembly occurs. This hypothesis remains to be tested by more vigorous experiments.

The pancreatic lipase-related protein-1 and -2 (PLRP-1 and PLRP-2) appear to be less important in lipid digestion and absorption under normal conditions in adults. Both of these enzymes have the highest expression level during the developmental period before the onset of pancreatic triglyceride lipase gene expression. The expression profile of these genes suggests that the related proteins may compensate for the low pancreatic triglyceride lipase activity during the suckling period, to ensure efficient fat digestion in newborns. The possible role of PLRP-2 in newborn fat digestion is supported by the observation that PLRP-2-deficient mice display higher fecal fat content and decreased rate of weight gain than do their wild-type counterparts when fed similar diets. In contrast, the role of PLRP-1 in fat digestion and absorption is less certain; *in vitro* analyses fail to detect significant lipolytic activity of this protein. No PLRP-1-deficient animal model is currently available to test for the function of this lipase *in vivo*.

CHOLESTEROL UPTAKE BY INTESTINAL MUCOSAL CELLS

The digestion of the surface phospholipids and the core triglycerides in bulky lipid emulsions results in the liberation of the dietary cholesterol and its transfer to phospholipid vesicles and bile salt micelles. These lipid carriers are responsible for cholesterol transport to the surface of the intestinal mucosa, where cholesterol can be absorbed into the enterocytes. Bile salt present in the lumen helps transport cholesterol across the unstirred water layer, which is a series of water lamellae at the interface between the bulk water phase of the lumen and the enterocyte cell membrane. Thus, abnormal bile acid and biliary lipid composition may affect cholesterol absorption through inhibition of this step of the absorption process. This hypothesis is substantiated by observations that mice defective in bile acid synthesis due to a genetic defect in the cholesterol 7α-hydroxylase gene *Cyp7α1* absorb dietary cholesterol minimally in comparison with wild-type mice. Likewise, defects in bile salt or phospholipid export from the liver to the bile, due to deletion of P-glycoprotein genes, also result in abnormal cholesterol absorption efficiency.

Once cholesterol is transported to the mucosal surface of the intestine by phospholipid vesicles and bile salt micelles, the cholesterol can be taken up by the enterocytes in a rapid process through passive diffusion across the cell membrane. Although recent data suggest the presence of an active transport mechanism for cholesterol uptake, interpretation of the data remains equivocal. The amount of cholesterol absorbed into the enterocytes can also be regulated by membrane surface proteins that are responsible for mediating cholesterol efflux.

Regardless of the precise mechanism by which cholesterol enters the intestinal mucosa, intestinal cholesterol uptake is a two-step process. The first step is a reversible process by which cholesterol in vesicles and micelles is embedded into the plasma membrane of the enterocytes. The amount of cholesterol that can be accommodated in the intestinal cell membrane is correlated with the sphingomyelin content in the membrane. Intestinal cell culture studies *in vitro* reveal that the rate of exogenous cholesterol uptake also decreases when the membrane is depleted of sphingomyelin. Thus, the amount of cholesterol that can be absorbed into the enterocytes is in part regulated by the sphingomyelin concentration in the plasma membrane. By extrapolation, cholesterol absorption and transport efficiency are also dictated by the level and activity of the sphingomyelin hydrolytic enzyme, sphingomyelinase, present in the intestinal lumen.

The second step in the cholesterol uptake process is irreversible; which membrane-bound cholesterol is transported to the endoplasmic reticulum, where the cholesterol can be utilized for lipoprotein assembly and secretion to the plasma compartment. The influx of membrane cholesterol into the cell interior requires membrane sphingomyelin hydrolysis after the exogenous cholesterol is embedded into the cell membrane. A by-product generated from sphingomyelin hydrolysis is ceramide, which regulates intracellular lipid trafficking and thus plays an important role in controlling the rate of lipoprotein being produced by the intestine. Accordingly, enzymes that regulate intracellular ceramide concentration, including the carboxyl ester lipase secreted by the pancreas (which can be taken up by enterocytes into the cell interior), are also

important regulators in determining the rate of cholesterol absorption and the type of lipoproteins produced in response to a fat meal.

Cholesterol uptake by intestinal cells may also be an active process mediated by transporter proteins on the brush border membranes of the enterocytes. The strongest evidence supporting the existence of cholesterol-transporting proteins comes from early observations that cholesterol absorption follows second-order reaction kinetics, with a high- and a low-affinity component. Hydrolysis of proteins off the brush border membranes reduces cholesterol absorption to a first-order reaction with only a low-affinity component. The hypothesis of a protein-mediated cholesterol absorption process is also supported by experiments showing that cholesterol transport activity in liposomes can be reconstituted with proteins extracted from intestinal brush border membranes.

The identification of the putative cholesterol transporter on brush border membranes remains elusive. Although numerous laboratories have attempted to identify the cholesterol transporter, its identity has remained controversial. One promising lead comes from results reported by Helmut Hauser and colleagues in Zurich. Their studies suggest that the scavenger receptor class B type I protein (SR-BI) may function as a cholesterol transporter in the intestine. According to their results, cholesterol uptake by the intestinal-cell-like Caco-2 cells is suppressed by SR-BI antibodies. The binding of apolipoprotein A-I to SR-BI on the brush border membranes also inhibits cholesterol uptake from lipid donor particles. In support of these *in vitro* observations, SR-BI is found to be expressed along the gastrocolic axis of the intestine, with the highest level of expression in the proximal intestine and decreasing to minimal expression level in the ileum. Furthermore, SR-BI is localized to both the apical and the basolateral surfaces of enterocytes. Thus, the localization of SR-BI in the intestine is consistent with the hypothesis of its possible role in dietary cholesterol absorption. Unfortunately, this hypothesis cannot be substantiated, because mice lacking a functional SR-BI gene absorb dietary cholesterol with an efficiency similar to that observed in wild-type mice. Additionally, SR-BI has been shown *in vitro* to modulate cellular uptake of cholesteryl esters and triglycerides in addition to facilitating unesterified cholesterol transport. Neither cholesteryl esters nor triglycerides can be absorbed prior to their digestion by lipases. Thus, the precise role of SR-BI in the intestine remains uncertain.

The controversy surrounding the possible existence of cholesterol transport proteins responsible for dietary cholesterol absorption may stem from differences in interpreting results obtained from *in vivo* and *in vitro* studies. In *in vitro* experiments with enterocyte cell culture or brush border membranes, the cholesterol substrate is usually supplied as vesicles and micelles. Importantly, the substrate concentration is usually kept at a low concentration to maintain cell and membrane integrity. At low concentrations, the higher affinity but lower capacity process predominates in a second-order reaction, thus allowing for the determination of a protein-mediated high-affinity process. In contrast, under *in vivo* conditions, in which there is constant bile flow with its accompanying cholesterol-containing micelles, substrate concentration is relatively high. The higher concentration of cholesterol substrate in the intestinal lumen will favor uptake through the higher capacity, though lower affinity, passive transport process. The failure to observe protein-mediated cholesterol absorption *in vivo*, and the lack of effect on cholesterol absorption by specific transporter knockout mice, may be related to the concentration of the substrate used. In this regard, an intestinal cholesterol transporter may have only an auxiliary function in cholesterol absorption when cholesterol concentration in the intestinal lumen is low. Alternatively, the transporter may target the cholesterol to a specific intracellular compartment in which it can be utilized efficiently for lipoprotein assembly and export. These two possibilities remain to be resolved.

Another line of evidence used previously to support the concept of a protein-mediated cholesterol absorption process is based on observations of the selectivity of cholesterol absorption. Plant sterols, including stigmatosterol, sitosterol, and sitostanol, have chemical structures very similar to that of cholesterol and yet are not absorbed by the intestine. These plant sterols and cholesterol have similar hydrophobicities and are expected to diffuse through the plasma membrane with similar efficiencies. Accordingly, the passive transport process alone cannot account for the selectivity in cholesterol absorption without the concomitant absorption of the plant sterols. However, recent studies have shed light on the selectivity of the cholesterol absorption process. These studies were based on investigations of sitosterolemic patients, who can absorb plant sterols with high efficiency. Results of these studies reveal that plant sterols can indeed diffuse into intestinal cells. The selectivity of cholesterol absorption is due to adenosine triphosphate (ATP)-binding cassette (ABC) proteins, which preferentially pump plant sterols through the apical membranes back to the intestinal lumen in an ATP-dependent mechanism. Sitosterolemic patients have inherited an autosomal recessive mutation in the gene encoding either the ABCG5 or ABCG8

protein. The mutated ATP transporter cannot excrete the plant sterols from intestinal mucosal cells, thereby resulting in plant sterol absorption and secretion with lipoproteins into the circulation. Thus, the normal function of the ABCG5 and ABCG8 proteins is the ATP-dependent excretion of plant sterols back into the lumen, prevention of further plant sterol processing, and sterol transport to the circulation. Interestingly, mutations in either of the genes for ABCG5 and ABCG8 also result in increased cholesterol absorption. Whether the increased cholesterol absorption is due to a direct effect of the normal function of the ABCG5 and ABCG8 proteins on cholesterol efflux or to an indirect effect due to modification of luminal lipid composition remains to be determined.

Another ABC transporter protein that has been implicated to play a role in regulation of cholesterol absorption is ABCA1. This protein was initially identified as a liver protein that regulates high-density lipoprotein (HDL) levels. Tangier disease, which results in the absence of HDL and familial HDL deficiency, is a direct result of ABCA1 gene mutations. Factors that activate ABCA1 gene expression, such as the liver X receptor (LXR) agonist rexinoids, are effective inhibitors of dietary cholesterol absorption in rodents. The latter observation led to the suggestion that ABCA1 may regulate cholesterol absorption by limiting the amount of cholesterol taken up by intestinal cells. However, it is important to note that ABCA1-deficient mice absorb cholesterol with normal efficiency. Moreover, ABCA1 has not been demonstrated to be present in enterocytes. Thus, the role of ABCA1 in cholesterol absorption may be indirect, and may be related to alterations in biliary lipid composition and/or other differences unrelated to lipid uptake by intestinal cells.

INTRACELLULAR CHOLESTEROL PROCESSING AND LIPOPROTEIN ASSEMBLY

Cholesterol entering the intestinal mucosal cells is unesterified and is packaged into lipoproteins as esterified cholesterol before secretion into the lymphatics. Approximately 70–80% of the cholesterol found in the lymph is esterified with fatty acids. Thus, cholesterol reesterification is an important component of the cholesterol absorption process. The enzyme responsible for cholesterol esterification in the intestine has been debated for a number of years. Some evidence suggests that intestinal cholesterol esterification is mediated by the pancreatic carboxyl ester lipase, whereas other evidence suggests that this process is mediated by another enzyme, acyl coenzyme A : cholesterol acyltransferase (ACAT). The discrepancy has been resolved based on studies with the carboxyl ester lipase-deficient mice. As discussed previously, these animals absorb dietary cholesterol with normal efficiency. Cholesterol secreted as chylomicrons in the carboxyl ester lipase knockout mice is mainly esterified with fatty acids, similar that observed in wild-type mice. Thus, this enzyme appears to play at best a supportive role for cholesterol esterification in the intestine.

Attention has also been focused on the role of ACAT in intestinal cholesterol esterification. Progress in definitively proving the involvement of ACAT in intestinal cholesterol absorption has been hampered for many years due to the difficulty in purification of this enzyme. The effect of ACAT inhibitors in blocking intestinal cholesterol esterification and dietary cholesterol absorption varies in different experiments. The discrepancy in these studies has been partially resolved by molecular biology tools, which show the presence of at least two distinct ACAT genes in the mammalian genome. The first ACAT gene, called *ACAT1*, is expressed primarily in adrenals and in macrophages, with minimal expression in liver and intestine. Thus, deficiency in ACAT1 does not have any effect on cholesterol esterification in the latter tissues. Accordingly, ACAT1-deficient mice also absorb dietary cholesterol with normal efficiency, as expected. Similarly, inhibitors that are designed based on suppression of ACAT1 activity may also have less effect on intestinal cholesterol absorption. The second ACAT gene, *ACAT2*, encodes the ACAT enzyme that is primarily responsible for cholesterol esterification in liver and in intestine. Knockout of the *ACAT2* gene in mice results in animals that are resistant to diet-induced hypercholesterolemia and gallstone formation. Interestingly, although the resistance to diet-induced hypercholesterolemia may be related to reduction of cholesterol absorption when the animals are fed a cholesterol-enriched diet, no difference in cholesterol absorption between wild-type and ACAT2-deficient mice can be observed when the animals are fed normal mouse chow. These latter results suggest that although ACAT2 is essential for intestinal cholesterol esterification and efficient cholesterol absorption when fed a high-cholesterol diet, other enzymes, possibly the carboxyl ester lipase or ACAT1, may substitute for ACAT2 in mediating intestinal cholesterol esterification, supporting cholesterol absorption under normal conditions.

GENETICS OF CHOLESTEROL ABSORPTION

The complexity of the dietary cholesterol absorption process, which involves the participation of a multitude

of different proteins, suggests possible genetic influence on regulating the amount of cholesterol absorbed by different individuals. A number of studies have provided evidence to support this hypothesis. First, variations in cholesterol absorption efficiency account for some of the differences between hypo- and hyperresponding rabbits after eating a cholesterol-rich diet. Second, cholesterol uptake by human intestinal biopsy samples can also be divided into three groups, with low, medium, and high rates of cholesterol absorption. Third, genetic differences in cholesterol absorption efficiency have also been demonstrated in nonhuman primates. Although these studies have failed to distinguish genetic and environmental factors as the determining factor in the observed difference in cholesterol absorption, more recent studies with inbred mice have added more strength to the concept of genetic regulation of cholesterol absorption. The various inbred strains of mice are established by repeated inbreeding such that the genetic composition within each strain is identical. Analysis of inbred mice has been used in the past to identify successfully novel genes important for determining atherosclerosis susceptibility. Using similar approaches, by screening for cholesterol absorption efficiency among the various inbred strains of mice housed and fed under identical conditions, the genetic influence of cholesterol absorption efficiency is now well established. The data clearly suggest the involvement of multiple genes in dictating cholesterol absorption efficiency.

Identification of the gene loci that dictate cholesterol absorption efficiency is now underway. The most extensive work thus far is being carried out in the laboratory of David Russell in Dallas and in Martin Carey's laboratory in Boston. Both laboratories use the quantitative trait loci approach to tentatively identify several gene loci that may have influence on cholesterol absorption efficiency. One of these loci is called *Chab1* (cholesterol absorption gene 1). This locus is localized to mouse chromosome 2 and includes genes for the ABC transporter protein ABCB5 and for the liver X receptor-α. The latter gene encodes a transcription factor that regulates expression of lipid metabolism genes. Other putative cholesterol absorption gene loci have been identified on mouse chromosomes 1, 5, 6, 10, and 15. These gene loci may be linked to the *ACAT2* gene and to genes that participate in bile acid metabolism. It remains to be determined whether any of these previously identified genes are directly responsible for the genetic influence on cholesterol absorption, or whether they are only situated in close proximity to authentic cholesterol absorption genes.

The list of candidate cholesterol absorption genes identified by the quantitative trait loci approach to date does not include several genes thought to be involved in the overall cholesterol absorption process. For example, genes for the putative cholesterol transporters SR-BI, ABCA1, ABCG5, and ABCG8 do not map to the absorption gene intervals identified to date. Likewise, the genes in the bile acid synthetic pathway, *Cyp7α1*, *Cyp7β1*, and *Cyp39a1*, do not map to the currently identified putative cholesterol absorption gene loci. These results do not imply that these genes are not involved with cholesterol absorption, but rather that there may be little or no interstrain variation of these genes in terms of their role in cholesterol absorption. The limited screening of inbred strains of mice to date also reduces the power of the quantitative trait loci approach. Nevertheless, these studies point to possibility of additional novel genes that may influence cholesterol absorption efficiency. The identification in these loci of the precise genes that participate in regulation of cholesterol absorption will provide valuable information toward understanding individual differences in cholesterol absorption efficiency and responses to dietary cholesterol.

INHIBITORS OF CHOLESTEROL ABSORPTION

The impact of dietary cholesterol absorption on plasma cholesterol levels, and hence risk of coronary heart disease, has led to increasing interest in lowering cholesterol absorption as a treatment strategy to reduce plasma cholesterol level. Because of the complexity of the cholesterol absorption process, numerous pharmaceutical targets have been designed in attempts to suppress cholesterol absorption. The most effective treatment to date is the use of bile acid sequestrants such as cholestyramine, which binds to bile salts in the intestinal lumen. As a consequence of binding, cholesterol solubility is reduced and the dietary cholesterol is excreted from the body instead of being absorbed by intestinal mucosal cells. Unfortunately, bile salt sequestrants are not well tolerated, thus limiting their use for treatment of hypercholesterolemia.

The ACAT enzymes, responsible for cholesterol esterification in the intestine, comprise another pharmaceutical target for suppression of cholesterol absorption. Several ACAT inhibitors with high potency for inhibiting cholesterol esterification in cultured cells have been synthesized by the pharmaceutical industry. Some of these compounds have been found also to be effective in suppressing cholesterol absorption in

animal models when the animals were fed a cholesterol-enriched diet. However, most of the ACAT inhibitors are not effective in inhibiting cholesterol absorption under more normal dietary conditions. Thus, results of ACAT inhibitor studies mimic those observed with ACAT2 knockout mice showing that ACAT-mediated cholesterol absorption may only be vital for cholesterol absorption during high-cholesterol feeding. Importantly, clinical trials of ACAT inhibitors in humans have been disappointing, and none of the compounds have shown significant reduction of cholesterol absorption and suppression of diet-induced hypercholesterolemia in human volunteers.

More recent studies have revealed the potential of two new classes of compounds in suppression of cholesterol absorption. One class of compounds selectively inhibits cholesterol absorption through interaction with specific sites on the brush border membranes. These inhibitors include the sterol glycosides synthesized by Merck Research Laboratories and ezetimibe, produced by Schering-Plough. The latter compound has also been shown to be effective in suppressing diet-induced atherosclerosis in a rodent model. Both of these compounds bind to brush border membranes in a saturable manner, suggesting the possibility that they may be interacting with cholesterol transporters in suppressing cholesterol absorption. It is also possible, however, that these compounds interact with specific lipid components in the brush border membrane, thereby preventing cholesterol trafficking into and out of the plasma membrane and/or its transport to an intracellular compartment where it can be used for lipoprotein synthesis and secretion. Thus, the exact mechanism by which these compounds suppress cholesterol absorption in animal models remains unknown.

The second class of compounds that show promise in suppressing cholesterol absorption includes reagents that activate ABC transporter expression in the intestine. The goal of the design of this class of compounds is to increase cholesterol export to the intestinal lumen, where it can be excreted out of the body. The design takes advantage of observations that agonists for the oxysterol LXRs and the bile acid farnesoid X receptor (FXR) are potent activators of ABC transporter gene expression. Because LXRs and FXR form obligate heterodimers with retinoid X receptors (RXRs) for their activities, recent studies have used an RXR-specific agonist to demonstrate feasibility of increasing ABC transporter expression in intestine as a mechanism to suppress cholesterol absorption in rodents. However, RXR interacts with a number of different transcriptional factors and can regulate genes that span several metabolic pathways. Thus, specific LXR or FXR agonists may be preferred as more specific regulators of cholesterol transport. The continued development of this class of compounds and testing for the efficacy in reducing cholesterol absorption in human subjects will be valuable.

acinus Smallest functional unit of the liver, which receives blood flow from the portal vein and hepatic artery.
angiogenesis Growth of new blood vessels.
ascites Collection of serous fluid (derived from liver and/or intestine) in the peritoneal cavity.
ischemia A reduction in blood flow of such magnitude as to cause tissue hypoxia.
reperfusion The restoration of blood flow following a period of ischemia.

The gastrointestinal (GI) circulation accounts for over 25% of cardiac output under resting conditions. Blood flow to the GI tract is dynamic, however, with tissue-specific increases caused by the ingestion of a meal and profound reductions in flow elicited by stresses that threaten to deprive the vital organs (e.g., brain, heart) of their normal blood supply. Although the different organs perfused by the GI circulation share common stimuli and mechanisms of blood flow regulation, significant differences related to tissue function have been described. As seen in most other vascular beds, impaired blood perfusion of GI organs can lead to profound organ dysfunction and tissue injury. The stomach, liver, intestine, and pancreas provide excellent examples of the unique and diverse anatomical features and regulatory mechanisms that distinguish the GI circulation from other regional vascular beds.

GASTRIC CIRCULATION

Introduction

Gastric blood flow plays an important role in sustaining the normal physiologic functions of the stomach and it helps to protect the gastric mucosa against ulcer formation. Intrinsic regulatory mechanisms ensure that blood flow is adjusted to meet the energy-demanding processes of gastric secretion and motility. Gastric blood flow also helps to maintain a barrier against back-diffusion of lumenal acid, thereby preventing mucosal damage and ulceration. Impairment of gastric blood flow renders the mucosa vulnerable to the damaging actions of gastric juice as well as ingested agents, such as ethanol, aspirin, and bacteria (e.g., *Helicobacter pylori*).

Anatomy

Oxygenated blood is provided to the stomach via the celiac artery, with deoxygenated blood drained by the portal vein. Small branches of the celiac artery give rise to arterioles in the external muscle layers and the submucosa. Some of the submucosal arterioles pierce the muscularis mucosae to produce the capillary network that supplies the mucosa. Hence, the tone of the submucosal arterioles determines the magnitude of mucosal blood flow. The mucosal capillaries drain into a central vein that begins just beneath the surface epithelial cells. These venules coalesce to form a dense venous plexus in the submucosa. The submucosal venous drainage penetrates the external muscle layers where additional venous blood is provided by the muscle microvasculature.

Hemodynamics

The parallel-coupled capillary networks of the gastric muscular layer and the mucosa are under separate control, responding independently to tissue metabolism, other local factors, and extrinsic neural input. Between meals, blood flow in the mucosal layer is approximately six times higher than that of the muscle layer, and approximately 75% of total gastric blood flow is distributed to the mucosa, with 25% directed to the muscle layer. This intramural distribution of blood flow is altered when either of the two layers becomes functionally active; i.e., when the mucosa is stimulated to produce acid, mucosal blood flow (and its percentage of total flow) preferentially increases.

Blood Flow Regulation

Gastric blood flow is controlled by neural, humoral, and metabolic factors. Sympathetic activation elicits reductions in total gastric blood flow and mucosal flow through arteriolar constriction. Parasympathetic nerves exert a tonic vasodilatory influence on gastric arterioles,

with vagotomy resulting in a reduction in blood flow. Gastrin and histamine, both powerful stimulants of gastric acid secretion, increase mucosal blood flow. Oxygen consumption by the stomach increases in proportion to acid production. Changes in both blood flow and oxygen extraction assist in meeting the demand for additional oxygen in the acid-secreting stomach. When gastric blood flow is reduced, however, acid secretion and blood flow may fall in parallel, owing to the fact that the rate of oxygen delivery to the parietal cells is limited by blood flow.

Pathophysiology

The gastric microcirculation contributes to gastric ulcer formation in several ways. Capillary transport of parietal cell-derived bicarbonate normally plays an important role in protecting the surface epithelium against acid-induced injury and ulceration. The mucosal capillaries originating near the gastric pits transport bicarbonate toward the mucosal surface, where it can diffuse into the interstitial compartment beneath the surface epithelial cells. The latter cells transport bicarbonate into the gastric lumen where it can buffer lumenal acid. As a consequence, there is an inverse relationship between gastric mucosal injury and the rate of vascular bicarbonate delivery to the mucosal surface.

Arteriolar constriction and capillary plugging with thrombi or activated leukocytes often accompany the ulceration process and are thought to promote mucosal injury by rendering the tissue ischemic and vulnerable to necrosis. Repair of gastric mucosal ulceration relies on the restoration of blood flow and on the growth of new blood vessels (angiogenesis), which usually sprout from venules.

HEPATIC CIRCULATION

Introduction

The hepatic circulation has many unique features compared to other vascular beds in the splanchnic circulation. There is the unusual presence of both an arterial input and a venous input that combine to deliver a large fraction of cardiac output to the liver. The acinar arrangement of the microvasculature creates a series of microenvironments within the organ that imparts a significant spatial resolution for specific biosynthetic, biotransformation, and detoxification functions of the liver. These and other unique features of the hepatic circulation serve to ensure that the varied and complex functions of the liver are maintained at levels that are optimal for the whole animal.

Anatomy

The liver receives blood from two sources: fully oxygenated blood is derived from the high-pressure, high-resistance hepatic artery and partially oxygenated blood comes from the low-pressure, low-resistance portal vein. Within the liver, these vessels give rise to numerous smaller vessels, called hepatic arterioles and terminal portal venules, which supply a small mass of parenchyma called the liver acinus. The mixture of arterial and venous blood from these terminal vessels drains into the sinusoids, which constitutes the capillary network of the liver. The sinusoidal capillaries are highly permeable to water and plasma proteins. The sinusoids radiate toward the periphery of the acinus, where they connect with the terminal hepatic venules and ultimately into progressively larger branches of hepatic veins and the inferior vena cava.

Hemodynamics

Total hepatic blood flow accounts for approximately 25% of resting cardiac output (1250–1500 ml/min) in the resting adult human. The portal vein supplies the liver with 70–75% of its blood and the hepatic artery provides the remaining 25–30%. Because of the higher oxygen content of arterial blood, the hepatic artery and portal vein contribute roughly equal amounts of oxygen to the liver in the fasting state. The mean blood pressure in the hepatic artery is approximately 90 mm Hg and that in the portal vein is approximately 10 mm Hg, resulting in a sinusoidal capillary pressure of 2–3 mm Hg. The low pressure within these highly permeable capillaries serves to minimize excessive loss of fluid and protein into the liver interstitium and the subsequent leakage of this plasma filtrate into the peritoneal cavity (ascites fluid).

Blood Flow Regulation

Increased blood flow in the portal vein leads to an increased hepatic arterial resistance and a reduction in portal vein flow produces hepatic arterial dilation. Although this reciprocal relationship between hepatic arterial and portal vein blood flows tends to maintain a constant total blood flow through the liver, flow in one system usually cannot fully compensate for the reduction in blood flow in the other system. However, the liver is more effective at maintaining a constant oxygen consumption because the extraction of oxygen from hepatic blood is very efficient. The small diffusion distances for oxygen transport between blood and hepatocytes accounts for this highly efficient oxygen extraction. Hepatic blood flow increases following

ingestion of a meal, largely due to an increased flow in the portal vein.

Capacitance Function

The liver represents the most important blood reservoir in human. It contains approximately 15% of the total blood volume of the body. Hepatic blood volume can nearly double when right atrial pressure is elevated. The capacitance function of the liver plays an important role during hemorrhage. After moderate blood loss, activated sympathetic nerves constrict the hepatic venules and expel enough blood to compensate for as much as 25% of the hemorrhage.

INTESTINAL CIRCULATION

Introduction

The blood circulation plays an important role in the support of intestinal functions, such as propulsion of chyme and assimilation of ingested nutrients. Intrinsic regulatory mechanisms allow the intestine to adjust the distribution of blood flow between the muscular and mucosal layers in accordance with local metabolic needs. An extensive network of collateral channels within and external to the gut wall helps to ensure adequate intestinal blood flow.

Anatomy

The small intestine receives blood primarily from the numerous vascular arcades arising from the superior mesenteric artery. The arterial arcades are connected by extensive collateral channels both within the mesentery (extramural) and within the bowel wall proper (intramural). The major arterial vessels supplying the mucosa, submucosa, and muscularis emerge from an arterial plexus within the submucosa. The submucosa proper has a very sparse vascular supply. The arterioles entering the muscle layer branch into capillaries running parallel to the muscle fibers. The mucosal villi are supplied by a single arteriole running centrally to the tip where the vessel branches into a fountain-like pattern of capillaries that drain into the centrally located vein. The venous drainage of the mucosa and muscularis empties into large veins within the submucosa. These veins enter the mesentery in parallel to the arterial arcades of the superior mesenteric artery and eventually drain into the portal vein.

Hemodynamics

Intestinal blood flow accounts for 10–15% of the resting cardiac output (500–750 ml/min) in the adult human. There appears to be an oral-to-anal gradient in blood flow (milliliters per gram of tissue) along the small intestine. In the resting state, approximately 65% of the total intestinal blood flow is directed to the mucosa, 25% to the muscularis, and the remainder to the submucosa. This distribution of flow within the bowel wall is usually attributed to the greater metabolic demand of the mucosa. Stimulation of mucosal epithelial transport processes favors improved mucosal perfusion, whereas enhanced motor activity redistributes blood flow to the muscle layers.

Blood Flow Regulation

Extrinsic control of intestinal blood flow is exerted by neural and humoral factors. Activation of parasympathetic nerves usually results in vasodilation (increased blood flow) mediated by acetylcholine. Sympathetic nerve stimulation elicits vasoconstriction (decreased blood flow) that is mediated by norepinephrine. This α-adrenergic vasoconstriction is short-lived because intestinal arterioles escape from the constrictor influence of norepinephrine, resulting in partial restoration of normal blood flow (autoregulatory escape). Local release of adenosine appears to mediate this autoregulatory escape. Hormones such as vasoactive intestinal peptide, cholecystokinin, and secretin can induce vasodilation and increase blood flow, whereas angiotensin II and vasopressin are potent constrictors of intestinal arterioles. Indeed, a large proportion of basal vascular tone in the intestine can be attributed to circulating angiotensin II and vasopressin.

Intrinsic control of intestinal blood flow is mediated by both metabolic and nonmetabolic factors. Ingestion of a meal results in an increase in both intestinal oxygen consumption and blood flow. The postprandial hyperemia is directly coupled to the increase in intestinal oxygen consumption. For any given increase in oxygen consumption, the greater the initial oxygen extraction, the greater the postprandial hyperemia. If the initial oxygen extraction is low, then the postprandial hyperemia is minimal and the increased oxygen demand is met primarily by an increase in oxygen extraction. The opposite holds if the initial oxygen extraction is high.

The postprandial hyperemia is confined to that segment of intestine directly exposed to chyme; segments distal to the bolus of chyme have normal resting blood flow. Of the hydrolytic products of food digestion, lumenal glucose and oleic acid are capable of eliciting an intestinal hyperemia. Intralumenal glucose presumably elicits a hyperemia due to stimulation of absorptive processes, since 2-deoxyglucose (which is not absorbed) does not elicit a hyperemia. The glucose-induced

hyperemia is mediated by metabolic factors, such as low tissue pO_2, and adenosine release. The same metabolic factors contribute to the oleic acid-induced functional hyperemia; however, a portion of the hyperemia can be attributed to oleic acid-induced irritation of the mucosa, which is linked to local release of vasoactive intestinal peptide. The importance of active transport of nutrients to the postprandial hyperemia is best exemplified by the differential responses of the jejunum and ileum to lumenal bile or bile salts. In the jejunum, bile does not elicit a hyperemia, whereas in the ileum (where bile salts are actively transported), lumenal bile produces a profound hyperemic response.

Pathophysiology

Occlusion of a major intestinal artery does not result in the expected reduction in intestinal blood flow. In adult animals, occlusion of a branch of the superior mesenteric artery results in only a 30–50% reduction in intestinal blood flow, which is attributed to the extensive network of intramural and extramural collateral channels. In neonatal animals, which have less developed collateral channels, a similar arterial occlusion reduces intestinal blood flow by 70%. This may explain why the neonatal intestine is more vulnerable to ischemic necrosis than adult intestine.

Reperfusion of the ischemic intestine exacerbates the microvascular dysfunction and tissue injury incurred during ischemia. The reperfusion-induced intestinal pathology is comparable to that observed during an intense inflammatory response. The reintroduction of oxygen upon reperfusion results in the local formation of oxygen radicals, which in turn initiate a series of events that promote the recruitment and activation of neutrophils. Extravasated neutrophils release a variety of proteases and reactive oxygen metabolites that mediate the mucosal dysfunction and epithelial necrosis induced by ischemia and reperfusion.

PANCREATIC CIRCULATION

Introduction

The pancreas has both exocrine and endocrine functions. The endocrine functions of the pancreas are localized to the islet cells and the secretory functions are localized to the ducts and acini. The human pancreas can secrete approximately 1 liter of juice every 24 h. The water and electrolytes delivered to pancreatic juice are ultimately derived from the blood. Thus, the pancreas controls its blood flow to cope with the demands of basal secretion and makes adjustments (arteriolar dilation) to ensure an adequate supply of blood flow to maintain maximal secretion. The hormones secreted by the islet cells modulate exocrine function.

Anatomy

The pancreas is supplied by arterial blood from two sources: the superior mesenteric artery and the celiac artery. The arteries entering the gland proper are the inferior pancreaticoduodenal artery (from the superior mesenteric artery) and the superior pancreaticoduodenal artery and branches of the splenic artery (from the celiac artery). Within the pancreas, arterioles supply the three functional components of the gland: the acini, ducts, and islets. The blood draining all three plexi drains into either the splenic vein or the superior mesenteric vein, which ultimately empty into the portal vein.

Portal Circulation

There is also an extensive portal system within the pancreas. Blood vessels draining the capillary plexus within the islets of Langerhans empty into the acinar and ductal plexi. Blood vessels draining the acinar capillary plexus perfuse the ductular plexus.

The functional significance of this intrapancreatic portal circulation is that the hormones secreted by the islets reach the exocrine portion of the gland (the acini and ducts) at very high concentrations. Virtually all of the peptides and hormones secreted by the islets exert an influence on pancreatic secretion. This can be attributed to the low molecular weight of these hormones and peptides, which allows them to readily filter across the fenestrated capillaries surrounding the acini and ducts.

Blood Flow Regulation

Pancreatic blood flow doubles after a meal. The kallikrein–kinin system, cholinergic and purinergic neurotransmitters, and gastrointestinal hormones (cholecystokinin and secretin) have all been implicated in postprandial hyperemia. The hyperemia-associated increase in pancreatic oxygen delivery appears to be linked to the increased metabolic demand imposed on the pancreas by the stimulated secretory processes. The postprandial hyperemia also provides the additional fluid that accompanies the enhanced electrolyte transport in pancreatic acini and ducts. The arteriolar dilation elevates pancreatic capillary hydrostatic pressure, which drives fluid across the capillaries into the interstitial spaces surrounding the ductal epithelium. The importance of these vascular adjustments

postprandially is underscored by the fact that during periods of maximal stimulation, the pancreas can secrete its weight in juice in less than 30 min.

adhesion Close approximation of portal tracts and hepatic veins. Adhesions indicate that loss of parenchyma has occurred, usually through the process of extinction.
parenchymal extinction Process of focal loss of hepatocytes, usually by a mechanism of ischemia. An extinction lesion is the histologic product of this process.
regression Process of return of liver parenchyma toward a normal histologic appearance, as in "regression of cirrhosis."
remnant Residual visible structure of a portal tract or hepatic vein after injury and repair.
septum Linear fibrous array that subdivides the parenchyma. Septa are actually planes when seen in three dimensions.
stellate cell Facultative fibroblast residing in the subendothelial space of sinusoids.

Cirrhosis is defined anatomically as a condition in which fibrous septa subdivide the hepatic parenchyma into residual masses with a nodular configuration. The septa are widespread throughout the liver. Cirrhosis develops incrementally with the accumulation of local scars. Thus, in early or focal disease, the diagnosis of cirrhosis depends on arbitrary quantitative limits.

PATHOGENESIS OF CIRRHOSIS

There are two basic mechanisms for the deposition of collagen, stellate cell activation and parenchymal extinction, and each is associated with a distinct histologic pattern of fibrosis. Both are generally initiated by hepatocellular injury.

Stellate Cell Activation

Stellate cells are quiescent fibroblasts that normally reside in sinusoidal walls within the subendothelial space of Disse. Stellate cells are activated by inflammatory mediators to commence collagen synthesis. Simultaneously, there occurs activation of tissue metalloproteinases that degrade collagen. When stellate cells are activated in low-grade disease, the collagen is deposited as delicate fibers in the sinusoidal walls, causing what is known as sinusoidal, or pericellular, fibrosis. This is most easily appreciated in the perivenular regions (Rappaport zone 3). It has been demonstrated in experimental animals that sinusoidal fibrosis is rapidly removed within weeks of the cessation of injury.

Parenchymal Extinction

Parenchymal extinction is defined as the loss of a contiguous group of hepatocytes (Fig. 1). Lesions may be small, involving a few hepatocytes, or larger, involving many acini or even a whole lobe. Extinction occurs

(A and G) Normal acini; the sequence of events leading to small regions of parenchymal extinction is shown in panels B–F and H–L. Obstructed veins are shown as black circles. (B) Obliteration of small portal and hepatic veins occurs early in the development of cirrhosis in response to local inflammatory damage. The supplied parenchyma becomes ischemic. (C and D) Ischemic parenchyma shrinks and is replaced by fibrosis (process of extinction). The shrinkage is accompanied by close approximation of adjacent vascular structures. (E) Septa are deformed and stretched by unsymmetrical expansion of regenerating hepatocytes. (F) Fibrous septa are resorbed. They become progressively thinner and then perforate before disappearing. Small residual tags may extend from portal tracts. Trapped portal structures and hepatic veins are released from the septa and are recognizable as deformed remnants that are irregularly distributed. Residual hepatic veins are often described as ectopic. Note the absence of portal veins. In alcoholic disease (G–L), the sequence of events may differ from that of other forms of chronic liver disease. (H) Sinusoidal fibrosis is often prominent, with a pericellular pattern of fibrosis prior to the development of parenchymal collapse. (I and J) Inflammation and fibrosis lead to hepatic and portal vein obliteration with secondary condensation of preformed sinusoidal collagen fibers into a septum. by a mechanism of ischemia secondary to obstruction of veins or sinusoids. After parenchyma collapses, adjacent regeneration compresses the collapsed regions into linear membranes recognized as septa. Large lesions are recognized by regions with closely approximated portal tracts separated only by collapsed stroma and fibrosis. Small lesions are identified by the close approximation of a small hepatic vein and its adjacent portal tracts (an adhesion).

A number of important consequences arise from the concept of parenchymal extinction: (1) although usually initiated by hepatocellular injury, extinction results when the circulation in a region fails, (2) each lesion of extinction has a natural evolution during the healing process, (3) cirrhosis is the accumulated result of a large number of independent and discrete lesions, and (4) the morphology of the cirrhosis is determined by the size and location of the vascular occlusion events as well as the degree of healing (regression) of each extinction lesion. The obstruction of small veins is a bystander event in response to local parenchymal injury. Thrombosis is most important in larger vessels, where local parenchymal inflammation is unlikely to damage the veins.

Natural History of Cirrhosis

The morphology of cirrhosis is determined by the amount of time that has elapsed from the onset of parenchymal extinction (Figs. 2 and 3). If active injury continues, new lesions of extinction will coexist with old lesions. If the primary disease is inactive and remote,

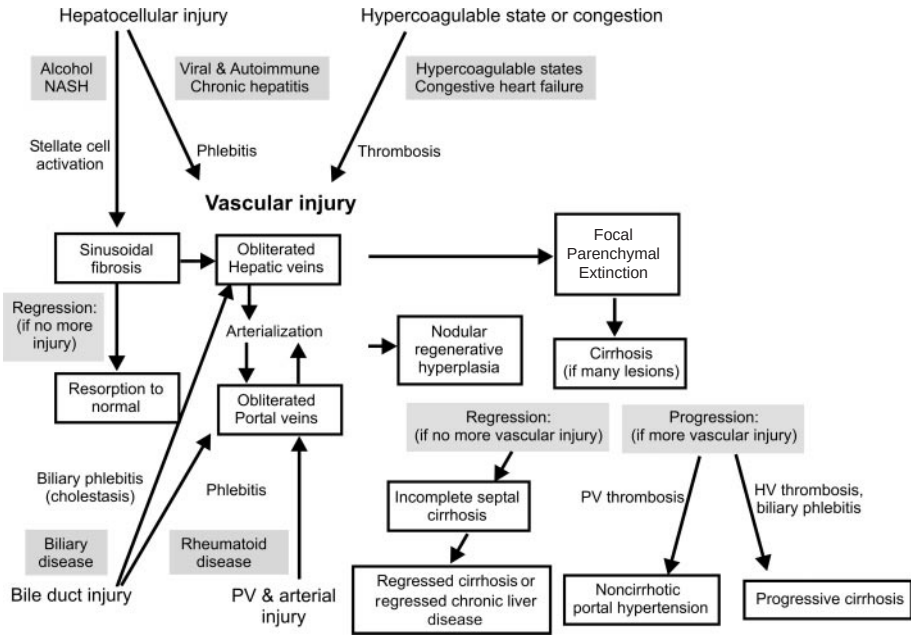

FIGURE 3 Summary of the factors that determine that natural history of chronic liver disease. There are five principal classes of disease leading to chronic liver disease (light gray boxes). Most patients with chronic liver disease have hepatocellular injury. This may lead to local activation of stellate cells and sinusoidal fibrosis that is largely reversible. Those patients developing obliteration of vessels, especially small hepatic veins (HV), develop lesions of parenchymal collapse (extinction) that heal as fibrous septa. When septa are numerous, the histologic features of cirrhosis are present. Biliary disease and rheumatoid disease are associated with predominant portal tract disease. Rheumatoid disease usually affects the portal vessels (PV), leading to multifocal atrophy of parenchyma with minimal or no fibrous septation, a condition recognized as nodular regenerative hyperplasia. In biliary disease, portal inflammation is an early event, leading to portal tract fibrous expansion and sometimes presinusoidal portal hypertension; zone 3 cholestasis occurs later, leading to bile salt injury of small hepatic veins. Thus, the order of vascular events is different but accumulation of extinction lesions eventually leads to cirrhosis. The outcome depends on the time course of disease activity (dark gray boxes). If injury ceases, regression occurs, because all extant lesions heal and new lesions do not appear. If injury continues, new lesions develop and there is progressive collapse and fibrosis, either from the continuing primary injury, secondary thrombotic events, or secondary bile salt injury to hepatic veins. NASH, Nonalcoholic steatohepatitis.

the liver will contain only lesions in late stages of repair. Fresh extinction lesions are represented by bridging necrosis in highly active hepatitis or milder lesions of focal congestion and apoptosis in mild hepatitis.

Once cirrhosis has developed, the hepatic blood flow is chaotic and sluggish. Portal vein flow may be biphasic or continuously retrograde. In addition, loss of anticoagulant function and prothrombotic effects of sepsis and cholestasis may contribute to the increased risk of thrombosis of the hepatic and portal vein. Portal vein thrombosis is found in up to 40% of cirrhotic livers examined at transplantation. Thrombosis of medium or large hepatic veins causes large regions of extinction to occur, explaining the markedly irregular capsular shapes found in a third of livers with late-stage cirrhosis (Fig. 1).

After primary liver disease goes into remission or is successfully treated, old extinction lesions (septa and adhesions) predominate. Fibrosis is progressively removed so that broad septa become delicate and delicate septa become incomplete and may even disappear. Frequent residual lesions are recognized as delicate fibrous spurs on portal tracts. Given sufficient time, micronodular cirrhosis may remodel into macronodular cirrhosis, incomplete septal cirrhosis, and eventually nearly normal livers. After portal tracts are released from septa, they often lack portal veins so that the post-regression liver is largely supplied by arteries. These

findings explain residual portal hypertension in patients with such livers. The major impediments to the reversibility of cirrhosis are continuing primary activity, secondary thrombosis, cholestatic decompensation, and the arterialized state of the liver.

ANATOMIC SUBTYPES

Several recognized patterns of cirrhosis can be understood, from this introduction, to depend on the severity of the underlying liver disease and the duration of inactivity prior to examination (Table I). The main types of cirrhosis are micronodular and macronodular; the former type has most nodules less than 3 mm in diameter and the latter type has most nodules greater that 3 mm in diameter. The World Health Organization (WHO) classification also defines a mixed category in which the nodules are both larger and smaller than 3 mm. Mixed cirrhosis is often found in primary biliary cirrhosis and primary sclerosing cholangitis. Incomplete septal cirrhosis is a highly regressed form of cirrhosis often associated with portal hypertension but normal hepatocellular function. Incomplete septal cirrhosis and noncirrhotic portal hypertension often represent late stages of regression. Portal vein thrombosis is often the complication that leads to portal hypertension in these cases, many of which would otherwise escape clinical attention.

Cirrhosis with regional parenchymal extinction, usually with severe micronodular cirrhosis, is a form of cirrhosis in which large contiguous regions of collapse and fibrosis have occurred (Fig. 1). This may be confused with postnecrotic cirrhosis, which is the fibrotic stage of severe acute hepatitis occurring with large contiguous regions of extinction. Because many of these patients have hepatic failure and jaundice, these livers are usually severely cholestatic.

EVALUATION OF LIVER SPECIMENS

Accuracy in staging liver disease depends on observer and sampling errors. Observer error can be minimized if the pathologist has complete knowledge of the clinical situation and a clear understanding of the natural history of the diseases within the differential diagnosis. Sampling error is impossible to avoid entirely, because the definition of cirrhosis requires involvement of the entire liver and the biopsy represents only a small portion of the total. Also, fibrosis in chronic liver disease is concentrated into fibrous septa that are not distributed uniformly. Sampling error depends on the character of the liver disease and is greatest in those diseases having a low density of diagnostic lesions in the tissue. In macronodular cirrhosis, the septa may be more than 1 cm apart, so that a small-needle biopsy may not have any septa. In contrast, a biopsy 1–2 mm in length may be sufficient for the diagnosis of micronodular cirrhosis. In one study, agreement of stage and corrected sinusoidal pressure was poor for biopsies less than 1.5 cm in length. Transjugular biopsies are generally smaller than percutaneous biopsies in both length and width. However, the advantage of a transjugular biopsy is the opportunity to obtain simultaneously a measurement of portal pressure.

Resection specimens should be examined for weight, color, thickened capsule, relative size of the lobes, regional parenchymal collapse, and patency of ducts, vessels, and any prosthetic stents. Uncomplicated cirrhosis is usually very uniform in appearance. Any heterogeneity should prompt extra sampling of vessels and ducts to discover the cause. Nodules with variance of size, color, or texture may be an indication of neoplasia. Dilated paraumbilical veins or severe congestion of nodules may correlate with Doppler evidence of reversed portal vein flow.

Staging Systems

Many staging systems are in wide use, including the METAVIR and Ishak systems, applicable for most forms of chronic liver disease, and the Scheuer and Ludwig systems for chronic biliary disease. These systems vary in the number of categories (0 to 4, 0 to 6, or 1 to 4) and the category definitions. These systems do not provide categories for the different severities of cirrhosis. The Laennec system attempts to standardize staging for all chronic liver disease on a scale of 0 to 4, with cirrhosis being grade 4 (Table II). An extension divides cirrhosis into subgrades 4A, 4B, and 4C, in recognition of the variable severity among cirrhotic livers. The definitions of each grade are based on the number and width of

TABLE II Laennec Scoring System for Grading Fibrosis in Liver Biopsies

Grade	Name	Criteria (septa thickness and number)	Descriptive examples
0	No definite fibrosis	—	—
1	Minimal fibrosis	+/−	No septa or rare thin septum; may have portal expansion or mild sinusoidal fibrosis
2	Mild fibrosis	+	Occasional thin septa; may have portal expansion or mild sinusoidal fibrosis
3	Moderate fibrosis	++	Moderate thin septa, up to incomplete cirrhosis
4A	Cirrhosis, mild, definite, or probable	+++	Marked septation with rounded contours or visible nodules; most septa are thin (one broad septum allowed)
4B	Moderate cirrhosis	++++	At least two broad septa, but no very broad septa and less than half of biopsy length composed of minute nodules
4C	Severe cirrhosis	+++++	At least one very broad septum or more than half of biopsy length composed of minute nodules (micronodular cirrhosis)

fibrous septa. This simplification decreases the opportunity for interobserver variation. The expanded scale allows quantification of changes with time in patients with cirrhosis. As with other systems, the Laennec system also reports grade of activity on a scale of 0 to 4, as well as noting etiology-specific features.

Stage should be estimated with a connective tissue stain. When the presence of a septum is uncertain, curved contours in the tissue may assist identification. Because all biopsies are susceptible to sampling errors, some measure of diagnostic certainty should be recorded, including comments on the size, fragmentation, and technical quality of a biopsy. When faced with a biopsy of regressed cirrhosis in which there are no visible septa, detection of obliterated veins may distinguish the biopsy from normal. Immunostain for CD34 may detect arterialized sinusoids that would otherwise appear normal.

Evaluation of Etiology

Although etiology is increasingly being determined by serological and other laboratory tests, the biopsy often provides important information. This is especially true when laboratory results are mildly abnormal or conflicting, or when more than one disease process is present.

Chronic Hepatitis

Chronic hepatitis is characterized by an infiltrate of lymphocytes with variable numbers of plasma cells. The infiltrate is both portal and parenchymal. In portal tracts, the infiltrate may be diffuse or concentrated in lymphoid aggregates. The parenchymal infiltrate is diffuse, involving all zones. In low-grade disease (activity grade 1), the infiltrate is not accompanied by visible necrosis. Mild to moderate disease (activity grades 2 and 3) is accompanied by acidophilic bodies and focal dropout of hepatocytes. In severe disease (activity grade 4), there is contiguous dropout that may span portal and venular regions (bridging necrosis). Activity at the portal–parenchymal interface is often called "piecemeal" necrosis or interface hepatitis; because this activity correlates with activity elsewhere in the parenchyma, its presence has no special significance.

Chronic hepatitis is most often caused by hepatitis B virus, hepatitis C virus, autoimmune hepatitis, and, rarely, by Wilson's disease or drug reactions. These forms of hepatitis usually cannot be distinguished histologically so that the diagnosis is made by serological or clinical features. Cytoplasmic inclusions of hepatitis B surface antigen, as detected by the presence of ground glass cells or immunohistochemical staining, are diagnostic of hepatitis B. Untreated autoimmune hepatitis is usually more active, compared to the other types. Plasma cells may be found in chronic hepatitis of any etiology but are more consistently prominent in autoimmune hepatitis. The pattern of fibrosis varies with the activity of the disease. Hepatitis C, as a low-grade disease, usually involves only the smallest hepatic veins and thus the individual extinction lesions are small but involve a large percentage of hepatic veins by the time cirrhosis is present. The resulting cirrhosis is micronodular. Hepatitis B and autoimmune hepatitis

involve larger hepatic veins so that larger extinction lesions occur, leading to cirrhosis with fewer such lesions (and more spared hepatic veins) and thus a macronodular pattern.

Fatty Liver Disease

Fatty liver disease is commonly caused by alcohol abuse or metabolic states with hyperinsulinemia, as seen in obesity or type 2 diabetes mellitus. Fatty liver disease is characterized by macrovesicular steatosis. Progressive disease activity involves steatohepatitis, defined by steatosis plus evidence of active or past necrosis. The minimum requirement for a diagnosis of steatohepatitis is debated. A reasonable definition would be steatosis with ballooning and one other feature of activity, such as Mallory bodies, pigmented macrophages in zone 3, or neutrophilic infiltrate. Fibrosis may be an indicator of previous steatohepatitis. In this setting, the fibrosis characteristically deposits in the walls of zone 3 sinusoids. Small hepatic veins are obliterated with focal collapse and approximation of small portal tracts and adjacent veins. When larger regions of parenchyma collapse, broad fibrous septa develop. The same sequence of events occurs with chronic viral disease, thus sinusoidal fibrosis is not pathognomonic of fatty liver disease.

Alcoholic and nonalcoholic fatty liver disease are often identical in histologic appearance, though generally alcoholic hepatitis is more active compared to nonalcoholic steatohepatitis. Low-grade steatohepatitis often occurs in patients with chronic hepatitis C and may be related to obesity in these patients. After onset of cirrhosis, the fat and activity tend to decline, making histologic diagnosis of fatty liver disease difficult in the late stages.

Biliary Disease

Chronic biliary disease is caused by long-standing obstruction of bile ducts, by cholestatic drug reactions, and, in children, by genetic abnormalities involving transport proteins. Large duct obstruction lasting many months can result in cirrhosis, though this seldom happens because of surgical intervention. In adults, the frequent causes leading to cirrhosis are primary biliary cirrhosis and primary sclerosing cholangitis. In primary biliary cirrhosis, there is inflammatory destruction of ducts less than 40 μm in diameter and these lesions are easily seen in needle biopsies. In primary sclerosing cholangitis, there is inflammation and fibrosis in the ducts larger than 0.4 mm; these lesions are seldom seen in small biopsies. In this disease, the ducts have concentric fibrosis called "onion-skinning." In cystic fibrosis, there are eosinophilic inclusions in the lumina of small ducts and occasionally fibrous strictures in large ducts. When duct lesions are not available for examination, chronic biliary disease can be suspected by prominent fibrous expansion of portal tracts accompanied by swelling of periportal hepatocytes (feathery degeneration), often with periportal Mallory bodies and a ductular reaction characterized by ductular proliferation, portal edema, and neutrophilic infiltration. In addition, there may be bile-stained hepatocytes, clusters of foamy or bile-stained macrophages, and liver cell rosettes. Ductular proliferation alone is not a reliable indicator of biliary disease because it may be a manifestation of regeneration in nonbiliary diseases.

Fibrosis in biliary disease is topographically variable and correlates with regions of high-grade duct obstruction. This correlation is most easily seen in primary sclerosing cholangitis and cystic fibrosis, in which whole segments may undergo extinction distal to sites of obstruction.

Metabolic Diseases

Many uncommon or rare metabolic diseases may result in cirrhosis. In the adult, metal accumulation is a frequent finding. Iron and copper are deposited in the liver in hemochromatosis and Wilson's disease, respectively. The overload is usually genetically determined but may be acquired through ingestion or, in the case of iron, by transfusion. Both metals are thought to injure hepatocytes by catalyzing generation of free radicals. These metals may be detected by histochemistry and the genetic predisposition can be determined by molecular analysis of the genome. Even large amounts of iron cause very slow progression of fibrosis and this progression is often enhanced by coincidental risk factors, such as steatohepatitis or viral infection. Iron and copper may accumulate in severe cirrhosis of any etiology and therefore their presence is not diagnostic of hemochromatosis or Wilson's disease. Copper stain is often negative in Wilson's disease, so quantitative copper content in the biopsy should be considered.

Congestive Cirrhosis

Congestive heart failure causes sinusoidal dilatation and mild hepatocellular atrophy. Fibrosis develops when local thrombosis causes obliteration of small hepatic veins. The fibrosis is therefore focal and is called cardiac sclerosis; complete cirrhosis does not occur from congestive failure alone.

Thrombosis of all three main hepatic veins causes hepatic enlargement and ascites (Budd–Chiari syndrome) with a markedly congested liver. The congestion

and fibrosis are topographically variable, with a dominant venocentric (reversed nodularity) pattern of necrosis and fibrosis. Secondary portal vein thrombosis is found in 20% of patients with Budd–Chiari syndrome. This event may cause the cirrhosis to remodel into a venoportal pattern of fibrosis, with portal tracts incorporated into the fibrous septa in a fashion similar to the more frequent types of cirrhosis. Early Budd–Chiari syndrome has obvious congestion on biopsy, with marked sinusoidal dilatation, hemorrhage into the liver cell plates, and sometimes infarcts. Late congestive cirrhosis may be similar to other forms of cirrhosis, and examination of medium to large hepatic veins may be necessary to confirm the diagnosis.

Venoocclusive disease begins as necrosis of sinusoidal endothelial cells with secondary fibrous obliteration of small hepatic veins. This disease occurs in response to radiomimetic drugs in preparation for bone marrow transplantation and rarely in response to ingestion of pyrrolizidine alkaloids from bush tea or contaminated bread.

homocysteine An amino acid that is converted to methionine with cobalamin as cofactor. Cobalamin deficiency leads to increased levels of homocysteine, which is used to diagnose cobalamin deficiency.

megaloblastic anemia Anemia characterized by peripheral macrocytosis (mean cell volume > 100 fL) and bone marrow containing megaloblasts due to impaired DNA synthesis. Cobalamin deficiency along with folate deficiency leads to megaloblastic anemia.

methylmalonic acid (MMA) A metabolite of methylmalonyl-coenzyme A1 that is excreted in the urine. Cobalamin deficiency leads to the accumulation of MMA; measurement of MMA in plasma is utilized for the diagnosis of cobalamin deficiency.

pernicious anemia Cobalamin deficiency due to the absence of intrinsic factor required for absorption of cobalamin. This deficiency leads to megaloblastic anemia.

vitamin B12 Cyanocobalamin used as a vitamin preparation therapeutically.

Cobalamin is a complex organometallic compound, which is composed of a tetrapyrrolic ring structure in the center of which is a cobalt ion. Cobalamin can be synthesized only by bacteria. It is incorporated into the food chain by certain animals, mainly herbivores, which then act as a source of nutrients for other animals. Liver, kidney, beef, fish, shellfish, eggs, and milk and other dairy products provide most of the cobalamin in a normal diet. The minimum daily requirement of cobalamin is approximately 2.5 μg. Cobalamin plays a critical role in cellular DNA synthesis, and its deficiency leads to anemia, neurologic disease, and other manifestations.

INBORN ERRORS OF COBALAMIN METABOLISM

Several inborn errors of Cbl metabolism have been described, each of which produces a distinct form of cobalamin, which in turn produces a clinical syndrome. These intracellular errors of cobalamin metabolism can be classified as follows:

1. Defective synthesis of adenosylcobalamin causing methylmalonic aciduria: intramitochondrial cobalamin reductase deficiency and intramitochondrial cobalamin transferase deficiency.
2. Defective synthesis of methylcobalamin causing hyperhomocysteinemia: cytosolic methionine synthase reductase defect and defective methionine synthase.
3. Defect of both adenosyl- and methylcobalamin synthesis, causing both methylmalonic aciduria and hyperhomocysteinemia: cytosolic cobalamin reductase defect—early onset; cytosolic cobalamin reductase defect—late onset; and defective cobalamin lysosomal efflux.

ETIOLOGY OF COBALAMIN DEFICIENCY

Dietary Intake

The dietary intake of cobalamin is usually adequate in people consuming at least dairy products. However, in true vegans and their breast-fed infants, dietary intake of cobalamin is insufficient and these individuals are at risk of developing cobalamin deficiency unless they receive supplementation. In addition, women who are only moderate vegetarians may become cobalamin deficient during pregnancy and lactation.

Gastrointestinal Diseases

In most cases, deficiency of cobalamin is due to malabsorption. Malabsorption can result from abnormalities at several levels.

Stomach

Defective release of cobalamin from food For the release of cobalamin bound tightly to proteins in food, acid and pepsin in the stomach are essential. People who are achlorhydric, often the elderly, are commonly unable to release cobalamin from food sources, but they can absorb crystalline B12, which is found in multivitamin preparations. Only a minority of people with this defect develop frank cobalamin deficiency, but many have biochemical changes including low levels of plasma cobalamin and high levels of MMA and homocysteine. Patients on drugs that suppress gastric acid production, such as proton pump inhibitors, may

 Copyright 2004, Elsevier (USA). All rights reserved.

also have a defect in cobalamin release from the food sources, but Cbl deficiency in such patients is very rare.

Pernicious anemia Pernicious anemia is considered to be the most common cause of cobalamin deficiency. The cobalamin deficiency is caused by the absence of intrinsic factor because of either atrophy of the gastric mucosa or autoimmune, cytotoxic T-cell-mediated destruction of parietal cells. It is most common in individuals of northern European descent and African Americans and is least common in Asians and southern Europeans. Patients with pernicious anemia have circulating antibodies to parietal cell antigens (90%) and to IF (60%).

Postgastrectomy Cobalamin deficiency develops following total gastrectomy or extensive damage to the gastric mucosa. Due to lack of IF, oral intake of B12 is ineffective and parenteral administration of B12 is essential to prevent cobalamin deficiency.

Helicobacter pylori Some studies have suggested a link between infection with *Helicobacter pylori* and cobalamin deficiency.

Intestine

Small intestinal colonization with bacteria Any condition leading to small intestinal colonization with bacteria (bacterial overgrowth) can cause cobalamin deficiency. This occurs due to utilization of dietary cobalamin by the bacteria. Intestinal blind loops, strictures, diverticula, and pseudo-obstruction are associated with bacterial overgrowth of the small intestine.

Ileal abnormalities Any condition leading to a defect in the absorptive capacity of the distal ileum can lead to cobalamin deficiency. Cobalamin deficiency is seen in regional enteritis (Crohn's disease), tropical sprue, gluten-sensitive enteropathy, Whipple's disease, tuberculosis, and resection of distal ileum.

CLINICAL MANIFESTATION OF COBALAMIN DEFICIENCY

The clinical features of cobalamin deficiency are megaloblastic anemia, neurological changes, and hyperhomocysteinemia. The major hematologic finding is a megaloblastic anemia with elevated serum bilirubin and lactate dehydrogenase levels that reflect the increased red blood cell breakdown due to ineffective erythropoiesis. The peripheral blood smear shows macrocytes, occasionally megaloblasts, and hypersegmented neutrophils (greater than 5% of neutrophils with five or more lobes or 1% with six or more lobes). Bone marrow aspiration and biopsy reveal a very hypercellular marrow with megaloblastic erythroid hyperplasia and giant metamyelocytes. The inadequate conversion of deoxyuridate to thymidylate, which leads to slowing of DNA synthesis and delayed nuclear maturation, and methionine deficiency play a central role in these abnormalities.

The neurologic features of cobalamin deficiency consist of the classic picture of subacute combined degeneration of the dorsal and lateral spinal columns, which is due to a defect in myelin formation by an unknown mechanism. The neuropathy is symmetrical and affects the legs more than the arms. It begins with paresthesias and ataxia associated with loss of vibration and position sense and can progress to severe weakness, spasticity, clonus, paraplegia, and even fecal and urinary incontinence.

Cobalamin and folate are essential for the metabolism of homocysteine and deficiency of either leads to hyperhomocysteinemia, which is recognized as an independent risk for cardiovascular disease, atherosclerosis, and venous thromboembolism. It appears that mild deficiency of cobalamin, which may not be recognized as classic cobalamin deficiency due to a lack of hematologic features, may cause elevation of plasma homocysteine and risk for atherosclerosis and thromboembolism. The optimum plasma cobalamin levels to achieve an optimum plasma homocysteine level are not defined. Furthermore, there are ethnic differences in the association between plasma levels of cobalamin and homocysteine. Several clinical trials are in progress to assess the role of vitamin B12 supplementation in lowering plasma homocysteine and its impact on cardiovascular disease event and mortality.

DIAGNOSIS OF COBALAMIN DEFICIENCY

Cobalamin deficiency can be evaluated by measuring serum cobalamin levels. The normal level of cobalamin in serum is considered to be >200 pg/ml; values <100 pg/ml indicate a clinically significant deficiency. Elevated serum MMA and homocysteine levels are considered useful in recognizing subtle cobalamin deficiency.

Schilling Test

To determine the pathogenesis of cobalamin deficiency, a Schilling test can be performed, which consists of three parts: In part (1), a patient is given radioactive cobalamin by mouth, followed soon by an intramuscular injection of unlabeled cobalamin. A urine sample is collected 24 h later and the amount of radioactive cobalamin excreted gives an indication of absorption.

Since cobalamin deficiency in most of the cases is due to malabsorption, only a small amount of radioactive cobalamin is typically absorbed and excreted in the urine. In part (2), the patient is given radioactive cobalamin bound to IF and excretion of cobalamin in urine over 24 h is measured. If urinary cobalamin excretion is normalized in the patient, it suggests IF deficiency, due to one of the causes listed above. If excretion of cobalamin does not normalize, it suggests small intestinal bacterial overgrowth or an ileal disease. In part (3), the patient is treated with antibiotics and the Schilling's test is repeated. Normalization of urinary B12 excretion suggests bacterial overgrowth as the cause of Cbl deficiency.

TREATMENT OF COBALAMIN DEFICIENCY

In patients with poor intake (vegans), daily oral administration of cobalamin (2 mg crystalline B12) is very effective. However, in most other cases, since the defect is malabsorption, parenteral therapy is preferred. Parenteral therapy is given as an intramuscular injection of cyanocobalamin. The treatment begins with 1000 μg cobalamin per week for 8 weeks followed by 1000 μg cyanocobalamin per month for the rest of the patient's life. High oral doses of B12 have also been reported to be effective, presumably because small (but sufficient) amounts of B12 are absorbed passively by the small intestine. Hyperhomocysteinemia is now recognized as a cardiovascular risk factor and since optimal cobalamin levels in serum are not known, in high-risk patients with high blood levels of homocysteine, oral administration of crystalline B12 and folate is advocated. Various outcome trials with B12 and folate are being conducted to evaluate the role of replacement in preventing coronary heart disease.

anastomosis Surgical union of two hollow organs, for example, blood vessels or parts of the intestine, to ensure continuity of the passageway.
fistula Abnormal connection between two epithelial-lined surfaces.
ischemic Inadequate supply of blood to a part of the body, caused by partial or total blockage of an artery.
lithotomy Body position in which the patient lies on their back on the examining table, with hips and knees fully flexed; also called dorsosacral position. For obstetric procedures, the buttocks are at the edge of the table and the feet are held in stirrups.
megacolon Massive abnormal dilation of the colon.
pouch of Douglas A pouch formed by a fold of peritoneum between the rectum and the uterus.
volvulus Twisting or axial rotation of a portion of bowel about its mesentery.

Colectomy is the excision of the colon in a segment or in its entirety. It is a common procedure performed either electively or as emergency; performance by a general surgeon requires knowledge of technique and careful planning and execution.

INTRODUCTION

Reybard, of Lyon, France, performed the first recorded colectomy, an anastomosis, in 1844. Since then, of course, there have been many changes in the field of surgery. Principles of antiseptic surgery following Lister's treatise in 1867, antibiotic prophylaxis, progress in general anesthesia, and intravenous fluid and blood transfusion have all made intraabdominal surgery increasingly safer. Current technologies in the form of stapling devices and laparoscopic instruments as well as newer imaging modalities have added to the surgeon's armamentarium. Depending on the disease and its extent and site, most colectomies result in restoration of gastrointestinal continuity.

The initial principles of bowel anastomosis first reported by Halsted are still practiced. The importance of no tension on the anastomosis, incorporation of the subserosa by suture, inversion of the mucosa, and adequate blood supply are tenets still upheld today. Closure of the mesenteric defect and a two-layered anastomosis are usually practiced but are not essential. Exposure of the site to be anastomosed is important and removal of serosal fat and epiploic appendages at the site of anastomosis is helpful, provided the serosa is left intact. The use of stapling sutures does not negate these principles for a successful anastomosis.

INDICATIONS

Colectomy is commonly indicated in the treatment of primary resectable colorectal carcinoma and the precancerous condition familial adenomatous polpyposis. It is also required in inflammatory bowel diseases such as ulcerative colitis, Crohn' s disease, and diverticulitis that have become refractory to medical therapy or are life threatening due to their complications (bleeding, perforation, or sepsis). Other conditions that may require excision of the colon include intestinal obstructions, perforation of the colon wall, ischemic colon, toxic megacolon, volvulus, and fistulas between the colon and other viscera.

PREOPERATIVE PREPARATION

The principle of preoperative care is that the patient is made as physically and biochemically fit as possible; in cancerous cases, patients are accurately staged prior to surgery. Hence, nutritional and biochemical status are evaluated and corrected as necessary. This maybe possible in elective cases, but in the emergency setting, time may not permit. Mechanical cleansing of the colon is helpful in colon surgery and along with antibiotics can reduce the incidence of infection rates following colorectal surgery. In a survey of colon and rectal surgeons, two-thirds of surgeons preferred polyethylene glycol electrolyte solution for their patients due to the reliability of the cleansing results. Prophylactic antibiotics complement cleansing to decrease the incidence of postoperative septic complications, because the concentration of bacteria per millimeter of effluent is not affected by mechanical cleansing. The antibiotic regime used most commonly is the one advocated by Nichols and Condon, consisting of a neomycin and erythromycin base, 1 g each orally at 1, 2, and 10 pm, on the day prior to surgery. More recently, many surgeons have

 Copyright 2004, Elsevier (USA). All rights reserved.

substituted metronidazole, 500 g, for erythromycin, because metronidazole is bactericidal against a wider spectrum of anaerobic bacteria.

Intravenous antibiotics are also given perioperatively to supplement the preoperative regime. Double prophylaxis (oral and intravenous) is most beneficial for procedures below the peritoneal reflection, for operations lasting longer than 3.5–4 hours, in immunocompromised patients (e.g., patients on steroids), and in situations in which mechanical preparation is impossible. The intravenous antibiotics are directed against aerobic and anaerobic bowel bacteria. Cefazolin (1 g, for aerobic and skin flora) is usually given and metronidazole (500 g, for anaerobic bacteria) is used at induction of anesthesia, the aim being to achieve a high tissue level at the time of surgery. Coverage with antibiotics is usually for 24 hours, although the preoperative dose is most critical.

Patients with known valvular disease of the heart or with implanted vascular or recently placed orthopedic prostheses also require additional prophylactic antibiotics. Intravenous ampicillin (2 g) and gentamycin (1.5 mg/kg) are given at 30 minutes to 1 hour before the procedure and at least one postoperative dose is given in place of cefazolin. Metronidazole is given as usual. Vancomycin is substituted for ampicillin in patients who are allergic to penicillins and cephalosporins.

Patients who have had colon and rectal surgery, especially pelvic surgery, are at risk for deep venous thrombosis complications. Patients should be given either subcutaneous heparin (5000 units) or low-molecular-weight heparin, or provided with compression stockings. Patients on anticoagulants such as warfarin need to stop the medication 2–5 days prior to surgery, with timing of medication dependent on individual patient risk.

SURGICAL TECHNIQUES

Right Hemicolectomy

Right hemicolectomy is undertaken with the patient placed in a supine position. The surgeon stands on the left side of the patient. The procedure incorporates the removal of the last few centimeters of the ileum, the ascending colon, and the first few centimeters of the transverse colon. Intraabdominally, the colon is mobilized along the avascular plane—the white line of Toldt (which fixes the colon to the lateral abdominal wall)—from the cecum to beyond the hepatic flexure. In mobilizing, the surgeon must be aware of the right kidney, second part of duodenum, right ureter, and right gonadal vessels.

The colon is reflected medially to expose the origin of the ileocolic artery. The surgeon performs ligation and division of the right branches of the middle colic artery, right colic vessels, ileocolic vessels, and vessels to last 5–10 cm of the ileum. The major vascular trunks should be double ligated to avoid risk of knot slippage and hemorrhage. If clamps are used, they are placed at the site of resection of both ends of the bowel, and the bowel is excised flush with the clamps. Many surgeons use staplers to divide and occlude the ends of the bowel prior to anastomosis. After removal of the specimen, the ileum is anastomosed in a side-to-side (functional end-to-end) fashion to the transverse colon. The side-to-side arrangement is used because the caliber of the small bowel and large bowel is very different.

In cases of hepatic flexure tumors, the excision is extended along the gastrocolic ligament toward the spleen. The splenic flexure and left colon can be mobilized if necessary. The omentum is resected if involved with cancer, otherwise it can be preserved. For an "extended" right hemicolectomy, most of the transverse colon is resected. For cancer cases, the surgeon needs to take the mesenteric dissection near their origin. The right colic artery should be ligated close to the superior mesenteric artery. Ligation of the middle colic artery needs to be customized to each patient. Patients with an occluded inferior mesenteric artery will need to have the left branch of the middle colic artery preserved for adequate blood supply to be maintained to the distal transverse colon and left colon.

Transverse Colectomy

Transverse colectomy is the excision of the transverse colon, with transection at the distal ascending and proximal descending colons. The resection requires ligation of the middle colic vessels. The stomach is detached from the transverse colon by division of the gastrocolic omentum. Both flexures are completely divided and the right and left paracolic gutters are mobilized. The site of resection is identified and the transverse colon is resected with its mesentery, and the greater omentum is included if resection is for malignant disease. The transverse colon is reflected upward to reveal the origin of the middle colic vessels beneath the peritoneum. The middle colic artery and its vein are ligated and divided. The bowel is reconstituted without tension.

Left Hemicolectomy

Left hemicolectomy is performed with the patient placed in the either the supine or the lithotomy position.

The surgeon stands to the right. Mobilization of the left colon begins with an incision of the white line of Toldt and extends around the splenic flexure. The spleen, tail of the pancreas, left kidney, left ureter, and left gonadal vessels are vulnerable in this procedure. The left ureter is identified best at the pelvic brim as it crosses the junction of the internal and external iliac vessels. The colon is mobilized medially to reveal the left colic and inferior mesenteric vessels.

Either the left colic artery or the inferior mesenteric artery can be ligated. The inferior mesenteric vein or left colic vein is also ligated. The left branch of the middle colic artery, the marginal vessels at midtransverse colon, and, on occasion, the superior hemorrhoidal artery are preserved. Less extensive or segmental resections involving only the affected portion of colon and its accompanying mesentery and lymph drainage are carried out for benign disease.

Anterior Resection

Anterior resection is indicated for rectal carcinoma between 5 cm from the anus and the rectosigmoid junction. The patient is placed in the lithotomy or modified lithotomy position using stirrups. This position allows for access through the anus for a low rectal anastomosis using a circular stapling device. In an anterior resection, the sigmoid colon is mobilized, the ureter is identified, and the resection is started at the junction of the sigmoid colon and the left colon. A high ligation should be performed on the superior hemorrhoidal vessels after the branches of the sigmoid arteries are divided. The dissection at this point needs to separate and preserve the sympathetic nerves to the pelvis from the mesocolon and mesorectum. The dissection over the pelvic brim into the pelvis starts the "total mesorectal excision" portion of the resection. By staying in the plane that is in front of the sympathetic nerves but outside the mesorectum, the surgeon can then remove all potentially cancerous lymph nodes. For a malignancy, the dissection should continue up to 4–5 cm beyond the lower border of the tumor in order to resect the complete zone of downward spread that can exist in the mesorectum.

The patient habitus (a thin female with a wide pelvis, compared with a narrow male pelvis), adequacy of the anal sphincter, encroachment of the tumor on the anal sphincters, and inadequacy of the distal margins are factors in determining the feasibility of anastomosis with a sphincter-sparing operation. The advent of circular stapling devices has allowed patients with very low-lying rectal cancer in whom the distal margin is at the minimal acceptable level, yet adequate for cancer clearance, to have sphincter-saving operations and coloanal anastomosis.

For anastomosing the colon to the distal rectum, prior to rectal cancer resection the rectum is stapled with a straight stapling device transversely across the rectum below the cancer. The bowel proximal to the staple is then clamped and the rectum is divided just above the stapler, and the cancer is removed. The circular stapling device with a trocar in its center is then placed in the anus. The trocar pierces the stapled top end of the residual rectum. The proximal bowel with the other end of the circular stapler is then connected to the lower end in the rectal remnant. Both parts are then closed and fired; the two rows of staples anastomose the bowel ends in a turned-in fashion (serosa to serosa). The resulting rings of residual tissue from inside the staple lines ("donuts") are then removed, with the circular stapler, via the anus.

Total Mesorectal Excision

Total mesorectal excision (TME) by sharp dissection, in conjunction with a low anterior resection or an abdominal perineal resection, has been shown to decrease the incidence of positive radial margins from 25% in conventional surgery to 7% in cases resected by TME. The hypothesis is that conventional surgery violates the circumference of the mesorectum during blunt dissection along undefined planes, leaving residual mesorectum in the pelvis and thus residual cancer. This has been reflected in the high rate of pelvic cancer recurrence in conventional surgery. The rectal mesentery is removed sharply under direct visualization, emphasizing autonomic nerve preservation, complete hemostasis, and avoidance of violation of the mesorectal envelope. The meticulous dissection is not without consequence; there is prolonged operative time and an increased anastomotic leak rate is noted. Anastomoses 3–6 cm from the anal verge have led to anastomotic leak rates of up to 17%. Some centers are routinely fashioning a protective diverting colostomy or ileostomy with a low anastomosis. Other postoperative complications related to the damage to the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissection, such as impotence and retrograde ejaculation, have been reported to be as low as 10–29% of cases, as compared to 25–75% seen in conventional rectal surgery. (see Figs. 1 and 2).

The type of surgery offered for low rectal cancers depends on an accurate staging of the tumor and the location of the tumor in relation to the surgical resection.

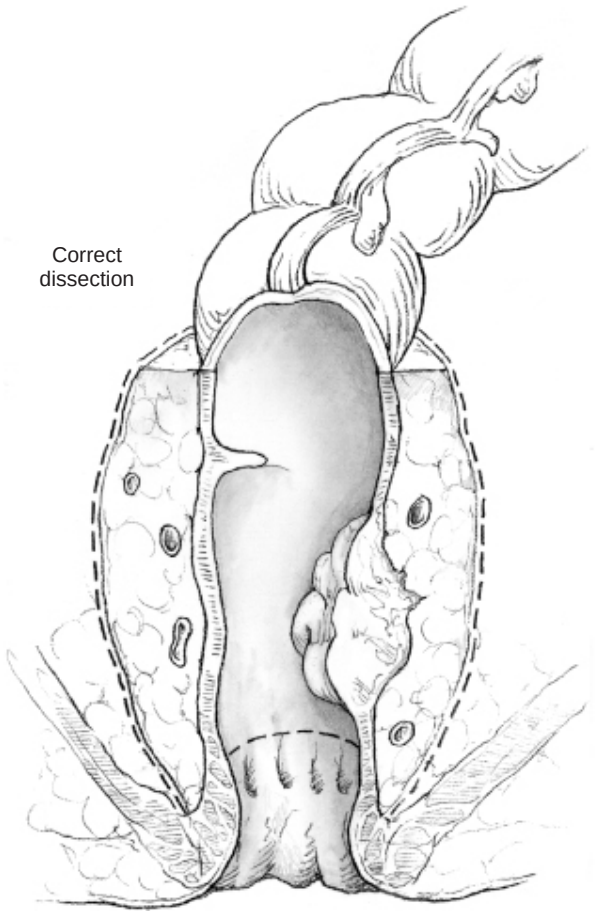

FIGURE 1 The proper plane for a total mesorectal excision is outside the mesorectal envelope, which would include all mesorectal fat, mesorectal lymph nodes, and any locoregional metastatic implants. However, the dissection is inside the pelvic autonomic nerves (both sympathetic and parasympathetic) and the pelvic side wall.

Clinically, the most reliable landmark is the dentate line where squamous mucosae of the anal skin merge into the columnar mucosa of the rectum. The dentate line is located in the middle of the anorectal ring, which is composed of the internal and external sphincters and the portions of the levators, the puborectalis. These muscles provide a high-pressure zone and are responsible for fecal continence. Commonly, the high-pressure zone proceeds 1–3 cm above the dentate line. But from a technical perspective, a tumor has to be located high enough above the top of the anorectal ring to allow for an adequate distal margin if sphincter preservation is to be achieved along with rectal cancer resection. However, a subset of rectal cancer patients are best treated by an abdominoperineal resection.

Abdominoperitoneal Excision

Abdominoperitoneal excision was first described in 1908 by Ernest Miles, though Czerny first performed the removal of the rectum via a combined abdominal and perineal approach in 1884. In this procedure, the patient is placed in a lithotomy with stirrups. There are two parts and two surgeons for this operation, with the abdominal operator standing on the left of the patient and the perineal operator sit facing the perineum. The abdominal resection is the same as for a low anterior tumor resection and its description is not repeated here, except to say that a preliminary examination is required to see whether the tumor is palpable above the pelvic floor and to assess the possibility of its removal.

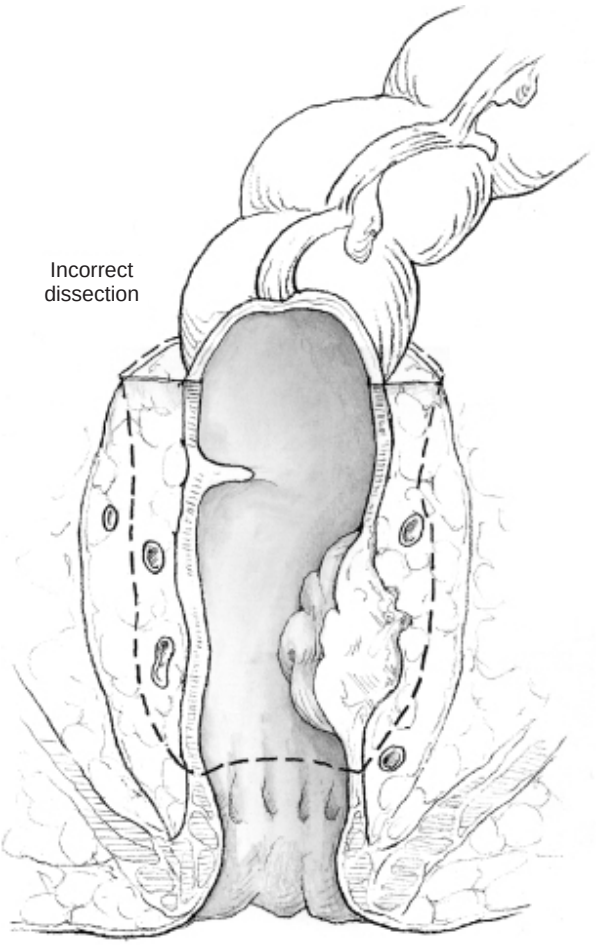

FIGURE 2 Blunt dissection of the mesorectum leads to a dissection plane that is within the mesorectal fat. Lymph nodes and/or implants can be left within the pelvis, leading to a higher recurrence rate.

Once the dissection has reached the level of the levator ani bundle, the peritoneum is divided down to the pouch of Douglas (in females) or to the Denonvilliers fascia at the seminal vesicles (in males). Anteriorly, the peritoneum is divided overlying the bladder, creating a plane of dissection anteriorly in males immediately posterior to the seminal vesicles and anterior to the rectum; in females, the plane lies posterior to the vagina. The posterior dissection is carried out using cautery for all of the mesorectum, from the sacrum proceeding as far as the coccyx.

The perineal dissection starts by placing a purse-string suture around the anus. A skin incision is then made in the form of an ellipse from the perineal body anteriorly, to the ischiorectal spines laterally, and extending posteriorly around each side to meet at the tip of the coccyx. The incision is deepened, exposing the coccyx. All vessels are ligated or cauterized. The perineal surgeon meets the abdominal surgeon behind the rectum but in front of the coccyx. After connecting the planes, the puborectalis muscle is then "hooked" by the hand of the perineal surgeon and divided with cautery. The anterior dissection is completed after the proximal portion of the specimen is inverted posteriorly in front of the coccyx out to the perineal surgeon. After carefully completing the dissection of the prostate or back wall of the vagina, the specimen is then removed. The perineum is closed with secure, interrupted sutures, ensuring hemostasis. A left-sided colostomy is fashioned but completed after the abdominal wound is closed.

Total Proctocolectomy with Ileal–Anal Anastomosis

Total proctocolectomy with ileal–anal anastomosis is a procedure that aims for the removal of all of the large bowel mucosa while preserving the anal fecal function.

POSTOPERATIVE COMPLICATIONS

Postoperative complications, as in many major operations, can generally occur early or late. Early complications can include hemorrhage, infections (wound, septicemia, peritonitis, and abscess formation), anastomotic leakage and stricture, deep venous thrombosis, and pulmonary embolism. Late complications are due to obstruction secondary to adhesions and local recurrence. Metastatic deposits can occur at a later time in the liver or peritoneum. Specific complications of the procedure, e.g., urinary dysfunction and impotence due to autonomic nerve damage in pelvic surgery, can occur.

Following resections of the colon and rectum, functional disturbances occur. Commonly, the frequency and consistency of the stool are altered after segmental colon resection. Usually, absorption of water and electrolytes occurs in the right colon, but following right colon resection and removal of the ileocecal valve, most patients experience only a mild increase in frequency with a looser stool. However, after a while, the remaining colonic mucosa adapts and efficiently absorbs water and electrolytes and so stool consistency and frequency return too normal. If treatment is required, it may take the form of stool bulk-forming agents in order to absorb excess stool water. Diarrhea secondary to bacterial overgrowth due to the degradation of primary bile salts to secondary bile salts occurs and can be treated with cholestyramine or low-dose antibiotics to reduce the bacterial population.

Constipation after segmental resection of the sigmoid is not unheard of and is most probably due to the disruption of the coordinated mass movement within the colon. Treatment initially should be with bulk-forming agents and a stool softener; however, most patients require stimulant laxatives to propel the fecal bolus into the rectum. Frequent small-volume stools, occasionally associated with seepage or frank fecal incontinence, occur after low anterior resection and coloanal anastomosis. The compliance of the proximal colonic segment above the anastomosis is less compared to that of the rectum, thus reducing the reservoir capacity of the colon. However, in most patients, the proximal bowel subsequently adapts and functions normally, with improved compliance and decreasing frequency of stools. In those patients who cannot adapt, bulk-forming agents are indicated.

LAPAROSCOPIC-ASSISTED COLORECTAL SURGERY

As surgeons become more comfortable with laparoscopic or minimally invasive techniques and more technologically advanced surgical instruments and staplers specifically designed for bowel work, it has become possible to perform laparoscopic and laparoscopic-assisted colon and rectal resections. The introduction of intestinal staplers has allowed milestones such as right hemicolectomy, sigmoid resection, low anterior resection, APR, and total abdominal and transverse colectomies to occur. This shift from conventional open colorectal surgery to minimally invasive surgery

is a continuation of the success derived from laparoscopic cholecystectomy and of the advantages of decreased morbidity and faster recovery due to smaller incision wounds.

The tenets of conventional surgery, exploration, resection, and anastomosis, can still occur via a smaller laparotomy incision, along with mini-incisions for trocars. Because the mesentery of the colon is a midline structure, the laparoscopic camera is first placed through a midline port; three to five more trocars, ranging in size from 5 to 12 mm, are then placed. Trocars are placed in all four quadrants of the abdomen. The colon is mobilized away from the left or right peritoneal reflections, up from the pelvis, or from its attachments to the omentum in exactly the same fashion as open surgery, but via laparoscopic instruments. The sigmoid colon, upper rectum, and right colon appear most amenable to laparoscopic techniques.

Various quality-of-life studies have reported that laparoscopic-assisted colectomy (LAC) results in a decrease in pain early after surgery, but that benefits are minimal. However, any benefit of LAC must also be shown to be efficacious in curing cancer. The final recommendation for the use of laparoscopic-assisted surgery in colon cancer awaits the outcome of ongoing prospective studies.

CONCLUSION

Collagenous colitis and lymphocytic colitis, which comprise the syndrome of microscopic colitis, are unique forms of inflammatory bowel disease. Unlike Crohn's disease and ulcerative colitis, they do not carry an increased risk of cancer, and they rarely require surgery. Few controlled trials of therapy have been performed, but, in general, these disorders appear to respond to antiinflammatory or immune modulator therapy.

Colitis Cystica Profunda and Solitary Rectal Ulcer Syndrome

DAVID E. BECK

Ochsner Clinic Foundation, Louisiana

colitis cystica profunda A benign pathologic condition characterized by mucin-filled cysts located deep to the muscularis mucosae.

intussception A condition in which the rectum slips inside itself; this condition can cause obstructive symptoms and damage to the rectum.

perineal protectomy A surgical procedure, performed via the anus, that excises redundant rectum and reconnects the two remaining ends.

prolapse Rectal intussception continues to the point that portions of the rectum are outside the anus.

solitary rectal ulcer syndrome A clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation.

Colitis cystica profunda and solitary rectal ulcer syndrome are closely related diagnoses and some authors consider them interchangeable. The etiology of these conditions remains unclear, but a common feature is chronic inflammation and/or trauma. The inflammation may result from inflammatory bowel disease, resolving ischemia, or trauma associated with internal intussception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool.

INTRODUCTION

Colitis cystica profunda (CCP) and solitary rectal ulcer syndrome (SRUS) are uncommon and controversial conditions. Cystica profunda is a benign condition characterized by mucin-filled cysts located deep to the muscularis mucosae. Although cysts can occur in any

 Copyright 2004, Elsevier (USA). All rights reserved.

segment of the digestive tract submucosa, they are most frequent in the colon and rectum. When these lesions are found in the colon or rectum, they are called colitis cystica profunda and appear as nodules or masses on the anterior rectal wall. Patients can be asymptomatic (with the lesions identified on screening endoscopy) or complain of rectal bleeding, mucous discharge, or anorectal discomfort. Most patients will admit to difficulty with bowel movements. CCP is a pathologic diagnosis whose most important aspect is to differentiate it from colorectal adenocarcinoma. This prevents unnecessary radical operations.

SRUS is a related clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation. Despite its name, patients with this condition can have single, multiple, or no rectal ulcers. When present, the ulcers usually occur on the anterior rectal wall just above the anorectal ring. Less commonly, they may occur from just above to 15 cm above the dentate line. Ulcers usually appear shallow with a "punched out" gray-white base surrounded by hyperemia.

DIAGNOSIS

In symptomatic patients, an endoscopic evaluation of the distal colon and rectum will reveal the lesions described above. Defecography documents intussusception in 45 to 80% of patients. The differential diagnosis of both CCP and SRUS includes polyps, endometriosis, inflammatory granulomas, infectious disorders, drug-induced colitidies, and mucus-producing adenocarcinoma. Differentiation among these entities is possible with an adequate biopsy. Biopsies obtained via a rigid proctoscope, or an endoscopic snare excision, may be necessary to obtain enough tissue for an accurate diagnosis. CCP is characterized pathologically by mucous cysts lined by normal columnar epithelium located deep to the muscularis mucosae. The overlying mucosa may be normal or ulcerated and the submucosa surrounding the cysts is fibrotic and contains a mixed inflammatory infiltrate. In adenocarcinoma, the epithelium is dysplastic and the surrounding stroma is reactive.

TREATMENT

Treatment is directed at reducing symptoms or preventing some of the proposed etiologic mechanisms. Conservative therapy (high-fiber diet and modifying bowel movements to avoid straining) will reduce symptoms in most patients and should be tried first. Patients without rectal intussusception should be offered biofeedback to retrain their bowel function. Pharmacologic therapy has had limited success, but it is reasonable to try this procedure before embarking on surgery. If symptoms persist, a localized resection may be considered in selected patients. Those suitable for localized resection should be significantly symptomatic, be good surgical risks, and have localized, accessible areas of disease. Patients with prolapse are considered for surgical treatment [abdominal rectopexy, segmental resection and rectal fixation, perineal protectomy (Altmeier), or a mucosal protectomy (Delorme)]. Those without prolapse may be offered excision, which varies from a transanal excision to a major resection with coloanal pull-through.

CONCLUSION

Colitis cystica profunda and solitary rectal ulcer syndrome are uncommon and related colorectal conditions. As benign conditions, efforts are directed to establishing the diagnosis, excluding malignancy, and treating symptoms. A directed history, physical examination, and endoscopic biopsy will confirm the diagnosis. Therapy to modify bowel movements and habits has had the most success. If these measures fail, surgical therapy to correct rectal prolapse or locally excise the lesions may be considered.

Pseudomembranous colitis is a pathological diagnosis of exudative plaques adherent to the colonic mucosa. This colitis is most commonly associated with antibiotic usage that leads to the disruption of the normal flora, allowing overgrowth of the bacterium *Clostridium difficile* and the elaboration of toxins. Although antibiotics are the most common cause, cancer chemotherapy also causes this colitis, and sporadic cases also occur. Pseudomembranous colitis is the most severe form in a wide spectrum of clinical diseases that result from *C. difficile* infection, with the associated self-limited diarrhea being more common and much less severe.

INTRODUCTION

Prior to the antibiotic era, pseudomembranous colitis (PMC) was a relatively rare disease and was associated with various risk factors, including surgery (especially of the gastrointestinal tract), shock, uremia, sepsis, ischemic cardiovascular disease, heavy metal poisoning, and colon cancer. However, in the past four decades, virtually all cases of PMC have been associated with *Clostridium difficile*, an anaerobic, gram-positive, spore-forming bacillus. More than 95% of *C. difficile* infections occur during or after antibiotic therapy, and almost every antibiotic has been implicated. In contrast, in antibiotic-associated diarrhea and antibiotic-associated colitis, only 10–30% and 60–75% cases, respectively, are associated with *C. difficile*. The increasing use of broad-spectrum antibiotics is reflected in the increasing incidence of *C. difficile* infections. The clinical manifestations of *C. difficile* infection range from asymptomatic carriage to *C. difficile*-associated diarrhea, to *C. difficile*-associated colitis, to the most severe form of PMC.

EPIDEMIOLOGY

Clostridium difficile is the most common organism isolated in nosocomial diarrhea. There are approximately 300,000 cases of *C. difficile* infection per year that occur in hospitals or long-term care facilities in the United States. Infection can occur sporadically or in outbreaks and can add an estimated cost of $2000 per patient to the cost of the hospitalization. Community-acquired *C. difficile* occurs less frequently and accounts for about 20,000 cases per year in the United States. *Clostridium difficile* can be found in up to 5% of healthy adults, and up to 20–30% of hospitalized patients will be colonized with *C. difficile* due to persistence of spores on contaminated surfaces. Transmission occurs via a fecal–oral route; the unwashed hands of the hospital staff are a common source.

Other risk factors for *C. difficile*-associated disease are age above 60 years, female gender, gastrointestinal manipulation with enemas or nasogastric tubes, inflammatory bowel disease, renal disease, chemotherapy, and HIV infection or AIDS.

PATHOPHYSIOLOGY

Exposure to antibiotics leads to alteration of the host's normal gut flora and presumably allows for the colonization of *C. difficile* acquired from the environment. The toxins produced by *C. difficile* in the intestinal lumen bind to the colonic mucosa and lead to the clinical manifestations of the disease. Although there are several toxic factors elaborated by *C. difficile*, only two are well studied. Toxin A is a 308-kDa enterotoxin and toxin B is a 269-kDa cytotoxin. Both toxins are endocytosed by the intestinal epithelium, where they can disrupt the actin cytoskeleton, leading to apoptosis. They can also induce macrophages and mast cells to elaborate inflammatory mediators such as tumor necrosis factor and interleukins. The major difference in the two toxins is that, in experimental animal models, toxin A leads to mucosal damage and the accumulation of viscous hemorrhagic fluid, whereas these enterotoxic activities do not occur with toxin B. However, toxin B cytopathic effects on cell culture lines are 1000 times more potent compared to

toxin A effects. Although *C. difficile* strains associated with clinical disease usually produce both toxin A and toxin B, there are reports of toxin A-negative/toxin B-positive strains that can also cause the full spectrum of disease, including PMC.

CLINICAL MANIFESTATION

Diarrheal symptoms usually occur within 1 week of starting antibiotics but can be delayed for as long as 8 weeks after discontinuing antibiotics, though the latter is uncommon. The reason for the range of clinical manifestations of *C. difficile* infection is not known, but the presence of immunoglobulin G (IgG) antibodies to toxin A may be one explanation; colonized asymptomatic patients are more likely to have IgG antibodies compared to patients who are symptomatic from *C. difficile*. Patients who are colonized with *C. difficile* are asymptomatic carriers and they continue to shed bacteria in the stool and represent a continued source of infection. In *C. difficile* diarrhea, there are usually only three to four loose watery stools and the patient may or may not experience lower abdominal crampy pain. Fever and leukocytosis are usually mild or absent. On endoscopy, the colonic mucosa is usually grossly normal. Patients with *C. difficile* colitis are clinically more ill. Constitutional symptoms of anorexia, low-grade fever, and nausea are usually present as well as profuse watery diarrhea with 5–15 stools per day, leading to dehydration and electrolyte abnormalities. Leukocytosis is typical and on endoscopic exam, there may be nonspecific patchy or diffuse erythematous colitis.

PMC will present with the same symptoms as *C. difficile* colitis, but on endoscopic evaluation, PMC will have the typical raised yellow or off-white plaques adherent to the colonic mucosa. Hypoalbuminemia occurs in a subset of PMC patients from protein-losing enteropathy; it may be secondary to the leakage of serum albumin from the affected colonic wall and can result in peripheral edema or anasarca. Although *C. difficile* colitis and PMC can diffusely affect the colon, the left colon and rectum are usually more severely affected. Some patients may present with colitis or PMC localized to only the right colon, but it is not known how commonly this isolated right-sided colitis occurs. In such cases, diarrhea may be mild or absent and the predominant symptoms are fever, right-sided abdominal pain, and tenderness with decreased intestinal motility.

Uncommonly, PMC can lead to toxic megacolon with associated ileus. At this point, patients may exhibit diffuse abdominal pain with high fever, chills, and minimal diarrhea secondary to the ileus. Laboratory evaluation may show a leukemoid reaction. Patient may require emergent laparotomy with subtotal colectomy if there is evidence of clinical deterioration due to imminent or actual perforation despite adequate antibiotic treatment.

Relapse of *C. difficile* is the recurrence of symptoms a few days to weeks or months after discontinuation of successful treatment; relapse may be due to the persistence of the original *C. difficile* or to reinfection by another strain. The frequency of relapses ranges from 5 to 50% and repeated episodes of recurrence are not common despite apparent successful treatment after each episode.

DIAGNOSIS

The gold standard for diagnosing *C. difficile* infection has long been the tissue culture test for toxin B. Filtrates of diarrheal stool are added to a monolayer of cultured fibroblasts; if toxin B is present, the cell culture will undergo a characteristic cytopathic effect. Preincubating the filtrate with antibodies against the toxin prevents the cytopathic effect and demonstrates that the cytotoxin present is toxin B from *C. difficile*. Sensitivity (94–100%) and specificity (99%) are both high and improve as the disease progresses along the clinical spectrum from diarrhea to colitis to PMC. The utility of the tissue culture test is limited by its expense and the time for testing, typically requiring 2–3 days. Thus, many hospital laboratories are using enzyme-linked immunosorbent assay (ELISA) technologies [also called enzyme immunoabsorbent assays (EIAs)]. These tests are rapid, less expensive, and widely used in the United States for the detection of toxin A or B. Although specificity is 99%, sensitivity ranges from 70 to 90% and may miss up to 10% of patients with *C. difficile* infection diagnosed either by endoscopy or by tissue culture test for toxin B. Thus, a negative EIA or ELISA test for either toxin A or B does not rule out *C. difficile*.

The latex agglutination test (LAT) detects the glutamate dehydrogenase produced by *C. difficile* rather than the actual toxins. The sensitivity of the LAT is equal to that of the EIA, but the specificity is lower because the protein is also produced by other colonic bacteria and nontoxigenic strains of *C. difficile*. Another diagnostic test is to culture stool for *C. difficile*. This test is limited by its cost, the time delay of 2–3 days for results, and its inability to distinguish between toxigenic and nontoxigenic strains; nontoxigenic strains would presumably not be capable of causing clinical disease. Asymptomatic carriers will have a positive culture.

Although endoscopy is the most rapid way to diagnose PMC, it is generally not recommended due to the high cost and the risk of perforation. It should be reserved for situations in which rapid diagnosis is needed, other test results are delayed and are not very sensitive, or if the patient has an ileus and no stool specimen is obtained.

TREATMENT

In mild disease, discontinuation of the antibiotic and supportive care lead to resolution in 15–20% of cases. Opiates and antidiarrheal medications should be avoided. Specific treatment should be initiated when supportive therapy fails after several days, if the culprit antibiotic cannot be discontinued, or if symptoms are severe. Specific treatment consists of either oral metronidazole at a dose of 250–500 mg four times a day or oral vancomycin at a dose of 125–500 mg four times a day, for 7 to 10 days. Although metronidazole can be administered intravenously at a dose of 500–700 mg three or four times a day if the patient is unable to take oral medication, it is not as effective as oral administration. Despite equivalent efficacy of metronidazole and vancomycin, metronidazole is the first-line therapy. Vancomycin is more expensive and there is the evidence that increased usage leads to the emergence of more vancomycin-resistant bacteria (such as enterococci) in hospital environments. Use of vancomycin should be reserved for patients who are unable to tolerate metronidazole or have failed to respond.

Recurrent infection with *C. difficile* is a difficult management problem, and no specific regimen is uniformly effective. One approach is a tapered dose regimen; a prolonged course of vancomycin is slowly tapered by reducing the dose and frequency over several weeks. Another approach is a pulse regimen; the antibiotic, with addition of cholestyramine, is given over 5- to 7-day periods, alternating with periods of no antibiotics. A combination of pulse or tapered regimen can also be effective. Another approach is the use of probiotics, such as *Lactobacillus GG* and *Saccharomyces boulardii*. *Saccharomyces boulardii* has been shown in controlled trials to decrease recurrences in combination with antibiotics, and especially with high-dose vancomycin. Probiotics in conjunction with antibiotics appear to decrease the frequency of recurrent episodes of *C. difficile*.

Surgical treatment is required in 4–5% of cases. The indications are clinical deterioration despite medical treatment, perforation, hemorrhage, sepsis, and multiorgan failure. The procedure of choice is total abdominal colectomy with ileostomy, because partial resections with diverting ileostomy or colostomy are associated with higher mortality rates.

Colitis, Collagenous and Lymphocytic

WILLIAM J. TREMAINE
Mayo Clinic

collagenous colitis Syndrome of watery diarrhea with colonic mucosal abnormalities that include a thickened subepithelial collagen band and a chronic inflammatory cell infiltrate in the lamina propria.

lymphocytic colitis Syndrome of watery diarrhea with colonic mucosal abnormalities that include intraepithelial lymphocytes and a chronic inflammatory cell infiltrate in the lamina propria.

microscopic colitis Syndrome of watery diarrhea with colonic mucosal abnormalities that include the histologic features of either collagenous colitis or lymphocytic colitis.

Collagenous colitis and lymphocytic colitis are two similar disorders that fit under the heading of microscopic colitis, a syndrome of watery diarrhea with a chronic inflammatory infiltrate in the colonic mucosa, and without specific colonoscopic abnormalities. These disorders have been recognized only in the past 25 years. Because colonic mucosal biopsies are necessary to make the diagnosis, many patients with microscopic colitis were previously diagnosed as having diarrhea-predominant irritable bowel syndrome or chronic diarrhea of unknown origin. The clinical features of collagenous colitis and lymphocytic colitis are similar, and differentiation is made by the histological findings.

CLINICAL AND PATHOLOGIC FEATURES

Clinical Presentation

The usual presentation of collagenous colitis and lymphocytic colitis is chronic watery diarrhea with a few stools, or up to 10 or more stools a day. Nocturnal stools, cramping abdominal pain, and fecal urgency are typical. About 40% of patients have an abrupt onset of symptoms and the rest have a gradual onset. Symptoms may be mild and intermittent, without nocturnal stools and with clinical features indistinguishable from diarrhea-predominant irritable bowel syndrome. Rarely, the diarrhea is severe, with up to 5 liters of watery stool per 24 hours reported. On physical examination, patients may have mild to moderate abdominal tenderness, or the exam may be normal.

The course of these diseases is variable. Symptoms may be intermittent, with apparent spontaneous resolution for months followed by recurrent symptoms. In others, symptoms are chronic or progressive.

Histopathology

Collagenous Colitis

The diagnosis of collagenous colitis is made by finding specific colonic mucosal histologic abnormalities in a patient with watery diarrhea. A continuous or patchy collagen band is present between myofibroblasts and around capillaries in the upper lamina propria. The width of the collagen band may vary from 7 to 100 μm, and the presence of the collagen band is necessary to make the diagnosis. Intraepithelial lymphocytes may or may not be present in collagenous colitis. There is a chronic inflammatory cell infiltrate in the lamina propria, composed mainly of lymphocytes, but also including eosinophils, mast cells, and some neutrophils. Crypt distortion with branching may be found.

Lymphocytic Colitis

There is no increase in the subepithelial collagen in lymphocytic colitis. By definition, intraepithelial lymphocytes are present. There is a chronic inflammatory cell infiltrate in the lamina propria, just as is found in collagenous colitis.

EPIDEMIOLOGY

The reported incidence of collagenous colitis is 1–2 per 100,000 persons, and the prevalence is about 15 per 100,000. Incidence and prevalence for lymphocytic colitis are unknown. The disorders have been reported from countries throughout the world. Most series of patients have shown a female predominance for collagenous colitis, but the female:male ratio has been nearly equal for lymphocytic colitis. The mean age for the onset of collagenous colitis is reported to be 59 years; for lymphocytic colitis, the mean age at onset is reported

 Copyright 2004, Elsevier (USA). All rights reserved.

to be 51 years. Four cases of collagenous colitis in children aged 5–12 years have been reported. A familial occurrence of microscopic colitis has been reported in seven families, each with two affected sisters. In one family, the sister who smoked had collagenous colitis and the sister who did not smoke had lymphocytic colitis.

POSSIBLE CAUSES

The causes of these disorders are unknown, but they are likely the result of mucosal injury from unidentified toxins in the fecal stream. Several different observations support this hypothesis. Fecal extracts from patients with collagenous colitis are cytotoxic to McCoy cell cultures, and mixing cholestyramine with the fecal extract eliminates the cytotoxic effect. However, only a minority of patients with collagenous colitis who are treated with cholestyramine improve, so toxins other than those bound by cholestyramine appear to be important in most patients. Ileostomy with diversion of the fecal stream results in clinical and histological remission, and restoration of intestinal continuity causes clinical and histologic relapse.

A recent study suggests that the diarrhea in collagenous colitis is mediated by up-regulation of nitric oxide synthase, with a marked increase in the production of intraluminal nitric oxide, which in turn causes the secretory diarrhea. However, the agents that induce nitric oxide production in these disorders are unidentified. Originally, the collagen band was thought to cause diarrhea by creating a barrier effect to prevent resorption of fluids, but the collagen band is likely a consequence of the mucosal injury and not the cause of the diarrhea.

It is unclear whether collagenous colitis and lymphocytic colitis are two distinct entities or are different expressions of the same underlying process. Indeed, biopsies showing collagenous colitis and lymphocytic colitis can been found in the same individual at one time, or on sequential exams.

DISEASE ASSOCIATIONS

Celiac sprue has been reported in some patients with collagenous colitis. In a series from the Mayo Clinic, among 45 patients with collagenous colitis in whom intestinal malabsorption was suspected and proximal small intestinal biopsies were obtained, 1 out of the 45 patients had celiac sprue. There are case reports of ulcerative colitis and of Crohn's disease that developed in patients with previously diagnosed collagenous colitis. Collagenous colitis has been found coincidentally in two patients with adenocarcinoma of the colon. However, colorectal cancer did not develop in a series of 117 patients with collagenous colitis followed for 7 years. The relative risk of overall malignancy and mortality is no different from that of the general population. Because collagenous colitis and lymphocytic colitis do not have a premalignant potential, there is no need for increased surveillance for colorectal cancer in this group, above and beyond the recommendations for screening in average-risk patients.

TREATMENT

Medical Therapy

Bismuth subsalicylate in a dose of nine chewable tablets per day in three divided doses appears effective in some patients with either collagenous or lymphocytic colitis, based on the findings in a small, placebo-controlled trial. A recent placebo-controlled trial in 28 patients with collagenous colitis showed efficacy of delayed-release budesonide, a corticosteroid with a potent local topical effect in the proximal colon and terminal ileum, but with less systemic effect than prednisone. A number of other drugs have been used in uncontrolled studies and treatment has been largely empirical. A stepwise approach is used for therapy. Patients with mild symptoms may get relief with symptomatic therapy such as loperamide, diphenoxylate with atropine, or bulk agents. For more troublesome symptoms, chewable bismuth subsalicylate tablets, four to nine per day, may be effective. In those patients who do not respond to bismuth, sulfasalazine or mesalamine may be beneficial. Other agents reported to be beneficial in small, uncontrolled series include cholestyramine and antibiotics such as metronidazole, erythromycin, and penicillin. For more severe symptoms, a corticosteroid such as prednisone or budesonide may be used. Patients dependent on or refractory to corticosteroids have been successfully treated with the immune modulators, 6-mercaptopurine and azathioprine. Octreotide has been effective in some patients with severe diarrhea.

Surgery

In a small number of patients with collagenous and lymphocytic colitis, the diarrhea remains severe despite medical therapy. With a diverting ileostomy, the diarrhea resolves. Some patients with collagenous colitis and with lymphocytic colitis have undergone proctocolectomy with ileal pouch to anal anastomosis.

CONCLUSION

Collagenous colitis and lymphocytic colitis, which comprise the syndrome of microscopic colitis, are unique forms of inflammatory bowel disease. Unlike Crohn's disease and ulcerative colitis, they do not carry an increased risk of cancer, and they rarely require surgery. Few controlled trials of therapy have been performed, but, in general, these disorders appear to respond to antiinflammatory or immune modulator therapy.

Colitis Cystica Profunda and Solitary Rectal Ulcer Syndrome

colitis cystica profunda A benign pathologic condition characterized by mucin-filled cysts located deep to the muscularis mucosae.

intussception A condition in which the rectum slips inside itself; this condition can cause obstructive symptoms and damage to the rectum.

perineal protectomy A surgical procedure, performed via the anus, that excises redundant rectum and reconnects the two remaining ends.

prolapse Rectal intussception continues to the point that portions of the rectum are outside the anus.

solitary rectal ulcer syndrome A clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation.

Colitis cystica profunda and solitary rectal ulcer syndrome are closely related diagnoses and some authors consider them interchangeable. The etiology of these conditions remains unclear, but a common feature is chronic inflammation and/or trauma. The inflammation may result from inflammatory bowel disease, resolving ischemia, or trauma associated with internal intussception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool.

Crohn's disease Chronic idiopathic inflammatory bowel disease characterized by patchy, transmural, and often granulomatous inflammation of any part of the gastrointestinal tract; the inflammatory process more often involves the ileum and colon.

indeterminate colitis Chronic idiopathic inflammatory colitis that cannot be classified with certainty as ulcerative colitis or Crohn's disease based on endoscopic, radiographic, and histopathologic criteria.

ulcerative colitis Chronic idiopathic inflammatory colitis, characterized by continuous superficial inflammation extending to a varying degree in a continuous fashion from the rectum to the proximal colon.

Inflammatory bowel disease (IBD) has been traditionally classified into ulcerative colitis (UC) and Crohn's disease (CD). In UC, the mucosal inflammation is limited to the superficial layers of the colon (mucosa and submucosa), whereas in CD, which can affect any part of the gastrointestinal tract, the inflammatory process is patchy, transmural, and often associated with granuloma formation. The term "indeterminate colitis" (IC) was originally used by pathologists to describe colitis observed in surgical specimens that could not be accurately classified as UC or CD. This was therefore a provisional classification prior to establishing a definitive diagnosis. More recently, the use of the term IC has been extended in the precolectomy evaluation of patients with IBD to characterize the type of colitis (in the absence of small intestinal inflammation) that cannot be classified with certainty as UC or CD. It is still debated whether IC represents a distinct clinical entity or simply a problem of classification at the time of evaluation.

INTRODUCTION

Recent advances in our understanding of the pathogenesis of mucosal inflammation in animal models and humans suggest that inflammatory bowel disease (IBD), and particularly Crohn's disease (CD), may represent a heterogeneous group of diseases based on clinical, subclinical, and genetic characteristics. This notion has been supported by the development of numerous animal models of IBD with distinct phenotypes and immunologic features following selective manipulation of a variety of genes, including those of pro-inflammatory or immunoregulatory cytokines. Given these advances, indeterminate colitis (IC) may in fact be a distinct manifestation within the inflammatory bowel disease spectrum.

INCIDENCE, NATURAL HISTORY, AND DIAGNOSTIC EVALUATION

Overall, 5 to 23% of initial diagnoses of IBD are classified as IC and its incidence is approximately 2.4 per 100,000. It has been reported that IC is associated with a higher risk of colorectal cancer development and increased mortality compared to ulcerative colitis (UC). Also, the cumulative incidence of colectomy in patients with IC in a population-based study was four times higher than in patients with definite UC. Since the cancer risk is related to the extent of colonic inflammation, the higher risk of colorectal cancer in patients with IC may be due to the fact that most patients classified as having IC are more likely to have pancolitis. In addition, the higher mortality rate in patients with IC reflects a more severe and extensive inflammatory process in patients with IC compared to patients with UC, since the majority of the deaths have been attributed to complications of colitis. Recent studies have shown that most patients with IC will be reclassified as having CD or UC within 8 years of the initial diagnosis. The probability of having a diagnosis of Crohn's disease was increased in patients with fever at their initial presentation, segmental endoscopic lesions, or extraintestinal complications and in current smokers, whereas the probability of having a diagnosis of UC was increased in patients who had not undergone appendectomy before diagnosis. Serologic testing in patients with an initial diagnosis of IC may be helpful in categorizing the disease and predict the follow-up diagnosis. The most extensively studied serologic markers in IBD include perinuclear anti-neutrophil cytoplasmic antibody (pANCA) and anti-*Saccharomyces cerevisiae* antibodies (ASCA). As subclinical indicators of immune dysregulation, these markers can be used in IBD to stratify patients based on clinical, immunologic, and

 Copyright 2004, Elsevier (USA). All rights reserved.

genetic characteristics. pANCA is detected in the serum of 60 to 70% of patients with UC and in 10–20% of patients with CD. ASCA is present in 50 to 70% of patients with CD and 6 to 14% of patients with UC. ASCA is rarely expressed in individuals who do not have IBD and thus is highly specific for CD. In a recent prospective study, pANCA and ASCA were studied in 97 patients with IC. ASCA-positive/pANCA-negative IC predicted evolution to CD in 80% of the patients. ASCA-negative/pANCA-positive IC predicted UC in 64% of patients, whereas this combination was 100% predictive of UC or "UC-like CD." The latter represent cases of Crohn's disease with left-sided colonic involvement, which resemble UC both clinically and endoscopically. Interestingly, almost half of the patients with IC were negative for both of these serologic markers and most of these patients (85%) continued to carry the diagnosis of IC in follow-up evaluation.

MEDICAL THERAPY OF INDETERMINATE COLITIS

Unfortunately, evidence-based medical treatment strategies are lacking for IC simply because randomized controlled trials have included only well-documented cases of UC or CD. Since many patients with IC will eventually be found to have either UC or CD, any therapy that is effective in both diseases may prove useful in the treatment of IC. The goals of medical treatment in IC are the same as in the other forms of IBD, namely, induction and maintenance of remission (absence of symptoms related to colitis such as abdominal pain, diarrhea, rectal bleeding, or tenesmus). The mainstay of medical treatment for mild to moderately active IC includes the use of aminosalicylates. There are three delivery systems for oral aminosalicylates and several topical (rectal) formulations. The oral formulations include azo-bond conjugates (sulfasalazine, olsalazine, and balsalazide), pH-dependent mesalamine with varied Eudragit (USP) coatings (Asacol, Salofalk, and Claversal), and time/pH release formulations of mesalamine encapsulated into ethylcellulose beads (Pentasa). Since IC usually involves the entire colon, combined administration of oral and topical 5-ASA may have an additive therapeutic effect. In patients with IC who fail to respond to 5-ASA treatment or those with severe disease, corticosteroids will often be required to induce remission. However, corticosteroids have no maintenance benefit in patients with CD or UC and therefore probably should not be used long-term in patients with IC either. In cases where IC becomes steroid-dependent, immunomodulatory treatment with 6-mercaptopurine (6-MP) or azathioprine (AZA) should be initiated. In patients who are intolerant to 6-MP/AZA or fail to respond adequately methotrexate can be tried. This drug has been shown to be effective for the induction and maintenance of remission in steroid-dependent, chronic active CD but is less effective in UC. However, its efficacy in IC is unknown. Novel treatments that target inflammatory mediators [e.g., tumor necrosis factor α (TNFα)] thought to be central in the pathogenesis of mucosal inflammation, such as the human/chimeric monoclonal antibody directed against TNFα, infliximab (Remicade), have been found to be highly effective for the treatment of inflammatory and fistulizing CD, but less so for the treatment of UC. In a small series of patients with treatment-resistant IC, infliximab was effective in 67% of patients and several patients avoided colectomy. Cyclosporine (CsA) may also be effective in patients with IC who failed to respond to corticosteroid treatment similarly to patients with UC. Successful induction of remission with CsA, however, will invariably require the long-term use of 6-MP/AZA for maintenance of remission.

SURGICAL THERAPY OF INDETERMINATE COLITIS

As discussed in a previous section, the risk of major surgery is increased several fold in patients with IC compared to those with UC. Ileal pouch-anal anastomosis (IPAA) has been considered the gold standard surgical treatment for UC and is generally contraindicated in patients with CD due to the high incidence of complications, including pelvic abscess, fistula, and pouch failure, which may require pouch excision. In some cases of Crohn's disease, those with no small bowel or ano-perineal disease may do well with restorative proctocolectomy. This treatment, therefore, has been advocated in a select group of patients. The major decision regarding surgical treatment of IC is whether to perform restorative proctocolectomy (IPAA) or total colectomy with ileostomy or in cases of rectal sparing subtotal colectomy with ileorectal anastomosis. The outcome of patients operated on for IC with IPAA, who did not develop CD in long-term follow-up evaluation, is reportedly as good as those operated on for UC, although other studies have reported a higher incidence of complications in patients operated on for IC. This discrepancy may be related to the differences in the definition of IC used in different studies. Nevertheless, the development of CD following IPAA for either UC or IC is associated with poor long-term outcome. Prior to surgery, however, extensive

evaluation of patients with an upper gastrointestinal series/small bowel follow-through or even wireless capsule endoscopy should be performed to rule out Crohn's disease of the small bowel and avoid performing an IPAA in these patients. IBD serologies precolectomy may be helpful in predicting the potential development of complications following IPAA for IC, but long-term follow-up studies are needed to assess their utility in this setting.

CONCLUSION

Indeterminate colitis was originally reported in colectomy specimens to describe the inflammatory process that could not be adequately classified as UC or CD. Recently, the term has been extended in cases of chronic IBD, without small bowel inflammation and inconclusive diagnostic features of either UC or CD on endoscopic and histopathologic evaluation. Although long-term follow-up evaluation may change the diagnosis to either UC or CD, a significant number of patients will still have IC. This observation supports the idea that although IC may represent a problem of classification at the time of evaluation in some cases, other cases may truly represent a distinct disease entity. Medical therapies are similar to those used for the treatment of UC and sometimes CD. Surgical treatment may be needed in those patients with severe treatment-resistant disease.

Colonic inflammation, distinct from that which characterizes Crohn's disease or ulcerative colitis, is occasionally caused by external agents that are used to treat other diseases or which may gain access to the colon through ingestion or other routes. Many of the agents associated with noninflammatory bowel disease colitis, including radiation, chemicals, and drugs, are suspected, but not necessarily proven, causative agents. Causation has been implied in case studies, but often carefully controlled clinical trials are not available or ethically possible, resulting in uncertainty as to whether or not a given agent is responsible for the colitis.

INTRODUCTION

Colitis, or inflammation of the colon, is most commonly associated with the inflammatory bowel diseases Crohn's disease and ulcerative colitis. These diseases have an unknown etiology and are characterized by their "relapsing–remitting" nature. Less common, but no less deleterious to the patient, is colitis occurring in the setting of exposure to a defined external factor. In many cases, colitis is caused by a therapeutic modality that is being used for an indication not related to the colon per se. Examples are ionizing radiation, chemotherapeutic agents, other drugs, or other chemicals present in the environment and to which patients may be exposed. In most cases, when a specific agent is identified as causing colitis, cessation of that particular agent leads to the resolution of the colonic inflammation. In other cases, however, removal of the associated agent (such as cessation of abdominopelvic exposure to ionizing radiation in the case of radiotherapy) does not result in resolution of the colitis. In these cases, chronic colonic inflammatory disease may develop, which is often difficult to manage and is associated with significant morbidity.

RADIATION-INDUCED COLITIS AND RADIATION ENTEROPATHY

Abdominopelvic exposure to ionizing radiation, such as that received during cancer radiotherapy, can result in the development of an acute colonic inflammation that often progresses to a chronic radiation enteritis. Irradiation results in a rapid cellular burst of free radicals that can cause single- and double-stranded DNA breaks, as well as damage to proteins, lipids, carbohydrates, and other molecules. Cells that are rapidly dividing and undifferentiated (such as stem cells in the crypt region of the intestinal mucosa) are most radiosensitive, particularly when they are in the G2 or M phases of the cell cycle, and are induced to undergo p53-dependent apoptosis. Following irradiation, there is rapid activation of the coagulation cascade and apoptosis of endothelial cells within the radiation field. There is also an acute inflammatory response characterized by leukocyte infiltration. This inflammatory response can exacerbate the radiation-induced epithelial damage. The acute phase of the response to ionizing radiation will resolve, but during most fractionation protocols, another dose of radiation is delivered before this resolution can occur. Thus, there is an "accumulated injury," which can exacerbate the endothelial response and lead to increased production of cytokines such as

 Copyright 2004, Elsevier (USA). All rights reserved.

transforming growth factor-β (TGF-β), which can delay the repair process further.

Epithelial damage is associated with decreased barrier function. This is due to a combination of direct epithelial cellular damage, decreased responsiveness to secretagogues, and damage to the basement membrane. The impaired barrier function may lead to increased bacterial translocation, which has the potential to exacerbate or prolong the injury, although this remains controversial. Indeed, it has been observed that acute clinical symptoms (from the second to the sixth week postirradiation) are manifested even at times when endoscopic and histological changes have normalized. Nevertheless, impaired barrier function is thought to contribute to the progression to chronic disease. The chronic phase of radiation enteritis is characterized by progressive fibrosis and vascular sclerosis. The fibrosis can lead to bowel wall thickening and narrowing of the colonic lumen, leading to stricture formation and dilation of the segment of bowel proximal to the area of stricture. These regions are also characterized by an inflammatory cell infiltrate and, on occasion, fistula and abscess formation as a result of perforation. The chronic fibrosis is thought to be mediated by TGF-β_1, which is initially expressed following radiation-induced cytokine release. TGF-β_1 overexpression has been observed in irradiated tissues, including the colon.

CHEMICALLY INDUCED COLITIS

The incidence of colitis induced by chemicals distinct from therapeutic drugs is rare. The most common of these, however, is disinfectant colitis caused by inadvertent exposure of the colon to the 2% glutaraldehyde solutions used to clean endoscopes. Glutaraldehyde-containing disinfectant solutions can cause an acute, nonspecific colitis or proctitis characterized by bloody diarrhea, cramping, and fever, in the absence of *Clostridium difficile* infection. There has been a report of glutaraldehyde-induced colitis mimicking pseudomembranous colitis. The development of acute colitis within 24 h after endoscopy, particularly when endoscopic findings are normal, should be considered iatrogenic in nature.

There are several experimental animal models of chemically induced colitis, designed to mimic various clinically important inflammatory diseases of the gut. Intracolonic trinitrobenzene sulfonic acid or dinitrobenzenesulfonic acid, often administered in an ethanol vehicle, has been used in a number of rodent species to mimic Crohn's disease. Typically, instillation of these agents causes a T-helper 1 (T_H1) T-cell-driven colitis with acute and chronic phases that resolve within several weeks. Dextran sodium sulfate administered in the drinking water to mice or rats causes an acute colitis mimicking ulcerative colitis. This is a mixed T_H-1/T_H-2-driven inflammation characterized by bloody diarrhea and a neutrophilic mucosal inflammation. Oral administration of oxazolone causes a T_H-2-mediated colitis in mice and rats. Intralumenal administration of acetic acid causes a nonspecific colitis in the rat, guinea pig, and rabbit.

DRUG-INDUCED COLITIS

Chemotherapy Agents

Chemotherapeutic drugs are occasionally associated with the development of various colitides. In general, patients undergoing combination chemotherapy for leukemias or advanced solid tumors are at risk of developing necrotizing enteropathy or neutropenic enterocolitis. It is believed that the primary cause is due to a drug-induced decrease in mucosal defense, perhaps as a result of compromised epithelial integrity, with subsequent infection, often polymicrobial. The colon becomes edematous and hemorrhagic with transmural necrosis. Involved areas are often sharply demarcated from uninvolved areas. Unlike radiation-induced enteropathy, patients in most cases recover with supportive care and administration of broad-spectrum antibiotics. There have been case reports of severe early-onset colitis, occasionally causing death, associated with taxane-based drugs used in the treatment of breast cancer (e.g., docataxel, paclitaxel). These agents do not cause typical neutropenic colitis, but rather a pseudo-membranous or ischemic colitis.

Antibiotics

Although antibiotic use does not directly cause colitis, administration of some antibiotics is often associated with the development of a pseudo-membranous colitis. Antibiotics disrupt the normal microbial balance in the colon, allowing overgrowth of some pathogenic species of bacteria, predominantly *C. difficile*. Particularly susceptible are surgical and intensive care patients. The majority of patients who contract *C. difficile* infection will develop diarrhea and 10% of these will progress to pseudo-membranous colitis.

Other Drugs

Some neuroleptic drugs have been associated with the development of colitis. Clozapine, used in some schizophrenic patients, is associated with the development of neutropenia and has, in some instances, been

linked to the development of a neutropenic colitis. Others have associated clozapine administration with eosinophilia and still others associate its effect with its anticholinergic activity. Phenothiazines have also been linked with the development of colitis, perhaps due to reduced blood flow in the bowel. Hypersensitivity associated with anti-epileptic drugs may include colitis. In all of these cases, colitis resolves with cessation of drug intake.

There is a growing literature detailing the development of colitis with the use of pseudoephedrine as a nasal decongestant. Several reports of ischemic colitis have been made, with the vasoconstrictor activity of the drug proposed as the cause. In each case, colitis resolved spontaneously when the pseudoephedrine use was halted.

Sumatriptan, a serotonin type 1 receptor antagonist used to treat migraine headaches, is associated with several side effects, including ischemic colitis, although most case reports are confounded by coadministration of other drugs.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are also associated with the development of colitis, presumably due to the fact that they decrease the production of prostaglandins involved in the preservation of gastrointestinal integrity. Several case reports demonstrate that NSAIDs that block both cyclooxygenase (COX)-1 and COX-2, or that selectively block COX-2, may induce nonspecific colitis or, more rarely, eosinophilic, pseudo-membranous, or collagenous colitis.

Effects of Drugs on Existing Colitis

Occasionally, patients with inflammatory bowel disease may experience relapse or exacerbation of their disease as a result of drugs they may be taking. For example, there are reports of exacerbation of inflammatory bowel disease (IBD) in patients taking NSAIDs. Of particular note is the fact that selective COX-2 inhibitors are capable of exacerbating colitis, despite the fact that they are touted as being "gastrointestinally safe." In addition, the immunosuppressant mycophenolate mofetil, which is used in IBD patients refractory to azathioprine and in renal transplant patients, has recently been associated with toxicity, including colitis, which has been described as "graft-versus-host disease-like."

5-aminosalicylic acid Drug that reduces inflammation in UC.
ankylosing spondylitis Chronic inflammation of the spine and adjacent joints.
arthralgia Pain in the joints.
azathioprine Immunosuppressive drug used in refractory UC.
ciclosporin Immunosuppressive drug used to treat acute severe refractory UC.
colonoscopy Examination of the colon, rectum, and terminal ileum using a flexible videoendoscope introduced through the anus, usually after preparation of the patient with laxatives to clear the colon of feces.
Crohn's disease Idiopathic chronic inflammatory disease of the entire gastrointestinal tract; included with UC in the category "inflammatory bowel disease."
cytokines Group of peptides produced by inflammatory and other cells; control cell function and may have pro- or antiinflammatory effects.
dysplasia Alterations in the microscopic appearance of the cells lining the colon; may herald the development of cancer.
episcleritis Inflammation of sclera of the eye, sometimes occurring in patients with active UC.
erythema nodosum Red, tender swellings, usually on the legs; may occur in patients with active UC.
ileoanal pouch Reservoir created from the distal ileum to connect ileum to anus after total colectomy.
ileostomy Operation in which, after removal of the colon (colectomy), the cut end of the ileum is brought through an opening in the abdominal wall. Ileal effluent is collected thereafter into a bag fixed over the stoma.
6-mercaptopurine Metabolic product of azathioprine; also used in refractory UC.
mesalamine Approved name for 5-ASA products.
prednisolone Corticosteroid drug used to reduce inflammation in active UC.
proctitis Inflammation of the rectum; the least extensive variety of UC.
pseudopolyp Polypoid projection from the mucosa into the lumen of the colon, resulting from healing after inflammation.
pyoderma gangrenosum Chronic skin ulcer sometimes complicating UC.
sclerosing cholangitis Slowly progressive inflammatory scarring of bile ducts, leading eventually to liver failure; may occur in association with UC.
sulfasalazine Drug containing both 5-ASA and a sulfonamide; useful in the treatment of UC.
tenesmus Persistent urge to defecate in patients with rectal inflammation.
toxic megacolon Dilatation of the colon occurring rarely in patients with severe attacks of UC; may cause colonic perforation and usually requires urgent surgery.
ulcerative colitis Idiopathic chronic inflammatory disease of the colon and rectum.
uveitis Inflammation of the anterior chamber of the eye, sometimes complicating active UC.

Inflammatory bowel disease comprises two chronic relapsing and remitting inflammatory disorders of the gastrointestinal tract, ulcerative colitis and Crohn's disease. The cause of these diseases is unknown. Each is a lifelong disease, characterized by recurrent episodes of diarrhea, which is often bloody, with abdominal pain, malaise, and weight loss. Unlike in Crohn's disease, gut inflammation in ulcerative colitis affects only the colon and rectum.

INCIDENCE AND CAUSE

Ulcerative colitis (UC) is likely to result from a genetically determined inappropriately prolonged mucosal inflammatory response to as yet unidentified environmental factors, including, for example, gut microbial products.

Epidemiology

In North America and Europe, the incidence of UC is about 10 new cases per year per 100,000 population, and its prevalence 150/100,000. In Africa, Asia, and South America, UC is less common, although now increasing in incidence, probably as a result of improved hygiene. UC is slightly more common in women. It has a major peak of onset at 20–40 years of age and a lesser one at ages 60–80.

Cause

Genetic Factors

UC and Crohn's disease (CD) are likely to be related heterogeneous polygenic disorders with no single

Mendelian pattern of inheritance. The contribution of genetic, as opposed to environmental, factors in UC is about 40%, and in CD, 60%. Epidemiological studies have shown that inflammatory bowel disease (IBD) is more common in Ashkenazi than in Sephardic Jews, and in North American Caucasians than in African-Americans. There is a 10-fold increased risk of IBD in the first-degree relatives of patients with UC. There is also high concordance for IBD in identical twins, particularly in CD (60%) as opposed to UC (10%).

The results of some genetic studies have varied according to the population under investigation. For example, the frequency of human leukocyte antigen (HLA) DR2 is increased in Japanese and Californians patients with UC, but not in British or European patients with UC. However, in several populations, susceptibility loci have been reported for UC on chromosomes 2 and 6, for CD on chromosomes 5 and 16, and for both on chromosomes 1, 3, 4, 7, and 12, suggesting that the two diseases are distinct, although sharing some susceptibility genes.

It is estimated that between 10 and 20 genes may be involved in the pathogenesis of IBD. Some of the pathophysiological abnormalities in IBD, such as abnormal immune regulation, increased gut permeability, defective colonic mucus, and disordered immune regulation (Table I), are probably genetically determined, but the clinical variability of IBD may also reflect genetic heterogeneity. In UC, for example, DR3/DQ2 is associated with extensive disease.

Genome scanning techniques using microsatellite markers have been employed to highlight areas of chromosomes linked to disease, including, for example, those on chromosomes 12 (*IBD2*) and 16 (*IBD1*). *IBD2* appears to make a major contribution to UC susceptibility but to have only a relatively minor effect in CD, for which there may be substantially more locus heterogeneity. The presence of perinuclear antineutrophil cytoplasmic antibodies (pANCA) in the serum of most patients with UC (but in only 5% of those with CD) is determined genetically. The genetics of IBD is currently under intense investigation; genetic clarification of this disease will have major implications for our understanding of its etiopathogenesis and for improving the treatment of IBD.

Environmental Factors

Several environmental factors appear to play a role in the causation of IBD.

Smoking Only about 10% of patients with UC smoke, compared with 30% of the normal population and with 40% of those with CD. UC commonly presents for the first time soon after a patient stops smoking, and nicotine patches have a modest therapeutic benefit. Nicotine and other constituents of tobacco have a variety of effects on the inflammatory response, but it is not known why these are beneficial in UC but harmful in CD.

Diet Up to 5% of patients with UC improve on avoidance of cow's milk; no other dietary influences are known.

Specific infection Despite its resemblance to, and occasional onset after, infectious diarrhea, there is no evidence that UC is due to a single infectious agent.

Enteric microflora The resident gut microflora are likely to be a major factor in the pathogenesis of IBD. Clinical and experimental evidence shows the importance of the fecal stream in driving mucosal inflammation. Patients with active IBD show loss of immunological tolerance to intestinal microflora. Antibiotics and, in preliminary studies, probiotics may have a therapeutic role in IBD.

Drugs Relapse of IBD may be precipitated by nonsteroidal antiinflammatory drugs (NSAIDs) and by antibiotics, the latter probably acting by altering enteric flora.

Appendectomy Appendectomy seems to protect patients from developing UC. In an inflamed appendix in genetically prone individuals, T lymphocytes may trigger inflammation (UC) in the more distal colon.

Stress Psychological stress is common in patients with IBD as a result of the unpleasantness, chronicity, and intractability of their illness. It is possible, however, that in some patients stress may trigger relapse of IBD (for example, by activation of leukocytes by enteric nerve endings in the gut wall) (Fig. 1).

Pathogenesis

Although the initiating factors in UC are unknown, altered immune regulation leads to mucosal inflammation, which is amplified and perpetuated by recruitment of leukocytes from the gut vasculature. Up-regulation of expression of nuclear transcription factors is likely to increase local release of cytokines and inflammatory mediators (Fig. 1). In UC, a non-T helper 1 (non-Th1) cytokine response generates a mainly humoral immune profile, whereas in CD, a Th1-induced cell-mediated response occurs (Table II). In UC, defective colonic mucus and abnormal mucosal permeability may facilitate access of bacterial and dietary products to the mucosa; furthermore, impaired availability of bacterially derived short-chain fatty acids may adversely affect colonocyte function.

Pathology

UC usually begins in the rectum, and either remains there or spreads proximally with time (Fig. 2). The colonic mucosa shows diffuse inflammation with hyperemia, granularity, and surface pus and blood, leading in severe cases to extensive ulceration (Fig. 3). This heals by granulation to form multiple pseudopolyps.

Microscopically, acute and chronic inflammatory cells infiltrate the lamina propria and crypts (producing crypt abscesses). Crypt architecture is distorted and goblet cells lose their mucin (Fig. 4). The mucosa is edematous with epithelial ulceration. Biopsies in long-standing total colitis may show dysplasia, in which epithelial cell nuclei are enlarged and crowded and lose their polarity; carcinoma may supervene.

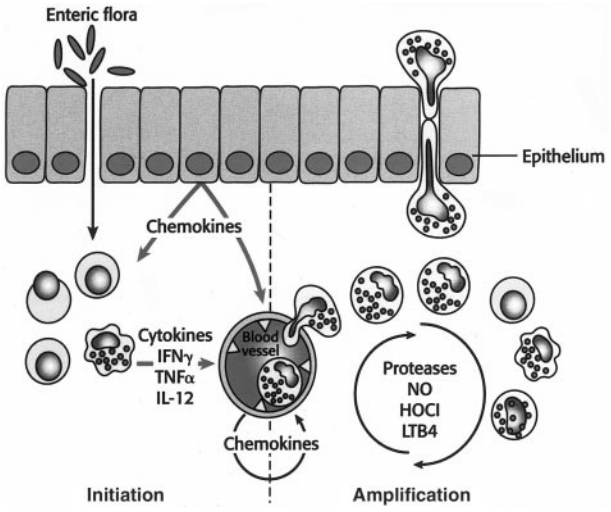

FIGURE 1 Mediators and mechanisms in the pathogenesis of inflammatory bowel disease. Although the initiating factors of the disease are uncertain, and may include a breakdown in tolerance to enteric flora, T cell and macrophage activation lead to production of cytokines acting at several levels. These include the local microvasculature, with generation of a chemokine gradient that causes transmigration of neutrophils, leading to tissue damage by metalloproteases and other reactive substances, augmentation of the inflammatory response, and disruption of the epithelial barrier, causing further ingress of enteric flora and their products. CLINICAL FEATURES AND COMPLICATIONS

Clinical Features

The onset of UC is usually gradual and its natural history is chronic, with relapses and remissions over many years. The features of active disease depend on the extent as well as activity of the disease:

1. Acute severe UC, which most commonly occurs in patients with subtotal or total disease (Fig. 2), causes profuse, frequent diarrhea (>6 loose stools per day) with blood and mucus, abdominal pain, fever, malaise, anorexia, and weight loss. The patient is thin, anemic, fluid depleted, febrile, and tachycardic. In patients developing toxic megacolon and/or perforation, there

is sudden worsening of abdominal pain, distension, fever, tachycardia, sepsis, and shock.

2. Moderately active UC, usually left sided (Fig. 2), causes rectal bleeding and mucus discharge with diarrhea (<6 loose stools per day), urgency, and sometimes abdominal pain.

3. Active proctitis causes rectal bleeding and mucus discharge, often with tenesmus and pruritus ani. There may be increased stool frequency but some patients are constipated, particularly proximal to the inflamed rectum. General health is usually maintained.

Extraintestinal Associations and Complications

Systemic associations and complications of UC, as of CD most commonly affect the liver and biliary tree, joints, skin, and eyes (Table III). Some complications occur mainly in active disease. In some instances, the condition is a metabolic complication of IBD (gallstones and urinary stones). In others, there is a genetic and/or immunological (ankylosing spondylitis, uveitis, arthropathy) association with IBD. The most important complications are sclerosing cholangitis, joint disease, osteoporosis, skin conditions, ocular diseases, and thromboembolism.

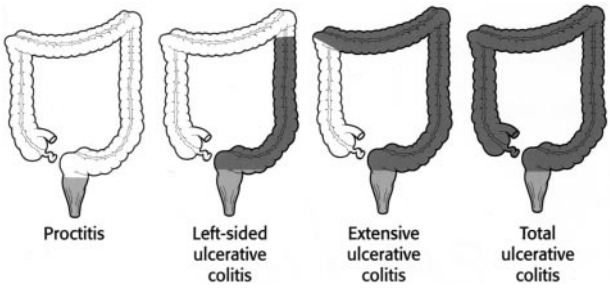

FIGURE 2 Distribution of UC. Reproduced from D. S. Rampton and F. Shanahan (2000), *Fast Facts—Inflammatory Bowel Disease*, with permission of Health Press Ltd., Oxford.

Sclerosing Cholangitis

Sclerosing cholangitis occurs in about 5% of patients with UC. Its pathogenesis is unknown, but it may occur years before the onset of overt colitis. It is characterized by gradually progressive obliterative fibrosis of the biliary tree and is sometimes complicated by cholangiocarcinoma. The risk of colorectal cancer in patients with UC and sclerosing cholangitis exceeds that associated with UC alone. Patients usually present with obstructive jaundice, cholangitis, or abnormal liver function tests at routine screening. The diagnosis may be suggested by ultrasound, computer tomography (CT), magnetic resonance imaging, and/or liver biopsy; endoscopic retrograde choledochopancreatography (ERCP) is useful for diagnosis and stenting of strictures. Although widely used, ursodeoxycholic acid is of unproved benefit. Liver transplant is the only hope of long-term survival; median survival without transplant is about 15 years.

Joint Disease

IBD-related arthropathy occurs in up to 10% of patients with UC. Pauciarticular disease involves less than five joints; characteristically it affects one large joint (for example, the knee) and is most common in women. Attacks usually coincide with relapse of colitis and may be due to deposition in the affected joint of gut-derived immune complexes. Pauciarticular disease is neither progressive nor deforming. In most patients, the joint symptoms resolve on successful treatment of the active UC. Sulfasalazine may be more effective for the joints than other 5-aminosalicylic acids (5ASAs). NSAIDs may exacerbate UC, and should if possible be avoided. Joint aspiration with steroid installation may help.

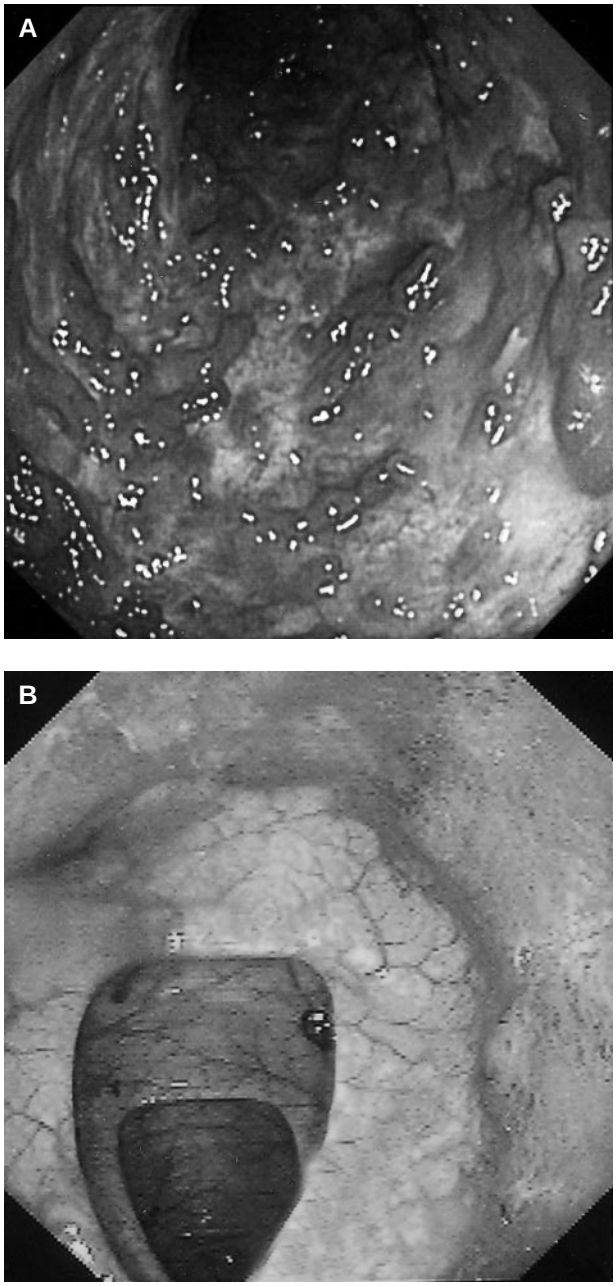

FIGURE 3 Colonoscopic appearance of (a) active UC, showing mucopurulent exudate, erythema, granularity, and superficial ulceration, and (b) inactive UC, showing erythema and edema, with a sharp "cutoff" to normal more proximal colonic mucosa.

Polyarticular IBD-related arthropathy affects more than five joints, particularly small joints in the hands. Symptoms are more common in women, chronic, and not clearly related to activity of UC. Management resembles that of pauciarticular disease, except that response of the arthropathy to treatment of UC is poor.

Ankylosing spondylitis is characterized by inflammation of the spinal column leading to formation of syndesmophytes between vertebra and later calcification and ossification of the interspinous ligaments. It affects about 5% of patients with UC and is usually accompanied by inflammation, erosion, and sclerosis of the sacroiliac joints (i.e., sacroiliitis). Although about 95% of patients without IBD who have ankylosing spondylitis are HLA-B27 positive, this is true of only 70% of patients with both diseases. Presentation is with back pain and stiffness, and diagnosis is confirmed by X ray. The course of ankylosing spondylitis is independent of the activity of UC and it may present years before the colitis becomes manifest. Treatment consists of vigorous physiotherapy, sulfasalazine, and, if tolerated, NSAIDs.

Osteoporosis

Osteoporosis is much less common in UC than in CD and is a consequence of chronic intestinal inflammation and its treatment with corticosteroids. The disease is asymptomatic for many years, presenting eventually with vertebral collapse or long bone fractures. Diagnosis is best made by bone densitometry. To prevent osteoporosis, patients should eat adequate amounts of dairy products and, if necessary, take calcium and vitamin D tablets. Patients should control their weight, stop smoking, and take regular exercise. Postmenopausal women are given hormone replacement therapy. Patients with proved osteoporosis are usually treated with cyclical bisphosphonates.

[a] Worsens when UC is active.

Skin Associations

Erythema nodosum occurs in about 8% of patients with UC, usually when the disease is active. Hot, red, tender nodules appear, usually on extensor surfaces of the lower legs and arms (Fig. 5); these nodules gradually subside after a few days and leave brownish skin discoloration. Treatment is of the active associated UC.

Pyoderma gangrenosum occurs in about 2% of patients with UC. There is initially a discrete pustule with surrounding erythema; this develops into an indolent, enlarging ulcer. The pustules most commonly occur on the leg (Fig. 6), sometimes at sites of previous trauma. Biopsy shows a lymphocytic vasculitis with neutrophilic infiltration. Pyoderma is often refractory to treatment; options include intralesional, topical, and systemic corticosteroids, and immunosuppressive drugs. Colectomy does not reliably induce healing of the skin lesion.

Ocular Associations

The eye is involved in about 3% of patients with UC, often when the bowel disease is active. Episcleritis causes burning and itching accompanied by dilated blood vessels at the site of inflammation. Uveitis is more serious and often recurrent, causing headache, red eye, and blurred vision: slit lamp examination shows pus in the anterior chamber. Treatment of both disorders includes topical steroids, cycloplegics, and therapy of active UC. Prompt referral to an ophthalmologist of UC patients with ocular symptoms is advisable.

Thromboembolism

A hypercoagulable state exists in both forms of IBD, leading to an increased incidence of both venous and arterial thromboembolism. This involves all components of the clotting system with elevations of fibrinogen, factor V, and factor VIII, and reduction of antithrombin III concentrations. There is also increased activation of platelets. Patients particularly at risk of thromboembolic complications are those with active disease.

INVESTIGATION

The aims of evaluative tests in UC are to establish the diagnosis and the extent and activity of the disease, to check for complications of the disease, and to guide treatment. In patients aged less than 50 years, the main differential diagnoses include infection and irritable bowel syndrome; while in older people, the differential diagnoses are primarily neoplasia, diverticular disease, and ischemia.

FIGURE 6 Pyoderma gangrenosum. Reproduced from D. S. Rampton and F. Shanahan (2000), *Fast Facts—Inflammatory Bowel Disease*, with permission of Health Press Ltd., Oxford.

Blood Tests

In patients with abdominal pain and/or diarrhea, results indicating anemia, elevated platelet count, and elevated erythrocyte sedimentation rate (ESR) may suggest active UC, but are not diagnostic. Elevated C-reactive protein and low serum albumin levels suggest active disease in patients with established UC; prior to diagnosis, they are only suggestive but not diagnostic of UC.

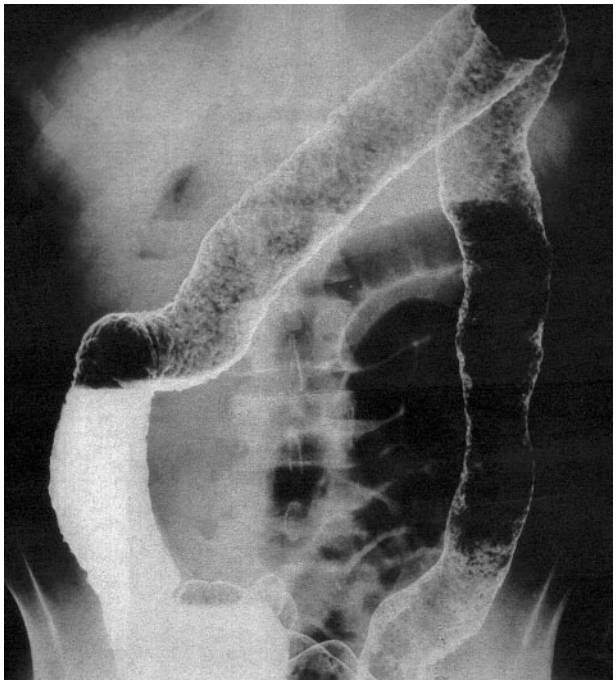

FIGURE 7 Barium enema, showing superficial ulceration in active total UC. This test has now been largely superseded by colonoscopy in patients with UC; both tests are potentially dangerous in active disease.

Liver function is abnormal in patients with hepatobiliary complications (Table III), and requires regular monitoring of patients on immunosuppressive therapy. Most patients with UC have circulating perinuclear antineutrophil antibodies, but the test for pANCAs is not sufficiently sensitive or specific to be of diagnostic value.

Regular blood checks are necessary to check for bone marrow depression and hepatitis in patients maintained on immunosuppressive drugs. Patients on sulfasalazine are, additionally, at risk for hemolytic anemia and folate deficiency.

Stool Microbiology

Stool microscopy shows red and white blood cells in active colitis, whether due to IBD or infection. Hot, fresh samples are essential to look for amebic trophozoites in stools of recent travelers. Even in patients with known UC, microbiological testing of stools may reveal associated infection when patients relapse.

Endoscopy and Histopathology

In patients with diarrhea, with or without rectal bleeding, rigid or flexible sigmoidoscopy with biopsy can provide immediate confirmation of colitis and its activity (Figs. 3 and 4). In patients who are not severely ill, colonoscopy is the best test for diagnosing UC and assessing its extent and activity. In acute severe UC, full colonoscopy may cause perforation and should be avoided. Inactive UC is characterized by mucosal edema, erythema, and granularity, whereas in active disease, there is also contact or spontaneous bleeding, mucopus, and ulceration (Fig. 3). In chronic UC, there are pseudopolyps and loss of the haustral pattern, with apparent shortening of the colon, and the mucosa may be atrophic. Colonoscopy is used for cancer surveillance in chronic extensive UC.

Radiology

In patients with active UC, a plain abdominal radiograph sometimes helps to assess disease extent, because fecal residue on the X ray may indicate sites of uninflamed colonic mucosa. Plain films are also used to exclude colonic dilatation (diameter more than 5.5 cm) in acute severe UC; in this setting, severe disease is also indicated by deep ulceration and coarse nodularity of the mucosa, or "mucosal islands," and linear gas tracking in the gut wall.

Double-contrast barium enema (Fig. 7) has largely been superseded by colonoscopy. In patients with active colitis, "air enemas," in which air is introduced into the

FIGURE 8 [^{99m}Tc]Hexamethylene propyleneamine oxime-labeled leukocyte scanning appearance of active UC, showing inflammation affecting colon up to hepatic flexure (extensive colitis).

unprepared rectum, are sometimes used to assess disease extent.

The intensity and extent of colonic uptake on an isotope scan taken 1 hour after injection of autologous leukocytes radiolabeled with [^{99m}Tc]hexamethylene propyleneamine oxime (HMPAO) provides information, noninvasively, about disease activity and extent (Fig. 8). Increased isotopic activity is not specific for UC and can also occur in other inflammatory gut diseases.

DRUGS USED IN THE TREATMENT OF UC

The mechanism of action, pharmacology, and side effects of drugs used as specific antiinflammatory agents in UC are discussed in the following sections.

Corticosteroids

By combining with intracellular glucocorticoid receptors, corticosteroids have multiple antiinflammatory actions (Table IV), but which of these is of predominant importance is unclear. Corticosteroids can be given intravenously, orally, or topically, the route selected depending on the severity and site of disease (Table IV). The side effects of conventional steroids have prompted a search for safer formulations. For topical therapy, two enema preparations (budesonide and prednisolone metasulfobenzoate) contain steroids that are poorly absorbed and/or undergo rapid first-pass hepatic metabolism, thereby producing fewer side effects and less adrenocortical suppression compared to other steroid enemas. Oral formulations are being developed to release prednisolone in the colon and thus reduce its systemic absorption and side effects. The many

side-effects of steroids are related to dose and duration of treatment except in avascular osteonecrosis.

Aminosalicylates

Like corticosteroids, 5-aminosalicylates have numerous antiinflammatory effects. Aminosalicylates are available orally (Table V) and as enemas and suppositories (Table VI). The original compound, sulfasalazine (Fig. 9), consists of 5ASA linked by an azo bond to sulfapyridine (Table V). The sulfonamide acts as a carrier to deliver 5ASA, the active moiety, to the colon, where it is released by bacterial action. About 20% of patients cannot tolerate sulfasalazine because of side effects, which are mostly due to sulfapyridine (Table VI). The newer oral 5ASA formulations (Table V) are much better tolerated. The pH-dependent delayed-release and, particularly, slow-release mesalazine preparations release 5ASA more proximally in the gut, making them useful in small-bowel CD as well as in UC and Crohn's colitis. In contrast, olsalazine and balsalazide, like sulfasalazine, release 5ASA by bacterial azo reduction in the colon and are used only in UC.

Although better tolerated than sulfasalazine, the newer 5ASA formulations (Table V) may also cause rash, headache, nausea, diarrhea, exacerbation of UC, pancreatitis, and/or blood dyscrasias (Table VI). Interstitial nephritis occurs in about 0.2% of patients on mesalazine, and watery diarrhea occurs in about 5% of patients on olsalazine.

Azathioprine and 6-Mercaptopurine

Azathioprine is a prodrug that is rapidly converted to 6-mercaptopurine (6MP). Azathioprine and 6MP (Table VII) modify the immune response by inhibiting DNA synthesis in T lymphocytes. Both drugs are used only orally and take up to 4 months to reach maximum efficacy. Homozygous deficiency of 6-thiopurine methyltransferase (TPMT), an enzyme causing their degradation, occurs in about 0.2% of the population and accounts for some of the side effects of these drugs, particularly bone marrow suppression.

Up to 20% of patients cannot tolerate azathioprine because of nausea, rash, fever, arthralgia, abdominal pain, and headache; for some patients, a switch to 6MP averts these problems. Acute pancreatitis occurs in about 3% of patients. Their other potentially serious side effects, bone marrow depression (particularly in the first few weeks of treatment; 2% of patients) and cholestatic hepatitis (0.5% of patients), necessitate regular blood monitoring; if available, TPMT levels should be checked prior to therapy to exclude a deficiency of this enzyme. There is an increased risk of infections. Long-term use may increase the risk of malignancy, particularly lymphoma.

Ciclosporin

Ciclosporin is a fungus-derived cyclic undecapeptide that reduces T helper cell and cytotoxic T cell function by inhibiting interleukin-2 (IL-2) gene transcription. The variable absorption of the conventional oral preparation (Sandimmun) necessitates intravenous therapy in active disease. Close monitoring of blood concentrations is used to optimize ciclosporin dosage. Because the cytochrome P450 enzyme system metabolizes ciclosporin, grapefruit juice, St. John's wort, and drugs that modify ciclosporin activity should be avoided. The most serious side effects of ciclosporin (Table VIII) are opportunistic infections (20% of patients), renal impairment (20%), hypertension (30%), hepatotoxicity (20%), and epileptic fits (3%).

Long-term use, for which there is no clear indication in UC, may predispose to lymphoma.

Antibiotics

Limited data suggest that oral tobramycin may improve outcome in acute severe UC. However, the use of antibiotics is usually restricted to bacteremia and endotoxic shock complicating severe acute colitis.

Other New Therapeutic Approaches

Recognition of altered cytokine expression in IBD has prompted trials using a variety of cytokine-related therapies (Table IX), of which only antitumor necrosis factor α (anti-TNFα) antibody (infliximab) has reached clinical use for refractory CD. In the longer term, it is possible that gene transfer techniques will be used to induce intestinal mucosal production of antiinflammatory cytokines such as IL-4 and IL-10.

Progressive elucidation of the pathogenesis of UC has led to the evaluation of a number of further therapies aimed at specific pathophysiological targets (Table IX). Although none has yet reached routine application, there is currently major interest in the possible therapeutic role of orally administered preparations of bacteria, or "probiotics," thought to have a beneficial effect on mucosal immune function. Recent trials suggest that capsules containing *Lactobacillus*, *Bifidobacterium*, and/or nonpathogenic *Escherichia coli* may have a prophylactic effect in UC and pouchitis, but further studies are needed to clarify their efficacy and safety.

MEDICAL MANAGEMENT

Treatment in UC is aimed to induce and then maintain remission. Management of UC comprises general measures, supportive treatment, and specific pharmacological and surgical therapies (Table X).

General Measures

Explanation and Psychosocial Support

Patients with newly diagnosed UC need a full explanation about their disease. This process can be facilitated by written information provided by patient support groups such as the Crohn's and Colitis Foundation of America (United States) and the National Association for Colitis and Crohn's Disease (United Kingdom). Services offered by such groups include not only educational literature and web sites, but also

Oral: Azathioprine (2–2.5 mg/kg/day), 6-mercaptopurine (1–1.5 mg/kg/day)
Indications
Steroid-dependent or -refractory UC
Side effects
General: Nausea, vomiting, abdominal pain, headache, arthralgia, fever, rash
Blood: Agranulocytosis, thrombocytopenia, macrocytosis
Infections: Opportunistic, including cytomegalovirus, herpes zoster
Hepatobiliary: Cholestatic hepatitis, acute pancreatitis
Malignancy: Lymphoma
Mechanism of action
Inhibition of T cell DNA synthesis

meetings at which patients and their families can share their problems, and counseling for individuals with difficulties relating to their illness. These groups can also direct patients to appropriate agencies in relation to employment and insurance problems. Importantly, support groups can exert political pressure to help maximize accessibility of health services and to generate funds for research.

Hospital Care

Patients with UC are best managed, whether as outpatients or during admission to hospital, by specialist gastroenterological medical, surgical, nursing, and dietetic staff working in collaboration, and with access to stoma therapists and counselors. Specialist IBD clinics are the best way of providing patients with joint medical/surgical consultations with open access for early review in the event of relapse (Table X).

TABLE VIII Ciclosporin

Preparations
Oral (5–8 mg/kg/day)
Intravenous (4 mg/kg/day)
Indication
Steroid-refractory acute severe UC (intravenous then oral)
Side effects
General: Nausea, vomiting, headache
Renal: Interstitial nephritis
Infection: Opportunistic, including *Pneumocystis carinii* pneumonia
Neurological: Epileptic fits, paresthesia, myopathy
Hypertension
Skin: Hypertrichosis, gingival hypertrophy
Metabolic: Hyperkalemia, hypomagnesemia, hyperuricemia
Liver: Cholestatic hepatitis
Malignancy: Lymphoma
Mechanism of action
Inhibition of T cell function and proliferation

Drugs

Iron and folic acid supplements are sometimes needed, as are drugs for osteoporosis. Antidiarrheal (loperamide, codeine phosphate, or diphenoxylate), opioid analgesic, antispasmodic, and anticholinergic drugs are avoided in active UC because they may provoke acute colonic dilatation. NSAIDs, and occasionally antibiotics, may provoke relapse of UC, and are not used unless essential.

Treatment of Active UC

Treatment in active UC is determined by the extent of disease and the severity of the attack. Knowledge of the extent of disease determines the feasibility of topical therapy, whereas the severity of the attack defines the optimal type and route of therapy, and whether patients can be treated as out-patients or need hospital admission.

In-Patient Management of Acute Severe UC

General measures These patients are admitted immediately to a gastroenterology ward for close joint medical, surgical, and nursing care. History and investigations help establish the diagnosis in patients presenting for the first time and, in those with established UC, exclude infection and assess disease extent and severity. Progress is monitored daily by clinical assessment, stool chart, 6-hourly measurement of temperature and pulse, blood count, ESR, C-reactive protein, routine biochemistry, and plain abdominal X ray.

Supportive treatment Intravenous fluids and electrolytes are required to replace diarrheal losses. Blood transfusion may be necessary. Patients can usually eat normally, with liquid protein and calorie supplements if necessary. Very sick patients may need total parenteral nutrition. To reduce the risk of venous and arterial thromboembolism, prophylactic subcutaneous heparin is given.

Specific medical treatment The cornerstone of specific medical treatment of acute severe UC remains corticosteroids. Ciclosporin is a useful adjunct, but thiopurines are too slow to work in patients with acute steroid-refractory attacks. 5ASAs (Tables V and VI) are continued in patients taking them on admission, but do not have a major role in acute severe UC.

Hydrocortisone (300–400 mg/day) or methylprednisolone (40–60 mg/day) (Table IV) given intravenously will improve about 70% of patients in 5–7 days.

TABLE IX Potential New Treatments for UC Aimed at Specific Pathophysiological Targets

Target	Agent[a]
Colonic bacterial flora	Probiotics (*Lactobacillus*, nonpathogenic *Escherichia coli*)
Epithelium	Short-chain fatty acid enemas, trefoil peptides
Leukocytes	
Reduce numbers	Apheresis, anti-CD4 antibodies
Reduce migration	Adhesion molecule antibodies or antisense oligonucleotides
Cytokines	
Reduce proinflammatory cytokines	NF-κB antisense oligonucleotide
Antagonize inflammatory cytokines	Anti-TNF antibodies, anti-IL-12 antibodies, IL-1, IL-2
Receptor antagonist	
Increase antiinflammatory cytokines	IL-10, IL-11, TGF-β, IL-4 gene therapy
Mediators	Cytoprotective prostaglandins
	Synthesis inhibitors and receptor antagonists of leukotrienes, thromboxanes
	Antioxidants
	Inducible NOS inhibitors
	Fish oil (eicosapentaenoic acid)
	metalloproteinase inhibitors
Vasculature	Heparin
Enteric nerves	Local anesthetics (lignocaine enemas)
Unknown targets	Nicotine

Oral prednisolone (40–60 mg/day) is then used to induce complete remission, tapering the dose to zero over 2–3 months. Conventionally, failure to respond to intravenous steroids after 5–7 days has indicated urgent colectomy, but use of ciclosporin is now an alternative.

Intravenous ciclosporin (4 mg/kg/day for 5 days) followed by oral ciclosporin (5–8 mg/kg/day) (Table VIII), given with continued steroids, averts colectomy in about 70% of patients not responding to intravenous steroids alone. Enthusiasm for this treatment has to be tempered by the frequency of relapse necessitating colectomy (up to 50%) that follows later withdrawal of ciclosporin, and by its serious adverse effects (Table VIII).

Toxic megacolon In sick patients with clinical and/or radiological evidence of incipient colonic dilatation, rolling into the knee–elbow position for 15 minutes every 2 hours may help to evacuate gas per rectum and prevent toxic megacolon. If colonic dilatation does occur, immediate surgery is needed if patients do not improve after 24 hours of treatment with rolling, antibiotics, and a nasogastric tube to aspirate bowel contents.

Colonic perforation and massive hemorrhage Emergency surgery is required for these rare complications of severe UC. Even with immediate surgery, the mortality of colonic perforation approaches 30%.

Active Left-Sided or Extensive UC

The principles of management of moderate attacks of UC resemble those described above. These patients, however, do not usually need hospital admission. Stools are examined to exclude infection. In mild attacks, an oral 5ASA (Table V), with twice daily 5ASA or steroid enemas, may suffice. Prednisolone, 20–60 mg/day for 2–4 weeks, depending on the severity of the attack, may be needed to induce remission, followed by gradual reduction of the dose to zero. About 30% of patients fail to respond to these measures within 2 weeks, or deteriorate, and need more intensive management. An alternative treatment in steroid-refractory patients who are not acutely ill, and in whom a response taking up to 4 months is acceptable, is oral azathioprine

(2–2.5 mg/kg/day) or 6-mercaptopurine (1–1.5 mg/kg/day) (Table VII).

Active Proctitis

The principles of treating proctitis resemble those for more extensive UC. Any coexisting constipation is treated with a high-fiber diet and/or a stool-softening laxative. Topical treatment is usually used in order to obtain increased drug concentrations in the rectal mucosa, without the risk of systemic side effects. Depending on disease extent, suppositories or enemas of 5ASA (Table V) or corticosteroids (Table IV) are used; up to 80% of patients respond in 4 weeks. In patients with unresponsive proctitis, options include oral or intravenous corticosteroids, and a thiopurine. Arsenic-containing suppositories (Acetarsol) may help but, to avoid toxicity, should not be used for more than 4 weeks. Experimental possibilities include ciclosporin, short-chain fatty acid or lignocaine enemas, and nicotine patches (Table IX). If all medical treatments fail, patients require panproctocolectomy, because limited colectomy has too high a recurrence rate to be a practicable option.

Maintenance of Remission of UC

An oral regimen of 5ASA for life (Table V) reduces annual relapse rate of UC to 25%, compared with 75% with no treatment. Some patients with recurrent attacks of distal disease prefer prophylactic 5ASA therapy given as daily or alternate daily enemas or suppositories. Patients with disease of limited extent and having relapses less than once a year may decline maintenance therapy. In patients who relapse repeatedly despite a 5ASA drug regimen, and/or when steroids are withdrawn after acute episodes, oral azathioprine or 6-mercaptopurine, monitored and given for at least 2 years, is of proved benefit.

Surveillance for Colorectal Cancer

The increased risk of colorectal cancer in chronic extensive UC (about 20% at 30 years after diagnosis) has led to colonoscopic surveillance, in which multiple biopsies from throughout the colon, and from any raised lesions, are taken every 1–3 years starting 8–10 years after diagnosis. If the biopsies show the premalignant changes of high-grade epithelial dysplasia (Fig. 10), colectomy is necessary. If there is confirmed low-grade dysplasia, either colectomy or, in patients reluctant to have surgery, more frequent surveillance is needed. Unfortunately, such surveillance has not yet been shown to reduce mortality from colon cancer in UC, perhaps because 25% of cancers occur in patients without dysplasia. Molecular biological techniques (e.g., DNA aneuploidy, p53 heterozygosity) are likely soon to supersede detection of dysplasia for cancer prevention in UC.

SURGICAL MANAGEMENT

The management of UC requires close liaison between physician and surgeon. Specialist care from a stoma therapist is also necessary. About 30% of patients with total UC require colectomy by 15 years after its onset.

Indications for Surgery

Indications for surgery can be categorized as follows:

1. Emergency colectomy is necessary in patients with colonic perforation or massive hemorrhage.
2. Urgent colectomy is necessary in patients with acute severe UC who fail to respond to intensive medical treatment in 5–7 days, or who develop unresponsive toxic colonic dilatation.
3. Elective colectomy is indicated in refractory chronic active UC, dysplasia, or frank carcinoma. Colectomy may be necessary in children with chronically active disease to prevent growth retardation and, very rarely, in patients with intractable pyoderma gangrenosum.

Options

There are several options for surgical management of UC (Fig. 11):

1. Proctocolectomy with permanent ileostomy has the lowest morbidity and mortality of the surgical options, is technically the easiest, and involves only one operation.
2. Colectomy with ileorectal anastomosis is useful in older patients with rectal sparing who cannot cope with a stoma or are unsuitable for an ileoanal pouch because of frailty or a weak anal sphincter. This option should not be chosen for patients with marked rectal inflammation, or for young patients (because of the risk of later rectal cancer).
3. Restorative proctocolectomy with ileoanal pouch avoids the need for permanent ileostomy. It is the favored operation in patients less than 60 years old with normal anal sphincter function. Construction of an ileoanal pouch usually requires a temporary ileostomy that is closed at a second operation a few months later.

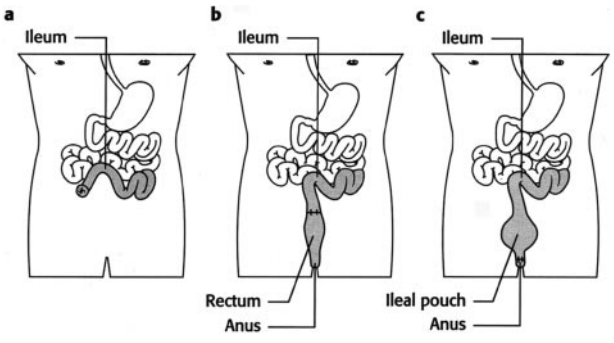

FIGURE 11 Surgical options in UC: (a) panproctocolectomy with ileostomy, (b) subtotal colectomy with ileorectal anastomosis, and (c) total colectomy with ileoanal pouch.

TABLE XI Complications of Ileostomy and Ileoanal Pouches

Ileostomy	Ileoanal pouch
Early	**Early**
Skin problems	Pelvic sepsis
Adhesive intestinal obstruction	Anastomotic leaks
Necrosis, fistulas, retraction, parastomal herniation	Adhesive intestinal obstruction
Excess stomal output (normal, approx. 500 ml/day)	
Late	**Late**
Sexual dysfunction	Poor function: diarrhea, urgency, incontinence
Uric acid renal stones	Sexual dysfunction
Pouchitis	
Vitamin B_{12} deficiency	

Complications

Complications of ileostomy and ileoanal pouch surgery are outlined in Table XI. Complications of ileoanal pouch surgery can lead to excision of the pouch and conversion to permanent ileostomy ("pouch failure") in about 10% of patients. Even after successful pouch surgery, daytime stool frequency is 4–7, urgency is common, and nocturnal incontinence is present in about 20% of patients.

About 30% of patients with pouches develop pouch mucosal inflammation of unknown etiology. The diagnosis of pouchitis is made in patients with worsening diarrhea, endoscopic signs of pouch inflammation, and acute inflammation histologically. Treatments include oral metronidazole and topical or oral steroids or 5ASAs (Tables IV and V). Probiotic therapy is a novel option, but a minority of patients with refractory pouchitis require pouch resection and a permanent ileostomy.

UC IN PREGNANCY AND CHILDHOOD

Fertility, Pregnancy, and Lactation

Female fertility is normal except in active UC. Male fertility in patients taking sulfasalazine is reduced as a result of azospermia, but this can be reversed within a few weeks by switching to a different 5ASA (Table V). Although the outcome of pregnancy is normal in quiescent UC, there is an increased rate of spontaneous abortion, premature delivery, and stillbirth in persistently active disease. Pregnancy has no consistent effect

on the activity of UC, although the disease occasionally flares in the puerperium.

Corticosteroids and 5ASAs can be used safely during pregnancy and lactation; withholding them exposes the mother and fetus unnecessarily to the risks of active disease. Although their teratogenic potential means that thiopurines should be avoided during pregnancy if possible, accidental pregnancies in patients taking these drugs have been uneventful. Surgery is occasionally necessary in very sick patients but has a high rate of fetal loss.

Childhood

UC may occur in children of any age. Allergy to protein in milk from cows produces a similar syndrome in babies after weaning and needs to be excluded. The diagnosis of UC in children is often delayed; it needs to be considered early not only in patients with diarrhea, but also in those with delayed growth and puberty. Prompt referral to a pediatric gastroenterology unit is advised for appropriate investigation.

The principles of treatment of UC in children resemble those in adults. However, the adverse effects of UC corticosteriods on growth and pubertal development mean that active UC should be suppressed promptly, undernutrition reversed, and prolonged courses of corticosteroids avoided. To maintain growth and development, prepubertal colectomy may be necessary. Azathioprine is a useful steroid-sparing agent in children for whom surgery is inappropriate or is declined.

PROGNOSIS

The risk of death in UC is highest in the first year of diagnosis and relates mainly to acute severe UC. In this setting, risk of death is now less than 2%. The overall mortality of patients with UC resembles that of the normal population.

FUTURE TRENDS

The intense research effort underway to clarify the genetics of inflammatory bowel disease is likely to have a major impact on its management. Identification of the genes involved, and the proteins they encode, will shed new light on the pathogenesis of the disease and is likely in turn to lead to new treatments. Such information will enable us to identify relatives of index patients who are at risk of developing IBD, to facilitate diagnosis, to predict the phenotype and natural history of the disease, and to determine the likely response of individuals to specific therapies. Advances in molecular biology are likely also to enable us to specify which patients with UC are at particular risk of developing colorectal cancer, such that colonoscopic screening may become obsolete.

Whatever advances are made in the coming years, the management of patients with UC will continue to require close collaboration between physicians, surgeons, nurses, dietitians, and counselors. Most importantly, the patient with UC must be viewed as a person rather than a case. As management becomes more complex, and the options more varied, it is essential that the patient remains at the center of the decision-making process: the individual with UC must be the final arbiter of the type of therapy he or she is to be given.

Colitis, Ulcerative (Pediatric)

Ulcerative colitis (UC), a chronic inflammatory bowel disease, is an important pediatric gastrointestinal disorder. It is a condition that causes significant morbidity, and rarely mortality, in children and adolescents. Despite the increased understanding of its pathophysiology and novel medical therapy, UC remains medically incurable. However, current medical and surgical therapeutic options have improved the overall outlook for children with UC.

EPIDEMIOLOGY

The incidence of ulcerative colitis (UC) appears to have remained fairly stable over the past 30 years, with a reported incidence in children of 1.5 to 10 cases per 100,000 and a prevalence of 18 to 30 per 100,000. Males and females are equally affected. Although presentation during adolescence is common, as many as 40% of children present before the age of 10 years and a number of well-documented cases have developed before the first birthday.

Risk factors associated with the development of UC during childhood include ethnic background and a positive family history of inflammatory bowel disease (IBD). Ashkenazic Jews are affected more often than other Caucasians, and Caucasians are affected more often than African Americans. Overall, 10 to 15% of children with UC have first-degree relatives with IBD. Although cigarette smoking apparently protects against the development of UC in adult populations, the data regarding exposure to cigarette smoke as a risk factor for the development of UC in childhood are less clear-cut. Epidemiological studies have documented, however, that passive smoking during childhood protects against the development of UC in adulthood.

GENETICS

The search for genes associated with the development of ulcerative colitis has begun to uncover intriguing possibilities. Genome-wide screens have suggested that there may be significant genetic heterogeneity between different ethnic and racial populations with UC. Interest has focused on the human leukocyte antigens for many years. Studies in both the United States and Japan have suggested a significant association between specific HLA-DR2 alleles and the development of UC. More recent studies from Korea and Mexico suggest a similar association with human leukocyte antigen (HLA)-DRB1 alleles. Gene mutations in the intracellular adhesion molecule (ICAM)-1 gene and the tumor necrosis factor (TNF) (or another nearby) gene have also been identified more frequently in patients with UC than in healthy populations or those with Crohn's disease. Finally, a recent report has identified a genetic polymorphism in the multidrug resistance 1 (MDR1) gene, associated with decreased production of P-glycoprotein, which is found more frequently in patients with UC than in controls. This abnormality likely impairs colonic defenses against lumenal bacteria or toxins, resulting in a chronic immune response. This observation is of particular importance, as an MDR1 knockout mouse has been shown to develop a form of colitis similar to UC that can be prevented by antibiotics. The Crohn's disease susceptibility gene NOD2/CARD15 is not associated with UC.

Other serologic markers may identify specific genetic subsets of UC. The best defined is pANCA, a perinuclear anti-neutrophil cytoplasmic antibody that is present in approximately 70% of UC patients but in only 6% of those with Crohn's disease and 3% of healthy controls. The presence or absence of pANCA is concordant within families and also tends to correlate with the presence of HLA-DR2. UC phenotype correlates poorly with the presence or absence of pANCA, except for patients with sclerosing cholangitis and UC, who are almost always pANCA positive. The fact that not all UC patients manifest this marker strongly suggests that UC is a genetically heterogeneous disorder.

CLINICAL FEATURES

Anatomic Distribution

Pancolitis is common in children with UC, with reports suggesting frequencies of 40 to 60%. Left-sided colitis is seen in approximately one-third of children and proctitis in approximately one-quarter. Although UC is described as a disease restricted to

 Copyright 2004, Elsevier (USA). All rights reserved.

the colon, several recent reports have demonstrated that pathologic changes may also be found in the proximal gastrointestinal tract. Endoscopic studies have revealed histologic esophagitis in 15–50% of children and gastroduodenal inflammation in 25–69%. Although the presence of granulomas can support a diagnosis of Crohn's disease, inflammation in the proximal gastrointestinal tract is not a sufficient finding to exclude UC.

Symptoms and Signs

Diarrhea, rectal bleeding, and abdominal pain are almost universal. Frequent loose stool can contain either streaks of blood or clots. Children describe both tenesmus and urgency, although the former symptom is at times misinterpreted as constipation. Acute weight loss is common, but linear growth is usually maintained. When only proctitis is present, children may have stools of normal consistency, no systemic symptoms, and minimal hematochezia.

At the time of initial presentation, disease activity can be quite variable. Approximately 50% of children present with mild symptoms, characterized by fewer than four stools per day, intermittent hematochezia, and minimal if any systemic symptoms or weight loss. These children generally have normal physical examinations or only minimal tenderness on palpation of the lower abdomen. Another third of children are moderately ill, with weight loss, more frequent diarrhea, and systemic symptoms. Physical examination demonstrates more significant abdominal tenderness. An acute fulminant disease presentation, characterized by severe crampy abdominal pain, fever, more than six diarrheal stools per day, and, at times, copious rectal bleeding, is seen in the remaining 10–15% of cases. These children commonly manifest tachycardia, orthostatic hypotension, diffuse abdominal tenderness without peritoneal signs, and distension. Toxic megacolon represents the most dangerous extreme of acute, fulminant colitis, but is unusual in children.

Extraintestinal Manifestations

Extraintestinal manifestations of disease have been described in many organ systems of the body, most commonly in the hepatobiliary tree, joints, skin, and eyes. Many of these inflammatory manifestations develop during bouts of increased colitis activity. Although the cause of these manifestations remains unknown, an anti-colonocyte antibody detectable in the sera of patients with UC has been shown to cross-react with antigens present in the skin, ciliary body of the eye, bile duct, and joints. One hypothesis for the development of extraintestinal symptoms in these organs is therefore that they occur when autoantibodies capable of recognizing these nonintestinal tissues develop as part of the humoral response characteristic of UC.

Hepatobiliary Disease

Abnormal liver function tests are common in children with UC, often seen transiently during periods of increased disease activity or associated with the use of a number of treatments including corticosteroids, sulfasalazine, parenteral nutrition, azathioprine, and 6-mercaptopurine. Unfortunately, however, more significant hepatobiliary problems are also seen in association with UC. Primary sclerosing cholangitis (PSC) occurs in 3.5% and immune hepatitis in $<1\%$ of children and adolescents with UC. Both conditions may be present before or at the time of the initial diagnosis of UC or can develop at any time during the course of the illness. Although most children described in the literature appear to have mild liver disease, this may be a function of relatively short-term follow-up. In adults, PSC commonly progresses to end-stage liver disease, requiring transplantation or death from cholangiocarcinoma. Immune hepatitis may also progress to end-stage liver disease. Neither hepatobiliary disease appears to positively or negatively influence the activity of colitis, but the presence of PSC in UC has been shown to enhance the risk of colorectal aneuploidy, dysplasia, and cancer. Absolute cumulative risk for colorectal cancer in UC patients with PSC after 10, 20, and 25 years of disease is 9, 31, and 50%, respectively, compared with 2, 5, and 10%, respectively, in UC patients without PSC. Since the time to dysplasia may be accelerated, once the diagnosis of UC is made in the setting of PSC, more frequent colonoscopic surveillance may be indicated.

Joint Disorders

Arthralgias are common in children with UC and arthritis, either a peripheral migratory type affecting the large joints or a monoarticular, nondeforming type primarily affecting the knees or ankles, is reported in 10 to 20% of children. The presence and activity of arthritis usually (but not invariably) correlate with the activity of the bowel disease. Ankylosing spondylitis occurs in up to 6% of adults with UC but is rare during childhood.

Skin Disorder

Both erythema nodosum and pyoderma gangrenosum have been seen in children, generally during periods of enhanced colitis activity. Erythema nodosum lesions appear as raised, erythematous, painful circular nodules that usually occur over the tibia but may be

present on the lower leg, ankle, or extensor surface of the arm. Lesions persist for several days to as long as a few weeks, but usually remit following treatments directed at the enhanced colitis activity. Pyoderma gangrenosum usually appears as small, painful, sterile pustules that coalesce into a larger sterile abscess. This abscess usually drains, forming a deep, necrotic ulcer. Lesions usually occur on the lower extremities, although the upper extremities, trunk, and head are not spared. Although pyoderma lesions have traditionally been quite resistant to therapy, the anti-TNFα monoclonal antibody infliximab or the immune modifiers ciclosporin or tacrolimus can rapidly heal the lesions and should be considered the current treatments of choice.

Thromboembolic Disorders

There have been case reports of thromboembolic complications in children with UC. Sites of venous or arterial thrombosis include the extremities, portal or hepatic vein, lung, and central nervous system. Though the presence of factor V Leiden mutations may be associated with this hypercoaguable state, other prothrombotic inherited abnormalities and other factors, such as hyperhomocysteinemia or resistance to activated protein C, do not appear to be important.

Ocular Disorders

Severe eye disorders, such as optic neuritis, are rare in children with UC. Less serious conditions including episcleritis and asymptomatic uveitis have been described. Other ocular disorders, such as posterior subcapsular cataracts or increased ocular pressure, may result from corticosteroid therapy.

Complications

Toxic Megacolon

This complication develops rarely with current medical management, although the literature reports rates of up to 5% of children and adolescents with UC. Toxic megacolon represents a medical and potentially a surgical emergency with the potential for rapidly progressive deterioration complicated by severe electrolyte disturbances, hypoalbuminemia, hemorrhage, perforation, sepsis, and/or shock. Precipitating factors include the use of anti-diarrheal agents, such as anticholinergics or opiates, and excessive colonic distension during enema or colonoscopy.

Carcinoma

UC is a premalignant disease, with a well-documented proclivity for adenocarcinoma. A flat dysplastic mucosa rather than an adenomatous polyp represents the precursor lesion. The genetic alterations that precede the development of dysplasia occur multifocally in the colon, so that the resulting adenocarcinomas may be evenly distributed throughout the colon. Multifocal or synchronous tumors are present in 10 to 20% of patients.

Duration of disease and extent of colitis are the two most critical risk factors for cancer in UC. Because of this, children with UC have a particularly high lifetime risk of colorectal adenocarcinoma. Less well-characterized risk factors include concomitant PSC; an excluded, defunctionalized, or bypassed segment of bowel; and depressed red blood cell folate levels. Although patients as young as 16 years of age have been demonstrated to have colonic aneuploidy, dysplasia, or cancer, as in adults the risk for these changes does not appear to be significant until after the first decade of illness.

Given the high risks of colorectal cancer, surveillance colonoscopy is recommended. Studies have documented that undergoing colectomy following detection of low- or high-grade dysplasia at surveillance can reduce the risk of advanced adenocarcinoma, thereby improving mortality in populations undergoing regular surveillance. Although no prospective studies have assessed the optimal schedule of surveillance, a cost–benefit analysis suggests colonoscopies every 3 years for the first 10 years of surveillance, generally starting 7 to 10 years after diagnosis, with more frequent investigations as the duration of colitis increases. Although many advocate initiating surveillance only after 15 to 20 years of disease in adults with left-sided colitis or proctosigmoiditis, the frequent proximal extension of these disease distributions in children mandates that at least a screening colonoscopy be performed in all children 7 to 10 years after diagnosis. Subsequent frequency of surveillance can then be determined based on whether the extent of colitis has increased. Surveillance assessments require a panendoscopy to the cecum, with two to four biopsies obtained every 10 cm from the cecum to the sigmoid and every 5 cm in the sigmoid and rectum. Additional biopsies must be performed if a mass or other suspicious lesion is identified. Current recommendations for colectomy include any identification of dysplasia (low- or high-grade) confirmed by two independent, experienced pathologists. Repeat colonoscopy for confirmation of dysplasia on new biopsies is not recommended. If indefinite dysplasia is identified, aggressive medical management to reduce active inflammation, followed by repeat surveillance colonoscopy within 3 to 6 months, is indicated.

Growth and Development

In contrast to children with Crohn's disease, disturbances in growth are unusual in children with UC. Although weight loss during periods of active colitis and decreased dietary intake is common, significant impairments in linear growth occur in only approximately 10% of children with UC. Differences in the cytokine alterations and the absence of small bowel involvement in UC are postulated to explain the difference in growth patterns between these two diseases. When children with UC are growing poorly, control of active disease, avoidance of excessive corticosteroid use, and improvement in caloric intake generally result in resumption in linear growth.

DIAGNOSIS

History

Clinical symptoms, including abdominal pain, diarrhea, and rectal bleeding, are often obvious. However, in children with mild disease activity or inflammation restricted to only the rectum, symptoms may be less obvious and more difficult to elicit, especially in children or adolescents who resist discussing their bowel habits. Nocturnal bowel movements and symptoms such as weight loss, poor growth, arrested sexual development, or, in the postmenarchal adolescent, secondary amenorrhea suggest an organic rather than a functional condition. A positive family history for IBD also should suggest the need to evaluate for possible UC.

Physical Examination

Children with active UC often have mild to moderate abdominal tenderness, especially in the left lower quadrant or in the midepigastric area. With fulminant disease, marked tenderness can be present. Rebound tenderness and increasing abdominal distension are particularly ominous signs and should alert the physician to possible toxic megacolon. The perianal area is generally normal. Extraintestinal manifestations, such as arthritis, erythema nodosum, or pyoderma gangrenosum, are important clues to the autoimmune nature of the child's illness.

Laboratory Studies

Laboratory studies cannot be used to make a diagnosis of UC. Rather, recommended laboratory studies (see Table I) help exclude other illnesses and provide evidence to support proceeding to more diagnostic radiologic and endoscopic procedures. Serologic testing for pANCA may be useful, as the presence of this marker is unusual in children who do not have IBD. A negative serologic study does not, however, exclude the possibility of UC, and studies have not demonstrated significant advantage to the use of this serologic testing over more traditional laboratory screening tests. The presence of anti-*Saccharomyces cerevisiae* antibody may suggest a diagnosis of Crohn's disease rather than UC. Stool studies for enteric bacterial and parasitic pathogens must be performed to exclude infectious colitis. Given the frequency with which children are exposed to antibiotics, screening for *Clostridium difficile* toxin must also be performed. If pathogens are present, monitoring the child's response to treatment is necessary, as it is not unusual for children with UC to present initially with superimposed infection. Microcytic anemia, mild to moderate thrombocytosis, elevated erythrocyte sedimentation rate, and hypoalbuminemia are present in 40 to 80% of cases. The total leukocyte count is normal to only mildly elevated, unless the illness is complicated by acute fulminant colitis. Elevated serum aminotransferase levels are present in 3% of children at the time of initial diagnosis and reflect signs of potential serious concomitant liver disease (chronic active hepatitis or PSC) in approximately half of them. In a number of children, however, all laboratory studies are normal.

Radiography

Radiographic studies have a limited role in the evaluation of a child with suspected UC. Barium enema is only rarely indicated, having been replaced by

colonoscopy. Abdominal ultrasound and computed tomography (CT) offer little help to establish the diagnosis. Plain films of the abdomen are important in determining the degree of colonic distension and the presence of possible toxic megacolon or perforation. In most circumstances, however, the child with suspected UC should undergo an upper gastrointestinal series with small bowel follow-through to help exclude the possibility of Crohn's disease. CT may also be helpful in this regard.

Endoscopy and Histology

Colonoscopy provides the best means of diagnosing UC, as the procedure allows direct visualization and biopsy of the mucosa of the entire colon. This provides the physician with the ability to accurately determine the extent, distribution, and histologic characteristics of the disease. Typically, UC is characterized by diffuse inflammation that begins at the anal verge and progresses proximally to a variable degree. Whereas rectal sparing is generally thought to indicate Crohn's disease, untreated children with UC have been described with rectal sparing at initial evaluation, only to manifest findings of typical UC at a later date. Endoscopically, active UC is characterized by diffuse exudates, ulceration, and marked hemorrhage. With milder disease activity, the mucosa may only appear erythematous, with loss of the normal vascular markings and increased contact friability. All children who undergo endoscopy should be biopsied. Mucosal biopsies are characterized by neutrophilic infiltration of the crypts, crypt abscesses, goblet cell depletion, crypt distortion, and a papillary configuration to the surface epithelium. Although these findings are not pathognemonic for UC (as they can be seen in cases of severe Crohn's colitis), the biopsies often allow differentiation between UC and both self-limited colitis and most cases of Crohn's disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for the child or adolescent with suspected UC is summarized in Table II. Though much of the differential diagnosis will be the same for children of all ages, as noted in Table II, a number of these conditions are likely to occur only in the very young. Similarly, a number of conditions in the differential diagnosis list can be excluded simply by ascertaining whether or not there is blood in the stool.

MEDICAL THERAPIES

Despite extensive research, UC remains medically incurable. Treatment is therefore designed to minimize symptoms and improve a child's quality of life with the hope that complications can be avoided or controlled with a minimum of treatment-induced toxicity. Unfortunately, as pediatric trials are limited, much of the data supporting the currently recommended treatments for children with UC have been extrapolated from adult studies. The following discussion focuses on those aspects of treatment that have been shown to be particularly effective in or unique to the pediatric population.

Nutritional Therapy

No nutritional or dietary therapies have been shown to be effective as primary treatment for children with UC. Rare children may benefit from an exclusion diet, presumably because their particular illness is at least in part an allergy rather than ulcerative colitis. Such a

patient is the exception, however, rather than the rule. Possibly because the colonocyte derives energy from short-chain fatty acids in the fecal stream, bowel rest to reduce the frequency of bowel movements is not effective therapy. Although preliminary treatment trials using short-chain fatty acids have demonstrated modest benefits in adults with UC, no pediatric trials have been reported. Supplementation of the diet with omega-3 fatty acids (fish oils) has been shown to offer some protection against early relapse in adults with UC, but again there are no comparable studies in children. Nutritional interventions in UC are therefore generally adjunctive to other treatments. Assurance of an adequate dietary intake promotes normal growth and prevents catabolism, thereby enhancing the effect of other treatment modalities. Nutritional support can be accomplished successfully by a number of approaches, including dietary supplementation and enteral or parenteral nutrition.

Corticosteroids

Corticosteroids remain the gold standard for inducing remission in children with moderate to severe colitis. These agents are not, however, effective or safe for maintaining remission. Their use in children with UC has largely been extrapolated from trials in adults, with current recommendations evolving from empiric use and clinical experience rather than controlled clinical trials. Systemically acting agents, including prednisone, methylprednisone, and hydrocortisone, are most frequently prescribed and result in response rates of 65–90% in children with moderate to severe disease. Intravenous and rectal formulations in addition to oral preparations make these medications suitable for a wide variety of treatment scenarios. Rectal preparations, including enemas, foams, and suppositories, are particularly suitable as adjunctive therapy for the child with severe tenesmus and urgency and may be the only treatment required in cases of limited proctitis. The use of corticosteroids must be weighed against their potential adverse effects (see Table III). Systemically active corticosteroids can interfere with linear bone growth even in the face of adequate dietary intake. Alternate-day dosing can minimize these effects while maintaining reduced disease activity and appears to have only limited deleterious effects on bone mineralization in children. However, in most cases, the deleterious effects of an extended course of steroids as well as their limited effectiveness for maintenance of remission make the long-term use of a corticosteroid inadvisable. Newer topically active corticosteroids with high first-pass metabolism, such as budesonide, have the potential to provide anti-inflammatory activity to the gut without systemic toxicity. Such an agent may offer particular advantages for the treatment of children, but only limited pediatric trials have been reported. The enema formulation of budesonide is as effective as rectal mesalamine and rectal hydrocortisone in the treatment of left-sided and distal colitis. Multiple courses of rectal budesonide are safe and effective for recurrent flares of UC. By contrast, the oral formulation that is currently available is a controlled ileal release capsule, which may not deliver adequate medication to the distal colon for effective treatment of UC. Studies of this formulation in children with UC have not, however, been performed.

5-Aminosalicylates

Clinical experience suggests that the 5-aminosalicylate (5-ASA) drugs (sulfasalazine, mesalamine, olsalazine, balsalazide) effectively induce and maintain remission in 50–90% of children with mild to moderate UC. These agents exert local anti-inflammatory effects through a number of different mechanisms including inhibition of 5-lipoxygenase with resulting decreased

production of leukotriene B4, scavenging of reactive oxygen metabolites, prevention of the up-regulation of leukocyte adhesion molecules, and inhibition of interleukin-1 (IL-1) synthesis. 5-ASA is rapidly absorbed from the upper intestinal tract on oral ingestion and various delivery systems have been employed to prevent absorption until the active drug can be delivered to the distal small bowel and colon. Sulfasalazine (Azulfidine) links 5-ASA via an azo bond to sulfapyridine. Bacterial enzymes in the colon break the azo linkage, releasing 5-ASA to exert its anti-inflammatory effect in the colon. Because the sulfapyridine moiety causes most of the untoward reactions to sulfasalazine and is thought to have no therapeutic activity, newer agents have been designed to deliver 5-ASA without sulfapyridine. Olsalazine (Dipentum) links two molecules of 5-ASA via an azo bond, whereas balsalazide (Colazal) links 5-ASA via an azo bond to an inert, nonabsorbable carrier. A number of other delayed-release preparations (Asacol, Claversal, Mesasal, Salofalk, Pentasa) prevent rapid absorption of 5-ASA (generically called mesalamine) by coating tablets or microspheres with different materials designed to dissolve and release medication in a time- or pH-dependent manner. Uncoated mesalamine is also available as a rectal suppository (Canasa/Salofalk) or enema formulation (Rowasa), which can be of significant value in the treatment of a child with UC or proctitis. Adverse reactions to all of the 5-ASA preparations have been described and have required discontinuation of treatment in 5 to 15% of cases. Serious complications reported in pediatric patients include pancreatitis, nephritis, exacerbation of UC, and sulfa- or 5-ASA-induced allergic reactions.

Antibiotics

There is little role for antibiotics in the primary therapy of active UC. Based on experience in adults, metronidazole is occasionally used for the treatment of mild to moderate UC or for maintenance of remission in the 5-ASA-intolerant or allergic patient. A controlled trial of ciprofloxacin as an adjunct to corticosteroids in adults with active UC demonstrated no benefit compared with placebo.

Immunomodulators and Biologicals

Although colectomy "cures" UC, many parents and physicians are reluctant to perform such an operation in children with even severely active UC. As a consequence, immunomodulators and new biologic agents are increasingly being used therapeutically when chronic or intractable symptoms are present. The most commonly prescribed treatments in this category are discussed below.

6-Mercaptopurine and Azathiopurine

6-Mercaptopurine and its prodrug azathioprine are purine analogues that inhibit RNA and DNA synthesis, thereby down-regulating cytotoxic T-cell activity and delayed hypersensitivity reactions. Both medications have steroid-sparing effects and effectively maintain remission in approximately two-thirds of children with UC. Onset of action is delayed (mean time to response of 4.5 ± 3.0 months), limiting the role of these agents for the induction of remission. Adverse reactions requiring discontinuation of treatment, such as allergic reactions, pancreatitis, abnormal liver function tests, or severe leukopenia, occur in less than 5−15% of pediatric patients. The recent availability of assays to measure the active metabolites of these agents offers the prospect of further enhancing treatment efficacy while reducing toxicity.

Ciclosporin and Tacrolimus

Ciclosporin and tacrolimus (FK506) are potent inhibitors of cell-mediated immunity that have been demonstrated to rapidly and markedly reduce severe colitis activity in 20 to 80% of children with fulminant UC who might otherwise require imminent colectomy. However, relapses necessitating colectomy occur within 1 year in 70 to 100% of initial responders during or after discontinuation of therapy. By contrast, if 6-mercaptopurine or azathiopurine is added to the regimen once ciclosporin or tacrolimus has induced remission, 60 to 90% of treated patients maintain long-term remission. These agents bind to intracellular receptors, forming complexes that ultimately down-regulate the production of cytokines IL-2 and IL-4. As a consequence, T-cell function and, to a lesser extent, B-cell function are impaired.

The use of these agents has been limited by drug-induced toxicity. Tremors, hirsutism, decreased renal function, and systemic hypertension are the most common side effects that have been described in children with IBD. However, isolated reports of pneumocystis carinii pneumonia (PCP), lymphoproliferative disease, and serious bacterial and fungal infections in ciclosporin-treated patients merit careful monitoring of all children treated with either drug, especially those treated in combination with corticosteroids and 6-mercaptopurine or azathiopurine. When these agents are used, PCP prophylaxis and anti-candida therapy are indicated.

Other Immunomodulators

Limited studies in adults have suggested that methotrexate may be an effective treatment for UC in patients who are intolerant of or resistant to azathioprine. Clinical trials in children have not been performed and clinical experience with this agent in children with UC is very limited.

Infliximab

The chimeric anti-TNFα antibody, infliximab, is a potent inhibitor of TNFα. Infliximab rapidly downregulates cytokine activity in Crohn's disease. This results in a rapid and significant decrease of disease activity. A few open-label trials in adults with UC and a single small open-label trial in children have demonstrated a meaningful clinical improvement in patients with chronic intractable and severe UC. Response to a single infusion lasts 4 to 12 weeks and repeat infusions are necessary to maintain response in virtually all responsive patients. Adverse reactions are primarily related to minor infusion reactions, but only a very small number of children with UC have been treated. More severe reactions, such as delayed hypersensitivity reactions, anaphylaxis, and reactivation of latent tuberculosis, have been seen in adults and children receiving infliximab for Crohn's disease or rheumatoid arthritis.

Surgery

Curative surgery requires total proctocolectomy with a reconstructive procedure (see below). This is indicated because of intractable or fulminant disease or because of the development of dysplasia or cancer. In fact, approximately 20% of children and adolescents require colectomy within 5 years of diagnosis because of intractable disease or fulminant symptoms. Although proctocolectomy and ileostomy result in a healthy patient with no risk of future recurrence, few children or parents readily accept the option of a permanent ileostomy. Most instead opt for restorative surgery [the ileal pouch–anal anastomosis (IPAA)], which allows the child to continue to defecate by the normal route. Although this can be performed as a one-stage operation, it is often advisable to carry out an IPAA as a two- or three-stage procedure, especially when there is any preoperative suggestion that a patient might have Crohn's rather than ulcerative colitis or when large doses of steroids have been used chronically. Reviews of pediatric surgical experience document that IPAA utilizing an ileal J-pouch (or less commonly a W- or an S-pouch) results in fewer daytime and nocturnal bowel movements and less fecal soiling than an ileoanal anastomosis without a pouch. Anorectal function is well preserved in children and postoperative fecal soiling is unusual. The most common early postoperative complication of IPAA is small bowel obstruction. Pouchitis, a chronic inflammation of the ileal pouch, is the most common late complication described, occurring in 19% of children and adolescents. Pouchitis generally responds to treatment with metronidazole, ciprofloxacin, 5-ASA, or corticosteroids.

COURSE AND PROGNOSIS

Clinical experience amassed since 1975 suggests that 70% of children with UC can be expected to enter remission within 3 months of initial diagnosis, irrespective of the severity of their initial attack. Though symptoms remain inactive in 45–58% over the first year after diagnosis, 10% of those initially presenting with moderate to severe colitis can be expected to remain continuously symptomatic. In any given year over the next decade, approximately 55% of patients have inactive disease, 40% have chronic intermittent symptoms, and 5–10% have continuous symptoms. Approximately 5% of all children require colectomy within the first year after diagnosis and 19–23% require surgery within 5 years after diagnosis. These rates rise to 9 and 26%, respectively, in the subgroup of children initially presenting with moderate to severe symptoms.

Children with proctitis or proctosigmoiditis have less morbidity, as more than 90% are asymptomatic within 6 months of diagnosis and less than 5% have continuously active disease. In contrast to adults, however, proximal extension of disease may occur in up to 70% of children over the course of follow-up. Colectomy may eventually be required in 5% of these patients.

the colon sigmoideum. Conversely, the thickness of the muscle layers of the colonic wall gradually increases from the cecum to the sigmoid colon. The characteristic macroscopic appearance of the colon is given by the three separate longitudinal "teniae coli," which are formed by a concentration of fascicles of the outer muscle layer, by "haustra," i.e., protrusions of the bowel wall between the teniae and the plicae semilunares, and finally, by appendages of adipose tissue, the appendices epiploicae, scattered on the serosal surface of the colon but absent in the cecum and rectum (Fig. 1).

VERMIFORM APPENDIX

The vermiform appendix represents embryologically an extension of the cecum. It consists of a blind tube with a diameter usually measuring 0.5 to 0.8 cm and with lengths ranging from 2.5 cm to more than 20 cm (average $\sim$8 cm). It arises from the posteromedial wall of the cecum approximately 1 to 3 cm below the ileocecal junction, where the three teniae coli converge and merge into the longitudinal muscle layer of the appendix. The strong circular and longitudinal muscle layers of the vermiform appendix prevent any substantial dilation of the lumen. Although the location of the base of the appendix, with respect to the cecum, is constant, the position of the tip is extremely variable. Mainly, the vermiform appendix is found in a retrocecal and retrocolic (posterior) or in a pelvic descending (anterior) position. Other positions, such as in front of and behind the terminal ileum, or descending to the right, occur more rarely. The mesentery of the appendix consists of a peritoneal fold contiguous with the mesentery of the terminal ileum. It extends along the entire appendix length and contains the appendical vascular supply. The functions of the vermiform appendix remain a matter of debate. The presence of numerous and hyperplastic lymphoid follicles in young individuals suggests specialized functions in the context of the mucosal immune system.

CECUM AND ILEOCECAL VALVE

The cecum is generally located in the right iliacal fossa. Commonly, it is entirely covered by peritoneum and in only a small percentage of individuals is it fixed posteriorly. Grossly, the cecum is wider than it is long and, due to large haustrae located medially to the tenia libera, an asymmetric shape characterizes it. The lack of a true mesentery accounts for its increased motility, which eventually can lead to cecal volvulus or even to cecal herniation into the groin channel. The large diameter of the cecum and the characteristic thin muscular layer in this portion of the large intestine also have important clinical implications. In fact, cecal cancers may reach a considerable size before causing symptoms, and obstructing processes of the left colon or rectum can cause perforation of the cecum, the site of lowest resistance within the colon.

The ileocecal valve is characterized by two rather horizontally oriented semilunar lips protruding into the posterior medial aspect of the cecum. At their end, the two lips merge into the frenula, which extends into transverse mucosal folds dividing the cecum from the ascendens colon. Whether the ileocecal junction is a competent valve is still uncertain. In normal individuals, reflux into the terminal ileum has been observed, especially when the cecum is empty. However, by increasing intralumenal pressure in the proximal colon, for instance, by obstruction beyond the cecum, the two semilunar lips forming the ileocecal valve tend to collapse together, preventing reflux. Conversely, although the ileocecal valve is formed by an extension of the enteric musculature and not by a true sphincter, it is usually assumed that this well-innervated enterocolic junction is also important in regulating the passage of ileal contents into the cecum.

COLON

The ascending colon is mainly involved in absorptive processes that eventually lead to feces formation. The ventral aspect is covered by the peritoneum, whereas the posterior surface is retroperitoneally fixed to the iliac fascia. A poorly formed mesocolon can occasionally be observed. The anatomic relationships of the ascending colon include the right kidney and ureter, the duodenum, the liver, and the gallbladder. The right colic flexure, also called the hepatic flexure, consists of a curve at the junction with the transverse colon. A peritoneal fold

extending from the hepatorenal ligament most likely supports this portion of the large intestine. The transverse colon is entirely intraperitoneal with the exception of its right end, which is in close contact with the duodenum and the pancreas. It courses diagonally across the upper abdomen from the ventrally located hepatic flexure to the left colic (splenic) flexure, which is located in the posterior plane of the abdominal cavity in a more cranial position than its counterpart on the right (Fig. 2). The left flexure forms an acute angle fixed to the diaphragm by the phrenicocolic ligament, which also sustains the lower pole of the spleen. The position of the middle part of the transverse colon is variable. In asthenic individuals, it may reach the pelvis. The descending colon first passes the lateral border of the left kidney and then curves medially, reaching the pelvic rim. The anterior surface is covered by peritoneum, whereas the posterior face lies retroperitoneally or is occasionally sustained by a mesentery. The sigmoid colon begins at the pelvic entrance. It is characterized by an S shape of variable length, a short mesentery, and therefore good mobility. The sigmoid colon may be in close contact with the urinary bladder, the ventral surface of the upper rectum, or, in females, the uterus and annexes. The junction between the sigmoid colon and the rectum is located 15 cm from the anal verge. It is characterized by fusion of the teniae into the complete longitudinal muscle layer of the rectum and by an abrupt loss of appendices epiploicae.

HISTOLOGY

The mucosa, the submcosa, the muscle coat, and the serosa constitute the wall of the large intestine. The mucosa has no villi and is characterized by crypts arranged in parallel. It consists of a single-cell layer of tall columnar epithelium covering the surface including the crypts, smooth muscle cells of the muscularis mucosae at the base, and, in between, a stromal compartment called the lamina propria. The columnar epithelium is supported by a thin collagenous basement membrane and represents an important border between the lumenal environment of the intestine and the inner environment. It is formed by highly specialized polarized absorptive cells located mainly at the surface and at the neck of the crypts, and by goblet cells, which secrete mucus granules and are particularly abundant in the crypts. Immature precursor cells with marked proliferative activity as well as specialized endocrine cells with multiple and still not fully understood regulatory functions are found toward the crypt base. As in the small intestine, Paneth cells are regularly found in the mucosa of the cecum and ascending colon. Numerous T lymphocytes are normally present within the colonic epithelium. Occasionally, eosinophilic granulocytes may also be observed within the epithelial layer. In contrast, neutrophilic granulocytes migrate into and through the epithelial cell layer only during inflammatory processes. The lamina propria contains a heterogeneous cell population consisting mainly of leukocytes, such as plasma cells, T and B lymphocytes, macrophages, and occasionally eosinophilic granulocytes or mast cells. In addition, scattered smooth muscle cells, blood capillaries, lymphatic vessels, and nerve twiglets, but not nerve ganglia, are arranged in its loose connective tissue. Lymphoid follicles are scattered throughout the entire mucosa of the large intestine but appear to be slightly more predominant in the cecum and rectum. Morphologically, two types may be identified: one type displays a pit-like follicle-associated epithelium. Many of these lymphoid follicles extend into the submucosa. The second type is entirely intramucosal, has a flat follicle-associated epithelium, and is observed mainly in the rectum.

The submucosa of the large intestine is very wide, constituting up to approximately half of the total wall thickness. It consists mainly of loosely organized strands of collagen and elastic fibers, vascular structures including arterioles, venules, and lymphatic vessels, few leukocytes, and two neural plexuses. The plexus of Meissner is located beneath the muscularis mucosae where nerve cells and glia cells may be grouped in intramural ganglia arranged in an irregular pattern, and with declining density along the distal segments. The second submucosal

plexus, Henle' s plexus, lies adjacent to the muscularis propria. Both plexuses are connected by interganglionic fascicles. A circular inner layer and a longitudinal outer muscle layer form the muscle coat of the colon. The plexus of Auerbach, also called the plexus myentericus, lies between these two muscle layers. It is morphologically related to the submucosal plexuses, but the ganglia are generally larger and they are arranged in a more regular pattern. The interstitial cells of Cajal form a complex cell network within the gastrointestinal tract wall. They are intercalated to the autonomic nerves of the plexus myentericus and to the smooth muscle cells of the inner portion of the circular muscle layer. These cells may act as a pacemaker to regulate smooth muscle contraction. Recently, Cajal cells have been implicated as possible cells of origin of human gastrointestinal tumors. The mesothelial cells of the serosa cover the external colon surface. A thin layer of loose connective tissue, commonly called the subserosa, separates the serosa from the external muscle layer.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The superior and the inferior mesenteric arteries provide the arterial blood supply of the colon (Fig. 3). The superior mesenteric artery branches into the ileocolic, the right colic, and the middle colic arteries. They supply the terminal portion of the ileum, the vermiform appendix, the colon ascendens, and part of the transverse colon. It is noteworthy that the right colic artery is missing in approximately 10% of individuals and that an accessory middle colic artery is present in approximately 10–20%. The inferior mesenteric artery branches in the superior left colic, the sigmoid, and the superior rectal arteries. All these major branches anastomose to form a series of arterial arches constituting the marginal artery of Drummond, which lies a few centimeters from the colonic wall and extends from the ileocecal region to the rectosigmoid junction. The connection between the middle colic artery and the left colic artery is called the arc of Riolan. It is located approximately at the junction between the transverse and the descending colon and connects the domains of the superior and inferior mesenteric artery. The arc of Riolan is absent in 0.1–1% of individuals. From the marginal artery, multiple small arteries, the arteriae rectae, enter the colonic wall along the line of the mesenteric insertion, where they branch to arterioles that extend symmetrically to the anti-mesenteric side and penetrate the muscular coat to reach the mucosa. The venous return reflects the arterial supply and thus bears the same names. The superior mesenteric and the splenic vein converge to the portal vein. The inferior mesenteric vein leads mostly into the splenic vein, rarely directly into the portal vein, and extremely rarely into the superior mesenteric vein. A peculiarity of the portal venous system is the absence of valves, which may lead to severe intestinal blood congestion by portal hypertension.

The lymphatic drainage follows in general the mesenteric vessels and converges to the cisterna chyli. The lymph channels pass several lymph nodes, which may be grossly gathered in four groups: the epicolic lymph nodes adjacent to the colonic wall; the paracolic lymph nodes, situated along the marginal arteries; the intermediate lymph nodes, alongside the main mesenteric vessels; and the central lymph nodes, at the mesenteric roots.

INNERVATION

The motor and secretory activities of the colon are regulated by the autonomic nervous system and by the neurohormonal system, which includes a complex network of modulators, such as serotonin, dopamine, somatostatin, bombesin, Substance P, and vasoactive intestinal peptides. The autonomic nervous system includes the sympathetic and parasympathetic pathways and it may be divided into components intrinsic or extrinsic to the colon, i.e., lying within or outside the colon wall, respectively. The intrinsic component is formed mainly by the neural plexuses described

above. It has a great functional significance since it is capable of working independently of the extrinsic component.

The extrinsic component of the parasympathetic innervation is formed by fibers originating either from the medulla oblongata or from the sacral segments of the spinal cord. The fibers from the medulla oblongata are gathered mainly in the vagus nerve, which descends along the esophagus, ramifies in the preaortal celiac regions, and extends approximately to the left third of the transverse colon. Synapses are formed in the ganglia of the submucosal plexus and the myenteric plexus. The sacral parasympathetic nerves form the pelvic nerves, which are located within the hypogastric plexus and contribute to the innervation of the distal colon segments. Conversely, the afferent sympathetic innervation originates from thoracic and lumbar segments of the spinal cord as part of the anterior spinal nerves. It then transverse the sympathetic ganglionic chain, mostly without making synapses, and forms the splanchnic nerves, which meet synapses located in preaortic ganglia, namely, the celiac, superior mesenteric, inferior mesenteric, and pelvic ganglia. The postganglionic adrenergic fibers eventually reach the colon along the adventitia of the arteries. Connections between the preaortic ganglia are numerous and as a consequence the respective innervation zones of the large intestine overlap to a considerable degree.

absorption Active or passive movement of a substance from the lumen of the gut (mucosal side) to the blood side of the gut (serosal).
apical membrane Side of an epithelial cell that faces toward the lumen, outside of the body; the mucosal side.
basolateral membrane Side of an epithelial cell that faces toward the blood or inside of the body; the serosal side.
conductance Electrogenic movement of a charged particle.
constipation Condition in which there is infrequent or difficult defecation or hard and dry stool.
cotransporter Membrane protein with which one or more substances are moved in concert. Typically, the energy gradient of one substance (almost always Na^+) is used to establish a gradient for the other(s).
crypts of Lieberkuhn Invaginations in the surface of the colonic mucosa, predominant location of fluid secretory processes. The base of the crypt contains the progenitor cells for the entire crypt as well as surface cells.
diarrhea Condition in which there is a two- to threefold or greater increase in the normal amount of fecal water content (approximately 300–450+ ml/day).
ion channel Membrane protein that forms a selective and regulated pore for the diffusion of a particular ion or ions. The direction of movement is dependent on the electrochemical driving force for the given ion, which is determined by the concentration of ion on each side of the membrane and the electrical potential across the membrane.
ion exchangers Subclass of cotransporters that move substances in opposite directions; antiporters.
ion pump Membrane protein in which ATP hydrolysis is used as an energy source to move one or more ions across the cell membrane.
secretion Active or passive movement of a substance from the blood side of the gut (serosal) to the lumen of the gut (mucosal side).
tight junction Complex of proteins near the apical side of epithelial cells; acts as a barrier to the movement of molecules between the cells.

Fluid and electrolytes are secreted as well as absorbed by the colonic epithelium. The net transport, in the normal state, is absorption of sodium, chloride, water, ammonium ions, and short-chain fatty acids, and net secretion of potassium, bicarbonate, and mucus. Similar to fluid processing in the kidney, both the secretory and the absorptive processes can be fine-tuned by selective regulation, such that homeostasis is maintained. Abnormalities in individual transport processes or abnormalities in their regulation can lead to excessive fluid loss (diarrhea) or excessive fluid retention (constipation), both of which can cause substantial symptomology and, if extreme, can be life threatening.

INTRODUCTION

For the average individual, the colon receives approximately 1.5 liters of fluid/solid load per day. On average, approximately 150 ml of water and 100–200 g of solid waste are excreted from the colon. The balance between these amounts constitutes the colonic processing of luminal contents. The colonic epithelium is capable of both secretion and absorption; the difference between these processes determines the final ionic and water composition of the fecal material. Under normal conditions, the integrated outcome of bidirectional fluid movement is absorption. Although the colon normally receives 1.5 liters of input per day, it is capable of processing approximately 2.5 liters per day. Delivery volumes in excess of 2.5 liters per day by the small bowel may exceed the absorptive capacity of the colon and lead to an overflow diarrheal state, despite otherwise normal colonic function. The colonic absorptive processes predominantly involve movement of sodium (Na^+), chloride (Cl^-), and water, such that 80–90% of the ileal fluid is removed from the gut lumen. The ionic composition of the ileal fluid delivered to the colon is essentially isosmotic to plasma, with 140 mEq/liter Na^+, 60 mEq/liter Cl^-, 70 mEq/liter HCO_3^-, and 7 mEq/liter K^+. The fecal ionic composition is reduced in Na^+ and Cl^- and enriched in K^+ and HCO_3^-. In addition to the net absorption of Na^+ and Cl^- and the net secretion of K^+ and HCO_3^-, short-chain fatty acids (SCFAs) and NH_4^+, both produced by colonic bacteria within the colon, are major constituents of colonic luminal fluid and are also absorbed. Mucus, secreted by the colonic mucosa, is hydrated and propelled along the crypt by fluid secretion driven by K^+ and/or Cl^- secretion within the crypts. The focus in this article is on the mechanisms whereby the colonic content is

modified, the regulation of those mechanisms, and the pathology associated with alterations in these processes.

CRYPT–SURFACE AXIS

The human colon contains millions of crypts of Lieberkuhn (Fig. 1a), with each crypt being 30–60 μm in diameter and 200–400 μm in length, composed of approximately 2000 cells, termed "enterocytes." The epithelial cells of the colon are generated from progenitor cells at the base of the crypts. Each crypt contains at least one stem cell, thus each individual crypt is considered to represent a clonal or quasi-clonal population of cells, based on DNA methylation patterns. Stem cells divide in an asymmetric manner, producing another stem cell and a cell destined for differentiation. The cells destined for differentiation migrate along the crypt axis and eventually form the surface cell layer. During the migratory process, the cells become more differentiated and less proliferative. The fully differentiated surface cells subsequently undergo apoptosis and slough off into the lumen. This process of enterocyte production, migration, and terminal differentiation occurs over a 4- to 8-day period, thus the stem cells of the crypt are highly proliferative and represent a major locale for tumorigenesis.

During the migration of enterocytes from the base of the crypt to the surface, the differentiation process results in functionally distinct cell populations. The three general cell types produced are goblet cells, columnar epithelial cells, and enteroendocrine or enterochromaffin cells. Of these, the latter represent only 5%. The enterochromaffin cells act as mechanical sensors within the epithelium and provide the initial signal for neuronal reflex regulation of transport. Goblet cells are mucus-secreting cells and occur along the length of the crypt as well as on the surface, varying little in function along the crypt–surface axis. The columnar cells are responsible for fluid and electrolyte transport but also secrete a mucus distinct from that produced by goblet cells. Columnar cell function varies greatly along the crypt–surface axis, with the early and midcrypt cells having a predominantly secretory function and the surface cells having a predominantly absorptive function. Columnar cells at the neck of the crypt display a mixed phenotype. Although the secretory function appears uniform along the length of the colon, the absorptive process (the functional fate of terminal differentiation) differs. Absorption in the proximal colon (ascending and transverse segments) is electroneutral, involving apical membrane cotransporters, whereas the process of absorption in the distal colon (descending and sigmoid segments) is electrogenic and involves apical ion channels.

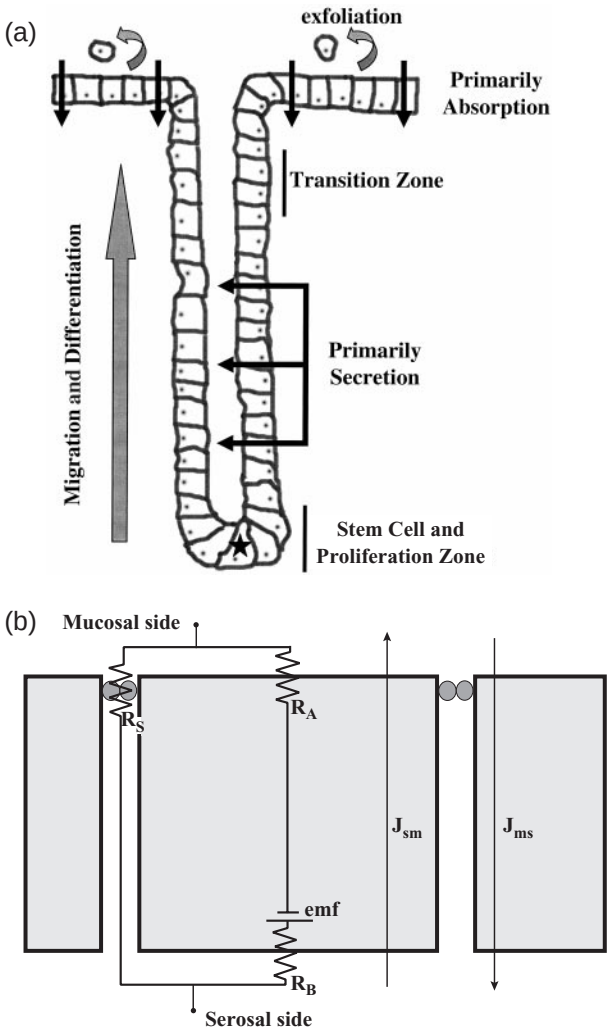

FIGURE 1 General aspects of colonic transport. (a) Crypt of Lieberkuhn functional model. Stem cells (★) at the base of each crypt proliferate and cells differentiate as they migrate toward the lumen surface. Surface epithelial cells undergo apoptosis and slough off. Cells in the lower crypt primarily secrete whereas surface cells are primarily absorptive. (b) Minimal equivalent circuit model for epithelial transport: R_S, the barrier to paracellular ion movement (tight junctions, ◯◯); R_A, the cell apical membrane barrier; R_B, the cell basolateral membrane barrier; emf, the electromotive force (energy source, Na^+,K^+-ATPase). Net transepithelial transport, or flux (J_{Net}), is determined by the difference between the serosal to mucosal flux (J_{sm}) and the mucosal to serosal flux (J_{ms}).

MECHANISMS OF FLUID AND ELECTROLYTE TRANSPORT

The consensus model of fluid and electrolyte transport by colonic epithelium was established in the 1970s and 1980s. The unidirectional movement of ions and thus

water by osmotic flow results from the polarized distribution of specific membrane proteins in epithelial cells and the occurrence of a barrier to flow between the cells. The net movement, or flux, of a substance across an epithelium (Fig. 1b), J_{Net}, is defined as the difference between the rate of absorption (mucosal to serosal flux), J_{ms}, and the rate of secretion (serosal to mucosal flux), J_{sm}. For passive diffusion, J_{Net} of a substance occurs down its electrochemical gradient. When J_{Net} cannot be explained by passive diffusion, an active transport system must be considered. The energy source (electromotive force, emf) for directed ion transport is principally supplied by the Na^+,K^+-ATPase, which pumps three Na^+ ions out of the cell per two K^+ ions into the cell and thus establishes an ion gradient for both K^+ and Na^+ across the cell membrane. The established electrical potential and the Na^+ concentration gradient then provide the energy for active transport of other ions. The epithelium represents two barriers or resistances to flux—the paracellular pathway and the transcellular pathway.

The paracellular space between adjacent epithelial cells is bridged by an intercellular functional complex that consists of three zones, the zonula occludins (tight junction), the zonula adherens (adherens junction), and the desmosomes. The tight junction is the anatomical locus of epithelial barrier function and determines the leakiness of the paracellular pathway. The relative permeability of the tight junction to specific ions, the ion selectivity, is in part determined by the isoform type and state of claudin proteins within the tight junctional complex. This leakiness of the tight junction can be described in electrical terms as the paracellular resistance, R_S (Fig. 1b). The paracellular resistance is higher in the colon than in the jejunum and ileum, increasing along the length of the colon from approximately $100\ \Omega \cdot cm^2$ in the proximal segments to approximately $300-400\ \Omega \cdot cm^2$ in the distal segments. Thus, the ability to establish and maintain transepithelial gradients increases along the length of the colon.

The flux across the epithelial cell is further determined by two components, the apical membrane resistance, R_A, and the basolateral membrane resistance, R_B (Fig. 1b). Thus, the net flux of a substance across the cell is determined by the net flux across the apical membrane, $J_{Net}{}^A$, in combination with the net flux across the basolateral membrane, $J_{Net}{}^B$. In colonic epithelial cells, $J_{Net}{}^A$ is considered to be rate limiting (e.g., $R_A \gg R_B$), although it is now appreciated that changes in $J_{Net}{}^B$ can have a regulatory effect on the magnitude of the cellular flux. Although poorly understood at present, regulatory changes in the paracellular resistance or flux pathway are also thought to occur and likely involve posttranslational modification of claudins, which comprise part of the tight junction complex. Increased paracellular permeability, particularly when ion selective, can enhance the rate of directed transport, or, when nonselective, can decrease the ability of the epithelium to maintain an ionic or osmotic gradient.

The functional phenotype of a transporting epithelial cell is determined by the identity of specific membrane transport pathways in the apical and basolateral membrane. The asymmetric distribution of proteins in the apical versus basolateral membrane produces cell polarity. The direction and magnitude of transport, that is, the conductance of a particular ion or molecule, are set by the relative activity of these apical and basolateral transport processes. Crypt cells are similar along the length of the colon, with the key features being apical K^+ and Cl^- ion channels in combination with basolateral Na^+,K^+-ATPase—the $Na^+/K^+/2Cl^-$ cotransporter 1 (NKCC1)—and K^+ ion channels. The surface cells of the proximal colon contain the apical Na^+/H^+ exchanger (NHE), the Cl^-/HCO_3^- exchanger (anion exchanger), and the Cl^-/OH^- exchanger [originally designated "down-regulated in adenoma" (*DRA*)], in combination with basolateral K^+ and Cl^- ion channels, the K^+/Cl^- cotransporter 1 (KCC1), the anion exchanger (AE), and Na^+,K^+-ATPase. The surface cells of the distal colon differ in that the apical membrane contains K^+ and Na^+ ion channels and two different isoforms of H^+,K^+-ATPase.

Absorption

The majority of NaCl and fluid absorption occurs in the proximal colon via an electroneutral process depicted in Fig. 2a. Na^+ enters across the apical membrane in exchange for H^+ via two isoforms of the Na^+/H^+ exchanger (NHE2 and NHE3), which have distinct regulatory profiles, although the functional significance of their redundancy remains unclear. *DRA* was originally described as a sulfate/oxalate exchanger and was later shown to have Cl^-/OH^- exchange as well as Cl^-/HCO_3^- exchange activity. Although apical AE isoform 1 (AE1) is present in rat colon cells, it has not been identified in human colon cells, thus *DRA* may serve as the apical anion exchanger (Cl^-/HCO_3^-) in humans. Cl^- enters via *DRA* in exchange for OH^- and via the AE and/or *DRA* in exchange for HCO_3^-. The driving force for apical Na^+ entry is maintained by active removal via the basolateral Na^+,K^+-ATPase. Cl^- exits the cell via basolateral KCC1, AE2 and AE3, and Cl^- channels. AE2 and AE3 provide a pathway for the basolateral entry of HCO_3^-. K^+ is recycled across the basolateral membrane by basolateral K^+ channels. The combined result of these transport processes is the net transport of NaCl

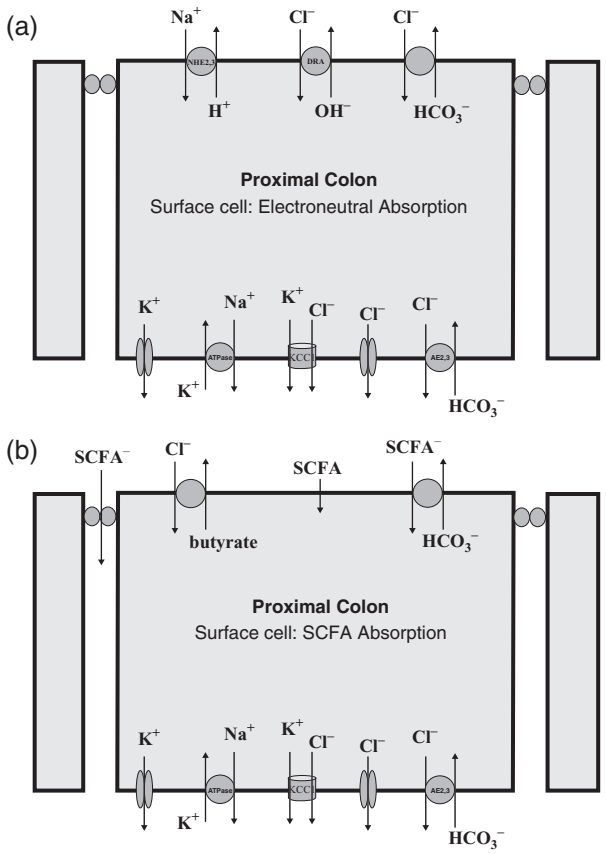

FIGURE 2 Cellular models for surface cell transport in the proximal colon. (a) Electroneutral absorption. Na^+ and Cl^- are taken up across the apical membrane by Na^+/H^+, Cl^-/OH^-, and Cl^-/HCO_3^- exchangers. Intracellular Na^+ is kept low by basolateral Na^+,K^+-ATPase. Intracellular Cl^- is kept low by basolateral K^+ and Cl^- cotransport, Cl^-/HCO_3^- exchange, and Cl^- channels. Note that HCO_3^- secretion occurs in conjunction with NaCl absorption, but does not result in a significant luminal pH change because H^+ is also secreted. NHE2,3, Na^+ and H^+ exchangers, isoforms 2 and 3; AE2,3, anion exchangers, isoforms 2 and 3. (b) Short-chain fatty acid (SCFA) absorption. Uncharged SCFA passively diffuses across the cellular membrane. $SCFA^-$ is absorbed across the apical membrane in exchange for HCO_3^-. Via a butyrate/Cl^- exchanger, Cl^- absorption can occur. $SCFA^-$ may also permeate the paracellular pathway driven by a negative lumen-to-serosa potential. The processes depicted here and in (a) occur within the same cells but are shown separately for clarity.

from lumen to serosa and the net movement of HCO_3^- from serosa to lumen. Activity of NHE2 and NHE3 does not significantly contribute to luminal acidification because the secreted H^+ is buffered by the OH^- and HCO_3^- secreted by the *DRA* and AE.

The surface cells of the proximal colon also have the capacity to absorb short-chain fatty acids (SCFAs) (Fig. 2b). Absorption occurs predominantly by nonionic diffusion; however, the charged forms can also be transported across the apical membrane via a $SCFA^-/HCO_3^-$ exchanger. There also exists an exchange process for butyrate and Cl^- in the apical membrane, thus, via $SCFA^-/HCO_3^-$ exchange coupled to Cl^-/butyrate exchange, net Cl^- absorption and HCO_3^- secretion can occur.

The cell model for electrogenic NaCl absorption occurring in the surface cells of the distal colon is depicted in Fig. 3a. Intracellular Na^+ is kept low by the basolateral Na^+,K^+-ATPase and provides the driving force for the electrogenic diffusion of Na^+ through an apical epithelial Na^+ channel (ENaC). The electrogenic movement of Na^+ from the lumen to the serosal side creates a negative lumen potential, which facilitates the cellular and/or paracellular diffusion of Cl^-. An apical K^+ channel provides a pathway for K^+ secretion. The driving force for K^+ secretion is dependent on the relative permeability of the apical membrane to Cl^-; that is, Na^+ entry can be "charge balanced" by either apical K^+ exit or apical Cl^- entry. At the basolateral membrane, K^+ channels provide a pathway to recycle K^+. The net movement of K^+ also depends on the relative activity of the apical K^+ channel with respect to that of the basolateral K^+ channel and the driving force across each respective membrane. The colon contributes to body K^+ homeostasis and can function both to secrete and to absorb K^+. The cells responsible for K^+ absorption are the same as involved in electrogenic Na^+ absorption. The cellular model for K^+ absorption, for the sake of simplicity, is shown separately in Fig. 3b. Two H^+,K^+-ATPases are responsible for the active exchange of luminal K^+ for intracellular H^+, the colonic H^+,K^+-ATPase (HKc) being sensitive to omeprazole and the other sensitive to ouabain. Accumulated intracellular K^+ exits the cell across the basolateral membrane either by a K^+ channel or by KCC1.

It is well appreciated that the colon absorbs ammonium from the lumen, because portal vein ammonium levels are higher than those of the systemic circulation. However, the exact mechanism of absorption is not understood. It is likely that, similar to SCFA absorption, both the passive diffusion of uncharged ammonia and the directed transport of ammonium ions contribute to the process.

Secretion

Within the crypts, NaCl, KCl, and HCO_3^- secretion can occur. The cellular model for these secretory processes is depicted in Fig. 4. In KCl secretion, both apical membrane Cl^- and K^+ ion channels are active, with a relatively less active basolateral K^+ channel. Intracellular Cl^- is accumulated above electrochemical

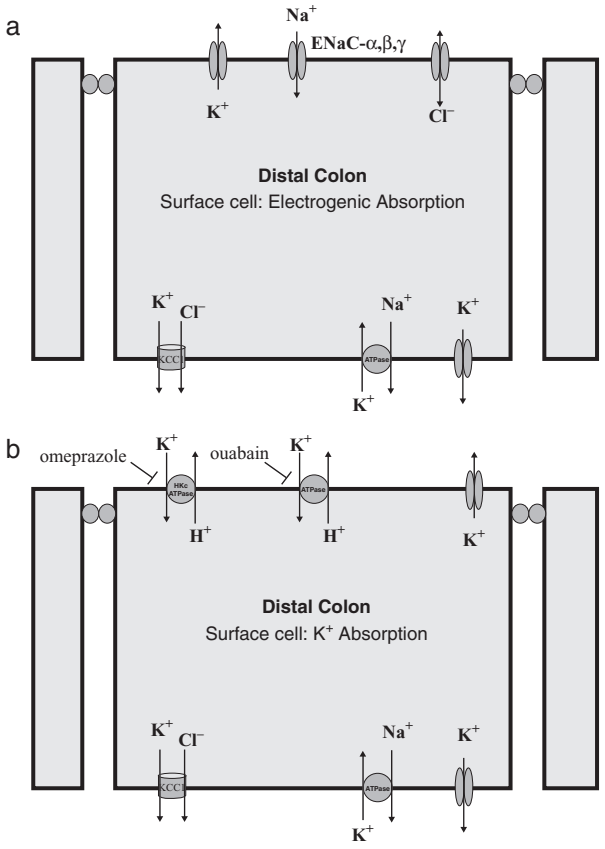

FIGURE 3 Cellular models for surface cell transport in the distal colon. (a) Electrogenic absorption of Na^+. Intracellular Na^+ is kept low by basolateral Na^+,K^+-ATPase. Na^+ absorption occurs via the passive diffusion of Na^+ through an apical α, β, and γ epithelial Na^+ channels (ENaC-α,β,γ). Apical K^+ and Cl^- channels provide a pathway for charge balance across the apical membrane. (b) K^+ absorption. Two distinct isoforms of H^+,K^+-ATPase provide a pathway for apical entry of K^+. The exit of K^+ across the basolateral membrane occurs by K^+,Cl^- cotransport and/or K^+ channels. The processes depicted here and in (a) occur within the same cells but are shown separately for clarity.

equilibrium by basolateral NKCC1. A basolateral Na^+,K^+-ATPase maintains the driving force for NKCC1. In NaCl secretion, the apical K^+ channel activity is relatively lower than that of basolateral K^+ channels such that K^+ preferentially recycles across the basolateral membrane. The electrogenic movement of Cl^- across the apical membrane creates a lumen negative potential, which acts to drive the paracellular movement of Na^+. Numerous apical Cl^- channels have been described, the two most prominent being the Ca^{2+}-activated Cl^- channel (CaCC) and the cAMP-activated Cl^- channel; the latter, designated the cystic fibrosis transmembrane conductance regulator (CFTR), was originally identified by genetic screening as the protein that is defective in cystic fibrosis. Subsequently, by electrophysiological studies, CFTR was identified as being a cAMP-activated Cl^- channel. Electrogenic HCO_3^- secretion can also occur via these apical Cl^- channels.

Mucus secretion by goblet cells serves to protect the epithelium from abrasion and to create a protective unstirred layer near the apical membrane. Goblet cell mucus secretion occurs via exocytosis of apically located mucus-containing granules. Movement of the granules is microtubule dependent and restricted by the actin cytoskeleton at the apical membrane. On stimulation of goblet cells by Ca^{2+} agonists such as acetylcholine (ACh) and histamine, but not by cAMP agonists, the granule contents are released into the lumen of the crypt or on the surface lumen. Columnar cells in the crypt can also secrete mucus contained within apical vesicles. In contrast to goblet cells, columnar cells secret mucus in response to cAMP agonists but not to Ca^{2+} agonists. Mucus within the granules is compact and in a somewhat dehydrated state; on exocytosis, hydration of the mucus results in an approximately twofold expansion in volume. Crypt fluid secretion is necessary both to hydrate the luminal mucus and to provide a flow for expulsion of the mucus from the crypt lumen.

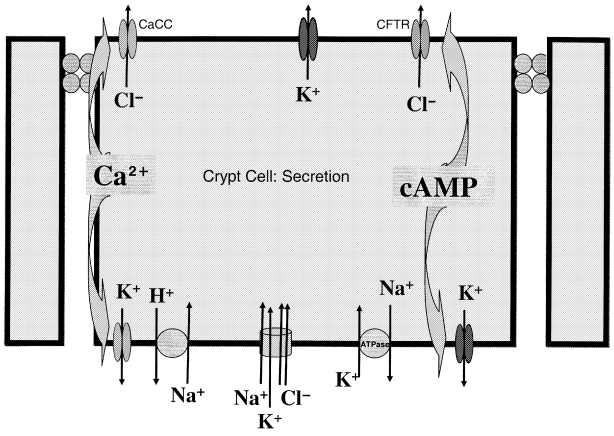

FIGURE 4 Cellular model for crypt cell secretion. Apical Cl^- channels provide an exit pathway for Cl^- across the apical membrane. Intracellular Cl^- is maintained by functional basolateral $Na^+/K^+/2Cl^-$ cotransport. Agonists that increase intracellular Ca^{2+} increase the activity of the apical Ca^{2+}-activated Cl^-channel (CaCC) and a Ca^{2+}-sensitive basolateral K^+ channel. Agonists that increase intracellular cAMP increase the activity of the apical cystic fibrosis transmembrane conductance regulator (CFTR) and, depending on the level of cAMP, either an apical K^+ channel or a basolateral K^+ channel. The directional flow of K^+ (e.g., secretion or basolateral recycling) is determined by the relative activity of the apical and basolateral conductive pathways. The cAMP agonists also up-regulate NKCC1 in the basolateral membrane.

REGULATION OF ABSORPTION

The normal default function of the colon is absorption, thus effects on net absorption are more typically associated with an inhibition of secretion. Electrogenic absorption in the distal colon is under more significant regulation than is the electroneutral absorption in the proximal colon. Nonetheless, electroneutral absorption is affected by a number of extracellular factors. NHE2 and NHE3 expression is up-regulated with Na^+ depletion and, in a nongenomic manner, with low-dose glucocorticoids and aldosterone. Stimulation of $\alpha 1$ or $\beta 2$ receptors increases NHE3 activity and thus increases absorption. Agonists that stimulate protein kinase C (PKC), calmodulin-dependent kinase II (CaMKII), or cyclic adenosine monophosphate (cAMP) inhibit NHE3 function; interestingly these second-messenger systems are also strong activators of secretion. Norepinephrine, somatostatin, and neuropeptide Y (NPY) are able to increase electroneutral absorption; however, their major influence on net transport is via inhibition of secretion. Electrogenic Na^+ absorption in the distal colon is strongly influenced by circulating glucocorticoids and mineralocorticoids. Both exert genomic early- and late-phase stimulation of apical Na^+ entry by effects on the apical Na^+ channel, ENaC. The early-phase response, which requires protein expression, is the up-regulation of ENaC activity in the apical membrane, whereas in the late phase, ENaC protein expression is increased along with an increase in Na^+,K^+-ATPase. Increases in intracellular cAMP increase ENaC activity, whereas increases in intracellular Ca^{2+} or PKC activity tend to diminish activity. ENaC is also subject to feedback inhibition by increases in intracellular Na^+. A number of studies have demonstrated that the expression of CFTR and CFTR activity has a negative effect on ENaC activity. Although CFTR abundance is low in the surface cells, it may play a significant role in the regulation of ENaC as well as in pathological conditions that increase CFTR activity, or in cystic fibrosis, in which ENaC-mediated Na^+ absorption is enhanced. Dietary Na^+ and K^+ depletion as well as aldosterone cause increased K^+ absorption by increasing the expression and activity of the H^+,K^+-ATPase.

REGULATION OF SECRETION

Homeostatic regulation of colonic function is primarily directed at inhibition of the absorptive pathway or stimulation of the secretory pathway. Regulation of secretion occurs by paracrine, autocrine, endocrine, and neuroendocrine mechanisms. Although a plethora of agents have been demonstrated to affect Cl^- and K^+ secretion, the majority of these do so by effects on intracellular cAMP, cGMP, Ca^{2+}, or PKC. Discussion of all the extracellular and intracellular regulatory pathways involved in the regulation of secretion is beyond the scope of this article, but the two most significant physiological agonists for secretion are acetylcholine (ACh) and vasoactive intestinal polypeptide (VIP), which cause increases in intracellular Ca^{2+} and cAMP, respectively. Both ACh and VIP are locally released by intrinsic primary afferents within the submucosal plexus in response to mechanical stimulus of enterochromaffin cells and subsequent 5-hydroxytryptamine (5-HT) release. Whereas the secretory response to cAMP agonists is long term, the secretory response to Ca^{2+} agonists is more transient.

A number of peptide and nonpeptide factors act on the secretory cells to produce an increase in intracellular cAMP, including VIP, adenosine, and prostaglandins. Increases in intracellular cAMP lead to the activation of protein kinase A (PKA), which in turn leads to the activation of the apical membrane Cl^- channel CFTR, activation of NKCC1, and activation of either or both apical and basolateral K^+ channels. Low levels of cAMP tend preferentially to activate the apical K^+ conductance and support KCl secretion, whereas high levels preferentially activate the basolateral K^+ conductance, and thus support NaCl secretion. Guanylin acting via apical receptors leads to an increase in intracellular cGMP, which activates CFTR via protein kinase G (PKG) and increases cAMP levels by inhibiting phosphodiesterase (PDE) breakdown of cAMP. cAMP may also, acutely increase the number of CFTR proteins in the apical membrane and thus further promote secretion.

ACh and histamine stimulate secretion by causing an increase in intracellular Ca^{2+} levels. For ACh and histamine, Ca^{2+} is increased in an inositol 1,4,5-trisphosphate (IP_3)-dependent manner. The increased Ca^{2+} leads to activation of apically located Ca^{2+}-dependent Cl^- channels and the stimulation of Ca^{2+}-sensitive basolateral K^+ conductance. The transient nature of this response has been attributed to the generation of inositol 3,4,5,6-tetrakisphosphate (IP_4) as well as phosphatidylinositol 3-kinase (PI 3-kinase)-dependent activation of PKC-ϵ and their respective negative effect on CaCC. Growth factors—epidermal growth factor (EGF), insulin, and insulin-like growth factor (IGF)—also exert a negative effect of Ca^{2+}-dependent Cl^- secretion by inhibition of the basolateral Ca^{2+}-dependent K^+ conductance. Enkephalins, neuropeptide Y, and somatostatin act to inhibit secretion by inhibition of ACh release; these substances also increase

Na^+ reabsorption. Bile acids, in part, stimulate secretion by an IP_3-dependent increase in intracellular Ca^{2+} and by increasing prostaglandin E_2 (PGE_2) release from colonic fibroblasts.

PATHOLOGICAL INFLUENCES ON SECRETION AND ABSORPTION

Dysregulation of colonic secretion and absorption underlies a number of digestive disorders. These conditions may arise from congenital or acquired defects. In addition, the presence of unabsorbed osmolytes in the lumen of the colon can result in an osmotic diarrhea. These osmolytes may either be voluntarily ingested or result from small intestinal malabsorption.

Congenital chloride diarrhea, or congenital chloridorrhea, is the result of a mutation in *DRA*, a condition known as Pendred syndrome that also results in deafness. Although *DRA* acts as a Cl^-/OH^- exchanger, there is some evidence that it can also effect Cl^-/HCO_3^- exchange. In addition, defective *DRA* leads to an increased intracellular pH, which in turn reduces the activity of apical anion exchange. Congenital chloridorrhea is characterized by an acidic watery diarrhea with chloride concentrations in excess of 90 mEq/liter (due to decreased Cl^- absorption) and metabolic alkalosis (due to decreased HCO_3^- and OH^- secretion). Defects in NHE3 cause congenital sodium secretory diarrhea, in which stool sodium and HCO_3^- are elevated, with only slight diarrhea and metabolic acidosis. Cystic fibrosis (CF) is the result of a defect in the cAMP-stimulated Cl^- channel, CFTR. CF results in a decrease in colonic secretion or an antidiarrheal state, which in 5–10% of CF newborns results in colonic obstruction (meconium ileus). Diarrhea is seen in some patients with CF due to steatorrhea caused by pancreatic exocrine insufficiency. Interestingly, the high prevalence CF (1 in 2500 births) may relate to a heterozygote protective effect against the development of acquired secretory diarrheas, particularly in cholera.

The major cause of acquired secretory and inflammatory diarrheas is pathogenic colonization within the gastrointestinal (GI) tract. Bacterial species that commonly affect colonic transport are *Vibrio cholerae, Escherichia coli, Clostridium difficile*, and *Salmonella typhimurium*. In children, rotavirus is a common cause of secretory diarrhea. Toxins produced by these organisms produce diarrhea (1) by increasing the chloride secretory pathway, (2) by indirectly or directly decreasing electrogenic Na^+ absorption, (3) by decreasing the tight junction permeability, thus making the epithelia more leaky, and (4) by initiating an inflammatory response, which in turn can activate the secretory pathway via the enteric nervous system. It should be noted that these toxins also increase fluid secretion in the small bowel, which can in and of itself produce an overflow diarrhea due to the increased fluid volume delivery to the colon.

Vibrio cholerae produces a number of toxins. Cholera toxin causes a covalent and irreversible activation of the G protein, G_s, which in turn activates adenylate cyclase and raises intracellular cAMP levels, activating CFTR. Zonula occludens toxin (ZOT) acts to increase the ionic permeability of the tight junctions, whereas other toxins result in the release of serotonin from enterochromaffin cells. *Escherichia coli* produces a heat-labile toxin (ST_b) that acts to increase intracellular cAMP and a heat-stable toxin (ST_a) that acts to reversibly increase intracellular cGMP, resulting in stimulation of CFTR. ST_a increases cGMP by hijacking the endogenous guanylin receptor, which, when active, acts as a guanylate cyclase. With cholera toxin and ST, activation of CFTR results in increased secretion of Cl^- as well as HCO_3^- via CFTR and the subsequent development of metabolic acidosis accompanying the diarrhea. *Clostridium difficile* produces two toxins, A and B, that increase tight junction permeability via glucosylation of Rho protein. Toxin A has also been implicated to increase intracellular Ca^{2+} and activate CaCC. Rotavirus and *C. difficile* act similarly, rotavirus producing a nonstructural glycoprotein, NSP4, which acts both to increase intracellular Ca^{2+} and thus stimulate CaCC as well as to decrease tight junction permeability.

The chronic diarrhea observed in colonic carcinoma is likely due to increased proliferation and decreased differentiation within the crypt cells. As mentioned earlier, a protein (*DRA*) found to be down-regulated in carcinoma is expressed predominantly on the fully differentiated surface cells, with little expression within the undifferentiated crypt cells. Thus, the loss of *DRA* in colon carcinoma is indicative of decreased colonocyte differentiation, which suggests an increase in the secretory cell population at the expense of a decrease in the absorptive cell population. A number of neoplastic disorders can lead to humoral-mediated chronic diarrhea. The VIP-secreting tumors (VIPomas), due to high plasma levels of VIP, present with profuse chronic watery diarrhea associated with hypokalemia and achlorhydria (WDHA syndrome).

SUMMARY

The overall state of colonic transport determines the water and electrolyte content of the feces and is the

integrated result of both absorptive and secretory processes. The normal balance is such that the net effect is absorption of salt and water and thus conservation of water. The absorptive process predominantly occurs at the surface cells and is electroneutral in the proximal colon and electrogenic in the distal colon, with the latter being more tightly regulated. The secretory process predominantly occurs in the crypts and is more uniform throughout the length of the colon. In contrast to the absorptive processes, the secretory processes are much more tightly regulated. Pathological disruption of the balance between the absorptive and secretory processes generally involves an increase in secretion and thus diarrhea.

hypoxia Condition that arises when the cellular demand for molecular oxygen necessary to maintain physiologic function exceeds supply.
ischemia Pathologic reduction in blood supply to a tissue.

Colonic ischemia is associated with a diverse array of pathologies wherein the epithelial barrier is compromised, including acute mesenteric ischemia, ischemic colitis, necrotizing enterocolitis, and inflammatory bowel disease. Although the underlying disease processes leading to colonic ischemia are numerous, a major consequence for the mucosal tissue is that oxygen demand exceeds supply, resulting in tissue hypoxia. Because the chemical reduction of molecular oxygen is the primary source of metabolic energy for all eukaryotic cells, hypoxia represents a severe threat to tissue function and survival. Hypoxia has an impact on intestinal cell function, which relates to disease processes. This entry reviews the molecular mechanisms underlying such events.

INTRODUCTION

Tissue ischemia and subsequent hypoxia are common physiologic and pathophysiologic occurrences. Because of its juxtaposition with the anoxic lumen of the gut, the colonic mucosa relies heavily on the rich mucosal vascular bed for oxygen supply and is consequently highly susceptible to ischemic/hypoxic insult (Fig. 1). Colonic ischemia can occur as a result of frank vascular occlusion or vasoconstriction, such as in cases of occlusive or nonocclusive acute mesenteric ischemia, respectively. Alternatively, at the tissue level, hypoxia can originate from fibrosis and microvascular breakdown associated with chronic inflammation. Furthermore, oxygen supply can be compromised as a function of a general decrease in perfusion in shock and hypotension, or may be due to whole body hypoxia (e.g., carbon monoxide poisoning, altitude sickness). Although other factors such as acidosis, insufficient tissue detoxification, and hypercapnia play a role in ischemic disease, a primary consequence common to all the pathophysiologic mechanisms is that cellular oxygen demand exceeds supply, leading to tissue hypoxia.

The intestinal epithelium represents an important dynamic barrier, preventing the free mixing of luminal antigenic material with the mucosal immune system, while at the same time facilitating antigen presentation and the development of oral tolerance. The epithelial barrier is maintained through the existence of tight and adherens junctions between cells. These junctions are dynamic structures, the organization and function of which are highly regulated processes. In both health and disease, intercellular tight junction permeability is under the regulation of a number of autocrine and paracrine factors that signal through basolaterally localized receptors. Though the mechanisms involved are still under investigation, it is clear that hypoxia, either directly or through ATP depletion, disrupts assembly of both tight and adherens junctions, crucially impairing barrier integrity. As a consequence, epithelial barrier dysfunction leads to dramatically increased transepithelial paracellular permeability, as has been documented both *in vitro* and *in vivo*. Under such conditions, luminal antigenic material gains unregulated access to the lamina propria, which houses the mucosal immune system. Resulting interactions between luminal antigens and cells of the mucosal immune system lead to the activation and development of inflammatory episodes, which actively contribute to ongoing disease processes.

Because of the challenge that hypoxia represents to physiologic cell function, an exquisite oxygen-sensing mechanism has evolved that allows a rapid, adaptive molecular response to occur. Activation of the adaptive response to hypoxia results in the expression of specific genes encoding proteins that increase tissue blood flow/oxygenation and promote cell survival in oxygen-depleted environments. Temporally downstream of the adaptive phenotype, and through independent signaling mechanisms, hypoxia also initiates an inflammatory response that can lead to epithelial dysfunction. The resulting increase in transepithelial permeability is an event that is of pivotal importance in the propagation of disease states in the large intestine, where inflammation and hypoxia are intimately associated.

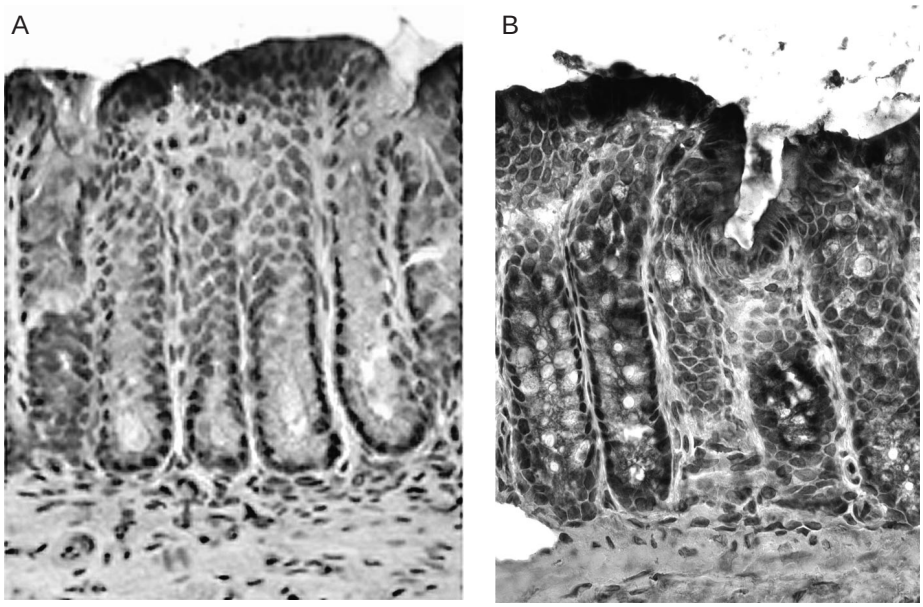

FIGURE 1 Immunhistological localization of retention of EF5 (a pentafluorinated derivative of etanidazole) as a marker of tissue hypoxia. (A) In control mice (room air), colonic sections demonstrate predominantly apical EF5 retention, indicating the presence of significant hypoxia under physiological conditions. (B) In contrast, animals exposed to 8% ambient oxygen for 4 hours display a profound increase in staining of the whole crypt. Under both conditions, staining is almost exclusively mucosal, supporting the concept that the epithelial barrier is specially challenged by oxygen deficiency.

MOLECULAR MECHANISMS IN THE INTESTINAL EPITHELIAL HYPOXIC RESPONSE

Adaptive

Due to the imminent threat that hypoxia represents to cell, tissue, and whole animal survival, mammalian cells have evolved a highly effective mechanism that allows a rapid molecular response through the induction of an adaptive phenotype. This response is mediated primarily by the heterodimeric transcription factor hypoxia inducible factor-1 (HIF-1), a master regulator of oxygen-dependent gene transcription. Whereas the β subunit is constitutively expressed and dimerizes with several other target proteins, HIF-1α is the specific and O_2-regulated subunit that determines biological activity. Under normoxic conditions, HIF-1α has a high rate of turnover, with the protein being targeted for immediate degradation by the ubiquitin/proteasome pathway in a manner dependent on the oxygen-dependent hydroxylation of proline residues. Hypoxia-dependent stabilization of HIF-1α results in its association with HIF-1β and the formation of a transcriptionally active complex that activates the expression of a number of genes with specific binding sites known as hypoxia response elements (HREs) in their promoter or enhancer regions. These genes encode angiogenic factors such as vascular endothelial growth factor (VEGF), vasodilatatory factors such as the inducible form of nitric oxide synthase (iNOS), and other factors such as erythropoietin (EPO), all of which can optimize tissue oxygenation. Furthermore, hypoxia induces the HIF-1-dependent expression of genes encoding glycolytic enzymes that facilitate the generation of cellular ATP through oxygen-independent pathways.

Apart from these general adaptive mechanisms, which are responses to the risk of metabolic demise during decreased oxygen levels, organ-specific mechanisms exist that preserve tissue function and constitute part of the specific hypoxic phenotype of that tissue. A resistance to impairment of barrier function by colonic epithelial cells in response to hypoxia is not found in barrier-forming cells derived from other tissues (endothelia, oral epithelia). Pivotal for this intestinal epithelial hypoxic phenotype is the HIF-1-dependent up-regulation of a number of barrier-protective genes, such as intestinal trefoil factor (ITF) and ecto-5′-nucleotidase (CD73). ITF is a small protease-resistant peptide that is widely expressed in the mammalian intestinal tract, especially in proximity to sites of mucosal injury.

ITF promotes epithelial barrier function, protects against injury, and facilitates repair following damage. One possible mechanism by which this is achieved is via the ITF-regulated expression of E-cadherin and α- and β-catenin, crucial components of the adherens junction. Here, ITF adopts a role as a motogenic factor that facilitates wound healing. ITF also supports barrier integrity, likely through epidermal growth factor (EGF)-dependent and -independent activation of the mitogen-activated protein (MAP) kinase pathway, which leads to reorganization of tight junctional components such as zonula occludens-1 (ZO-1) and claudin-2.

The potential relevance of CD73 in the regulation of barrier function was revealed following observations that neutrophil-derived adenosine monophosphate (AMP) promotes endothelial barrier function through CD73-dependent conversion into adenosine. Though the exact mechanisms remain unclear, the effect is most likely conveyed via an increase of intracellular cAMP that results from adenosine activation of the A_{2b} receptor. Inflammatory cells accumulate at hypoxic/ischemic tissue sites and represent a significant source of extracellular AMP. Furthermore, hypoxic epithelia generate extracellular AMP, allowing it to contribute to this pathway in either an autocrine or paracrine manner.

Both ITF and CD73 are dramatically induced by hypoxia in colonic epithelial cells. Functional HRE consensus sequences that exist within the regulatory domains of these genes mediate transcriptional activation in hypoxia. Furthermore, *in vivo* data clearly support the concept that these two genes constitute part of an innate protective phenotype of intestinal epithelia. Treatment with the specific CD73 inhibitor, α,β-methylene-ADP, leads to augmentation of the intestinal barrier injury induced by hypoxia. Similarly, ITF knockout mice display increased susceptibility in their intestinal permeability response to hypoxia. Thus, intestinal epithelial cells are equipped with adaptive mechanisms that promote cell and tissue survival and enhance epithelial barrier function in hypoxia.

Inflammatory

In a number of pathologies, colonic ischemia is associated with the induction of inappropriate inflammatory episodes that may actively contribute to ongoing disease processes, particularly through the disruption of epithelial barrier function. Exposure of intestinal epithelial cells to hypoxia results in the induction of an inflammatory phenotype, typified by the expression of proinflammatory markers, decreased capacity of the epithelium to restitute following immune cell transmigration, and decreased ion and fluid transport. A primary factor in hypoxia-elicited epithelial cell dysfunction is mediated through the basolaterally polarized release of epithelial tumor necrosis factor α (TNFα), which synergizes with immune-derived cytokines such as interferon γ (IFNγ; present at physiologically high levels in the colonic mucosa) to cause dramatically increased transepithelial permeability to antigenic material and subsequently to promote mucosal inflammation. Inhibition of hypoxia-elicited TNFα using thalidomide or neutralizing antibodies reverses hypoxia-elicited increases in IFNγ-induced permeability. Because TNFα is a major therapeutic target in inflammatory disease of the intestine, the molecular mechanisms underlying hypoxia-elicited TNFα have been investigated. The hypoxia-elicited epithelial expression of TNFα appears to be HIF-1 independent and is dependent instead on the activation of the proinflammatory transcription factor nuclear factor κB (NF-κB) and coincidental degradation of the cyclic AMP response-element binding protein (CREB). NF-κB activation and CREB depletion rely on the phosphorylation-dependent targeting of inhibitor κBα (IκBα) and CREB, respectively, to ubiquitination and subsequent proteasomal degradation. Interestingly, IκBα and CREB share similar phosphorylation sites that act as targeting sequences for ubiquitination and subsequent degradation, implicating a common signaling pathway, leading to hypoxia-elicited activation of these distinct pathways. The net result of NF-κB activation and coincidental CREB degradation is the activation of inflammatory gene expression.

CLINICAL RELEVANCE AND FUTURE PERSPECTIVES

Mucosal hypoxia is an important contributing factor in ischemic disease of the large intestine. Furthermore, it has become increasingly clear that disease processes not classically associated with hypoxia are significantly influenced by hypoxia-related pathways. For example, significant signaling cross-talk between hypoxia and inflammatory pathways exists. This is exemplified by TNFα-dependent induction of HIF-1α in normoxia. Traditionally, inappropriate activity of the mucosal immune system has been deemed responsible for much of the pathophysiology of inflammatory bowel disease. However, mounting evidence indicates that intestinal epithelial hypoxia, due to microvascular breakdown resulting from either tissue fibrosis or mesenteric vasculitis, might be an important factor in mediating

barrier disturbance associated with the disease. Evidence for a role of epithelial hypoxia in inflammatory disease processes in the gut stems from observations both in human disease and animal models. For example, in experimental colitis, the degree of intestinal hypoxia has been directly related to the severity of disease; conversely, knockout of hypoxia-induced adaptive genes such as ITF increases susceptibility. Thus, it is likely that hypoxia significantly contributes as a pathological stimulus in chronic inflammatory disease in the gut.

Bacterial translocation and endotoxemia are devastating complications in intensive care patients. Following intraoperative hypovolemia and/or vasoconstriction associated with surgery, intestinal permeability increases and the degree of endotoxemia is related to this increase. Endotoxemia not only may arise from disturbances of intestinal perfusion, but may also contribute to it by further decreasing intestinal blood supply and increasing mucosal permeability through the induction of inflammatory episodes. These events may constitute a self-propagating series of events that raise challenges to effective therapeutic intervention. These two distinct clinical entities exemplify the crucial importance of intestinal barrier integrity and the profound impact that ischemia/hypoxia exerts on this system. Consequently, innate mechanisms that protect against hypoxia are of fundamental importance. One such mechanism could be the HIF-1-regulated expression of barrier protective genes. Efforts to better understand this pathway as a therapeutic modality could prove beneficial to diseases that are characterized by barrier disruption. Taking into account the significant progress made in immunomodulatory therapy in Crohn's disease, this could constitute a profoundly new approach in the sense of an "epithelial therapeutic." One such approach already under investigation is the use of recombinant trefoil factor, which has proved beneficial in the reduction of inflammation and in acceleration of healing in a rat model of colitis.

Due to its role as a master regulator of hypoxia adaptive responses, enhancement of the HIF-1 pathway, e.g., through stabilization of HIF-1α, could consequently lead to a broad barrier protective response involving multiple downstream effectors. In cancer therapy, suppression of the adaptive HIF-1 response is required, but in the case of ischemic disease in the colon, support of barrier function through induction of the same pathway would be a desirable consequence. Data from studies utilizing induction of HIF-1α by pharmacologic intervention (peptide inhibitor of HIF-1α degradation) in models of ischemic injury have provided promising preliminary data. Although these or other approaches constitute significant advances, a better understanding of the complexity of the hypoxia/inflammation interrelationship is required to permit useful clinical applications.

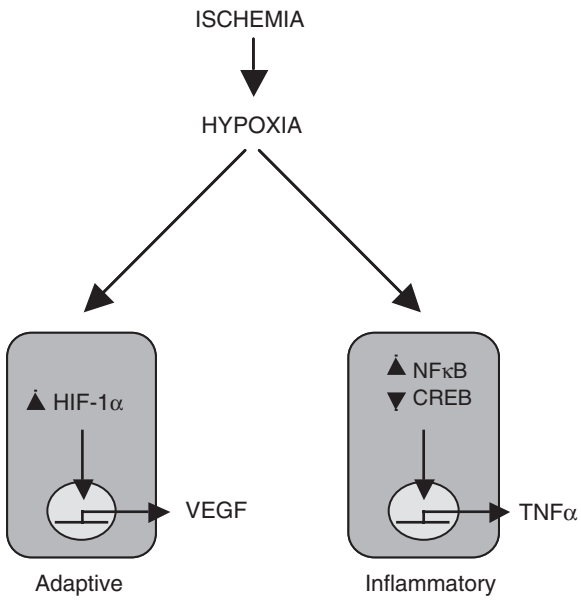

FIGURE 2 Distinct molecular mechanisms underlie the induction of adaptive and inflammatory responses of colonic epithelial cells to hypoxia. Mucosal ischemia leads to intestinal epithelial cell hypoxia. A rapid adaptive response is induced through the accumulation of hypoxia inducible factor-1α (HIF-1α), an event that leads to the induction of transcription of a number of adaptive genes, typified by vascular endothelial growth factor (VEGF). Temporally downstream, an inflammatory response to hypoxia occurs that is mediated through the activation and suppression of nuclear factor κB (NF-κB) and cyclic AMP response-element binding protein (CREB), respectively. TNFα, Tumor necrosis factor α.

SUMMARY

Colonic ischemia is a relatively frequent pathophysiologic occurrence that leads to colonic epithelial cell hypoxia and the activation of distinct molecular pathways. Adaptive and inflammatory responses to hypoxia are mediated through HIF-1α and NF-κB/CREB (Fig. 2). A greater understanding of the oxygen-sensing and signaling mechanisms leading to the activation of these pathways will lead to a more rational definition of novel therapeutic targets in ischemic disease in the large intestine.

The motility requirements of the colon are threefold: first, to cause extensive turning over and mixing movements; second, to cause slow net distal propulsion of colonic contents; and third, to produce infrequent mass movements. This article discusses the types of colonic contractions and their spatiotemporal organization and

regulation, as well as disordered motility in conditions such as diarrhea, constipation, irritable bowel syndrome, and inflammatory bowel disease.

REQUIREMENTS OF COLONIC MOTILITY FUNCTION

The colon is the last major organ in the gastrointestinal tract. As such, it plays a critical role in regulating the frequency of defecation and consistency of stools. These two parameters are determined by the rates of absorption and secretion, the rate of propulsion, and the degree of mixing and turning over of lumenal contents in the colon. The colon absorbs primarily water and some electrolytes to maintain homeostasis. The colonic mucosa is tight and, therefore, its absorption rate is slower than that in the small bowel. Consequently, for adequate absorption an important requirement of colonic motility is to mix and turn over the lumenal contents frequently and regularly and at the same time propel them slowly for their uniform and prolonged exposure to the mucosa.

Another major requirement of colonic motility is rapid propulsion of the feces during defecation. Such rapid propulsion is also required infrequently over the rest of the colon, which, otherwise, has sluggish movements to accommodate the slow absorption rate. These rapid propulsions are called "mass movements." In health, mass movements occur only a few times a day in the colon. However, these rapid propulsions play an important role in colonic motor function since a significant decrease in their frequency causes constipation and a significant increase in their frequency causes motor diarrhea. Motor diarrhea results from frequent mass movements as opposed to secretory diarrhea, which results from excessive secretions. The softer stools in motor diarrhea are due to the lack of absorption of water due to rapid propulsion.

TYPES OF COLONIC CONTRACTIONS

The colonic circular smooth muscle cells generate three types of contractions: (1) rhythmic phasic contractions (RPCs); (2) giant migrating contractions (GMCs); and (3) tone. The longitudinal muscle cells also generate similar contractions but the role of these contractions in colonic motor function is minimal due to their axis of contraction. The longitudinal muscle contractions would reduce the length of a colonic segment without directly shortening the lumen size and, hence, will be minimally ineffective in propulsion. On the other hand, contractions of circular smooth muscle cells partially or completely occlude the lumen, causing mixing and/or propulsion. An underlying requirement for propulsion in the gut is that the circular muscle contractions must propagate. Additionally, the larger amplitude contractions occlude the lumen strongly and are more effective in propulsion. Similarly, a higher frequency of propagating contractions propels lumenal contents more frequently. Nonpropagating contractions, on the other hand, cause basically the mixing and turning over of lumenal contents with minor propulsion due to the to-and-fro movement of contents during contractions.

Rhythmic Phasic Contractions

Rhythmic phasic contractions are responsible for the mixing and slow net distal prolusion in the colon. The extensive mixing and slow distal propulsion in the colon are achieved because the RPCs in the colon are largely nonpropagating and small in amplitude so that they only partially occlude the lumen (Fig. 1).

Giant Migrating Contractions

The mass movements in the colon and rapid expulsion of feces during defecation are achieved by GMCs. These are large-amplitude, lumen-occluding contractions that rapidly propagate over fairly long distances in the colon (Fig. 2). In higher species, such as humans and dogs, these contractions occur infrequently (a few times a day). However, in rodents, these contractions occur regularly and are primarily responsible for their colonic motor function. One major difference between rodent and human GMCs is that, in rodents, most of them do not propagate or propagate only over short distances. The reason that GMCs occur regularly in rodents may be that they pass fecal pellets, which may require stronger propulsive forces. The phasic contractions do occur in the rodent colon, but they are very small in amplitude compared with the amplitude of GMCs and, therefore, have only a minor effect on colonic motility. The GMCs have the characteristics of peristaltic contractions, as descending relaxation precedes their distal propagation. By contrast, the RPCs do not produce descending relaxation. This distinction is often missed in the literature.

The GMCs not only produce mass movements, but they are also important physiological stimuli to produce the sensation of intermittent abdominal cramping (see Fig. 3). Strong contractile forces generated by GMCs can exceed the nociceptive threshold of the gut wall receptors and activate sensory neurons. In addition, if rapid propulsion due to a GMC is not accompanied by descending relaxation to accommodate the large bolus of digesta being propelled, or if a lumenal obstruction exists ahead of a GMC, distension may occur in the

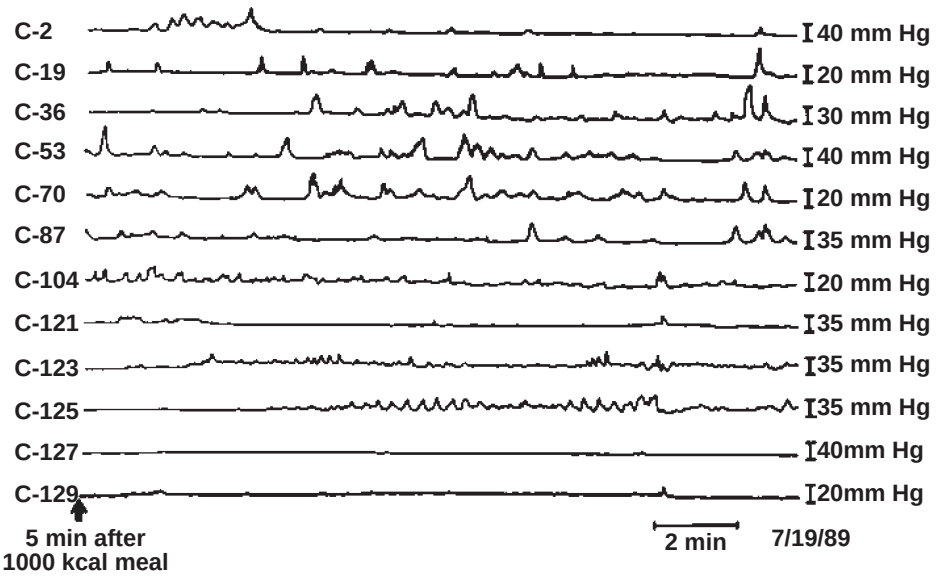

FIGURE 1 Postprandial RPCs recorded from human colon by a 12-channel manometric device. Note that the RPCs show little propagation.

descending segment, which may act as a stimulus to activate stretch sensory receptors.

Tone

The colonic circular smooth muscle cells also generate tonic contractions, which can last from several minutes to hours. Typically, the tone in the circular muscle is increased following a meal. However, an increase in tone by itself does not cause any significant mixing or propulsion. It may, however, enhance the mixing and propulsive functions of phasic contractions and GMCs by reducing lumenal diameter.

REGULATION OF COLONIC CONTRACTIONS

The three types of colonic contractions, discussed above, and their spatial and temporal organizations are regulated at multiple levels to achieve the desired motility functions. The basic scheme is as follows: (1) the mechano- and chemoreceptors in the mucosa sense the presence and characteristics of lumenal contents and send appropriate signals to the myenteric ganglia either directly or via interneurons; (2) the excitatory and inhibitory motor neurons release their respective neurotransmitters when excited by the above inputs; (3) the neurotransmitters bind to membrane receptors on smooth muscle cells or diffuse through the membrane to initiate cascades of signaling pathways to phosphorylate or dephosphorylate contractile proteins; (4) an important condition to initiate these smooth muscle signaling cascades in response to ligand–receptor binding is that the smooth muscle must be depolarized; (5) the myenteric neurons also have the ability to contract smooth muscle cells during their depolarization, independent of any input from mucosal sensory neurons, and colon contractions can occur even when the lumen is completely empty. This suggests that some neurons in the enteric ganglia may spontaneously and periodically release excitatory neurotransmitters to stimulate excitatory motor neurons (6). The gut is an intelligent organ. The mixing and propulsion at any given location depend not only on the lumenal contents at that location, but also on the conditions orad and aborad to that location. This modulation of motility function is achieved by reflexes mediated by orad- and aborad-projecting interneurons in the gut wall, as well as by reflexes mediated by vagal and sympathetic neurons and circulating hormones. Both the extrinsic neurons and hormones eventually work through the enteric ganglia and smooth muscle cells described in (2), (3), and (4) to stimulate or inhibit contractions. (7) Finally, the colon also responds to emotions and stress generated in higher centers. These effects are mediated by extrinsic neurons described in (6). Some salient features of multiple mechanisms in the regulation of colonic motility are discussed below.

Sensory Regulation

The intrinsic primary afferent neurons (IPANS) have their nerve endings in the mucosa close to

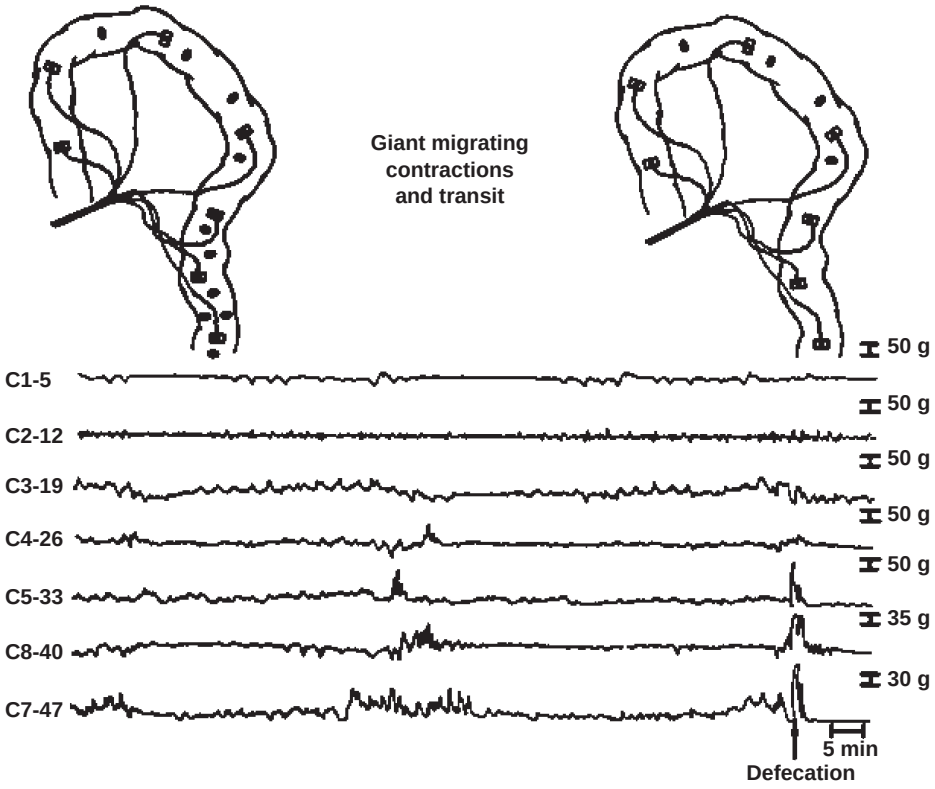

FIGURE 2 Colonic motor activity recorded from canine colon by surgically implanted strain gauge transducers. A set of 10 radio-opaque markers was positioned in the colon. There was little propulsion of the markers during the occurrence of RPCs. However, when a GMC occurred in the distal colon, all markers ahead of its starting point were expelled during defecation. enterochromaffin (EC) cells containing serotonin. Mucosal stimulation releases 5-hydroxytryptamine (5-HT) from these cells, which acts on 5-HT type 4/5-HT type 1p receptors on IPANS to send a signal to the enteric ganglia either directly or via interneurons. The neurotransmitter for IPANS is acetylcholine, acting on nicotinic receptors, and calcitonin gene-related peptide (CGRP), acting on CGRP receptors. In the small bowel, at least, CGRP administered close intra-arterially stimulates both RPCs and GMCs. The 5-HT released from EC cells may also act on 5-HT type 3 receptors of first-order extrinsic sensory neurons to send signals to higher centers. It has been hypothesized that this route may transmit nociceptive signals, but a complete understanding of this afferent sensory limb is lacking.

Balloon distension is sometimes used as an experimental tool to elicit stretch-induced reflexes from the colon. However, distension is not the primary stimulus for spontaneous colonic contractions in the fasting and postprandial states. Unless there is a lumenal obstruction, the colon may rarely distend to thresholds required for stretch-induced reflexes. The lumenal volume of the colon is normally enough to accommodate the fecal material before any significant stretch can occur under healthy conditions. The primary physiological sensory stimulus is the gentle contact of digesta to stimulate the chemo- and mechanoreceptors in the mucosa. These receptors can be activated experimentally by applying chemicals to the mucosal surface or by stroking the mucosa. Stretch and contractile receptors are, of course, present in the colon wall, but they are more likely to be utilized under abnormal conditions.

Motor Neurons

The enteric ganglia in the myenteric plexus project excitatory and inhibitory motor neurons to smooth muscle cells. Acetylcholine (ACh) is the established physiological neurotransmitter of excitatory motor neurons to stimulate all three types of contractions,

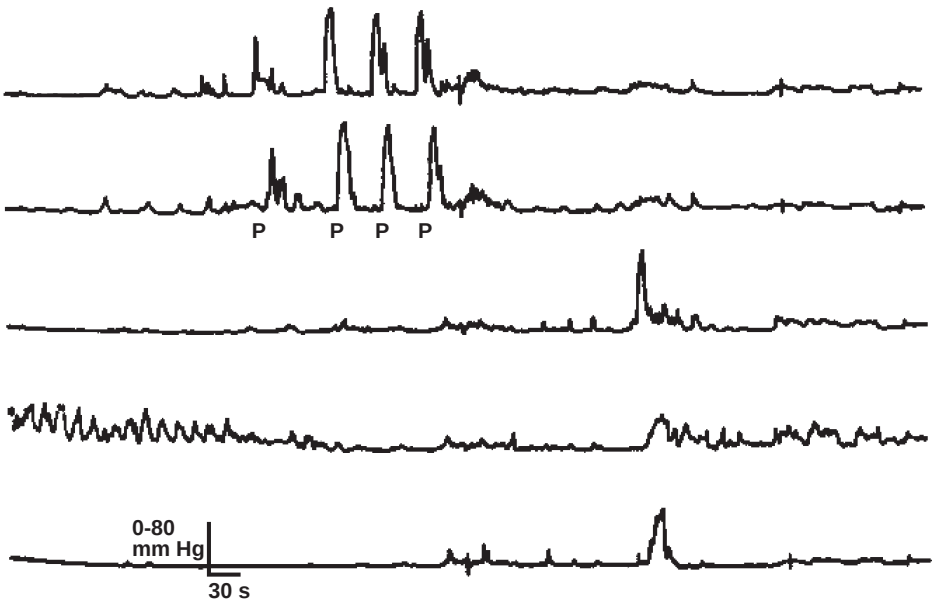

FIGURE 3 Colonic motor activity recorded by a manometric device from a patient with idiopathic chronic constipation. Each occurrence of a GMC was associated with the sensation of abdominal cramping. i.e., RPCs, GMCs, and tone. The primary inhibitory neurotransmitters are nitric oxide (NO) and vasoactive intestinal polypeptide (VIP). Of these, NO seems to play a more prominent role for inhibitory control in colonic motility. The smooth muscle cells are in their basal resting state in the absence of any excitatory or inhibitory input from the motor neurons. They contract in response to the release of ACh, subject to the concurrent occurrence of a slow-wave depolarization. Under some conditions, there may be a constitutive release of NO in the basal resting state of cells, but the excitatory input dominates to stimulate ACh-induced contractions. The hypothesis that spontaneous colon contractions occur by the inhibition of inhibitory input to smooth muscle cells *in vivo* lacks evidence. The sudden block of neural conduction, *in vivo* or *in vitro*, sometimes stimulates colon contractions, but they are transient, lasting only a few minutes. The major role of inhibitory motor neurons is in response to specific inputs, such as those that produce descending relaxation or inputs from higher centers in which case the increased inhibitory excitation may overcome the cholinergic excitatory input and prevent the occurrence of contractions, even when the sensory signals to stimulate them are present.

Tachykinins, particularly substance P (SP), are also putative neurotransmitters of excitatory motor neurons and are co-localized with ACh in the myenteric neurons. However, their precise physiological role is not understood. Exogenously administered substance P stimulates GMCs as well as RPCs in the canine colon and it is also released in the ascending limb of the peristaltic reflex in an organ bath, which suggests that it may participate in the stimulation of GMCs, along with ACh. Substance P inhibitors, however, do not block the spontaneous phasic contractions in intact conscious dogs, indicating that SP may not mediate their spontaneous stimulation.

Interneurons

As noted above, the enteric motor neurons and smooth muscle cells are the primary regulators of gut contractions at any given location, in response to sensory input from the same location. However, in the context of overall gut function, these two regulatory mechanisms need integrated information from proximal and distal locations to fine-tune the mixing and propulsion rates in the segment under their direct control. This information may come from proximal and distal segments within the same organ, such as occurs in an "ileal brake," or it may come from adjacent organs, such as duodeno-gastric and colo-ileal reflexes to regulate the rate of emptying of the proximal organ

into the next gut organ. The information from the distal locations is used to sense the state of digestion and the readiness of the distal segments to receive more digesta. The information from the proximal segments is used to prepare the distal segments for the arrival of new digesta. This coded information is transmitted by interneurons. The extrinsic neurons and hormones also perform a part of this function, but these will not be discussed here.

Peristaltic reflex that manifests as a GMC in the intact conscious state is the most studied reflex involving interneurons. But, as noted above, GMCs occur only infrequently. The rest of the time, the orad or aborad transmission of information in the colonic interneurons is used to fine-tune the spatiotemporal patterns of RPCs for optimal digestion. Note also that the descending inhibition occurs only with GMCs; the RPCs do not produce descending relaxation.

A majority of interneurons in the human colon are immunoreactive for choline acetyltransferase (ChAT) and nitric oxide synthase (NOS). Specifically, approximately 90% of the orad-projecting neurons in the human colon contain ChAT, whereas no ascending neurons contain NOS. On the contrary, approximately 46% of the aborad-projecting neurons contain NOS immunoreactivity alone, 29% contain both ChAT and NOS immunoreactivities, and approximately 20% contain ChAT activity alone. In agreement with the orad or aborad projections of ChAT-containing neurons, both the orad and aborad reflexes are blocked by nicotinic receptor blockade with hexamethonium. The average length of orally and aborally projecting neurons is approximately 10 mm. This suggests that a chain of interneurons, where each neuron innervates the lateral excitatory or inhibitory motor neurons in the ganglia, as well as orad- or aborad-projecting interneurons in the same ganglia conveys the information along the entire length of the colon. The interneurons in the human colon display the Dogiel type 1 morphology. Although a physiological role for NO as one of the inhibitory neurotransmitters in the gut is well established, a physiological role for NO in the interneurons has not yet been identified.

The human colonic interneurons also display immunoreactivity for other neurotransmitters, including tachykinins, VIP, calretinin, and 5-HT. These neurotransmitters may perform specialized roles, which have largely not yet been identified. The roles of neurotransmitters, other than ACh, are likely to be supportive rather than primary. It must be noted, though, that the neurochemical coding of interneurons in the colon of animals, such as guinea pig, differs substantially from that in the human colon.

Electrophysiological Regulation (Slow Waves)

Periodic depolarization of smooth muscle cells, called slow waves, is an important mechanism of the regulation of gut contractions. The slow waves regulate the maximum frequency of RPCs, their timing of occurrence, and the direction and distance of their propagation. A phasic contraction can occur only once during cell depolarization. Therefore, the maximum frequency of contractions at a given location cannot exceed the frequency of slow waves. The slow waves are omnipresent but contractions occur only under the conditions of concurrent depolarization and excitatory neurotransmitter release from motor neurons. The frequency of slow waves in the intact human colon is highly irregular and varies from approximately 2 to 13 cycles/min. Since a local contraction occurs only once during a slow wave depolarization, it will propagate distally only if the slow waves are phase-locked in that direction. In the colon, the slow waves exhibit very poor coupling, which is the reason that the phasic contractions do not propagate or propagate only over very short distances. This is the underlying cause of slow distal propulsion of colonic contents, as noted above.

The importance of coordination of the actions of slow waves and excitatory neural input to regulate contractions is sometimes overlooked in the literature. This confusion arises because, in other organs, the muscle cells alone regulate spontaneous contractions, such as the cardiac muscle that contracts with every membrane depolarization. The colonic smooth muscle cells do not contract with every depolarization. In other organs, such as those containing only skeletal muscle, the neurons alone regulate contractions. On the other hand, the excitatory input from neurons alone cannot contract colonic smooth muscle cells. Also, the colonic smooth muscle cells are not like the vascular smooth muscle cells, which generate predominantly a tone to regulate blood flow. The colonic muscle generates three distinct types of contractions, RPCs, GMCs, and tone, to regulate motility function.

Unlike the small bowel and stomach, the colon of most species, such as human and dog, also generates long-duration phasic contractions. These contractions are not regulated by the omnipresent slow waves as discussed above; they are regulated by contractile electrical complexes (CECs) that occur intermittently. The frequency of CECs and their corresponding long-duration contractions in the human colon varies from approximately 0.5 to 2 per minute. The short- and long-duration phasic contractions together are responsible for the extensive mixing and slow net distal propulsion in the colon.

The gut of most species exhibits three types of interstitial cells of Cajal (ICC): one layered network in the myenteric plexus (ICC-MP), one in the submucosal plexus (ICC-SP), and one in the circular muscle layer (ICC-IM). The hypothesis is that the ICC (MP) drive the slow waves in the small intestine, whereas ICC (SP) drive them in the colon. The ICC (IM) may mediate the inhibitory neuronal input to muscle cells. The majority of the studies in support of this hypothesis have been carried out in the rat and mouse guts. The dissection of submucosa from the rat colon muscle strips obliterates phasic contractions regulated by slow waves. The presence and distribution of ICC in the human colon, however, differ substantially from those in rodents. The highest density of ICC in the human colon has been reported to be in the myenteric plexus. The ICC (SM) at the inner layer of the circular muscle are sparse and may not form a continuous network as has been reported in rodents. The density of ICC (IM) is several-fold less than that of ICC (SM) or ICC (MP) in the entire human colon. The differences in the distributions of ICC between humans and rodents leave open the question whether there are differences in their roles in the two species. Several studies have reported a decrease in the density of ICC or damage to their processes in colonic motility disorders, such as constipation, but in most of these reports the concurrent absence of slow waves or impaired inhibitory motor function related to the defects in ICC was not investigated.

Excitation–Contraction Coupling through Cell Signaling

On ligand binding to surface receptors, a number of signaling cascades, starting with the activation of G-proteins, are brought into play for smooth muscle cells to contract. An immediate-early event is the increase of cytosolic [Ca^{2+}]. This event utilizes Ca^{2+} influx through L-type Ca^{2+} channels, as well as calcium release from the endoplasmic reticulum. The gut smooth muscle cells express primarily the M_2 and M_3 receptors. M_3 receptors are coupled to G_{q11} protein and M_2 to $G_{\alpha i3}$. The activation of G_{q11} by M_3 receptors activates phospholipase C to hydrolyze inositol phospholipids. The hydrolysis of phosphatidylinositol 4,5-biphosphate generates two second messengers, inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 acts on its receptors on the endoplasmic reticulum to release calcium from intracellular stores. Ca^{2+} release from these stores also occurs in response to ryanodine. DAG, on the other hand, activates protein kinase C (PKC), which translocates it from the cytosol to the plasma membrane. The activation of G-protein and PKC is also linked to the opening of L-type calcium channels for Ca^{2+} influx. The activation of PKC and increase of cytosolic [Ca^{2+}] are key steps in cell contraction, but several other steps, such as the release of arachidonic acid from membrane phospholipids and activation of mitogen-activated protein kinases, also play important roles in excitation–contraction coupling in colonic smooth muscle cells. The expression of some of these signaling molecules is altered in inflammation, leading to motility abnormalities.

COLONIC MOTILITY DYSFUNCTION IN INFLAMMATION AND IRRITABLE BOWEL SYNDROME

Colonic Inflammation

The classic concept of inflammatory bowel disease has been that an autoimmune disorder results in uncontrolled inflammation in which the rest of the cells in the gut wall are "innocent bystanders" and get hurt. Accumulating evidence over the past decade or so shows, however, that although an immune disorder is a major component of this disease, the rest of the cells, including smooth muscle cells, enteric neurons, epithelial cells, myofibroblasts, and glia, play an active rather than a passive role in both acute and chronic inflammations. The role of smooth muscle cells and enteric neurons is twofold: (1) to generate abnormal motility patterns that produce the symptoms of diarrhea, urgency of defecation, and abdominal cramping; and (2) to secrete cytokines and chemokines and express cell adhesion molecules on their surface to amplify the inflammatory response triggered by the activation of resident and infiltrating immunocytes in the muscularis externa.

In both acute and chronic inflammation, rhythmic phasic contractions and tone are suppressed in the colon, whereas the frequency of GMCs is significantly increased. The absence of phasic contractions and decrease of tone result in the lack of mixing and slow propulsive movements, thus decreasing the uniform and prolonged exposure of the lumenal contents to the mucosa for absorption. The absence of phasic contractions also allows rapid propulsion of colonic contents, which otherwise move slowly to and fro. At the same time, frequent mass movements produced by the increased frequency of GMCs propel the fecal contents rapidly to further decrease their mucosal contact. When the GMCs occur in the distal colon or propagate from the proximal colon to the rectum, they produce a sense of urgency by forcefully propelling the bolus ahead of them against the anal sphincters. In addition, the GMCs, by their strong contractile force and/or by distending the

descending segment beyond the nociceptive threshold, may produce the sensation of abdominal cramping. The nociceptive threshold in the inflamed colon is reduced due to hyperalgesia and allodynia, further increasing the incidence of abdominal cramping. In health, the GMCs are rarely felt to be painful because of the lack of hyperalgesia and because of intact descending relaxation that accommodates the large bolus that is propelled rapidly by a GMC.

Primary cultures of human colonic smooth muscle cells, as well as longitudinal muscle/myenteric plexus strips, secrete a panel of cytokines and chemokines and express cell adhesion molecules in inflammation and on exposure to cytokines, such as tumor necrosis factor α and interleukin-1β. The recruitment of smooth muscle cells and enteric neurons, which are in much greater numbers than the immunocytes, may be essential for full-blown inflammation in the muscularis. Thus, the colonic smooth muscle cells and enteric neurons may serve as secretory cells, although their normal function is to contract and release neurotransmitters, respectively.

Both of the above changes in cell behavior, i.e., altered motility patterns and secretions of inflammatory mediators, are mediated by altered gene expression of key signaling molecules through the activation of transcription factors, such as nuclear factor κB (NF-κB). Calcium influx through L-type Ca^{2+} channels plays a critical role in the contraction of smooth muscle cells. Recent findings show that calcium influx through these channels is reduced in inflammation. Other findings also show that inflammation, as well as oxidative stress, activates NF-κB and, thereby, suppresses contractility. The inhibition of NF-κB in single cells or in intact animals reverses the suppression of contractility. Regulation of gene expression in colonic smooth muscle cells to affect their contractility, as well as in enteric neurons to affect neurotransmitter release, may be a potent target of molecular medicine to normalize motility disorders.

Irritable Bowel Syndrome

Irritable bowel syndrome results from motility dysfunction and visceral hypersensitivity. It is characterized by visceral pain accompanied by diarrhea (IBS-diarrhea; IBS-d), constipation (IBS-constipation; IBS-c), or alternating diarrhea and constipation (IBS-diarrhea/constipation; IBS-d/c). The symptoms of diarrhea and constipation result directly from enteric neuromuscular disorders. Since mental stress exacerbates the symptoms of IBS or can even precipitate them, abnormal input from the central nervous system and/or spinal cord may also play an important role in producing motility dysfunction in these patients.

Unlike in IBD patients, RPCs and tone are not generally suppressed severely in IBS patients. However, the precise alterations in the spatiotemporal patterns of RPCs that may lead to altered transit in IBS-d or IBS-c have not been identified for several reasons: (1) As noted above, the colonic RPCs are highly disorganized in space and are irregular in frequency, which makes it almost impossible to analyze them visually. (2) The manometric or solid-state transducer devices record primarily the lumen-occluding contractions. Most colonic RPCs do not occlude the lumen. Therefore, these devices do not record all RPCs. (3) Cleansing the colon prior to motility recordings by intralumenal devices may significantly alter its motility patterns. Under normal conditions, the colon is seldom empty. (4) The colonic motility is neither uniform nor consistent throughout its length, which reflects different mixing and propulsion rates in different segments of the colon. Reliable conclusions on colonic motility can be made only by concurrent recordings from the entire colon. This is technically challenging. (5) The normal transit time from the appearance of digesta at the ileocolonic junction to defecation is on the order of 36 to 48 h in the human colon. During this period, the motility patterns change almost continuously throughout the colon. Shorter periods of recording are unable to provide a complete understanding of motility patterns in either health or disease. These difficulties have led some investigators to speculate that there may be no abnormal motility in IBS patients. This hypothesis does not explain the rapid or slow transits in the colon in IBS-d and IBS-c patients, respectively, as well as intermittent occurrences of abdominal cramping.

GMCs play a major role in motility dysfunction in IBS patients as they can be related to all three major symptoms of this disease: rapid transit, slow transit, and visceral pain. Patients with constipation have been reported to have a significantly lower frequency of colonic GMCs than healthy subjects. The smaller frequency of GMCs would not only reduce mass movements, which are essential in an otherwise sluggish motility environment, but they may also affect the propulsive force required for defecation and the strong contractile stimulus required in the rectum to relax the anal sphincters. On the other hand, an increase in the frequency of GMCs causes motor diarrhea by producing excessive mass movements. Hyperalgesia in IBS patients coupled with the occurrence of GMCs can produce the sensation of abdominal cramping. In comparison with rhythmic phasic contractions, the GMCs are easier to record and analyze because they are mostly lumen

occluding. However, long-term recordings from the entire length of the colon may still be a prerequisite for a complete understanding of their contribution to colonic motor function in both health and disease.

Colonic Obstruction

adynamic ileus Absence of intestinal motility, often occurring for several days following surgery.
diverticulosis Herniations of the mucosa and submucosa through the muscular wall of the colon.
intussusception Invagination or telescoping of proximal bowel into the adjacent distal bowel, often resulting in bowel obstruction.
volvulus Abnormal twisting of a segment of bowel on itself in the longitudinal axis, often resulting in bowel obstruction.

Colonic obstruction refers to blockage of fecal or other luminal contents from movement in the anal direction within the colon. There are many causes of colonic obstruction, most of which can be subdivided into mechanical or nonmechanical categories; nonmechanical obstruction may be congenital or acquired.

INTRODUCTION

Mechanical colonic obstructions are caused by a tumor or other lesion that results in narrowing or total stricture of the bowel lumen, thereby preventing intestinal contents from moving toward the anus. Nonmechanical colonic obstruction results from failure of normal propulsive motility. Commonly, this is due to a condition called adynamic ileus, which usually has a reversible cause. A more severe and prolonged form of ileus is termed colonic pseudo-obstruction, which is a syndrome with all the signs and symptoms of mechanical obstruction in the absence of an occluding lesion. Patients with this syndrome may have an underlying congenital defect involving absence of the nerve supply to the intestinal wall or lack of circular smooth muscle, which causes severe dysmotility that can lead to megacolon. An example of congenital aganglionosis is Hirschsprung's disease. Colonic pseudo-obstruction that is acquired later in life after trauma or surgery is referred to as Ogilvie's syndrome.

ETIOLOGY

By far the most common cause of mechanical colonic obstruction is cancer, which accounts for 60–70% of all cases. Most colorectal cancers occur in the distal third of the colon and up to 10% of these patients will require emergent surgery for decompression. Up to 20% of cases of colonic obstruction are caused by a volvulus. The most frequent site of colonic volvulus is the sigmoid colon. Other sites, in order of decreasing frequency, are the cecum, transverse colon, and splenic flexure. Diverticular stricture is the third most common cause of mechanical colonic obstruction. Diverticulosis is common in the United States and Western world in general, with a prevalence approaching 40% in some case series. Diverticulitis refers to inflammation in the involved segment of bowel, causing a perforation of the colonic diverticulum. Progression of this process can lead to complications that include development of a localized abscess, fistula formation, stricture, and complete bowel obstruction. Less common causes of mechanical colonic obstruction include intussusception, stricture secondary to inflammatory bowel disease, fecal impaction, and extrinsic compression (i.e., from intraabdominal adhesions, masses, or hernia).

Nonmechanical colonic obstruction likewise has many causes and can be categorized as either congenital or acquired. Congenital absence of the enteric nervous system (aganglionosis), lack of circular smooth muscle, or loss of extrinsic nervous supply to the bowel can all lead to ineffective colonic motility and ultimately functional obstruction of the lumen. Hirschsprung's disease is the classic example of congenital colonic aganglionosis. Due to lack of enteric inhibitory motor neurons, the involved segment of bowel fails to relax, resulting in narrowing of the lumen and obstruction to the passage of feces. This usually occurs in distal colonic segments or in the rectum and leads to megacolon in severe cases. Familial visceral myopathies, or progressive dystrophy of intestinal smooth muscle, can be the underlying cause of failure of propulsive motility resulting in nonmechanical (i.e., functional) obstruction. Finally, systemic neurologic disorders such as Parkinson's disease and brain stem lesions can lead to colonic dysmotility and functional obstruction via

compromise of nervous signaling from the brain and spinal cord to the bowel.

The most common acquired nonmechanical cause of acute colonic obstruction is Ogilvie's syndrome, which involves gross dilation of the cecum and proximal colon in the absence of an anatomic lesion. The etiology of this process is unknown; a postulated mechanism involves impairment of the autonomic nervous supply to the colon, usually following trauma or surgery. Metabolic disturbances (i.e., hypokalemia, hypomagnesemia, or hypocalcemia) or use of narcotic drugs may occur in conjunction with Ogilvie's syndrome and contribute to colonic dysmotility or may occur independently as a cause for transient colonic obstruction. Other drugs implicated as a cause for nonmechanical intestinal obstruction include calcium channel blockers, tricyclic antidepressants, antihistamines, phenothiazines, and clonidine. Endocrine disorders, such as hypothyroidism, also remain an important underlying factor in functional colonic obstruction.

Acquired colonic obstruction may be associated with a variety of degenerative changes to the musculature and nervous supply of the bowel that occur in other systemic diseases. Infiltrative diseases such as amyloidosis involve disruption of the contractile proteins in intestinal smooth muscle due to deposition of amyloid in the muscle. Systemic sclerosis causes similar disruption that is secondary to fibrosis and smooth muscle atrophy in the involved segments of bowel. Some visceral neuropathies reflect autoimmune attack on the enteric nervous system and can be the cause of intestinal pseudo-obstruction. Neuropathies of this nature occur in Chagas' disease and paraneoplastic syndrome secondary to small cell carcinoma of the lung. Circulating antineuronal antibodies directed to neural elements of the enteric nervous system occur in both Chagas disease and paraneoplastic syndrome and, when present, can lead to functional dysmotility.

SYMPTOMS

Whether the cause is mechanical or nonmechanical, most patients with colonic obstruction develop similar symptoms. Abdominal pain, distension, and bloating are the most common presenting symptoms. The degree of abdominal pain varies considerably among affected patients and is usually more severe if total obstruction or peritonitis is present. If the pain is severe and persistent, then a complication such as bowel perforation or strangulation must be considered. Depending on the degree to which the obstruction impedes the forward propulsion of the luminal contents, the patient may experience constipation or diarrhea. Change in stool caliber may reflect the location of the obstruction. Patients often report pencil-thin stools when a partially obstructing lesion is present in the distal colon or rectum. Vomiting can be a late symptom but is uncommon in colonic obstruction. Other symptoms, when present, may suggest the underlying cause of the obstruction. For example, weight loss, blood in the stools and poor appetite are common in patients with colorectal cancer.

DIAGNOSIS

Making the diagnosis of colonic obstruction always starts with taking a history and performing a physical exam. The most frequently reported symptoms are abdominal pain, distension, and bloating; however, it is important to consider that lack of pain does not exclude the diagnosis. This is especially true in elderly patients or postoperative patients being treated with narcotic medications. Duration of symptoms may also provide a clue to the cause of the obstruction. Acute onset of symptoms is common with volvulus or intussusception; whereas insidious onset tends to occur in patients who have colorectal cancer. The physical exam usually reveals a tympanitic, distended abdomen with tenderness to palpation that is often more severe below the level of the umbilicus. Even with complete mechanical obstruction, bowel sounds are usually present and may sound like "rushes and tinkles." Nevertheless, there are no pathognomonic physical exam signs or symptoms for colonic obstruction.

Plain radiographs should be taken with the patient both in the supine and the upright positions. The characteristic finding will be dilated loops of bowel proximal to the site of obstruction with little or no gas in the distal colon or rectum. Air/fluid levels in the proximal colon or small bowel may also be present and suggestive of an obstruction. Computed tomography (CT) scan of the abdomen is helpful in distinguishing between partial and complete obstruction and can identify segments of bowel that may be strangulated.

Ultimately, most patients with suspected colonic obstruction will undergo a proctosigmoidoscopy to identify the site and potential cause of the obstruction. If a neoplastic process is discovered, histologic evaluation of biopsy specimens can provide a definitive diagnosis. Exceptions are patients with signs of peritonitis, strangulation, or bowel perforation. Water-soluble contrast enema may be performed to confirm the diagnosis and define the site of the anatomic obstruction. Any

colonoscopic examination must be done with caution to avoid causing perforation secondary to air insufflation during the procedure.

There are no reliable blood tests that confirm the diagnosis of colonic obstruction. Nevertheless, it is useful to obtain blood work for measurement of serum electrolytes, kidney function, and complete blood count. These tests can reveal whether a patient is dehydrated, losing blood, or showing signs of infection. A serum lactate level is usually obtained and, if elevated, suggests compromise of blood supply to the affected bowel.

TREATMENT

The treatment of colonic obstruction depends on the cause and whether it is partial or complete. Complications secondary to the obstruction, such as bowel strangulation or perforation, can also change management. As a general rule, treatment for partial obstruction begins with supportive care. Intravenous fluids are given to restore blood volume and prevent dehydration and electrolyte imbalances are corrected. A nasogastric tube can be placed to decompress the stomach and proximal small bowel. Oral intake should be avoided. If there are signs of peritonitis, antibiotics are administered. Air or contrast enemas are sometimes useful in relieving obstructions, especially if caused by intussusception. Possible precipitants such as narcotic or anticholinergic medications are used sparingly, if at all, and promotility drugs such as neostigmine are often helpful. Colonoscopic placement of a rectal tube may be done to decompress the colon when supportive measures have failed.

Surgery is usually needed if a partial obstruction does not resolve or if the colonic obstruction is complete. It is also reserved as an option for patients who develop a complication, such as bowel strangulation or perforation. The type of surgery will depend on the cause of the obstruction, the patient's clinical condition, and the findings during the operation.

active colonic injury Colonic mucosal disease characterized by neutrophilic inflammation of the mucosa, cryptitis, and crypt abscesses, with or without ulcers.

chronic colonic injury Colonic mucosal disease characterized by alterations in the cellular components and architecture, suggestive of ongoing injury.

colitis Inflammation of the colonic mucosa characterized by neutrophilic and/or mononuclear cell inflammation in the lamina propria, with associated injury to the colonic epithelium.

inflammatory bowel disease Chronic, idiopathic inflammatory disease of the colon, specifically Crohn's disease and ulcerative colitis.

ischemia Pattern of disease injury characterized by fibrin and hemorrhage in the lamina propria, crypt loss and regeneration, and necrosis of the mucosa. This pattern of injury may be seen in association with a variety of vascular insults, infections, and medications.

Colonoscopy has assumed a major role in the evaluation of patients with lower gastrointestinal bleeding. As a result, clinicians increasingly encounter the presence of colonic ulcers and, thus, are faced with the problem of diagnosing these lesions based on the anatomic distribution, endoscopic appearance, and pathologic features of the affected areas of mucosa. A variety of different disease processes may lead to mucosal ulceration. Some are associated with specific pathologic features that may help clarify a specific etiology. Diagnosis requires knowledge of the more common types of colonic ulcers and information regarding methods to identify the etiology based on the clinical, endoscopic, and pathologic features of these lesions.

VASCULAR DISORDERS

Ischemic Colitis

Ischemic colitis is classified as occlusive or nonocclusive disease (Table I). Acute ischemic colitis results from a sudden reduction of splanchnic blood flow and may develop in association with a variety of systemic diseases, including atherosclerosis, diabetes mellitus, cardiovascular disease, vasculitis, hypercoagulable states, and hypertension; low-flow states, including cardiac failure, systemic hypotension, and sepsis; and certain drugs, including oral contraceptives and cocaine. Acute ischemic colitis may also occur as a result of mechanical occlusion of blood flow due to an incarcerated hernia, volvulus, intussusception, or adhesions.

Ischemic colitis may develop at any age, but is most common in older individuals. The clinical manifestations vary according to the underlying etiology, the severity of the injury, and the distribution of disease. Patients typically complain of rapidly progressive crampy abdominal pain associated with abdominal distension, bloody diarrhea, leukocytosis, and fever. Extensive ischemic colitis may be associated with peritoneal signs, ileus, shock, and mental status changes.

Endoscopically, affected areas often demonstrate mucosal ulceration, friability, and erythema, or even pseudomembranes composed of sloughed epithelium admixed with fibrin and inflammatory cells. The distribution of disease tends to reflect the vascular supply to the colon, with a predilection to occur in "watershed" areas that lie within anastomosing branches of the arterial tree. Thus, the splenic flexure and rectosigmoid colon are particularly common areas affected by ischemic injury.

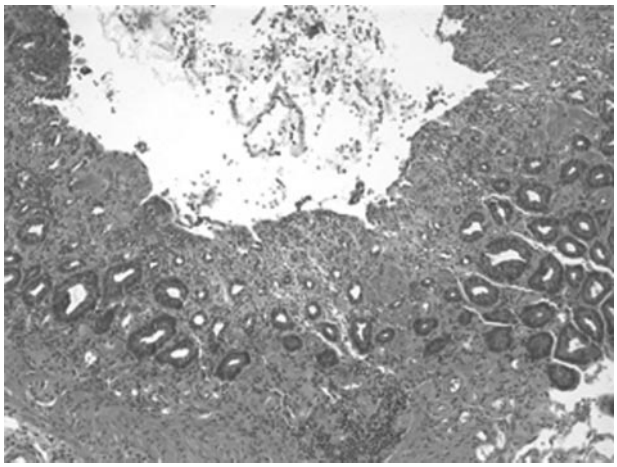

FIGURE 1 Ischemic colitis. The mucosa is ulcerated and the crypts appear small and regenerative. The lamina propria is filled with fibrin and extravasated red blood cells.

Pathologically, the mucosa may show a variety of changes, depending on the stage of disease. Early histologic features of acute ischemic colitis include crypt necrosis, edema, hemorrhage, and fibrin deposition in the lamina propria (Fig. 1). With progression, the mucosa may become entirely necrotic, resulting in the formation of ulcers. Extensive sloughing of mucosa and the development of pseudomembranes may also be apparent. With progression, the deeper layers of the bowel wall may become affected, resulting in transmural necrosis, serositis, and perforation. If the ischemic insult is reversed, or is only mild, the mucosa will undergo healing and repair, which, in some cases, may be complete. However, repeated injury may result in the development of chronic changes such as crypt architectural abnormalities, atrophy, fibrosis, and chronic inflammation, features that can mimic inflammatory bowel disease. Injury to the submucosa and muscularis propria usually heals with scar tissue.

Milder forms of ischemic colitis that are confined to the mucosa are frequently reversible and may be managed expectantly. However, transmural necrosis usually represents a surgical emergency and necessitates surgical resection of the involved areas. Complications of ischemic colitis include bacterial superinfection, particularly by *Clostridium difficile*, stricture, and the development of colonic obstruction.

Vasculitis

Many forms of systemic vasculitic illnesses, such as polyarteritis nodosa, Churg–Strauss syndrome, Henoch–Schönlein purpura, systemic lupus erythematosus, rheumatoid disease, Wegener's granulomatosis, hemolytic uremia syndrome, and Behçet's disease, may involve the gastrointestinal tract, resulting in colonic ulceration. These diseases commonly affect small arteries, capillaries, and venules, and thus may be encountered anywhere in the colon.

Clinical manifestations of vasculitic injury to the colon include abdominal pain and distension, bloody diarrhea, and fever. The endoscopic appearance of the affected colon is variable, depending on the severity of the disease. Mucosal erythema associated with shallow ulcers may be present in milder disease, whereas more extensive disease shows marked mucosal erythema and ulcers, epithelial necrosis, and, occasionally, transmural injury with perforation.

Histologic features that suggest the presence of an underlying vasculitis involve mucosal changes of ischemic colitis, including regeneration of colonic crypts, hemorrhage and fibrin deposition in the lamina propria, and ulcers; combined with the presence of leukocytoclasis and fibrin deposition within blood vessel walls. Also, rare vasculitic syndromes, such as enterocolic lymphocytic phlebitis, are encountered exclusively in the gastrointestinal tract. This unusual form of vasculitis is confined to the intestinal tract and is characterized by the presence of lymphocytic inflammation of medium and small veins.

The management of patients with vasculitis-induced colitis involves the use of immunosuppressive therapy. Patients who develop necrosis are at risk for the development of bacterial superinfection, bleeding, and colonic perforation in the acute setting and may require surgical intervention. Chronic complications, such as colonic strictures or obstruction, may also require surgical resection of the affected areas.

Radiation-Induced Injury

Radiation injury may produce acute or chronic colonic ulcers via two different mechanisms. Radiation is directly toxic to the colonic mucosa and causes mucosal necrosis and ulcers, which develop shortly after the initiation of therapy. However, radiation also causes progressive obliteration of blood vessels and may produce ischemic-type colonic ulcers in the months to years following therapy. Colonic disease usually occurs as a result of radiotherapy for a variety of tumors, such as those that arise from the prostate, urinary bladder, uterus, distal colon, and pelvic bones and soft tissues. The distal colon, particularly the rectosigmoid colon, is most frequently affected. Acute radiation injury, which is manifest approximately 7–14 days after initiation of therapy, is heralded by

the onset of lower abdominal pain, abdominal distension, rectal bleeding, diarrhea, mucoid discharge, and tenesmus. The endoscopic findings include edema, erythema, erosions, and friability. Vascular telangiectasias may present as well.

Pathologically, acute radiation injury is characterized by submucosal edema. However, there may also be active colitis with crypt abscesses, increased neutrophilic inflammation in the lamina propria, and ulceration associated with epithelial cell necrosis. The disease is largely confined to the mucosa, with sparing of the deeper layers of the bowel wall. In most cases, the symptoms of acute radiation colitis are self-limited and resolve with cessation of radiotherapy. Therapy consists predominantly of supportive care. In the months to years following radiotherapy, patients may develop chronic sequelae due to the effects on blood vessels and soft tissues. Radiation-induced vascular ectasia may develop in thin-walled venules and capillaries and lead to gastrointestinal bleeding. Chronic radiation injury results in progressive intimal and fibrous obliteration of arteries, which ultimately compromises the vascular supply to the affected colon and produces ischemic ulceration of the mucosa. In this setting, patients usually present with lower gastrointestinal bleeding due to vascular telangiectasias. If there is an ischemic component to the injury, they may also complain of crampy lower abdominal pain, bloody diarrhea, tenesmus, and/or rectal bleeding.

The endoscopic appearance of chronic radiation injury is characteristic. In many instances, the mucosa is atrophic and vascular ectasias are present. The mucosa may be friable and erythematous with superficial ulcerations as a result of vascular obliteration and ischemic injury. The histologic hallmark of chronic radiation injury is manifest by damage to endothelial cells and blood vessels, particularly arteries. Increased subepithelial collagen deposition may also be seen, in addition to crypt architectural distortion and atrophy of the mucosa (Fig. 2). Affected arteries show luminal obliteration, intimal hyperplasia, and abundant "foam" cells within the muscular wall (Fig. 3). "Atypical" fibroblasts, with abundant eosinophilic cytoplasm and hyperchromatic nuclei, may also be present in the stroma.

Chronic complications of radiation injury include stricture formation and serosal adhesions. These complications may become severe enough to warrant surgical resection. Lower gastrointestinal bleeding from mucosal and submucosal telangiectasias is a frequent occurrence and may be treated with argon plasma coagulation laser therapy. Post-irradiation sarcomas and carcinomas have been reported to develop after a long latency period as well.

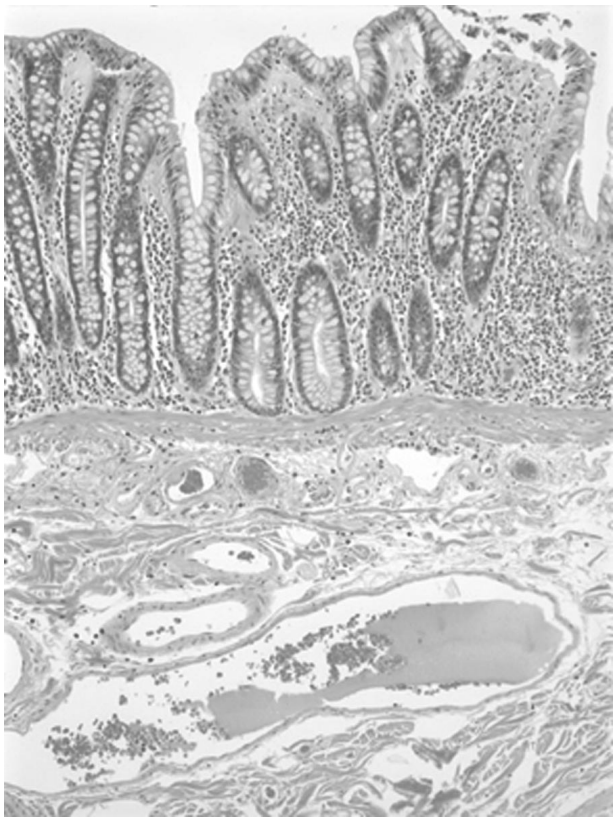

FIGURE 2 Post-irradiation changes include subepithelial collagen deposition and vascular ectasia in the submucosa.

INFECTIOUS COLITIS

Bacterial Colitis

Acute Self-Limited Colitis

Acute self-limited colitis is one of the most common causes of colonic ulcers. The majority of cases develop as a result of exposure to an infectious agent or toxic substance. Unfortunately, an etiologic agent is not identified in up to one-half of cases of acute self-limited colitis. Patients typically present acutely with crampy abdominal pain, bloody diarrhea, and fever. Laboratory tests often reveal leukocytosis and the presence of fecal leukocytes on stool examination.

The endoscopic features of acute self-limited colitis are usually evident within the first 4 days of onset of symptoms. The colonic mucosa appears erythematous, edematous, and friable, with small ulcers and superficial erosions that do not demonstrate a predilection for any specific site within the colon. Pathologically, the features of acute self-limited colitis are quite consistent. Early changes include edema, increased active (neutrophilic) inflammation in the lamina propria and epithelium, and crypt abscesses and ulcers. With

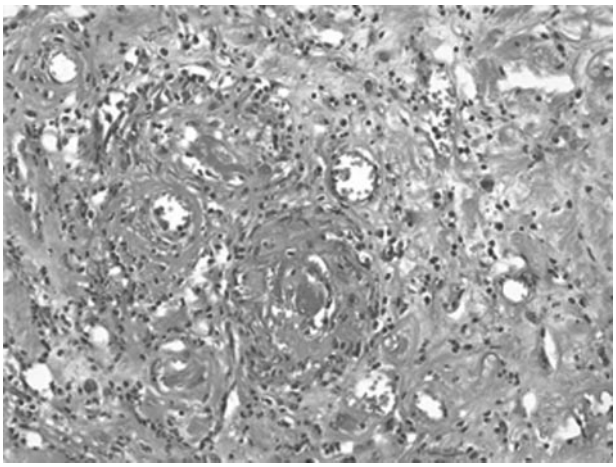

FIGURE 3 Radiation injury induces intimal hyperplasia and luminal narrowing of the submucosal blood vessels. In this example, mural foam cells are associated with inflammation. The submucosa is fibrotic, and scattered atypical stromal fibroblasts are present.

progression, edema becomes less prominent and the neutrophilic inflammation regresses. During the final stages of resolution, the epithelium regenerates to restore normal architecture to the mucosa. Architectural distortion and marked mononuclear cell inflammation of the lamina propria are usually conspicuously absent in cases of acute self-limited colitis. Generally, the disease is confined to the mucosa, with sparing of the deeper layers of the bowel wall. In most instances, acute self-limited colitis resolves spontaneously or following antibacterial therapy. On resolution, there is normally complete restoration of the mucosa to the pre-disease state. Because the disease is usually limited to the mucosa, it generally heals without any significant complications.

Clostridium difficile-Induced Pseudomembranous Colitis
