Having said this, to accept the fact of inheritance is to acknowledge a certain rigidity in biological development, and to accept the fact of cumulative natural selection is to acknowledge a certain rigidity in evolutionary history. Thus one might infer from widespread acceptance of evolution to widespread acceptance of innateness. However, such inference has proved problematic. One stumbling block has been the great variety of ways in which innate traits can be characterized. They can be described variously as:

- Traits that develop in the absence of contact with conspecifics, such as web building in spiders;
- Traits that are characteristic of particular species, such as species-specific birdsong;
- Traits that are evolutionary adaptations, such as "dancing" in bees;
- Behaviors that are unlearned, including so-called reflex actions;
- Behaviors that develop fully formed in animals that have been prevented from practicing them.

While often in agreement, these definitions are not coextensive. Linguistic ability is very much characteristic of the human species, but it does not develop in the rare cases in which human children grow up in the absence of contact with conspecifics. So, some worry that there may be no single property that all purportedly innate characteristics have in common. Certainly there has been no agreed-upon definition in the scientific or philosophical literature despite a considerable amount of work toward this end. Much of this work has been done by ethologists (beginning with Konrad Lorenz) in the 1940s who sought to explain the peculiar character of a class of inherited behavioral characteristics in nonhuman animals. These behaviors have in common that they are performed in very stereotypical ways, are inherited, are triggered by relatively simple proximal stimuli, and can be triggered in circumstances in which their performance is disadvantageous to the animal in question. Ethologists argued that these traits are properly thought of as innate. However, they were well aware of the problem of providing a clear characterization of innateness. In light of the apparent profusion of possible definitions, Lorenz (1950, 261) argued that what these putatively innate behaviors have in common is that they are all genetic.

Are Innate Traits Genetic Traits?

Despite the *prima facie* plausibility of innate traits being the products of genetic structure, this idea has come under fire from a number of developmental biologists as well as philosophers of biology. In part this is because while it is true that all organisms inherit genetic structure from their parent or parents, it is false to suggest that this is the sum total of their inheritance (see Heritability).

Developmental systems theorists (such as Griffiths and Gray [1994]) point out many inherited characteristics are reliably passed from generation to generation via nongenetic channels. Organisms inherit taught hunting behaviors, food sources, and nest sites and even gut microfauna from their parents. None of these are transmitted via the inheritance of their parents' DNA. Given this, one cannot infer that if innate traits are inherited, they must also be genetic.

If innate traits are to be characterized as genetic, there must first be a robust theory of what it means for a trait to be genetic. However, the idea that such a robust theory will be found has been the subject of considerable skepticism, most famously from Richard Lewontin (1974), who points out that one cannot mean that a "genetic trait" so called is caused exclusively by genes. All traits require both genetic and nongenetic precursors in their development. Furthermore, genes and environment interact in the course of development, so that one cannot determine the extent to which each is a cause of the development of any particular trait. Put more technically—genes and nongenetic developmental

resources are typically nonadditive contributors to phenotype, and one therefore cannot partition the variance due to each (although one can partition the additive and nonadditive portions of variance) (see Heritability).

Recent Work on Innateness

Recent work has sought to tie the idea of innateness to particular biological processes. André Ariew (1999) proposes an account of innateness based on C. H. Waddington's notion of developmental canalization. This is the process by which developmental pathways are buffered against environmental perturbation. William Wimsatt (1999) argues that innateness is caused by generative entrenchment. This is the process by which adaptations that have been historically important become locked into a lineage as later adaptations are built atop them and are thus developmentally dependent upon them. But such strategies have the disadvantage of requiring the scientific community to settle on a particular biological process (generative entrenchment, canalization, or some other) as the source of all innateness. This leads back to the original problem with the biological characterization of innateness, namely that there appear to be a variety of processes that give rise to evolutionary and developmental rigidity.

Another alternative is to avoid Lewontin's argument by characterizing genetic traits in terms of genetic information (as did Lorenz, although his description of genetic information was rather sketchy). However this strategy has proved contentious (see Biological Information). Griffiths and Gray (1994) argue that all traits are products of information from both genetic and nongenetic developmental resources. Therefore, attempting to single out sources of developmental information will not provide an explanation of the distinctive nature of innate traits. Indeed, Griffiths has recently argued that the use of the term "innate" ought to be abandoned altogether (Griffiths 2002). However, Maclaurin (2002) suggests that one can nonetheless recognize particular groups of developmental resources (genes among them) as very unequivocal sources of developmental information about particular traits. Thus, innate traits can be characterized as those that are products of information from particular developmental resources that are maintained in populations by a variety of mechanisms. But this is likely to be controversial, as it rejects the idea that innate traits are necessarily genetic and it embraces the idea that innateness is a matter of degree.

The central advantage of making this move is that it focuses the study of innateness on the existence and nature of mechanisms that serve to maintain particular traits in biological populations. In doing so, it avoids the implausible assumption that the development of some traits is entirely ruled by the presence of some particular set of genetic (and perhaps environmental) precursors. This broadening of the notion of innateness is very much in line with recent findings in genetics. A study was begun in 1972 on the lives of 1,037 newborns in the city of Dunedin in the South Island of New Zealand. The most remarkable finding of the study to date has been a gene (monoamine oxidase A) that predisposes young people to violent behavior in later life. Those with low-active versions of the gene did four times the number of rapes, robberies, and assaults as they progressed to adulthood, *but only if they had also been maltreated as children.* Remarkably, the same maltreatment produced no corresponding psychological maladjustment in individuals with high-active versions of the gene (Caspi et al. 2002). No one would have called such environmentally mediated behavior innate in the old Lorenzian sense of the word, and yet here there is a very important and complex set of mechanisms that maintain a cycle of violence in a human community.

As more is learned about such inherited interactions, the study of innateness will increasingly be focused on the enhancement or amelioration of characteristics that are currently innate.

INSTRUMENTALISM

Though John Dewey coined the term *instrumentalism* to describe an extremely broad pragmatist attitude toward ideas or concepts in general, the distinctive application of that label within the philosophy of science is to positions that regard scientific theories not as literal and/or accurate descriptions of the natural world, but instead as mere tools or "instruments" for making empirical predictions and achieving other practical ends. This general instrumentalist thesis has, however, historically been associated with a wide variety of motivations, arguments, and further commitments, most centrally concerning the semantic and/or epistemic status of theoretical discourse (see below). Unifying all these positions is the insistence that one can and should make full pragmatic *use* of scientific theories either without believing the claims they seem to make about nature (or some parts of nature) or without regarding them as actually making such claims in the first place. This entry will leave aside the question of whether the term *instrumentalism* is properly restricted to only some subset of such views, seeking instead to illustrate the historical and conceptual relations they bear to one another and to related positions in the philosophy of science.

Loci Classici

Broadly instrumentalist sentiments concerning scientific theories have a remarkably long intellectual pedigree: indeed, Popper's (1963) famous critique of the position as intellectually sterile counts Andreas Osiander (author of the unsigned preface to Copernicus' *On the Revolutions of the Celestial Spheres*), Cardinal Bellarmino, and Bishop Berkeley as notable early defenders of the view (but cf. Fine 2001), even while resisting Duhem's claim to find its historical antecedents in classical Greek thinkers. Furthermore (as Popper and others note) the influential instrumentalism of nineteenth-century physicist Ernest Mach is rooted in a critique of Newtonian mechanics (and its concepts of absolute space, time, and motion) strikingly similar to Berkeley's own. Mach (1911) also resembles Berkeley in embracing a radical phenomenalism, insisting that what is represented " behind the appearances exists *only* in our understanding, and has for us only the value of a *memoria technica* or formula" (49): He argues that laws of nature (e.g., Snell's law) and theoretical hypotheses (e.g., the atomic hypothesis) are simply conceptual devices for the systematic classification, summary, organization,

and coordinated expression and prediction of innumerable particular appearances (Mach [1893] 1960, 582f). Thus, Mach insists that theoretical concepts like 'atoms' are merely "provisional helps" and are ultimately to be dispensed with not because they seek unsuccessfully to describe a reality beyond appearances, but rather because they *successfully* but only *indirectly* describe coordinated and systematized collections of experiences themselves.

The instrumentalist impetus familiar from more recent philosophy of science, however, is rooted more fundamentally in developments within physics at the turn of the century, and in the related logical, epistemic, and historical concerns about the status of scientific theories articulated by thinkers like Pierre Duhem and Henri Poincaré (Worrall 1982) (see Duhem Thesis; Poincaré, Henri). The progress of physical science had by this time begun to suggest that there might be quite genuine cases of differences between actual competing scientific theories that could not possibly be adjudicated by any straightforward appeal to empirical tests or observations: to use a famous example of Poincaré's (though not a case of actual competing theories), any set of measurements of the angles in a triangle marked out by appropriately oriented perfectly rigid rods can be accommodated by the assignment of any number of different combinations of underlying spatial geometries and compensating "congruence relations" for the rods in question; if the sum of the angles differs from 180 degrees, for instance, one may either interpret the underlying geometry as Euclidean and conclude that the distance marked out by each rod varies with its position and/or orientation or assume that the distance marked out by each rod remains constant and conclude that the underlying geometry of the relevant space is non-Euclidean. Poincaré's response to this problem of theoretical underdetermination was *conventionalism*, that is, he regarded such theoretical matters as the assignment of a particular physical geometry to space as a matter of choice or convention to be decided on grounds of greatest convenience (see Conventionalism). And this in turn implied, he suggested, the distinctively instrumentalist conclusion that the quite useful ascription of a particular geometry to space by a theory should not be construed as literally attributing anything (truly or falsely) to nature itself: "[T]he question: Is Euclidean geometry true? . . . has no meaning. We might as well ask if the metric system is true, and if the old weights and measures are false. . . . One geometry cannot be more true than another; it can only be more convenient" (Poincaré [1905] 1952, 50).

To important, distinct worries about theoretical underdetermination Duhem added a further concern about the role played by idealizations in physical theories, and both he and Poincaré noted the long history of repeated and radical discontinuities in the dominant theoretical conceptions of particular domains of nature. But both argued that this history of scientific revolution and wholesale replacement is characteristic only of efforts to "surmise realities hidden under data observable by the senses" (Duhem [1914] 1954, 274). These data name only "the images we substituted for the real objects which Nature will hide forever from our eyes" (Poincaré [1905] 1952, 161). Thus, while both Duhem and Poincaré retained full confidence in the "experimental laws" or generalizations about observable phenomena uncovered by scientific investigations, each denied that such investigations were able to penetrate the actual constitution of nature, or that mathematical theories were able to describe it. Duhem went so far as to consign the explanatory ambitions of theories to the realm of metaphysics rather than science.

Thus recognizing that scientific theories or theorists *aspire* to describe an underlying, inaccessible reality and/or explain observable events by appeal to it, both Duhem and Poincaré simply reject these ambitions as ultimately either unscientific or unsatisfiable in some way. Both ranged at different times and in different works through a wide variety of importantly divergent attitudes (and not all the same ones between them) toward the cognitive, semantic, and epistemic status of theories, including the views that extant scientific theories were not in fact making claims about inaccessible realities behind observable phenomena, that the scientific enterprise need not do so, and that it should not. Moreover, there is reasonable controversy over classifying either thinker as ultimately an instrumentalist in any of these straightforward senses: in his latest work, Poincaré (1999) wholeheartedly embraced the reality of atoms, while Duhem consistently held that scientific theories are able to establish "natural classifications" of the phenomena.

Even this brief excursion through instrumentalist themes in Mach, Duhem, and Poincaré offers some sense of the variety of distinctive further commitments with which the general claim that scientific theories should be understood simply as useful instruments rather than accurate descriptions of inaccessible domains of nature has been conjoined. Among such further commitments are the following suggestions:

- Theoretical discourse is simply a device for organizing or systematizing beliefs about observational experience and its meaning is therefore exhausted by or reducible to any implications it has concerning observable states of affairs (reductive instrumentalism);
- Theoretical discourse has no meaning, semantic content, or assertoric force at all beyond the license it provides to infer some observable states from others (syntactic instrumentalism);
- Even if such discourse is both meaningful and irreducible, it can nonetheless be eliminated from science altogether (eliminative instrumentalism); and
- Even if the literal claims of theoretical science about the natural world are neither reducible, nor meaningless, nor even eliminable, such claims are nonetheless not to be believed (epistemic instrumentalism).

The Language of Science: Reductive, Syntactic, and Eliminative Instrumentalism

It is quite striking that even some of Duhem and Poincaré's explicit reservations about scientific theories have a semantic or linguistic character: Duhem ([1914] 1954) claims that "hypotheses [are] not judgments about the nature of things, only premises intended to provide consequences conforming to experimental laws" (39) and that theoretical propositions "are neither true nor false ... only convenient or inconvenient" (334), while Poincaré ([1905] 1952) adds that the "object of mathematical theories is not to reveal to us the real nature of things," but "only ... to co-ordinate the physical laws with which experiment makes us acquainted" (211). Perhaps less surprising is the fact that such a generally linguistic or semantic strategy of analysis was appealing to logical empiricist thinkers.

The logical empiricists' efforts to effect a reduction of all scientific language to a privileged phenomenological or observational basis (a project pursued most notably by the early Carnap, but also influentially by Bridgman) quite naturally grounded an instrumentalism about scientific theories of the sort described above as reductive (see Bridgman, Percy; Carnap, Rudolf). But even after this attempted reduction came to be widely regarded as a failure and such logical empiricists had given up the notion that the semantic content of apparently theoretical discourse was "really" exhausted by its implications concerning collections of observable events or subjective experiences, the distinctively syntactic variety of instrumentalism offered a fallback position: perhaps theoretical claims carry no straightforward ontological commitments regarding unobservable entities, even if they cannot be fully reduced to claims about immediately accessible experiences or states of affairs. More specifically, some logical empiricists suggested that theoretical claims are properly regarded as devoid of any semantic content whatsoever beyond the license they provide to draw inferences from one observable state of affairs to another. In the spirit of Duhem and Poincaré, this view regarded theoretical claims as nonassertoric, that is (appearances to the contrary), as not making claims about what the world is like and not possessing truth values at all.

Of course, this somewhat counterintuitive view of the semantics of theoretical discourse might be evaded by embracing the arguably more natural view (equally in the spirit of Duhem and Poincaré) that such discourse is simply *eliminable* from science altogether. This eliminative form of instrumentalism also gained considerable currency among logical empiricist thinkers, especially following the formulation and proof of an influential theorem by William Craig. Craig's theorem showed that for any recursively axiomatized first-order theory T, given any effectively specified subvocabulary O of T (mutually exclusive of and exhaustive with the remainder of the vocabulary of T), one can effectively construct another theory, T', whose theorems are exactly those of T that contain no nonlogical expressions besides those in O. As Hempel was the first to realize, this theorem implies that if the nonlogical vocabulary of any given scientific theory is partitioned into theoretical and observational components, the theory can be replaced with a "functionally equivalent" Craig transform that preserves all the deductive relationships between observation sentences established by T itself, since (by Craig's theorem) "any chain of laws and interpretive statements establishing [definite connections among observable phenomena] should then be replaceable by a law which directly links observational antecedents to observational consequents" (Hempel [1958] 1965, 186). This implied in turn, Hempel noted, that theoretical terms could be eliminated from theories altogether without losses in the purely observable consequences (deductively) obtainable from them, creating the following "Theoretician's Dilemma":

> If the terms and principles of a theory serve their purpose [of deductively systematizing the theory's observational consequences] they are unnecessary, as just pointed out; and if they do not serve their purpose they are surely unnecessary. But given any theory, its terms and principles either serve their purpose or they do not. Hence, the terms and principles of any theory are unnecessary. (Hempel [1958] 1965, 186)

The apparent feasibility of this eliminative instrumentalist program was further advanced by a related (and earlier, though largely unrecognized at the time) innovation of Frank Ramsey's: He proposed replacing any finitely axiomatized theory with a sentence that existentially generalizes on all the theoretical predicates of that theory. This "Ramsey sentence," he argued, has the same observational consequences as the original theory and therefore captures all the "factual content" of the original.

The significance of Craig's theorem was, however, immediately controversial. Nagel (1961), for instance, famously argued (136–137) that it is of quite limited relevance to the actual eliminability of theoretical discourse from science because:

(i) there is no guarantee that the axioms of T' delivered by Craig's method will not be "so cumbersome that no effective logical use can be made of them";
(ii) in fact, the axioms of T' will be infinite in number, no matter how simple the axioms of T itself, and correspond one-to-one with all the true statements expressible in the language of T', rendering them "quite valueless for the purposes of scientific inquiry"; and
(iii) Craig's method can actually be applied only if one knows, in advance of any deductions made from them, all the true statements in the restricted observational language.

In addition, Glymour (1980, Ch. 2) offers elegant technical objections to Ramsey's proposal, most importantly that as a theory of truth it fails to respect even the most elementary forms of demonstrative inference: For example, the Ramsey sentence of a conjunction may be necessarily false while the Ramsey sentences of each conjunct is individually true.

More recently, however, the profound differences between actual scientific theories and the sorts of artificial formal systems to which tools such as Craig's theorem and Ramsey's technique apply have led these formal results to be regarded as increasingly irrelevant to the genuine prospects for instrumentalism. More specifically, philosophers of science have become increasingly convinced that

(i) there is no strict, principled, or systematic division of the vocabulary of a theory into observational and theoretical parts;
(ii) the parts of a theory bear important logical, epistemic, and cognitive relations to one another that go far beyond what is captured by mere deductive systematization; and
(iii) scientific theories may not be best regarded as axiomatic formal systems in any case.

Thus, at least part of the solution to the Theoretician's Dilemma, as Hempel himself recognized, is to reject the claim that the only function of theoretical terms is to deductively systematize a theory's observational consequences.

Credibility and Belief: Epistemic Instrumentalism

Even as the philosophical fortunes of these distinctive semantic and eliminativist theses have declined, interest has remained strong in the broader instrumentalist conception of theories as tools for pursuing practical ends rather than accurate descriptions of nature itself. The most influential recent approaches have pursued this conception by exchanging the logical empiricists' reductive, syntactic, and eliminativist commitments for epistemic alternatives, that is, more recently influential forms of instrumentalism grant both the assertoric force and the ineliminability of theoretical claims but insist that such theories should simply be *used* for prediction of experimental outcomes and other practical goals without a requirement of *belief* in the claims they in fact make about nature itself (or some parts thereof). A further recent trend has been to make the case(s) for instrumentalism piecemeal, arguing that quite specific features of a given scientific theory (e.g., quantum mechanics, evolutionary biology) either require or recommend an instrumentalist stance toward that theory.

One prominent example of general instrumentalism of this epistemic variety is constructive empiricism of Bas van Fraassen (1980). Like Duhem and Poincaré, van Fraassen appeals to the underdetermination of theories by evidence to challenge the conclusion that empirically successful scientific theories describe what inaccessible domains of nature are really like, and he insists that even a reflective endorsement of the actual inferential and other practices of science itself requires only a cognitive attitude of *acceptance* toward theories, rather than belief. He argues that it is epistemically supererogatory to believe any more of scientific theories than that they are *empirically adequate*, that is, that what they say about *observable* phenomena is true, and he insists that epistemic prudence recommends agnosticism regarding even the most successful theories' claims about unobservables. Thus, constructive empiricism regards scientific theories as reliable tools for anticipating how observables will behave, while it resists the conclusion that such theories describe what unobservable domains of nature are really like—but on epistemic rather than semantic grounds.

Of course, constructive empiricism still relies fundamentally on an extremely controversial

distinction (albeit itself naturalized) between observables and unobservables, so it is important to note that the distinctively epistemic form of instrumentalism *need* not rely upon any such distinction: As Fine (1991) argues the guiding commitment of instrumentalism is simply to the *reliability* of a causal story, which "treats all entities (observable or not) perfectly on par":

> Of course if the cause happens to be observable, then the reliability of the story leads me to expect to observe it (other things being equal). If I make the observation, I then have independent grounds for thinking the cause to be real. If I do not make the observation or if the cause is not observable, then my commitment is just to the reliability of the causal story, and not to the reality of the cause. (86)

Perhaps the most fully developed form of epistemic instrumentalism that eschews any important distinction between observables and unobservables is the historically oriented variety inspired by thinkers like Thomas Kuhn and pursued more recently by Larry Laudan. Like Duhem and Poincaré, these thinkers draw centrally on the history of repeated fundamental changes over time in the descriptions of nature offered by dominant scientific theories, in support of a skeptical attitude toward the claims of the dominant scientific theories of the present day. Kuhn ([1962] 1996) not only appeals to this history to undermine the notion that contemporary science is in possession of any final theoretical truth about a stable natural world, but also famously claims that the very "notion of a match between the ontology of a theory and its 'real' counterpart in nature now seems to me illusive in principle"; nonetheless he insists that scientific theories have improved over time "as instruments for puzzle-solving" (206). Laudan (1981a) argues that the long historical record of successful but ultimately rejected scientific theories undermines any justification for inferring even the approximate truth of contemporary scientific characterizations of nature (observable or not) from their dramatic empirical successes, but insists nonetheless not only that such theories can and should be used to tackle and solve a wide variety of empirical and conceptual problems, but also that there is a clear sense in which cumulative progress in this regard has been achieved over time, by attaining with the theoretical instruments of science an ever larger and more various set of effective solutions to such problems (Laudan 1977 and 1981b) (see Kuhn, Thomas).

As these influential formulations of the view illustrate, epistemic instrumentalism seems committed to some distinction between believing a theory to be true and accepting or using it *without* believing what it says. Perhaps unsurprisingly, the cogency of this distinction has itself been the target of recent influential criticisms of epistemic instrumentalism, on the grounds that these cognitive attitudes simply cannot be distinguished in the way that one or more forms of instrumentalism require. Horwich (1991) points out, for example, that some accounts of belief itself simply identify it as the mental state responsible for use, while Blackburn (1984) argues that there is no room for a distinction between merely "accepting" a statement with a truth condition and simply believing it to be true (see Fine 1986, especially sec. 4). By contrast, Sober (2002) defends the distinction, pointing out not only that idealized models known to be false are often accepted or used as the basis for accurate predictions across a range of phenomena, but also that recent work in model selection theory shows why models (statements containing adjustable parameters) known to be false will routinely serve as the basis for more accurate predictions of new data than competitors known to have higher likelihood conferred on them by the available data or even by competitors known to be true. Thus, he argues, not only is there a genuine difference between the goal of seeking instrumental or predictive reliability and the goal of seeking truth, but this distinction is respected within scientific practice itself, which typically chooses models (with adjustable parameters) with the former and fitted models (once parameters have been adjusted) with the latter goal in mind.

In a related vein, Nagel (1961, 139) famously argues that there is a "merely verbal" difference between the instrumentalist contention that a theory offers satisfactory techniques of inference and the realist contention that it is true. More recently, Stein (1989) has argued that the dispute between realism and instrumentalism is not well joined: There would be no appreciable difference (or no difference that makes a difference) between the two positions once

(a) realism becomes sophisticated enough (as Stein suggests it must) to (i) give up its pretensions to metaphysically transcendent theorizing, (ii) eschew aspirations to noumenal truth and reference, and (iii) abandon the idea that a property of a theory might somehow explain its success in a way that does not simply point out the use that has been made of the theory; and
(b) instrumentalism becomes sophisticated enough (as Stein suggests it must) to recognize the scope of a theory's role *as an instrument* to include not just calculating experimental

outcomes, but also adequately representing phenomena in detail across the entire domain of nature and providing resources for further inquiry.

Thus, Stein argues for a convergence between the appropriately restricted ambitions a sophisticated realism holds out for theories and the appropriately expanded ambitions a sophisticated instrumentalism holds out for them, and indeed, that in the work of the deepest scientists (his examples are Maxwell, Newton, and Einstein) the two attitudes are present together in such a way that the alleged contradiction between them simply vanishes. Thus, even as instrumentalism persists as a viable and influential position in the contemporary philosophy of science, its comparative merits and even the coherence of its formulation remain the subject of deservedly intense controversy.

INTENTIONALITY

Some things are *about,* or are *directed on,* or *represent* other things. For example, the sentence 'Cats are animals' is about cats (and about animals); this entry is about intentionality; Emanuel Leutze's most famous painting is about Washington's crossing of the Delaware; lanterns hung in Boston's

North Church were about the British; and a map of Boston is about Boston. In contrast, #a$b, a blank slate, and the city of Boston are not about anything. Many mental states and events also have "aboutness": the belief that cats are animals is about cats, as is the fear of cats, the desire to have many cats, and seeing that the cats are on the mat. Arguably some mental states and events are not about anything: Sensations, like pains and itches, are often held to be examples. Actions can also be about other things: Hunting for the cat is about the cat, although tripping over the cat is not. This (rather vaguely characterized) phenomenon of aboutness is called intentionality. Something that is about (directed on, represents) something else is said to "have intentionality" or to be an "intentional mental state."

This medieval terminology was reintroduced by the Austrian philosopher, Franz Brentano ([1874] 1995), in his book *Psychology from an Empirical Standpoint*, although Brentano himself did not use the word "intentionality." (For a brief history of the terminology, and further references, see Crane 1998a; for an account of Brentano's thought, see Moran 2000, Ch. 2.) In a famous passage, Brentano ([1874] 1995) claimed that every mental state/event has intentionality:

> Every mental phenomenon is characterized by what the Scholastics of the Middle Ages called the intentional (or mental) inexistence of an object, and what we might call, though not wholly unambiguously, reference to a content, direction towards an object (which is not to be understood here as meaning a thing), or immanent objectivity. In presentation something is presented, in judgement something is affirmed or denied, in love loved, in hate hated, in desire desired, and so on. (88)

Brentano's use of "intentional inexistence" is liable to confuse. Brentano did not mean that mental states are about peculiar nonexistent objects, but was rather referring to the (admittedly obscure) sense in which the object of a mental state is "in" the mind. The terminology of intentionality can also be confusing, for at least two reasons. First, intentionality has nothing in particular to do with intending, or intentions. Intentions—for instance, the intention to adopt a cat—are just one of many types of intentional mental states. Second, intentionality must be sharply distinguished from intensionality (Searle 1983). Mental states are not intensional, only sentences (and, for some sentences, other linguistic entities). A sentence S is intensional, or is an *intensional context*, just in case substitution of some expression a in S with some coreferring expression b yields a sentence with different truth value from the truth value of S. So, for example, "Necessarily, the number of planets is nine" and "Hegel believed that the number of planets is seven" are intensional. Substituting "nine" for the coreferential "the number of planets" turns the first false sentence into the true sentence "Necessarily, nine is nine" and the second true sentence into the false sentence "Hegel believed that nine is seven." As the first example indicates, a sentence can be intensional and yet have nothing to do with intentionality. Conversely, sentences that report intentional mental states/events need not be intensional (Crane 1998a). For example, "Berkeley heard the coach" is (arguably) not intensional: If that sentence is true, and if "the coach" and "Locke's favorite carriage" refer to the same thing, then "Berkeley heard Locke's favorite carriage" is true.

Paradoxes of Intentionality

As informally explained above, an intentional mental state (for example) is "about" something. The belief that Brentano is Austrian is about Brentano. The object that the state is about is called the intentional object of the state. (Intentional objects are sometimes taken to include states of affairs as well as particulars like Brentano: The belief that Brentano is Austrian could be said to be about Brentano's being Austrian.) So there should be a relation of aboutness that holds between a mental state and an object just in case the state is about the object—"the intentional relation," in Brentano's terminology.

Thinking of intentionality in this way, as a relation to intentional objects, leads to three classic "paradoxes of intentionality" (Thau 2002). The first paradox is that the intentional object need not exist (at any time). The belief that the fountain of youth is in Florida bears the intentional relation to the fountain of youth, and the fountain of youth does not exist. But if a is related to b, then there is such a thing as a and such a thing as b. One rather extreme solution, famously proposed by Brentano's student Alexius Meinong, is to hold that there are objects that do not exist. In this view, there *is* a fountain of youth, and the belief that the fountain of youth is in Florida bears the intentional relation to that (nonexistent) object. (This is Meinong's view, but not his terminology. Meinong used "subsists" to mean *exists*, and "exists" to mean something like *spatiotemporally exists*. Thus, in Meinong's terminology, Mont Blanc exists, the number 7 subsists but does not exist, and the fountain of youth neither exists nor subsists.)

The second paradox is that a mental state can bear an intentional relation to something without there being any particular thing that the state bears the relation to. If one wants a cat, but has no particular cat in mind, then one's state of wanting a cat bears the intentional relation to an object—a cat, presumably—yet there is no particular cat that the state bears the intentional relation to. But if *a* is related to something, then there is a particular object that *a* is related to.

The third paradox is that a mental state can bear the intentional relation to *a,* but not bear the intentional relation to *b*, even though *a* is *b.* The belief that the first postmaster general was a United States president is about the first postmaster general, but not about the inventor of bifocals, even though the inventor of bifocals was the first postmaster general, namely Benjamin Franklin. But if *a* bears a certain relation to *b*, and $b = c$, then *a* is related by the same relation to *c.*

In *Psychology from an Empirical Standpoint* Brentano ([1874] 1995) himself did appear to think that a mental state was always related to an intentional object, but in an appendix he insisted that the "only thing which is required by mental reference is the person thinking. The terminus of the so-called relation does not need to exist in reality at all" (272).

The moral of the paradoxes of intentionality is that thinking of intentionality in terms of the intentional relation is a bad idea. A better way involves drawing a distinction between the *representational content* of a mental state (or some other thing that has intentionality) and the objects (if any) the mental state is about. So, for example, the belief that the fountain of youth is in Florida has as its content the proposition that the fountain of youth is in Florida, and there is no object that the belief is about—at any rate, not the fountain of youth (the belief is about Florida). To believe that the fountain of youth is in Florida is to stand in the belief-relation to the proposition that the fountain of youth is in Florida. This proposition exists whether or not the fountain of youth does (it does not contain the fountain of youth as a constituent), and this proposition is true just in case there is such a thing as the fountain of youth and it is located in Florida. Similarly, the desire that one have a cat has as its content the proposition that one has a cat, and there is again nothing that the belief is about—at any rate, no particular cat. Finally, the belief that the first postmaster general was a United States president and the belief that the inventor of bifocals was a United States president are both about the same object, namely Benjamin Franklin. However, there is some truth behind the original mistaken claim that the two beliefs are about different objects. This can be brought out by noting that the contents of the two beliefs are true at different possible worlds (of course, the contents are both false at the actual world). Specifically, the first proposition, but not the second, is true at a possible world in which the first postmaster general became president and the inventor of bifocals never entered politics. The truth of the first proposition at a world depends on the political fortunes of whomever is the first postmaster general at that world—whether or not that individual invented bifocals.

Brentano's Two Theses

Brentano ([1874] 1995) proposed two theses that form the basis of contemporary discussions of intentionality:

1. No "physical phenomenon" has intentionality.
2. Intentionality is *the mark of the mental:* All and only mental states/events have intentionality.

> [I]ntentional in-existence is characteristic exclusively of mental phenomena. No physical phenomenon exhibits anything like it. We can, therefore, define mental phenomena by saying that they are those phenomena which contain an object intentionally within themselves. (89)

Brentano's examples of physical phenomena were not, say, brain processes, but were (chiefly) perceptible properties, like "color, sound and warmth" (92). Nonetheless, mainly through the influence of Roderick Chisholm, Brentano came to be associated with the doctrine that intentionality is not reducible to the physical—in the contemporary sense of 'physical' (see Physicalism). Although quite dubious as an interpretation of Brentano (Moran 1996), it started a debate that continues to this day. Chisholm himself argued for the irreducibility of intentionality by first transforming this thesis into one about the sort of language adequate for psychology. Thus recast, the thesis of the irreducibility of intentionality becomes one about the ineliminability of intensional contexts, like "Revere believes that the British are coming," in the language of a scientific psychology. (Chisholm called such sentences "intentional sentences.")

Chisholm's (1957) reformulation of "a thesis resembling that of Brentano" is:

> [W]e do not need to use intentional language when we describe non-psychological phenomena; we can express all of our beliefs about what is merely 'physical' in sentences which are not intentional. But ... when we

> wish to describe perceiving, assuming, believing, knowing, wanting, hoping, and other such attitudes, then either (a) we must use language which is intentional or (b) we must use terms we do not need to use when we describe nonpsychological phenomena. (172–173)

Chisholm argued for his "linguistic version" of Brentano's first thesis as opposed to various behavioristically inspired analyses of "intentional language." Chisholm did not conclude that the failure of reduction impugned the reality of intentional mental states, but Quine ([1960] 1998) famously did:

> One may accept the Brentano thesis as either showing the indispensibility of intentional idioms and the importance of an autonomous science of intention, or as showing the baselessness of intentional idioms and the emptiness of a science of intention. My attitude, unlike Brentano's, is the second. (221)

Many philosophers are not so pessimistic, and there are many suggestions for providing a physicalistic or naturalistic reduction of intentionality. This is discussed in the following section.

Brentano's first thesis is true but has been (fruitfully) misinterpreted. Brentano's second thesis, on the other hand, has been correctly interpreted but seems obviously false, because of examples given in the first paragraph of this article. However, as discussed in the final section, Brentano's second thesis is in better shape than initial appearances suggest.

Reducing Intentionality

Many philosophers hold that there must be a physicalistic/naturalistic reduction of intentionality—at least if intentionality is a genuine phenomenon. Fodor (1987) is a prominent example:

> I suppose that sooner or later the physicists will complete the catalogue they've been compiling of the ultimate and irreducible properties of things. When they do, the likes of *spin, charm,* and *charge* will perhaps appear on their list. But *aboutness* surely won't; intentionality simply doesn't go that deep. . . . If the semantic and the intentional are real properties of things, it must be in virtue of their identity with (or maybe of their supervenience on?) properties that are themselves *neither* intentional *nor* semantic. If aboutness is real, it must be really something else. (97)

There are many different approaches to providing the reduction of intentionality that Fodor says we need. Most adopt some kind of divide-and-conquer strategy. First, a distinction is made between *original* intentionality and *derivative* intentionality (Haugeland 1998; see Searle 1992 for a similar distinction between *intrinsic* and *derived* intentionality). A thing has derivative intentionality just in case the fact that it represents such-and-such can be explained in terms of the intentionality of something else; otherwise it has original intentionality. Often the intentionality of language and other sorts of conventional signs is said to be derivative. Language, in this view, inherits its intentionality from that of mental states, specifically from the intentions and conventions adopted by language users (Grice 1989). This is an attractive and plausible claim, although it is not obvious, and has been denied (see e.g., many of the essays in Davidson 1985). However, if it is correct, then the problem of reducing intentionality is itself reduced to the problem of reducing the intentionality of the mental.

Theories that attempt to provide a physicalistic reduction of intentionality fall into three broad groups. The first group comprises causal covariational theories (Stampe 1977; Dretske 1981; Stalnaker 1984; Fodor 1990). The basic idea is that mental states represent in much the same way that tree rings represent. The number of rings on a tree represents the tree's age, because the fact that the tree's age is n years old causes the tree to have n rings, or (a refinement) would cause the tree to have n rings in optimal conditions. A simple example of a causal covariational theory is this: A belief state S represents that p (that is, has propositional content that p) if and only if the fact that p would cause a subject to be in S. (This formulation takes the notion of a *belief state* for granted; a physicalistically acceptable version of the theory would have to provide a further reduction of a belief state.)

The second group comprises teleological theories (Papineau 1987; Millikan 1993; Dretske 1995). The basic idea is to explain the intentionality of mental states in terms of their biological functions, which might in turn be given a reductive account in terms of evolutionary history. A simple example is this: A belief state S represents that p if and only if in conditions in which a subject's cognitive system is functioning as it is designed to function by evolution, the subject would be in S when and only when it is the case that p (see Function).

The third group comprises functional role theories. Here the basic idea is that a representation or symbol means what it does because of its *functional role*—its causal interaction with other representations. A simple example (for public language): A two-place sentence connective * means *and* if and only if the acceptance of sentence P and sentence Q is disposed to cause the acceptance of the sentence $P \wedge * \wedge Q$ (i.e., P concatenated with * concatenated

with Q), and the acceptance of $P \wedge * \wedge Q$ is disposed to cause the acceptance of P and the acceptance of Q. If this is to be an account of thought rather than language, then there must be an appropriate range of neural representations—perhaps words in a "language of thought." In "long-armed" theories, functional roles are taken to include causal interactions with the environment (Harman 1999); "short-armed" functional role theories exclude such causal interactions, and for that reason are often taken to be accounts of the so-called "narrow content" of mental states (Block 1986).

Two other notable approaches should be mentioned. One is Dennett's (1987) instrumentalism, which attempts to vindicate intentional notions from a physicalistic perspective without providing explicit reductions of the sort just illustrated. The other is Brandom's (1994) inferentialism, which attempts to reduce intentionality to normativity, in particular to norms governing inferential practices.

Intentionality as the Mark of the Mental

Brentano's second thesis is independent of (the misinterpretation of) his first, that intentionality cannot be given a physicalistic reduction. The irreducibility of intentionality does not imply that all and only mental states/events are intentional. Searle is an example of a philosopher who holds that intentionality is irreducible, yet that sensations are not intentional. Neither does the converse implication hold: if intentionality is the mark of the mental, it might still be reducible. Tye and Dretske, whose views are mentioned below, think that intentionality is the mark of the mental and that it can be given a physicalistic reduction.

Brenanto's second thesis divides into two parts:

- Intentionality is *sufficient* for mentality and
- intentionality is *necessary* for mentality.

The sufficiency claim is false—at least if 'intentionality' is used in the broad and loose contemporary way, to include nonmental entities like sentences, paintings, and maps (see the beginning of this article). However, the sufficiency claim might be amended as follows: Original intentionality is sufficient for mentality. According to the revised sufficiency claim, the mental is the source of all intentionality. This revised claim still faces problems. First, if the indication of a tree's age by the number of its rings is an example of intentionality at all, then it is presumably original intentionality. And if it is original intentionality, the sufficiency claim is false. Again, the sufficiency claim is false if the intentionality of language does not derive from the intentionality of the mental. But these are controversial issues, and there is at least some prospect of defending a modified version of Brentano's sufficiency claim.

Matters might seem even less promising with the other part of Brentano's second thesis, the claim that intentionality is necessary for mentality. At any rate, some philosophers think that sensations are obviously nonintentional. However, the claim that bodily sensation is a form of perception of one's own body was defended in the 1960s by D. M. Armstrong (1968) and has been revived today by a number of philosophers including Dretske (1995), Lycan (1996), and Tye (1995). And if this thesis is correct, then because perceptions have intentionality, bodily sensations are not counterexamples to the claim that intentionality is necessary for mentality. (See Brentano [1874] 1995, 82–85, for his account of the intentionality of pain, which anticipates many modern discussions.)

More problematic cases are provided by certain "objectless" emotions, like forms of anxiety or depression, where one is hard put to say what one is anxious or depressed about (Searle 1983). For defenses of Brentano's second thesis against this sort of example, see Tye (1995, 128–131) and Crane (1998b).

Assuming that every mental state/event is intentional, a further issue arises, whether the representational content of a mental state determines "what it's like" to be in the state—the state's qualia. Dretske, Lycan, and Tye, among others, endorse this determination claim. Such an "intentional theory of qualia" is controversial and has been widely discussed in the literature on consciousness.

IRREVERSIBILITY

Chunks of ice melt in warm water, but warm water never spontaneously forms chunks of ice. Gases expand to fill their containers, but uniformly spread gasses never contract into one corner of their (isolated) containers. These examples illustrate an incredibly pervasive regularity. Certain types of processes proceed only in one direction: they occur, but their time reverses do not. And this appears to be a matter of law. These processes are said to be irreversible. (This notion of irreversibility should be distinguished from a similarly termed notion that appears in classical thermodynamics: A system is said to undergo a "reversible change" when it changes so slowly that it remains very near thermal equilibrium throughout [Uffink 2001].)

Irreversible processes typically involve temperature-difference equalization, diffusion, the completion of chemical reactions, and certain phase transitions. More generally, isolated systems (or, rather, systems that can be treated as isolated) tend to move toward states of equilibrium. What explains this regularity? The simplest hypothesis is that fundamental laws of nature explicitly require that isolated systems tend toward equilibrium, and the science of thermodynamics provides a system of postulates that yields just this constraint.

Thermodynamics introduces a physical quantity, *thermodynamic entropy*, which is defined for systems at equilibrium. The thermodynamic entropy of a system measures how much of the system's energy is available for conversion into useful work (the higher the entropy, the less energy is available). The second law of thermodynamics says that the entropy of an isolated system never decreases (Sklar 1993, 21).

Irreversible processes—for example, a chunk of ice melts in warm water, a gas spreads to fill its container—involve increases in entropy. The second law rules out the time reversals of these processes because this would involve *decreases* in entropy. Despite the elegance and practical indispensability of classical thermodynamics, its

postulates do not have the character of fundamental dynamical laws, which are thought to govern the detailed motions of the microscopic constituents of matter.

The natural next suggestion is that the fundamental dynamical laws themselves are time asymmetric and this asymmetry helps explain irreversibility. For example, particle physics has produced evidence that there are *T-symmetry violations*—interactions that have (slightly) different chances than their time reverses. So it is believed that the dynamical laws are not time symmetric. However, these slight differences in chances do not have a significant effect on the manner in which macroscopic systems undergo thermodynamic change. So this time asymmetry in the laws does not help explain irreversibility (Sklar 1993, 248).

Thus the following question is left open: How does the sort of irreversible behavior captured by the postulates of thermodynamics arise from the fundamental dynamical laws?

Statistical Mechanics

It is simplest to introduce statistical mechanics in the context of classical mechanics. As a simple example, consider a number of billiard balls, undergoing perfectly elastic collisions on a frictionless table (Figure 1). Suppose that at some initial time the balls are concentrated in the upper-left corner of the table and that they spread out over the course of a minute. Now perform a thought experiment. At the end of the minute, stop time, reverse the velocities of the balls, and start time again. The balls will retrace their original paths and return to the corner of the table in which they began.

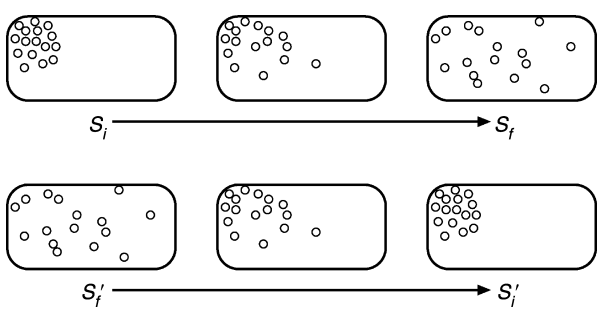

Fig. 1. The initial state of the table (S_i), in which the balls are concentrated, evolves into a final state (S_f), in which the balls are dispersed. Reversing the velocities of the balls in S_f results in a state S_f', which evolves into a state S_i' in which the balls are concentrated (Goldstein 2001).

This thought experiment illustrates a striking fact about classical mechanical laws of motion: Whenever a process is allowed by the laws, so is the time reverse of that process. So, given just these laws, there is no hope of showing that entropy-decreasing processes are downright disallowed. The best that can be hoped for is a statistical argument that entropy-decreasing processes are highly improbable. This observation is known as the reversibility objection (famously put to L. Boltzmann by J. Loschmidt [Sklar 1993, 35]).

There are many approaches to producing such an argument (Sklar 1993). One approach introduces the notion of *Gibbs entropy*. Gibbs entropy is a quantity defined not for individual systems, but for probability distributions over phase space (measuring the extent to which such distributions are spread out). This approach seeks to explain irreversibility by deriving certain facts about how such probability distributions evolve under the laws. It has been objected that this sort of result does not address the phenomenon to be explained, *viz.,* that *individual* isolated systems tend to increase in entropy (Lebowitz 1993; Goldstein 2001; Maudlin 1995). *Interventionism* attempts to avoid the reversibility objection by observing that thermodynamic systems interact with their environments. This observation is correct but does not avoid the difficulty, for one can shift attention to a larger system that is not subject to such interference.

The above difficulties are avoided by a highly influential approach to explaining irreversibility, which has its roots in the work of Ludwig Boltzmann.

Phase Space

The *phase space* of a system is a set of points, each of which is a dynamical state for the system to be in at a time. In the case of a number of classical point particles, each point of phase space determines the position and momentum of each particle. Phase space is also equipped with some additional geometric structure, including a measure that determines the volume of each of its regions. (Since the total energy of a classical system remains constant over time, attention can be restricted to that portion of phase space associated with some particular fixed total energy of the system.)

Phase space is carved up into disjoint sets, called *macrostates* (Figure 2). Points of phase space (or *microstates*) that are in the same macrostate are alike with respect to macroscopic parameters. For

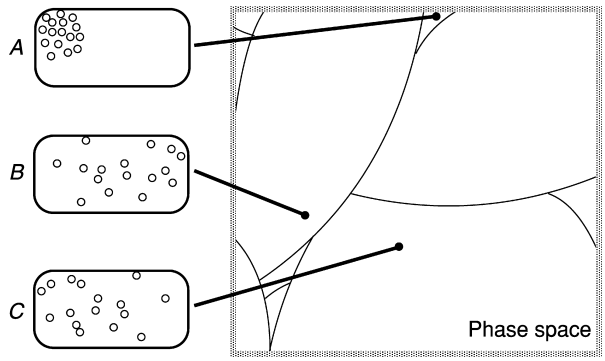

Fig. 2. Schematic representation of the phase space of a system of hard spheres. The space is divided into macrostates, which vary greatly in size. The space is dominated by equilibrium states such as *B* and *C*, which are shown in the left-hand column. Only a tiny proportion of phase space consists of far-from-equilibrium states such as *A*.

example, they have roughly the same temperature and pressure distributions.

Boltzmann noticed that for combinatorial reasons, macrostates vary greatly in size, and the variation is systematic. If all else is equal, macrostates in which the particles are spread out over physical space are bigger than ones in which they are clumped together, and macrostates in which the particles are moving with a large variety of momenta are bigger than ones in which, say, all have the same momentum.

That observation motivates the following definition: The statistical-mechanical entropy (also known as the *Boltzmann entropy*) of a point in phase space is a measure of the size of the macrostate to which it belongs—the bigger the macrostate, the greater the entropy. More precisely: the statistical-mechanical entropy of a point in phase space is proportional to the logarithm of the volume of the macrostate to which it belongs. For macroscopic systems, the imbalance in sizes of macrostates is overwhelming. Virtually all of phase space consists of points representing states in which the system is at equilibrium. This vast imbalance in size of macrostates can be used to explain why irreversible processes are so common.

A Statistical Explanation of Irreversibility

Consider a system consisting of a (nearly isolated) gas confined to a box. Take a particular low-entropy macrostate *L*, in which the gas is concentrated in the left half of the box. Notice that the phase space for this system is dominated by points whose entropies are *higher* than that of *L*. In other words, phase space is dominated by points in which the gas is *more spread out* than it is in *L*. So it is reasonable to think that practically all of the states in *L* have futures in which entropy *increases*. In other words, it is reasonable to think that practically all of the states in *L* have futures in which the gas *spreads out*.

So the following *appears* to be a statistical explanation of why gases spread out: the vast proportion of microstates compatible with a given gas-is-in-the-left-half macrostate have futures in which the gas spreads out. But as it stands, this explanation is defective. The trouble is that exactly analogous reasoning shows the following: The vast proportion of microstates compatible with a given gas-is-in-the-left-half macrostate have histories in which the gas *was more spread out in the past!*

And it is certainly *not* true that gases that are at one time concentrated in the left half of their boxes tend to have recent pasts in which they were dispersed throughout those boxes. A promising way out of this difficulty is to introduce an assumption concerning the initial state of the universe, *viz*., that the universe started in a state of extremely low entropy. For example, one might posit an additional law of nature that has the effect of constraining the initial state of the universe in this way (Penrose 1993). Given such a law, the following modified explanation is available: almost all of the microstates compatible with a given gas-is-in-the-left-half macrostate *and compatible with the low-entropy constraint on the initial state of the universe* have futures in which the gas spreads out. Furthermore, the modified explanation (unlike the original one) does not lead to the incorrect retrodictions about the past history of the gas.

The global picture is this: judging purely by size of regions of phase space, one would expect for the universe to start (and stay) in global equilibrium. But restricting attention to just those regions of phase space compatible with a low-entropy initial condition, one would expect for global entropy to start low and increase over time. And it is reasonable to think that in a world with global increase of entropy, irreversible processes abound.

Entropy in Contemporary Physics

The explanation given above worked under the assumption of classical mechanics. Whether an explanation of the same type is consistent with contemporary physics remains to be seen. It is a reasonable (but as yet unproven) hypothesis that a definition of statistical-mechanical entropy in terms of phase space volume can be given in the context

of general relativity (Bekenstein 2001 appraises this hypothesis).

It is expected that a general treatment of relativistic statistical-mechanical entropy would require a quantum-mechanical theory of gravitation (Wald 1998). Such a theory has been notoriously elusive. Nevertheless, the study of gravitational entropy is an active area of research. For example, theorists have offered statistical-mechanical measures of the entropy of black holes, from both the standpoint of quantum field theory (Sorkin 1998) and the standpoint of string theory (Horowitz 1998).

KIN SELECTION

See **Natural Selection**

KINETIC THEORY

Kinetic theory explains the properties and behavior of physical systems on the basis of the hypothesis that they consist of a great number of particles (e.g., molecules or atoms) in motion (Greek: *kinesis* = motion). Its most important application is the kinetic theory of gases, but it can be applied to liquids and collections of subatomic particles as well. This discussion will be restricted to the kinetic theory of gases, as this suffices to clarify the nature of kinetic theory and to highlight its philosophical aspects.

The kinetic theory of gases proceeds from two principles:

1. *An ontological principle*: Gases are composed of freely moving particles subject to the laws of classical mechanics (atomism, mechanism); and
2. *A methodological principle*: The behavior of gases is analyzed not by tracing the trajectory of every individual particle but by applying statistical methods to the collection of particles as a whole (see Classical Mechanics).

The theory is historically and conceptually related to the theories of statistical mechanics and thermodynamics. Statistical mechanics is a generalization of kinetic theory that emerged in the course of the latter's development by Ludwig Boltzmann and J. W. Gibbs. Thermodynamics is a phenomenological theory that accounts for the behavior of

gases without a hypothesis about their microscopic constitution (see Thermodynamics).

Therefore, thermodynamics can be regarded as a competitor to kinetic theory, a relation that is a topic of philosophical debate. The kinetic theory of gases has played a significant role in the shaping of modern physics and has been relevant for the philosophy of science in a variety of ways, having had an impact on the development of its ideas. The kinetic theory of gases is regularly employed in philosophical discussions.

The Kinetic Theory of Gases in Historical Perspective

An essential feature of the kinetic theory of gases is the identification of temperature with molecular motion, specifically with the mean kinetic energy of molecules: $T \sim <\frac{1}{2}mv^2>$, where T is the temperature and m and v are the mass and velocity, respectively, of an individual molecule. In the second half of the nineteenth century, this kinetic view of heat replaced alternatives such as the caloric theory, which assumed that heat was a substance ("caloric"), and the wave theory of heat, which took heat to be vibrations of an ether. Before 1850, some kinetic theories of gases were advanced, which attempted to explain Boyle's law that at constant temperature the product of pressure and volume of the gas is constant (known since 1662). These theories did not have much impact because Newton had already explained Boyle's law by means of a static molecular theory of gases. The earliest kinetic theory was Daniel Bernoulli's ([1738] 1965) in which pressure is proportional to molecular velocity squared. It did not yet have a temperature scale, however. Bernoulli derived the formula (still accepted in modern kinetic theory)

$$PV = \frac{1}{3}N<mv^2>,$$

where P is the pressure, V is the volume, N is the number of molecules, and m and v are the mass and velocity, respectively, of an individual molecule. Kinetic theories were proposed by John Herapath in 1820 and J. J. Waterston in 1845 in which temperature was related to molecular velocity: Herapath (wrongly) supposed that T was proportional to v; Waterston took T to be proportional to v^2. Both theories were ignored (for historical references, see Brush 1965–1972 and 1976).

Around 1850, the scientific scene turned favorable for kinetic theories: Joule and others established the law of conservation of energy (or convertibility of heat and work), which gave essential support to the kinetic view of heat. This paved the way for the important kinetic theory of Rudolf Clausius ([1857] 1965). Like earlier theories, Clausius's statistical hypotheses were of a simple kind: calculations were based on a random variation in the *direction* of particle velocities; their *magnitude* was represented by one average value. In response to an objection by Buys Ballot, Clausius introduced the "mean free path" of molecules and calculated that this path is so small that gases mix quite slowly despite the high velocities of individual molecules.

In the 1860s, Clausius's theory was further developed by James Clerk Maxwell, who at first regarded his work on gas theory as an "exercise in statistics"; he did not (yet) believe in the atomistic view of matter. Maxwell's theory explained many properties of real gases; most important were its predictions regarding transport phenomena (heat conduction, diffusion, viscosity). On the basis of Maxwell's approach, Boltzmann later developed a general transport equation (the Boltzmann equation), which is still employed today. Maxwell refined Clausius's statistical analysis: Instead of using merely one average velocity, he introduced a statistical distribution function $f(v)$ for molecular velocities (a Gaussian curve), where v is the velocity of individual molecules. Boltzmann generalized Maxwell's distribution law for situations in which external forces are present (leading to what is now called the *Maxwell–Boltzmann distribution law*):

$$f(v) = N\sqrt{\frac{2m^3}{\pi k^3 T^3}}v^2 e^{-(\frac{1}{2}mv^2 + V[x])/kT}$$

where m and v are the mass and velocity, respectively, of an individual molecule; k is Boltzmann's constant; and $V[x]$ is a potential due to an external force depending on the position x. This law applies only to equilibrium situations; in order to explain the tendency toward equilibrium, Boltzmann advanced the H-theorem (see below).

A fundamental element of kinetic theory is the equipartition theorem, which states that every degree of freedom of the system takes up an equal part of the total kinetic energy. The theorem had an important anomalous consequence: Its prediction for the specific heat ratio gases is at odds with the experimentally obtained value for many ordinary gases (e.g., oxygen, nitrogen). This "specific heat anomaly" was discovered by Maxwell (1875), who called it "the greatest difficulty which the molecular theory has yet encountered." Boltzmann's proposed

solution—the "dumbbell model" of diatomic molecules—was controversial at the time because it disregarded spectral evidence for internal atomic structure (see de Regt 1996). In his famous 1900 lecture, William Thomson (Lord Kelvin) (1904) labeled the equipartition problem as one of two "nineteenth-century clouds over the dynamical theory of heat and light." Today Boltzmann's model is accepted as an idealization: nineteenth-century objections to the model have dissolved since quantum mechanics has separated internal atomic structure (spectra) from mechanical degrees of freedom (see Quantum Mechanics).

In the early twentieth century, kinetic theory was incorporated into statistical mechanics, due to the work of J. W. Gibbs. Kinetic theory itself did not witness serious changes anymore; the most important twentieth-century contributions consisted in methods for solving the Boltzmann equation, notably by S. Chapman and D. Enskog (Brush 1976, chap. 12). Kinetic theory was fruitfully applied to other topics, such as radiation transfer, ionization, chemical reactions, evaporating liquids, and neutron transport. While kinetic theory remains a paradigm nineteenth-century theory, it has had a profound influence on twentieth-century physics, especially on the genesis and development of quantum theory: Boltzmann's work was a key element of Planck's solution of the problem of black-body radiation, marking the beginning of quantum theory in 1900.

Kinetic Theory: Atomism and Scientific Realism

Kinetic theory is based on an atomistic ontology. The unobservability of atoms led to philosophical disputes over their existence, and kinetic theory played a pivotal role in debates between scientific realists and their opponents.

Around 1850, atoms were regarded as fictional entities. However, due to the impressive successes of the kinetic theory in later years, more and more scientists took a realist stance toward the theory. But while the existence of atoms was gradually accepted by the scientific community, their structure was still open to debate and speculation. In the second half of the nineteenth century, various models of atomic structure were proposed. Maxwell treated atoms as hard elastic spheres and later as centers of force. By contrast, Kelvin's vortex theory represented atoms as spinning rings of a homogeneous, frictionless, incompressible fluid. Meanwhile, estimations of molecular sizes were made, first by J. Loschmidt (1865), who also calculated the number of molecules per volume unit (today this number, which is the same for every gas at standard temperature and pressure, is known as Avogadro's number). Subsequently, J. D. van der Waals replaced the ideal gas law ($PV = nRT$, where P is the pressure, V the volume, n the number of moles of the gas, R the ideal gas constant, and T the temperature) by an equation of state for real gases, containing correction terms depending on intermolecular forces and the size of the molecules:

$$\left(P + \frac{an^2}{V^2}\right)(V - nb) = nRT,$$

where a and b are constants depending on the type of molecule, n is the number of moles, and R is the molar gas constant.

These scientific successes firmly but only temporarily established the atomistic worldview and an accompanying realistic view of scientific theories. After 1880, kinetic theory lost momentum, and in the final decade of the nineteenth century the theory was strongly attacked by anti-atomists who based their objections on a positivist philosophy of science. A notable early example is J. B. Stallo's ([1884] 1960) criticism of kinetic theorists for having "faith in spooks" and for wasting "their efforts upon a theory so manifestly repugnant to all scientific sobriety" (151). The most important anti-atomist was Ernest Mach, whose radical empiricist movement (to which the young Max Planck adhered) influenced twentieth-century philosophy of science, particularly the logical positivism of the Vienna Circle (see Mach, Ernest; Vienna Circle).

The tide turned once again in the early twentieth century. In the course of his work on black-body theory, Planck was converted to atomism and became a staunch opponent of Mach. In 1905, Einstein published an explanation of Brownian motion—the observable irregular motion of small particles suspended in fluids, discovered by Robert Brown in 1828—on the basis of kinetic theory: Brownian motion results from the impact of surrounding molecules on the particle, and Einstein ([1905] 1965) derived a prediction of the mean displacement of Brownian particles. This prediction was successfully tested by Jean Perrin (1913), who subsequently made it into a strong case for the reality of atoms in his book *Les Atomes.* As such, Einstein's explanation (independently developed by Smoluchowski) was the final vindication of kinetic theory and atomism.

Today, the existence of atoms is uncontested among scientists, but the case of atomism and kinetic theory is still used in philosophical debates

about the status of unobservable entities, particularly (not surprisingly) by realists. For example, Salmon (1984, 213–227) returns to Perrin's argument in order to defend scientific realism; he argues that from the fact that there are many independent methods of determining Avogadro's number, which all arrive at the same result, one must conclude that this number describes something real and that molecules thereby exist. (For an illuminating analysis of the debate between realists and instrumentalists from the perspective of the development of kinetic theory, see Gardner 1979.)

Kinetic Theory: Explanation and Reduction

Kinetic theory is often cited as a paradigmatic example in philosophical discussions about explanation and reduction. In the context of his deductive-nomological model of explanation, Carl Hempel cited kinetic-theoretical explanations of phenomenological gas laws (such as Boyle's law) as exemplary cases of "theoretical explanation" (see Explanation; Hempel, Carl Gustav). Crucial in Hempelian theoretical explanations (where the explanans refers to theoretical, that is, unobservable, entities) are the so-called bridge principles connecting the theoretical and the observational level. In the case of kinetic theory, the bridge principles relate macroscopic features such as temperature and diffusion rate with microscopic properties such as velocity and kinetic energy of the gas molecules (Hempel 1966, 73).

Contemporary philosophers who reject Hempel's model of explanation feel nonetheless obliged to give alternative interpretations of how kinetic theory explains gaseous behavior. Apparently, the fact that kinetic theory provides scientific explanations is undisputed: Any respectable theory of explanation should be able to account for the explanatory power of kinetic theory. Thus, the presently influential unificationist conception of explanation argues that kinetic theory provides explanations because it unifies many (sometimes seemingly unrelated) facts about nature: It accounts not only for Boyle's law, but for many other phenomenological gas laws as well, and also relates gaseous behavior to other natural phenomena governed by the laws of mechanics (Friedman 1974, 14–15). Alternatively, the causal conception of explanation claims that it is the causal-mechanical features of the kinetic theory that do the explanatory work (Salmon 1984, 227–228).

A related philosophical issue is that of intertheoretic reduction. According to Nagel (1961, 342), the relation between kinetic theory and the phenomenological theory of thermodynamics is "a classic and generally familiar instance of such a reduction" (see 338–345 for an account). *Pace* Nagel, the reduction of thermodynamics to kinetic theory is not completely unproblematic: kinetic theory appears to be unable to account for the tendency toward equilibrium described by the second law of thermodynamics. This inconsistency was already observed by Maxwell (1872), in his famous thought experiment known as Maxwell's Demon: Maxwell imagined a microscopic but "very observant and neat-fingered being" manipulating molecules in such a way as to make heat flow from a cold to a hot body, thereby contradicting the second law of thermodynamics (see Irreversibility). Boltzmann's ([1872] 1966) H-theorem was intended as a microphysical analogue to the second law. Boltzmann defined a function H on $f(v^2)$ and proved that H always decreases. As such, H can be regarded as a microphysical counterpart of entropy S. Boltzmann's proof required an extra statistical hypothesis, the *Stosszahlansatz* (molecular chaos): there is no statistical correlation between colliding molecules before and after the collisions. However, if the system behaves according to deterministic Newtonian mechanics (as kinetic theory presupposes), the *Stosszahlansatz* cannot be absolutely true.

This incompatibility between mechanical laws (read: kinetic theory) and thermodynamics was made explicit in the reversibility objection (Thomson [1874] 1966; also known as Loschmidt's [1876] *Umkehreinwand*): If one considers a process and reverses the velocity of every molecule, the resulting process will be physically possible as well. This contradicts the second law, and the experience that irreversible processes exist in nature. Boltzmann responded to the objection with his famous equation $S = k.\log W$, relating the entropy S of a macroscopic state to the number (W) of possible microscopic states corresponding with the macroscopic state in question (in other words, to its relative probability). This equation, which lies at the basis of statistical mechanics, implies that entropy decrease is not impossible but only very improbable: Because there are many more microstates corresponding with a macrostate of high entropy (disorder), the probability that the system develops into a state of higher entropy is much greater than vice versa. In contrast to Boltzmann's response, however, some authors take an antireductionist approach by claiming that the second law has absolute (ontological) validity and that attempts at reducing thermodynamics to mechanics are misguided (e.g., Prigogine 1980). A more detailed

overview of philosophical issues related to kinetic theory can be found in Sklar (1993).

THOMAS KUHN

(18 July 1922–17 June 1996)

Thomas S. Kuhn was the most widely read, and most influential, philosopher and historian of science of the twentieth century. *The Structure of Scientific Revolutions*, first published in 1962, challenged then-dominant philosophical views of science regarding progress, rationality, observation, theories, and language. The book has been continuously in print for forty years; it has been translated into more than twenty languages, and the various editions have sold over a million copies. Unlike all other books in the history or philosophy of science, *Structure* was, and is, still widely read outside of the philosophical community.

Kuhn was also the author of *The Copernican Revolution*, and in 1978, *Black-Body Theory and the Quantum Discontinuity, 1894–1912*, as well as numerous essays, most of which were reprinted in two collections, *The Essential Tension* (Kuhn

1977) and *The Road since Structure* (Kuhn 2000). Although the monographs each made important contributions, respectively, to contemporary understanding of the Copernican revolution and of the early stages of the quantum revolution, none of the other work has attracted nearly as much attention as *Structure*, especially within philosophy of science. If Kuhn had written only these two monographs and the articles, he would have merited a minor footnote as a historian of science in the twentieth century.

Although Kuhn was the most influential philosopher of science of the twentieth century, his formal training was in physics, and his next career turn was to the history of science. He was trained as a physicist, receiving a B.S. in 1943, an M.A. in 1946, and a Ph.D. in 1949 from Harvard in that discipline. Moreover, his first teaching position, at University of California, Berkeley, from 1956 to 1964, and his second, at Princeton University (1964–1979), were in history departments and in the history and philosophy of science program at Princeton, but not in philosophy. Only when he moved to Massachusetts Institute of Technology in 1979 did he become a member of a philosophy department (though it was the *Linguistics and* Philosophy Department). He was elected president of the Philosophy of Science Association in 1989, after having been a member of that association for only a few years.

Revolutions and Two Kinds of Science

The main thesis of *Structure* is that the development of the natural sciences and their subfields proceed through alternations of two kinds of scientific development: *normal* and *revolutionary* science (see Scientific Revolutions). A period of normal science produces cumulative progress in understanding of the domain of that field and involves the application and refinement of generally accepted theories to the unresolved questions in a domain according to an agreed understanding both of what constitutes a reasonable question and on the criteria used to adjudicate answers. Revolutionary change involves rejection of a significant portion of the theories, methods, and criteria for problem solution, and their replacement by new ideas. In revolutionary change at least some of the previously "solved" problems are rejected or reopened. One of the most controversial claims of the book was that there was incommensurability between a revolutionary theory and the one it supplanted (see Incommensurability).

The book received both widespread praise and condemnation. In addition to the claims about "revolutions," which were very controversial, critics argued that Kuhn's account of science made it neither rational nor objective. Kuhn regarded this as a misinterpretation of his views. In addition to the claim about incommensurability, he claimed that when a scientific revolution occurs, "the world changes," and both of these claims provoked philosophical outrage in many critics (see Shapere 1964 for an example). An elaboration of the basic views of the book is presented first; discussion of controversies and consequences follows. For an extensive discussion of the meanings and history of the phrase 'scientific revolution' (see Scientific Revolutions).

Understanding Kuhn's account is complicated by the fact that throughout his career he was in the process of refining his positions to clarify them, to meet objections and to eliminate misunderstandings. *Structure* was only published in its actual form because Kuhn had agreed to write an entry for the Encyclopedia of Unified Science series and the editors pressed him to produce a manuscript (see Unity of Science Movement). His personal preference would have been to continue to develop the ideas and to relate them in more detail to the existing tradition in philosophy of science, with which he was then acquainting himself. In the Preface, he apologizes for leaving out many topics and more precise references because of lack of space. After the somewhat negative reception of the book, he suggested a major terminological change in the second edition (1970), which he did not incorporate in the text generally, but only in a postscript, which has been largely ignored by readers and critics. He continued to work throughout his life on a clearer and more definitive formulation of his views and he died in 1996 without having completed that project. Thus any evaluation must be of work still in progress.

Structure

In the first edition of *Structure*, Kuhn defined the two kinds of scientific development in terms of *paradigms.* Normal science involves the articulation and refinement of a paradigm that is shared by the relevant scientific community; in revolutionary scientific change, one paradigm is rejected and another takes its place. One reason for the widespread influence of the book outside of the community of philosophers and historians is that the conception of a group or community guided by a *paradigm* seemed to have explanatory value in many settings. This use of the term has become firmly entrenched as a standard expression in English and appears in cartoons and business management

courses, although most of its contemporary users have no notion of its source.

However useful the term 'paradigm' has proven to be in the general culture, it was the cause of considerable criticism in the reception of the book because critical readers perceived that he was using the term very variously and loosely. One critic presented a taxonomy of twenty-two distinguishable senses of the term in *Structure* (Masterman 1974). Kuhn disagreed with the precise count, but was sufficiently persuaded by Masterman's critique and those of many other critics that clarification was required. Many of the criticisms were aired at two important conferences that focused heavily on his work, in London in 1965 and Champaign, Illinois, in 1969. The proceedings of these were eventually published as *Criticism and the Growth of Knowledge* (Lakatos and Musgrave 1974) and *The Structure of Scientific Theories* (Suppe 1977). Kuhn was also conducting graduate seminars at Princeton that were attended by philosophers of science on the faculty, as well as historians and graduate students from both disciplines. As a result of these influences and further reflection, in the postscript to the second edition of *Structure* in 1970, he expressed a desire to replace the term 'paradigm' with two new terms, 'disciplinary matrix' and 'exemplar,' which he believed expressed the two main distinct uses he had made of "paradigm." Similar qualifications of the view in *Structure* are expressed in his contributions to those two conferences.

The six elements that Kuhn intends to include in a *disciplinary matrix* are:

(i) equations or other symbolic representations,
(ii) instruments,
(iii) standards of accuracy and experimental repeatability,
(iv) metaphysical assumptions,
(v) the domain of inquiry, and
(vi) exemplars.

The *domain of inquiry* includes the problems that workers in the field regard as relevant but unsolved. An *exemplar* is, as we have seen, the second meaning of 'paradigm,' and Kuhn emphasizes that these are *concrete* examples of problem solutions. One of the most crucial points in his emphasis on exemplars is that they give guidance to future research by example; these examples are implicitly constrained by rules and are instances of a method, but neither the rules nor the method is explicit in them. A scientific field or specialty is given its coherence partly by the shared examples, but it is given its diversity of approaches by the possibility of researchers interpreting those examples somewhat differently from one another. Researchers can all agree that they want to do for their field what Newton did for his, but they may disagree fairly radically about what that was, and therefore on what they intend to achieve. Some of the confusion in interpreting *Structure* was due to the fact that one sense of paradigm, that is, exemplars, are an element of the other sense (disciplinary matrices).

Disciplinary Matrices and "The Scientific Revolution"

In the Ptolemaic/Aristotelian scheme that dominated scientific thought in the Western world for almost two millennia, one of the fundamental metaphysical assumptions is that there are unbridgeable differences between terrestrial and celestial phenomena, while the Copernican/Newtonian view assumes the uniformity of laws throughout the universe. The former emphasizes qualitative explanations; the latter, quantitative predictions. Famously, the telescope, particularly in the hands of Galileo, was a critical instrument in the arguments against the static Ptolemaic/Aristotelian view of the heavens. While Kuhn was still a graduate student, James Conant, a chemist who was then president of Harvard, asked him to assist in preparing a historically oriented physics course for non-science majors. In the process of preparing for this course, Kuhn, who had read little or no history of science previously, spent an extensive period of time reading Aristotle.

He describes how as he read Aristotle he discovered that Aristotle had known almost no mechanics, if one understands mechanics as the system discovered by Galileo, Newton, and others. This baffled Kuhn because Aristotle's contribution to logic remained of central importance at least until the twentieth century, and Kuhn believed that Aristotle's observations in biology provided models that were instrumental to the emergence of the modern biological tradition. If Aristotle had been both a keen observer and the epitome of reasoning, how could he be so mistaken (Kuhn 2000, 16)?

His conceptual difficulty led Kuhn to reflect that perhaps Aristotle's (translated) words did not mean quite the same to the modern reader as they had to Aristotle. This thought, together with continued concentrated immersion in the texts, led to an abrupt revelation:

> Suddenly the fragments in my head sorted themselves out in a new way, and fell into place together. My jaw dropped, for all at once Aristotle seemed a very good

> physicist indeed, but of a sort I'd never dreamed possible. Now I could understand why he had said what he'd said, and what his authority had been. Statements that had previously seemed egregious mistakes, now seemed at worst near misses within a powerful and generally successful tradition. (Kuhn 2000, 16)

This experience initiated the intellectual development that led to *Structure* and his position on revolutionary change of worlds and worldviews, a position that raised problems that he would continue to struggle with until his death in 1996. The careful reader can detect this theme of sudden revision already in Kuhn's first book, *The Copernican Revolution*, published in 1956, although it is probably only with hindsight that one can see the importance of the idea. Writing that monograph cemented many of the major themes of Kuhn's later work in its detailed description of the complex transformation from the world as described by Ptolemaic astronomy and Aristotelian physics (or perhaps medieval neo-Aristotelian physics) to the worldview that developed through Copernicus, Kepler, and Galileo, to culminate in Newton.

In assessing this sudden transformation and the significance of the process of writing this book on Kuhn's subsequent views, it is essential to recall the unique character of the Copernican-Newtonian revolution. Indeed, for many historians and philosophers, it is called *the* Scientific Revolution. Before this revolution, humans saw themselves as situated on a motionless Earth in the center of a relatively small finite universe. Terrestrial substances were divided into four kinds, and the motions of objects depended on the substances composing them; each kind had a natural motion defined in terms of the center of the universe located at the center of the Earth. Celestial substances were a different matter—or rather were *not* matter—and followed circular paths.

By the end of the Scientific Revolution, humans were on an Earth that was not only rotating at 1,000 miles per hour but also one that was traversing an orbital path around the sun at an even greater velocity. They were not at the center of the solar system, but on the third planet from the sun. Nor is the sun at the center of the universe, for the universe is infinite and there is no center at which to be located. Terrestrial and celestial objects were now subject to the same governing laws, and those laws were abstract, quantitative, and mathematical rather than qualitative and teleological.

Notice that two abrupt changes are involved here. One is the change in the scientific worldview—the Ptolemaic/Aristotelian view that had evolved little over almost two millennia was suddenly replaced by the Copernican/Newtonian view. The second is that Kuhn's understanding of Aristotle's worldview and the relation between Aristotle's views and post-Newtonian views underwent an instantaneous change when his jaw dropped. Until much later (Kuhn 2000), Kuhn did not distinguish these two kinds of changes, one of which is a personal psychological transformation, and the second a social and epistemological change in a community. Neither the scale nor the processes of these two kinds of change are identical, and some of the lack of clarity of his earlier views is due to failure to make this distinction.

Progress

The question of scientific "progress" is a complicated one in Kuhn's thought. He clearly believed that there is directionality to scientific change, that, for example, scientific disciplines frequently split into subdisciplines that become fields in their own right, and that this process is never reversed. And at the most general level, as mentioned above, he thought that one can distinguish pre-paradigm from paradigm-driven fields. But directionality does not mean that it is movement toward some ultimate end rather than simply solutions to current problems.

As indicated above, many of Kuhn's later views are already discernible in *The Copernican Revolution*, but there are other points at which his ideas had clearly developed in the six-year period between that work and *Structure.* In the conclusion to the former book, he discusses the fact that progress in scientific concepts is not cumulative. "But though the achievements of Copernicus and Newton are permanent, the concepts that made those achievements possible are not" (Kuhn 1957, 264–265). This is clearly consistent with his more elaborated view in *Structure* that science does not make cumulative progress with respect to the underlying structure of the world, and is closely connected with his controversial views about how the "world changes" during evolutionary periods.

However, in *The Copernican Revolution* he still holds that the list of solved problems is cumulative across even the Scientific Revolution. "Only the list of explicable phenomena grows; there is no similar cumulative progress for the explanations themselves" (265). By the time he wrote *Structure*, Kuhn had ceased to think that even the list of explained phenomena was cumulative. The beginning of the evidence for this was already in *The Copernican Revolution*, but he had not seen it as such.

For example, in the Ptolemaic/Aristotelian view of the world, since the Earth was (almost) at the center of the celestial sphere of fixed stars, there was a trivial explanation of why there was no apparent parallax in the position of the fixed stars over a period of six months. On the other hand, given the Copernican view of the Earth as orbiting around the sun, one would expect to see the stars appear at slightly different angles when observed at intervals of six months because the Earth is at opposite sides of its orbit. Since no parallax was observed, this was taken by many as evidence for the Ptolemaic/Aristotelian view. The Copernican explanation of the lack of observed parallax was to infer that the distance to the fixed stars was so great that the angle of parallax was less than the limit of observation (Kuhn 1957, 159).

In this instance, what was an unproblematic observation in the Ptolemaic system was "explained" by an assumption that was seen as ad hoc by traditional astronomers when propounded. The detection of parallax remained an issue for Copernican and successive astronomical views even after the invention of the telescope, and it was not until 1838 that the first measurements demonstrating parallax were made (163).

One of the exemplars of the Copernican/Newtonian view was the pendulum. In this case the universal laws of gravitation, force, and acceleration combine to give a derivation of a precise quantitative law stating that the period of a pendulum depends only on its length. The place of the pendulum in the development of Copernican/Newtonian physics is very important. The properties of a simple ideal pendulum are easy to establish, but more complex approximations to actual physical instantiations pose important puzzles for normal science. For the Ptolemaic/Aristotelian view, a heavy object suspended from a string or chain is of no theoretical interest because it is an example of constrained motion—the string or chain prevents the object from pursuing its natural motion toward the center of the Earth and universe. The example of the pendulum was of central importance for some of Kuhn's most controversial views on world change during revolutions, a topic that will be discussed later.

Normal Science

According to Kuhn, normal science consists of periods of cumulative progress in which scientists apply generally accepted theories to the unresolved questions in a domain according to shared assumptions about what constitutes the important problems and what would count as a solution. He characterizes "normal science" as a very sophisticated form of puzzle-solving that can require great ingenuity but occurs within a stable framework of tradition.

Kuhn's characterization of "normal science" was criticized from at least two directions. Popper argued that if Kuhn were correct, then normal science was in fact not science at all, because scientists under those conditions were presupposing the cognitive elements of the disciplinary matrix and not testing them (Lakatos and Musgrave, 1974) (see Popper, Karl Raimund). According to Popper, the Kuhnian characterization of science requires that the laws and theories under consideration be falsifiable and that experiments be attempts at falsification. Kuhn did not accept this criticism—his view was that the presuppositions were necessary in order to make progress. Continual reexamination of what is taken as basic knowledge would impede the process of extending knowledge. He also held that it was only through the vigorous pursuit of normal science that further revolutions could be achieved.

A second criticism was that Kuhn's account made so-called normal science, which is quantitatively the large majority of scientific activity, uninteresting and routine. Although his use of the term "puzzle solving" to describe normal-scientific activity may have made it sound more routine, Kuhn certainly did not think that normal science was uninteresting and routine. The phrase "puzzle solving" may have been unfortunate, because it tends to suggest crossword puzzles or jigsaw puzzles, challenges that have been created by humans with explicit rules and a solution that is known in advance before the puzzle solvers enter the activity.

In contrast, the "puzzles" of normal science are posed by scientists, but the answers are not known by anyone in advance, and the rules for solution are given at best implicitly by previous exemplars. Both features—the difficulty of solution and the bridge to the next revolution—can be illustrated by many examples, but the refinement of the Newtonian theory of the solar system is a particularly clear one.

The textbook accounts say that Newton derived Kepler's laws from his own laws of motion, but this is a derivation in the sense of physicists, not of philosophers or logicians. Kepler's first law states that the planets move in elliptical orbits with the sun at one of the foci of the ellipse. However, the derivation of an elliptical orbit for one body revolving around a second body holds only when no other forces are acting on these bodies than the mutual force proportional to the inverse square of

their distance apart. Thus, this derivation is possible only if the effects of all the remaining planets on the orbit are ignored, and it is clear from Newton's law of gravitation that there is a non-null effect. So the "derivation" involves a deliberate simplification, though one that was unproblematic at the time of Newton.

However, as telescopic observation improved, the discrepancy from the Keplerian model was observationally recorded, and one of the puzzles of the astronomical tradition became to provide a more exact mathematical analysis that did not oversimplify as much. For example, by 1770 it was noted that there were deviations in the motions of Jupiter and Saturn from predictions. Laplace established in 1775 that these deviations were periodic (with a period of 929 years!) and showed that the deviations followed from a mathematical analysis that included the gravitational attraction between those two planets. There is a crucial mathematical fact that intrudes here, *viz.,* that the problem of solving the differential equations for two bodies acting under the influence of gravity has a general analytic solution, but in general there is no closed analytic solution for equations involving three or more bodies. Thus significant new mathematical tools were required to solve the puzzle. And the puzzle led to the major mathematical discovery of the mathematical fact just cited, so the process influenced the development of not only astronomy but mathematics as well.

The better mathematical approximations fit well with observation until about the 1840s, when it became clear that the predictions for Uranus did not fit the data. The possibility of an undiscovered planet was one potential explanation, though others were also offered, including the possible failure of the inverse square law for gravitation. However, the standards of astronomy at that post-Keplerian point would not permit as a "solution" the mere postulation of such a planet, but required calculations to determine the location of the hypothetical planet, and observations of the planet and its positions.

When the relevant calculations were made and the appropriate portion of the sky observed, astronomers saw Neptune. But not for the first time! Once the existence of Neptune was known and its orbit calculated backward, astronomers learned that on several occasions the planet had been seen and noted, but that the observers (including Galileo) did not discern that it was a planet. This episode provided (though it was hardly necessary) more confirmation of the universal applicability and validity of the Newtonian equations.

A similar situation arose late in the nineteenth century with respect to the planet Mercury, whose orbit likewise did not fit predictions according to the standards of the time. Astronomers hypothesized another inner planet, calculated its orbit and mass, and even named it: Vulcan. However, nature was not so cooperative in this instance and Vulcan was never observed. The anomaly of Mercury's orbit later became one of the important phenomena predicted correctly by general relativity theory and was a crucial part of the overthrow of Newtonian theory. Rigorous pursuit of increasingly precise predictions within the normal-science tradition of Newtonian astronomy provided the data that gave observational leverage to the overthrow of that tradition.

Rationality

Perhaps the most common and outraged criticism of Kuhn's work was that it denies the rationality of science, because the acceptance or rejection of a new theory depends not only on "scientific" factors but also on social factors. Kuhn's response was indignation and perplexity. The first sentence of *Structure* promises (or warns) that "History, if viewed as a repository for more than anecdote or chronology, could produce a decisive transformation in the image of science by which we are now possessed." One important respect in which Kuhn wanted to correct the image of science was in the general understanding of what constitutes its rationality.

The generally accepted philosophical view of scientific rationality in the 1950s was that science rested on a basis of *observation statements*—these statements were thought to be neutral with respect to the various theories to be compared and to be unproblematic with respect to verification (see Logical Empiricism; Verifiability). While there were disagreements about the character of observation statements (whether they were subjective reports of the agent's perceptions or reports of external states that were intersubjectively agreed upon) and about whether their verification was absolute or not, the assumption of a basis of observation sentences was shared by Carnap, Hempel, and almost all others working at the time (See also Carnap, Rudolf; Hempel, Carl Gustav; Observation; Physicalism; Protocol Sentences). So the first element of scientific rationality was the observational base.

The second component of scientific rationality consisted of the method of establishing verification, confirmation or falsification of theories on the

basis of observation sentences (see Confirmation Theory; Observation). Significant controversies raged among those who shared this framework over such issues as whether the basic concept should be probability (see Popper, Karl Raimund; Reichenbach, Hans), confirmation, or refutation, but all shared the overarching program of articulating exactly how the logical relation between theory and observation was to be analyzed. The guiding motivation for this program was the success that had supposedly been obtained in the foundations of mathematics. Mathematical logic had proved to be an enormously successful tool for representing mathematical statements and for analyzing the proof relations among the statements. The second stage in securing the foundations of science was to be a comparable analysis of scientific reasoning. In particular since the surprising success of mathematical logic consisted largely in showing how semantic conceptions, such as entailment, could be rendered into equivalent syntactical forms, such as derivability in a formal system, the goal was to provide a syntactic characterization of the process of theory evaluation.

Summarizing, the two principles are that the basis of evaluating scientific theories was a shared collection of observation sentences and that evaluation is to be done according to a single algorithm, which was to be proved optimal. Given these conditions, it follows that if two scientists disagree about theory choice, then either

- they are using different evidential bases; or
- (at least) one of them is not using the proper algorithm for theory evaluation.

Thus, if Carnap's original program, to prove that there is a unique correct quantitative confirmation function, could have been carried out, any scientific controversy must result from ignorance or inductive error; scientific controversies are an inefficiency in the progress of science. Furthermore, the scientific community, or at least the ideal one in which all scientists follow the algorithmic ideal, has no discernible function except to make the process of scientific development move faster by having more hands to make the tasks lighter. In the ideal scientific community, in this view, there would be no disagreements about theory evaluation. If Carnap's program does not succeed, then one must make a reevaluation of the nature of scientific controversies (see Carnap, Rudolf; Inductive Logic).

One consequence of Kuhn's work and the subsequent discussion has been to encourage alternative approaches to rationality. The Bayesian approach to theory evaluation would undoubtedly have commanded some attention in any event, but interest in this alternative to the traditional approaches was undoubtedly increased by the desire to find ways to accommodate Kuhnian insights in a more formal structure. The view that apparent incommensurability stems from scientists using very different prior probabilities is explored in interesting depth in Salmon (1990) (see Bayesianism).

Rationality and the Social

Since finding a formal analog for inductive logic to the very successful formal deductive foundation of almost all of mathematics was taken as key to demonstrating the rationality of the scientific method, it is not surprising that Kuhn was accused of advocating irrationality when he questioned the possibility of this project. On this point he was very clear in his own mind that the traditional attempts to underwrite the rationality of science misunderstood the history and character of the scientific process. For him, the process of theory choice by the scientific community was the touchstone of rationality, and his goal was to better understand that process. In other words, the scientific process is not rational because the community is embodying an independently specifiable algorithm for theory choice, but the process is rational because it is being carried out by the community.

There are two importantly different ways of understanding this claim. The first is based on an idea from information theory and signal processing. A classical engineering problem was how to improve signal detection given either imperfect detectors or noisy signal channels. Early researchers in the field showed that with imperfect signal detectors one could obtain an arbitrarily good improvement in the accuracy of signal detection by combining a sufficiently large number of the imperfect detectors and taking the result from the majority of the detectors. The application of this analogy is to think of scientists as imperfect detectors of the signals sent by nature, perhaps under experimental questioning, regarding the best of a set of available theories.

This model depends on (at least) two crucial assumptions. One assumption is that the scientists/detectors are more likely to choose the better theory or to detect the correct signal, than the alternative theory/signal. Lest the reader think that "better theory" presupposes too much, note that for these current purposes, one can take *better theory* in a limited way to mean the better theory from an available specified set for the purposes of fitting

experimental results, making correct predictions, and cohering with other theories in the near future. This argument can be formulated in a way that is agnostic about metaphysical truth and realism—indeed, both realists and anti-realists can adopt this assumption. If there are more than two theories in contention, then the assumption need only be that the better theory is more likely to be chosen than any individual competitor. One does not need the stronger assumption that the better theory is more likely to be chosen than the disjunction of the competitors. And the difference in probability of the better theory being chosen does not have to be great; even small differences can be leveraged with enough agents.

Secondly, the scientists/detectors must be appropriately independent of one another. Otherwise they will all simply reproduce the same errors. Elaboration of this assumption is a complicated and subtle matter, and only an approximation can be given here. The detectors cannot be statistically independent, for if each is more likely to detect the true theory than not, then their conclusions will be at least weakly correlated. The proper statement of the assumption is that their correlation is entirely due to their propensity to detect the true theory. If the detectors are all made in the same factory, and thus are subject to the same biases and will produce the same result, true or false, then they are not independent in this sense. If the scientists are all trained by the same narrow-minded dissertation advisor and thus will produce the same result, true or false, regardless of the facts of the matter, then they are not independent in this sense.

This emphasis on the independence of judgment suggests an atomistic view of the scientists that is at odds with the emphasis Kuhn places on the weighty role played by the social community of scientists. As Kuhn discussed in *The Essential Tension* (Kuhn, 1977), the process of being trained as a scientist in a particular specialty is simultaneously a process of making the trainee conform to the standard acceptable canons of the discipline while trying to preserve the freedom and independence of judgment that will enable the new specialist to explore and evaluate alternative approaches to anomalies in the discipline. The process of training ranges inclusively from training in specific experimental or mathematical fields to absorption of the cultural tales of the field (Traweek, 1988).

This model of the scientific community is oversimplified in many ways, but it brings out important points. If not exclusively, at least largely, the community must consist of inquirers who are responsive to information about the world—they must be rational inquirers as individuals. But there are also issues of optimality at the level of the community, and one can speak of rationality at the level of the structure of the community.

Kitcher (1993) develops a version of this approach. Since there is no theory-choice algorithm, a point he takes as given, it is important to have a diversity of approaches to theory testing and evaluation. If everyone agreed on and pursued the most plausible direction, then potentially promising theories might well be ignored, often at a considerable loss to the community. One could add to his point that a diversity of cognitive styles and variability in willingness to take risks would also be beneficial. In these matters there remains the difficult task of maintaining the right balance in the essential tension Kuhn noted, the balance between having sufficient communal agreement on enough matters to define a field while leaving room for vigorous debate on others.

An alternative, bolder interpretation is that the rationality is present only at the level of the community. As Longino puts it: "Objectivity, then, is a characteristic of a community's practice of science rather than of an individual's, and the practice of science is understood in a much broader sense than most discussions of the logic of scientific method suggest" (Longino 1990, 74). In her analysis, there are four conditions that a community must satisfy in order to qualify as rationally developing scientific knowledge:

1. There must exist within the community recognized and approved forums or avenues for the criticism of theories, evidence, experiments, assumptions, and inferences.
2. The criticism must be effective in that the community at times changes its belief and practices in response to it. Criticism is not merely tolerated and ignored.
3. As a background for criticism, the community must have publicly recognized and shared standards that provide the criteria for evaluating theories, hypotheses, experiments, data analysis, etcetera. These establish standards for the quality and relevance of criticism.
4. Communities must be characterized by appropriate levels of equality of intellectual authority. This does not require that all members of the community have equal influence, but that any disparities be due to past accomplishments or training and not to political, economic, or other factors not directly

related to the epistemological task at hand (Longino 1990, 76–81).

Whether communities or individuals are the fundamental basis of rationality in science is still under debate and development, but there is no question that participants such as Kitcher and Longino are continuing a debate opened by *Structure.*

Contexts: Discovery, Justification, Development

Perhaps the most important break with the standard philosophy of science tradition was Kuhn's rejection of the distinction, due to Reichenbach, between the context of discovery and the context of justification. At the very beginning of *Experience and Prediction*, Reichenbach distinguishes the descriptive task of epistemology, *viz.,* "giving a description of knowledge as it really is," from the main evaluative task of epistemology of considering "a logical substitute rather than real processes" (Reichenbach 1938, 5) He concludes that "it will therefore never be a permissible objection to an epistemological construction that actual thinking does not conform to it" (6). Reichenbach (and many other logical empiricists) saw the task of philosophy of science as providing a "rational reconstruction" of scientific processes. These reconstructions substituted abstract logical operations for the actual psychological processes. Probably Kuhn's most important contribution was to bring both history of science and psychology into contact with philosophy of science.

At the time Kuhn was writing *Structure*, almost all of philosophy of science focused on the context of justification, understood as analyzing the relation between a theory axiomatized as a set of sentences in a formal language and evidential sentences from an agreed-on base also represented in a formal language. Kuhn's use of history was frequently seen as dealing with the context of discovery and thus as irrelevant to philosophy of science. Kuhn's insight, which is now generally accepted among philosophers of science, is that theories and evidence undergo significant transformations during the period between the time the theory is first formulated and the time it reaches the final form that is enshrined in textbooks. Most of the process of scientific development occurs between the time of discovery and the time at which a formal justification is developed, and formalization is ill-suited to represent those processes of development.

To develop Kuhn's ideas, it is essential to distinguish a third context, that of *development.* This is the stage in which an embryonic, or perhaps fetal, scientific theory is nurtured and developed so as to analyze its implications. The most famous and dramatic example is the Copernican revolution discussed above. Copernicus' theory of planetary motion described the motion of the planets in terms of circular motion with epicycles on the main cycles, and attributed the movement to a rather mystical force emanating from the sun but pushing the planets around in their orbit. It took more than a half century after Copernicus for Kepler to develop the description of the elliptical orbits, and another half century before Newton provided the dynamics to explain the approximately elliptical orbits in terms of a force attracting the planets to the sun. Although Kuhn sometimes describes scientific revolutions as sudden, he had documented in his first book the century and a half that was required for the Ptolemaic/Newtonian revolution to unfold.

The Scientific Revolution

The issue of the context of discovery is closely related to the character of normal science. As indicated earlier, in Kuhn's view, the adoption of a new disciplinary matrix by a community requires an extended period that looks instantaneous only from a rather distant perspective. For a new disciplinary matrix to be taken seriously by the community, it must solve some of the outstanding problems that have eluded solution with the older disciplinary matrix. But the new disciplinary matrix at that stage has not been developed sufficiently to resolve many of the outstanding problems or to provide new alternative solutions to previously solved problems. Thus much of the process of normal science is the development of new scientific ideas, instruments, mathematics, and experimental methods. The formalized theories on which logical empiricism focused are an end product and do not represent the character of most of the activities of scientists (see Logical Empiricism).

Gestalts and World Changes

One of the significant oversimplifications in *Structure* is that Kuhn uses the same vocabulary to describe the process of change in a scientific community and in an individual—both are characterized as "Gestalt switches," or instantaneous changes of perspective, familiar from such psychological examples as the Necker cube: a two-dimensional configuration of lines that can be seen in either of two three-dimensional orientations. (The relevance of Gestalt psychology to philosophy of science was also argued by Hanson [1958] in his *Patterns of*

Discovery. Although Hanson published these ideas earlier and Kuhn acknowledges Hanson's work in *Structure*, Kuhn had been familiar with the Gestalt examples from his time at Harvard. There is also a question of the scale of revolutions and various perspectives on them. The Copernican–Newtonian revolution took over a century, but this looks relatively abrupt compared with the millennium and a half of domination by the Aristotelian–Ptolemaic disciplinary matrix before the Scientific Revolution, and the two and a half centuries subsequently by the Copernican–Newtonian.

The contrast between the psychological processes by which an individual comes to accept one theory rather than another and the social processes by which the consensus of the scientific community shifts can be illustrated by examples. Galileo quickly adopted the Copernican framework but was part of a long and tragic struggle within (and without) the scientific community. The Gestalt character of how perception can change is illustrated by Kuhn's discussion of Planck's discovery of the constant that bears his name. In his earliest paper, Planck uses a quantity that is equal to the constant, but his conceptualization of it at that time was not that it was a constant, but was simply another quantity that emerged in accounting for the data. It was not until considerably later that Planck conceived of it as a fundamental constant (Kuhn 1978).

Two of the passages that most disturb critics of *Structure* are Kuhn's comments that before Galileo there were no pendula and that when scientists change their disciplinary matrix, as we have seen, the world changes. However, one way of interpreting Kuhn's pendulum comment less dramatically can be derived from recent work on the view that science consists primarily of modeling (Giere 1988 and 1999; Cartwright 1983). If a pendulum is to be understood as described in physics textbooks as a *point mass* suspended from a *massless*, completely *inelastic* string with *no resistance* to the medium in which it moves, then there are no pendula in the physical world, neither before nor after Galileo. However, from Galileo on, the worlds of natural philosophers and physicists include abstract pendula of all various masses and string length. And with these in the mental space of the scientist, the world looks very different because many physical objects approximate the properties of an ideal pendulum so that prediction is possible and fruitful.

Later Work

The main focus of Kuhn's later work was on language, attempting to understand and explicate precisely the nature and causes of incommensurability. This direction began in the 1960s while he was at Princeton, where Quine's ideas about radical translation were a dominant theme of discussions (see Quine, Willard Van). In the postscript to the second edition of *Structure* and subsequent work Kuhn often used the term "translation" and was interested in the parallels between language learning and scientific development. For example, he claimed repeatedly that Aristotelian "physics" cannot be translated into Newtonian terms. A frequent criticism of this claim was that it implied falsely that no one who knew Newtonian mechanics could understand Aristotle, whereas Kuhn himself explicated Aristotle. His response was that the process of learning Aristotle's science was a process of second-language learning, and the ability to speak two languages does not guarantee that what is said in one can be translated without remainder into the other.

In discussing "incommensurability" claims, it is important to bear in mind what Kuhn meant and not overinterpret the claim. He used the term in its historical mathematical sense, in which a mathematician says that the square root of 2 is incommensurable with any rational number. This means that no rational number is a square root of 2. On the other hand, one can approximate the square root of 2 as precisely as you wish by rationals. It is not clear whether Kuhn was committed to this latter consequence, that one could approximate Aristotelian claims as precisely as one wishes by Newtonian statements, but it is at least evident that his terminology did not imply that no comparison could be made between the two theories.

It is unfortunate that Kuhn did not more systematically develop his conception of disciplinary matrix, because it might have led him to recognize that in addition to the semantic incommensurability that most concerned him, other sources and kinds of incommensurability also abound. The Millikan–Ehrenhaft controversy over the electron illustrates how metaphysical and experimental commitments can produce incommensurable analyses of experimental results.

Around 1910, many physicists believed that there was a fundamental particle, now known as the electron, which had the minimal unit of negative electrical charge. In other words, all electrical charges were multiples of the charge of the electron. But many others were still not persuaded of the existence of such quantized particles. Millikan (1911), believing strongly in the existence of the electron, embarked on the research project of determining more precisely the value of the charge.

His method was to produce small oil drops that were ionized by radiation so that the drops were charged. He then observed their behavior in both the presence and the absence of an electrical field.

Meanwhile, Ehrenhaft, who was opposed to ideas of quantization, and perhaps even of atomism, was performing similar experiments to test whether the basic unit of charge existed. Ehrenhaft used small particles of metal rather than oil drops. These had the advantage that they were even smaller than the oil drops and were not susceptible to evaporation, as the oil drops were. Ehrenhaft's experimental procedure produced data that led to calculations of various charges smaller than the unit charge that Millikan reported (Ehrenhaft 1941).

Millikan, being an atomist, believed that Ehrenhaft's particles were so small that they were subject to irregularities in their motion caused by encounters with individual atoms and that Ehrenhaft's results were thus unreliable.

Ehrenhaft rejected Millikan's claims and pointed out that Millikan's process of analyzing data included omission of microscopic observations that produced data inconsistent with his atomic hypothesis. Ehrenhaft also argued that his own data were more reliable because his particles were not subject to any evaporation and could be produced as exact spheres, whereas oil drops were only approximately spherical. Ehrenhaft was never persuaded of Millikan's results, but Millikan (1965) received the Nobel Prize in 1924 for this work.

The differing metaphysical assumptions—continuity versus atomism—led to differing experimental approaches and to divergent interpretations of the reliability of data. Since those metaphysical assumptions were not only in the background, but also the subject at issue for Ehrenhaft, the result was incommensurability. (For a much more detailed discussion of the controversy and issues, see Holton 1978.)

Influence

Assessments of Kuhn's influence vary enormously, and although most philosophers of science would agree that his influence was very large, some would not; and among those who do agree, there is disagreement about whether it was positive or negative. Those who argue that his influence was slight, point to the fact that almost all of the elements of *Structure* can be found in other philosophers of science writing at the time—Hanson (1958), Hesse (1966), Feyerabend (1993), Toulmin (1961), and others. However, the constellation of ideas in *Structure* and the rhetorical tone caught readers' attention in a way that produced much more dramatic results did than any of the others. Feyerabend made more radical claims than Kuhn and was largely dismissed or ignored, and the others made less sweeping claims and attracted less attention. For complex reasons that are not fully understood, *Structure* struck a resonant chord and transformed philosophy of science.

Some of the disagreement stems from unclear aspects of the book. As discussed earlier, although Kuhn changed his mind about the central term of the book, "paradigm," he did not rewrite the book to reflect that change. This decision was the result of Kuhn's recognition that reworking *Structure* was not a very good option, since he was still in the midst of reworking many of his views, and so the "postscript" strategy was a stopgap measure until he could reach the stage where a new and more thorough book was prepared. During the 1960s and 1970s Kuhn gave frequent graduate seminars on *Structure* and his further thoughts, as well as giving lectures and publishing intermediate elaborations. In 1977, he published *The Essential Tension*, a collection of his essays ranging from reprintings of pre-*Structure* papers to items that appeared for the first time in that volume. The "essential tension" referred to is that between the desire to assimilate all data/observations within the current paradigm and the desire to find revolutionary new solutions.

The characterization of revolutionary science has attracted the most attention—both positive and negative—from readers of *Structure.* Much of the popularity of the book outside the community of philosophers and historians derived from the conceptual tool it provided to analyze change and often to attempt to bring about a "change of paradigm." The book especially attracted interest from the social sciences because, in addition to the two types of science discussed earlier, Kuhn also described the "pre-paradigm" periods of the physical sciences before they achieved maturity. Whether any changes in these sciences are due to *Structure* or whether they are positive is mostly outside the scope of this entry. In particular, the widespread use of "paradigm" to mean something like a holistic worldview has its origin in the first edition of *Structure* and is rather distinct from the official approach of the second edition, which replaces "paradigm" with the disciplinary matrix with various explicit dimensions.

Although *Structure* was one of the major final blows to the logical positivist program, Kuhn's relations with at least two of the major figures in that program were cordial. *Structure* was originally

published in the Encyclopedia of Unified Science series, which was the primary publishing format for logical empiricism (see Logical Empiricism). Carnap, one of the editors, was enthusiastic about publishing *Structure*. Although it was demonstrated in a paper by English (1978) that Carnap's own account of the relation between theory and evidence leads to incommensurability, since the meaning of theoretical terms is given implicitly by the relation of the theoretical terms to observation terms, this has not been generally noted. Also, in Carnap's account of probability and changes in probability assignments, he recognizes that in addition to conditionalization on new evidence, sometimes probability assignments are made in a global way that do not rely on evidence. This distinction is not exactly that between normal-science belief revision and revolutionary belief revision, but it is also not entirely foreign to it (see Carnap, Rudolf).

Hempel was a colleague of Kuhn's at Princeton and they were frequent interlocutors. Both influenced each other's views, and by the late 1970s their positions on many issues were very similar, although they had arrived at those positions from different directions. Kuhn came to emphasize more that revolutionary changes were made for good reasons, though he continued to assert that particularly at early stages of revolutionary change there were also good reasons against the eventual successful theory. And he continued to emphasize that there was no formal algorithm for theory evaluation that could be appealed to (see Hempel, Carl Gustav).

Some examples of Kuhn's influence within philosophy of science have already been given. Kitcher (1993) refers to Kuhn as one of the two most significant influences on his work and thought (the other is Hempel). Longino (1990) does not delineate her debts so explicitly, but there are far more references in her work to Kuhn than to any other philosopher of science. Kuhn's inclusion of values in the disciplinary matrix fostered the possibility of feminist philosophy of science, which studies, among other topics, the extent to which assumptions about gender influence the choice of research topics, funding, and scientific prestige, as well as biases with regard to theory selection (see Feminist Philosophy of Science). Another consequence of note was the development by Joseph Sneed, Wolfgang Stegmuller, and others of a formalization of theories inspired by Kuhn (for more details, see Theories).

One of the effects of *Structure* was that researchers in a number of fields beyond philosophy of science cited it as justification for emerging new domains in the study of science or for transformations of old ones. Sociologists of science, which had been dominated by a model of scientific development emphasizing the rational and cumulative character of scientific knowledge, was emboldened to investigate issues of authority and power and other issues at the level of the scientific group (Crane 1972). Kuhn's introduction of Gestalt psychology into discussions of scientific change helped to encourage both psychologists and philosophers to investigate these further. Productive examples can be found in Brewer and Chinn's (1994) research on anomalous data and Giere's *Explaining Science* (Giere 1988). Anthropology of science, which did not exist in any significant way prior to *Structure*, began to study scientific communities in the same ways in which other esoteric cultures were investigated (e.g., Traweek 1988). Some of the influence, and debates about it, continue. For example, Duschl (1990) and others are currently arguing for transformation in science education on the basis of what they perceive as a Kuhnian understanding of the process of scientific development.

In conclusion, the influence of Kuhn in philosophy of science is difficult to gauge because a great deal of what he argued for is now taken as part of the underlying assumptions. Studying history of science, having more realistic accounts of scientific development, and appreciating the relevance of theories of cognition and of social processes are all accepted and valued by the mainstream of philosophy of science. Thus what is attributed to Kuhn are primarily the claims about incommensurability and the dichotomous nature of scientific change, which are the less plausible parts of his views with the hindsight of fifty years. Kuhn's work has achieved a transformation of views of science that makes his most valuable contributions invisible to many current philosophers of science.

L

IMRE LAKATOS

(5 November 1922–2 February 1974)

Lakatos was born Imre Lipsitz to Jewish parents in Budapest on November 5, 1922. He was not sent to a Jewish school, and when his family moved to Debrecen in eastern Hungary (in 1932) he attended the local *realgymnasium* (a secondary school with an emphasis on the sciences). Having excelled at school Lakatos went on to study mathematics, physics, and philosophy at the University of Debrecen, from which he graduated in 1944. During the war years he gravitated to the Marxist left. When the Nazi occupation of 1944 placed Hungarian Jews in mortal danger, he used a false identity to escape the labor gangs and the deportations, unlike many of his family and friends, including his mother and grandmother, who died in Auschwitz. During the occupation he belonged to an underground Marxist group, and late in 1944 he adopted the name "Lakatos" ("Locksmith"). After the war he continued his education, now at the prestigious Eötvös College in Budapest. At this time he wrote his first published works, on politics and its relation with science, written from a Marxist perspective. In 1947, he was awarded a Ph.D. for his dissertation *On the Sociology of Concept Formation in Natural Science.* Meanwhile, the Moscow-backed communist government in Hungary suffered from a shortage of dedicated Marxists to fill its offices. Thus it was that in 1947, the young Lakatos was attached to the Ministry of Education with responsibility for the "democratic reform of higher education." In practice this meant a rapid expansion in student numbers, together with brutal measures to bring independent intellectual centers under Party control—including Eötvös College, where Lakatos is still remembered for his role as denouncer-in-chief. At this time he was also a research student of the Hegelian-Marxist philosopher György Lukács, and he traveled to Moscow University in 1949. On his return to Hungary in the spring of 1950, he was arrested, charged with "revisionism," and imprisoned for almost four years (including a period in solitary confinement), one of many Party members caught up in the Stalinist purges. On his release after Stalin's death Lakatos returned to academia. Between 1954 and 1956, he worked on probability-and-measure theory under the mathematician Alfred Rényi. Crucially, one of his tasks was to translate into Hungarian György

Pólya's *How to Solve It*, a book on mathematical heuristics (Pólya, working in the United States, wrote *How to Solve It* for his undergraduates). At the same time, Lakatos began to question the entire edifice of Marxist thought. When demonstrations against the government erupted in October 1956, Lakatos was at the forefront of the student movement demanding academic and intellectual freedom. His conviction that science and philosophy should suffer no external control was by now firmly established. The uprising was quashed by Soviet troops, and Lakatos left Hungary for Vienna in late November 1956.

In 1957, he secured a Rockefeller fellowship to King's College, Cambridge, England, where (supervised by R. B. Braithwaite) he wrote a Ph.D. thesis, *Essays in the Logic of Mathematical Discovery,* a later version of which was eventually published as *Proofs and Refutations.* On taking his doctorate in 1960 he joined the London School of Economics (LSE), where he remained until his untimely death. In 1969, he was appointed professor of logic. During this time, his philosophical interests broadened to include physical science, and he developed his Methodology of Scientific Research Program. On the political front, the LSE was the British center of the student uprising around 1968. Remembering the damage done to Hungarian intellectual life by political interference both from the state and from student activists, Lakatos urged the university to resist demands for a student role in policymaking. In public he insisted on clear distinctions: between logic and psychology; between science and pseudo-science; and in this case, between the "constructive" student demand for the right to criticize the university and the "destructive" demand to take part in its decision-making processes. In private his tone was playful and his logic supple. In his publications he sharply distinguished his position from that of "irrationalists" such as Feyerabend (see Feyerabend, Paul); in his lectures he recommended Feyerabend to his students; and, in letters, he and Feyerabend argued for so long and took each other so seriously that in the end their positions were in danger of collapsing into one another. This combination of public dogmatism and private openness was motivated by an acute sense of the fragility of intellectual liberty. The enemies of free inquiry, whether they be totalitarian governments or ideologically blinkered students, cannot be resisted by the force of argument alone. Defenders of freedom, Lakatos thought, must stand ready to use whatever combination of rhetoric and military force the occasion demands.

In the early 1970s, Lakatos was full of plans for books and papers on mathematics and science, but he was dogged by ill health. He died after a heart attack on February 2, 1974, aged fifty-one.

Proofs and Refutations

Lakatos' earliest published works are Hungarian book reviews written in 1946–1947 when he was finishing his first Ph.D., *On the Sociology of Concept Formation in Natural Science.* These book reviews range over politics, science, and literature, but they invariably criticize their subjects from a Marxist perspective. For example, one author claims that as the result of scientific progress, modern man is alienated from nature—but, contends Lakatos, this is the case only under capitalism. In another review Lakatos complains that undialectical thinking makes a mystery of the fact that yesterday's progressive social class can become tomorrow's empty husk. Lakatos' concern in these reviews and in his work for the Ministry of Education was to place the resources and achievements of bourgeois intellectual life at the disposal of the new, postwar, communist reality. No doubt he reasoned that this was the only hope for their survival and growth. If intellectual culture remained bourgeois and "idealist," it would die for lack of relevance.

Lakatos had abandoned this Marxist framework by the time he began his Cambridge Ph.D. a decade later. Nevertheless, he retained a dialectically oriented study of the emergence of novel concepts. Indeed, two themes—the growth of knowledge and the relation between intellectual life and politics—dominated his writing from his first postgraduate publications of 1946 to his death in 1974. At the beginning of his Cambridge thesis, he declared: "The three major—apparently incompatible—'ideological' sources of [this] thesis are Pólya's mathematical heuristic, Hegel's dialectic and Popper's critical philosophy" (Lakatos [1962] 1978, 70n). The thesis is a case study in the growth of informal mathematics, that is, mathematics that have not been translated into the language of a system of formal logic. The case in hand is the Descartes–Euler formula, $V - E + F = 2$, where V is the number of vertices of a polyhedron, E the number of edges, and F the number of faces. A cube, for example, has 8 vertices, 12 edges, and 6 faces: $8 - 12 + 6 = 2$. The formula holds for the Platonic solids and many other polyhedra. Obvious questions arise: Does it hold for all polyhedra, or only for a special class of them? What exactly is a polyhedron anyway? Formal logic (that is, the logic

expressed in such systems as the predicate calculus) offers no answers to these questions, though it may help to clarify answers found by some other means. If, therefore, one supposes that the rationality of mathematics lies entirely in its use of formal logic, then there can be no rational means of addressing these questions. One can only hope to stumble on an answer by a lucky guess, intuitive leap, or stroke of genius. This is where Pólya enters the picture.

Pólya's books on mathematical heuristics began as teaching aids. Some of his tips on mathematical research are altogether general (e.g., Do you know how to solve a problem similar or related to the one in hand?), while others are topic specific (e.g., If you want to discover new theorems about solids, remember that theorems in plane geometry often have three-dimensional analogues). These research strategies are fallible, but they do offer students and researchers in mathematics a more productive approach than simply tinkering with the material and hoping that luck or inspiration will supply an insight. Pólya's heuristics also suggest a philosophical account of the growth of mathematical knowledge (psychologistic talk of "inspiration" or "genius" is no account at all). Pólya suggested that Lakatos should use the Descartes–Euler conjecture as a case study. Philosophically, Pólya contributed three further thoughts to Lakatos' thesis:

1. Natural science and mathematics have many heuristic patterns in common. Pólya's work provides examples in pure mathematics of enumerative induction, inference to the best explanation, and the testing of general hypotheses by checking that their logical consequences are true.
2. The mathematical operations used to test a conjecture may eventually form the kernel of a proof. For example, one wishes to test the Descartes–Euler formula. One could try lots of different polyhedra in turn, but this would be hopelessly slow. One can, however, generate a vast collection of polyhedra out of the Platonic solids by "roofing" (building a pyramid taking one side of an existing polyhedron as its base) and "slicing" (cutting off a corner). It is easy to check that roofing and slicing do not change the alternating sum $V - E + F$. One has, therefore, checked the hypothesis for all polyhedra generated from the Platonic solids by roofing and slicing. But, by rearranging the elements, one also has the means to prove it for this class of solids.
3. Proofs and tests may suggest definitions and theorems. Pólya provides cases in which, rather than first seizing on definitions and conjectures by luck or insight and then later finding a suitable proof, mathematicians tailor their definitions and theorems to suit a promising proof idea. For example, the roofing-and-slicing idea suggests a definition: Let polyhedra constructed from the Platonic solids by finite iterations of roofing and slicing be called "P-constructable." The earlier argument is now the proof of a theorem: For all P-constructable polyhedra, $V- E + F = 2$.

The introduction of new definitions leads to Hegel. From Hegel, Lakatos learned that the arrival of new concepts in science is not usually announced by an explicit definition. Rather, existing concepts are developed in use. This may be a surreptitious expansion occasioned by consideration of a new sort of object. For example, in Lakatos' case study, the concept 'polyhedron' is quietly stretched as mathematicians contemplate solids with holes and solids formed by joining simple polyhedra at a vertex or along an edge. Lakatos also shows how a new proof can reinvent an entire field of study. Cauchy suggested a proof of the Descartes–Euler formula that involved removing one side of a polyhedron and flattening the remaining figure onto a plane. This is to treat a polyhedron as a closed surface rather than as a solid, and thereby to shift the problem from geometry to topology. Such changes, from minor concept-stretching to revolutions in the very subject matter, may not be apparent when they happen. They may come to light only later, when the growth of knowledge is rationally reconstructed. This explains the unusual literary structure of Lakatos' essay. The main text is a dialogue in a fictional mathematics class, while the historical sources are supplied in footnotes. Philosophical rational reconstruction is not concerned with accuracy in historical detail. Rather, the point is to make known the subterranean conceptual shifts masked by the use of old words for new ideas.

A consequence of Pólya's heuristic is that one may end up proving something deeper and more interesting than first intended. Lakatos' "dialectical" interest in conceptual change shows that as a result of trying to prove a theorem, one may end up with a whole new theoretical language. Thus, Lakatos' second Hegelian inheritance was a distinction between formal logic, which analyzes and rearranges the conceptual resources already available, and a heuristic rationality that develops new concepts out of old. A movement to a new language L_2 may introduce contradictions and refutations that were not present in the conceptual order associated

with the old language L_1. Formal logic would recommend sticking with L_1, but this may be overridden if there are good heuristic reasons to prefer L_2. Indeed, the contradictions and refutations thus introduced may require improvements to the mathematical theory that might not otherwise have been made. Hegel expressed this distinction in psychologistic terms inherited from Kant: Formal logic is the natural tool of the Understanding, while "dialectical" or "speculative" thinking is the business of Reason. Lakatos preferred to distinguish between "language statics" and "language dynamics," but the point is the same. The logical analysis of concepts alone can only clarify and entrench the present conceptual order, when the real philosophical task is to understand the progress from one stage of conceptual development to the next.

Lakatos' third Hegelian lesson is that there is no general method for the development of concepts. Hegel is associated with the thesis–antithesis–synthesis schema, but one ought not to expect to apply this formula mechanically. In Hegel's work the development of any concept comes in three "moments," the third being in some sense a return to or rediscovery of the first, suitably modified by passage through the second. However, the details in any given case cannot be anticipated. There are no laws of dialectical growth as there are laws of formal logic. "Formalism," for Hegel, is the false supposition that there is a universal scientific method that may be grasped abstractly in advance of any particular inquiry. In his Cambridge thesis, Lakatos explicitly denied the possibility of a general system of heuristic rules, though this passage vanished from published versions of the text.

After Pólya and Hegel, Lakatos' third source was Popper and his critical philosophy (see Popper, Karl Raimund). Popper argued that empirical science is not built up by establishing true laws of nature. Rather it develops by the refutation of conjectures. Popper's view depends on the asymmetry between proof and disproof: No argument can conclusively prove a general statement because no argument can rule out altogether the possibility that an exception to the proposed law will be discovered in the future. On the other hand, a single counterexample is sufficient to refute a general statement. Because Popper put refutation rather than confirmation at the core of his model of science, he had no need for a nondeductive logic of induction. Pólya's thought that mathematics shares heuristic patterns with natural science enabled Lakatos to import Popperian ideas about science into his thinking about mathematics. Specifically, he developed Pólya's observation that a theorem and its proof may evolve together so that the final theorem is carefully tailored to capture the results of an insightful proof strategy. Lakatos gave this a Popperian gloss: Mathematics evolves through a process of conjecture and refutation. What is more (following Pólya), the same thought experiment can be both proof and test. This is most obvious when all the steps in a proof are reversible. However, a proof with nonreversible steps in it can also function as a source of counterexamples because it decomposes a theorem into its logical dependencies. One theorem may depend on many lemmas, and by finding a counterexample to a lemma, one may refute the theorem itself (alternatively one may learn that the lemma is stronger than it need be, and so one can improve the proof). Mathematics, in this view, is not about proving theorems from self-evident axioms. It is a matter of offering conjectures for refutation—but the refutations are found in proofs and other thought experiments rather than in empirical experiments and observations. This, then, is Lakatos' first Popperian thesis.

The second Popperian lesson is that formal logic is indispensable to the development of concepts. In Hegelian dialectic, no conception is simply false. A concept is found to be one-sided, partial, or otherwise inadequate. This inadequacy is exposed by contemplation of its dialectical twin. Finally, a new conception supersedes them both, repairing the inadequacy but preserving what was true in the original. Hegel thought that this process of conceptual evolution had to be separate from the work of formal logic. Formal logic requires that terms keep their meanings unchanged from start to finish, otherwise one commits the fallacy of equivocation. On the other hand, the very point of dialectic is to develop the meanings of terms. Hegel attempted to exhibit a dialectical logic that made no appeal to the notion of contradiction found in formal logic precisely because he understood the nature of formal rigor. However, this separation is artificial. Mathematical practice does not divide into formal and dialectical phases. Mathematical thought experiments, whether they function as proofs or tests, are structured by formal logic. The criterion for a successful proof is still given by the formal definition of a valid argument.

Lakatos' third Popperian claim is that mathematical heuristic does not begin inductively from facts, but from guesses at solutions to problems and questions. Neither science nor mathematics can start from bare facts because facts do not spontaneously order themselves into inductive tables. They can be so ordered only in the light of

a conjecture, a problem, or some other governing idea. This is as true of mathematical facts about the parts of polyhedra as it is of empirical data. Indeed (still following Popper), there are no bare facts, in either science or mathematics. In particular, there are no self-evident mathematical axioms. Hence Lakatos is anti-foundationalist and fallibilist in his philosophy of mathematics.

Some of the fictional dialogue in Lakatos' Ph.D. thesis concerning the Descartes–Euler formula was published in four parts in the *British Journal for the Philosophy of Science* (Lakatos 1963–1964). This treatment is confined to the early history of the formula, during which the proofs and refutations made appeal to geometric intuition. It stops short of the absorption of the formula into the relatively abstract systems of modern algebra. A common criticism was that Lakatos' view did not apply to these more abstract parts of modern mathematics. Lakatos' plans to publish a more comprehensive account were cut short by his death in 1974, but selections from his thesis were published posthumously as *Proofs and Refutations* (Lakatos 1976). This material extended the Descartes–Euler story to include algebraic treatments, and included studies of topics from analysis and set theory. Lakatos was in no doubt that his heuristic view applied to the whole of mathematics. In the introduction to *Proofs and Refutations*, Lakatos described the book as an argument against "formalism," which he defined as the tendency to identify mathematics with its formal axiomatic abstraction. This, he argued, caused the philosophical neglect of everything about mathematics not captured in fully formalized axiom systems of meta-mathematics. In particular, the history and heuristics of mathematical practice vanish from sight. When one comes to assess Lakatos' philosophy of mathematics, it is well to distinguish this anti-formalism from the claim that the growth of mathematics is marked by dramatic refutations of a Popperian sort—for, in the case of advanced mathematics, the former claim is rather more plausible than the latter.

Transition to Research Programmes

Lakatos observed that his three "ideological" sources appeared to be inconsistent. In fact, the inconsistency is more than apparent. Popper held that epistemology can have no interest in the process of conjecture production and that philosophers ought to confine their attention to the logic of conjecture evaluation. Pólya, on the other hand, showed that there can be a fallible logic of conjecture production (his heuristic). Moreover, though he separated them in thought, Pólya's studies showed that the "contexts of discovery and justification" overlap in practice, because the same thought experiment can function as a test and then later as a proof. Unsurprisingly, the deepest contradictions are between the Popperian and Hegelian elements. Though Lakatos argued that theorems develop by responding to counterexamples, he quickly introduced a distinction between "logical" counterexamples (that is, counterexamples in the ordinary Popperian sense) and "heuristic" counterexamples (cases that, while not strictly inconsistent with the theorem in hand, show it to be conceptually deficient in some respect). Logical counterexamples belong to language statics (in Hegelian terms, the rigid, formal logic of the Understanding). Heuristic counterexamples belong to language dynamics (in Hegelian jargon, the dialectic of Reason). Popper was contemptuous of any philosophy that paid attention to fine distinctions of meaning. In his view, scientists use explicit, stipulative definitions to establish their terms with as much precision as required for the task in hand, and philosophers ought to do likewise. He had no sympathy with the Hegelian project of revealing the subtle shifts of meaning hidden in the evolving use of a single word. This, though, is precisely what Lakatos did with the central terms of his dialogue ('polyhedron,' 'proof,' etc.). Therefore, much of Lakatos' achievement in *Proofs and Refutations* could never be absorbed into Popperian philosophy.

The final contradiction in *Proofs and Refutations* between Popper and Hegel concerns the possibility of a general method. Hegel, though he organized some of his works into triples within triples, insisted that there is no general logic of scientific or philosophical progress. Each episode in the intellectual history of humanity has its own character, which must be traduced if it is forced into some all-purpose mould. Popper, for his part, believed himself to have discovered a general logic of science. Science, in his view, has a characteristic logical process (philosophically articulated as critical rationalism) that distinguishes it from other activities in general and from pseudo-science in particular. *Proofs and Refutations* vacillates between these extremes. On the Popperian side, Lakatos offers highly general heuristic patterns that might find application outside mathematics. There is no reason in principle why lemma incorporation or "monster adjustment" (to take two examples) should not be found in the development of legal arguments (for example) (*monster adjustment* is the redescription of an outlandish counterexample in such a way that it ceases to be outlandish and

thereby ceases to be a counterexample.) On the Hegelian side, Lakatos offers no *general* solution to the problem of identifying ad hoc-ness and degeneration, preferring instead to appeal to the judgment of persons with refined mathematical taste. Indeed, he argues that any of his heuristic patterns can lead to triviality and degeneration if pursued mindlessly (in this sense *Proofs and Refutations* is an anarchist tract in the sense of Feyerabend). These tensions between the Hegelian and Popperian elements of Lakatos' early views became acute as he tried to move beyond the piecemeal studies of his Ph.D. thesis.

As it turned out, Lakatos tended to land on the Popperian side of dilemma. In 1965 (the year after he published part of his thesis in the *British Journal for the Philosophy of Science*), he wrote a brief paper titled "A Renaissance of Empiricism in the Recent Philosophy of Mathematics?" (Lakatos 1978b). In this paper he developed a contrast between "Euclidean" and "quasi-empirical" theories. In a so-called Euclidean theory, truth flows down from self-evident axioms to derived theorems. In a quasi-empirical theory, falsehood is transmitted up from theorems to axioms. Such theories are *quasi*-empirical because the falsifying criticism need not come from empirical observation or experiment. He went on to claim that mathematics is quasi-empirical in this sense. In other words, he stripped the Hegelian elements from his earlier work, leaving a straightforwardly Popperian philosophy of mathematics that required him to claim that the growth of mathematics is marked by Popperian refutations.

The Methodology of Scientific Research Programs

While Lakatos was working on his philosophy of mathematics, the Popperian school had identified the alleged relativism and irrationalism of Thomas Kuhn as the principal philosophical threat to free enquiry (see Kuhn, Thomas). Lakatos agreed that Kuhn's philosophy had to be resisted, but by the late 1960s, he was convinced that Popper's account of scientific method was not adequate. To meet the need, he developed his own Methodology of Scientific Research Programs (Lakatos 1978a) (see Research Programs). In his Cambridge Ph.D. dissertation, he had suggested that theorems and proofs ought not to be regarded as separate entities. A theorem and its proof evolve together, and this common evolution makes sense of the terms employed in stating the theorem and the lemmas deployed in the proof. The natural unit of philosophical appraisal is thus not the theorem, but the theorem–proof pair. Similarly, in *Methodology of Scientific Research Programmes*, he replaced the single theory as the unit of appraisal with the "program," a temporal sequence of theories. In both cases the point was to allow philosophers to understand the growth of knowledge over time.

Two features distinguish the Methodology of Scientific Research Programs from Lakatos' earlier work on mathematics. One is the almost total absence of any discussion of shifts in meaning. The distinction between language statics and language dynamics that motivated the search for hidden conceptual changes was quietly dropped. The other is the specification of criteria by which progress and degeneration might be judged. The early Lakatos agreed with Hegel (and Feyerabend) that there can be no general rule for judging scientific progress, because each moment in the growth of knowledge has its own inner logic, which it is the task of philosophy to exhibit. In the absence of a general rule, it is a matter of judgment whether this or that development represents progress or degeneration. Feeling the threat of Kuhn's "irrationalism," the later Lakatos tried to articulate explicit criteria to do the job that he had previously left to good scientific taste. Indeed, he dismissed the exercise of taste as "elitism," which is ironic given his determination to exclude students from university decision making. At the same time, Feyerabend, in conversation and correspondence, persuaded Lakatos that a rigidly mechanical rule would fail to respect the special merits of individual programs. Therefore, he found himself arguing that his Methodology of Scientific Research Programs is *both* sufficiently exacting to distinguish progressive from degenerative programs *and* sufficiently supple to account for particular cases.

After Lakatos' death, there were sporadic attempts to develop his Methodology of Scientific Research Programs and to apply it more widely than Lakatos was able to in his lifetime (e.g., Howson 1976). Some philosophers attempted to develop his papers on mathematics into a Methodology of Mathematical Research Programs (e.g., Hallett 1979). None of these efforts succeeded in rebutting the charges of rigidity and arbitrariness leveled against Lakatos' later work, and the supply of would-be heirs eventually dried up. On the other hand, there has lately been a rising tide of historically oriented philosophy of mathematics, for which *Proofs and Refutations* is often cited as an inspiration. *Proofs and Refutations*, with its three ideological sources, is subtle and rich, while *Methodology of Scientific Research Programme*s is

relatively rigid and ideologically uniform. Moreover, Kuhnian relativism was a temporary threat, while formalism is a permanent menace. For these reasons, one may expect *Proofs and Refutations* to be the most durable part of Lakatos' contribution to philosophy.

LAWS OF NATURE

The main difficulty in developing an account of laws is to distinguish laws from accidental truths without leaving mysterious how scientists could ever gain knowledge of laws. Those accounts that adequately distinguish laws from accidental truths fail to make clear how scientists could ever determine which general truths are laws; and those that make knowledge of laws feasible seem unable to adequately distinguish laws from accidental generalizations.

Contrast the following generalizations:

All spheres of gold have a mass of less than 100,000 kg.
All spheres of U^{235} have a mass of less than 100,000 kg.

Assuming both are true, the former is merely accidentally true, whereas the latter expresses a lawful relation; the critical mass of U^{235} makes it impossible for there to be spheres of U^{235} of such a large mass. The question is what makes for the difference. A simple regularity view of laws is inadequate, since both generalizations describe regularities. Moreover, the distinction cannot be drawn based on features of the generalizations themselves, as Hempel and Oppenheim (1948) attempt to do; both generalizations are universal in form, are of unlimited scope, make no essential reference to particulars, and involve purely qualitative predicates. Therefore, either there must be something outside the regularity (and the generalization used to describe it) that makes one a law and the other not, or law claims must be in some way stronger than universal generalizations. The former option is the route taken by sophisticated regularity accounts, which Dretske (1977) labels "universal truth + *X*." According to such views, laws are simply regularities (leaving aside probabilistic laws for the moment), but some regularities are not laws. There is nothing about the regularities themselves that distinguishes laws from accidental regularities. Law statements are universal generalizations that satisfy some additional external criterion. There are as many such accounts as there are functions for laws. For example, laws might be those generalizations that are used to make predictions (e.g., Goodman 1954), are resilient (Skyrms 1980), function in explanations (e.g., Braithwaite 1953), are integrated into the best systematization of the facts (e.g., Lewis 1973), and so on. Alternatively, many have argued that laws are not mere regularities, but are ontologically stronger. There

are two main accounts that follow this route: those that conceive of laws as nomically necessary regularities (e.g., Pargetter 1984) and those that conceive of laws as relations between universals (Dretske 1977; Armstrong 1983; Tooley 1987).

Possible-Worlds Accounts

Perhaps the most natural way to distinguish laws from accidental regularities is to conceive of them as nomically necessary truths, since laws seem to involve some sort of natural (as opposed to logical) necessity. "It is a law that α" is equivalent to "It is nomically necessary that α"; and the latter is true if and only if α is true in all nomically accessible worlds. Accidental generalizations, as distinguished from laws, are not true in all nomically accessible worlds.

Four problems arise for such accounts. First, they are committed to metaphysically dubious entities. Bigelow and Pargetter (1990) have attempted to address this problem by conceiving of possible worlds as complex structural universals. However, one might still find this objectionable, since it requires a commitment to uninstantiated structural universals, else there would be only one possible world—the complex structural universal that is instantiated by the actual world. In fact, in order to use possible worlds to make sense of logical necessity, such an account requires the existence of nomically impossible universals. Otherwise, "It is a law that α" would be equivalent to "It is logically necessary that α," since all possible worlds would be nomically accessible.

This leads to a second difficulty, that of providing an account of nomic accessibility that does not rely on a prior understanding of lawfulness. It would be circular, for example, to analyze "It is a law that α" is true if and only if α is true in all nomically accessible worlds and then require an understanding of "It is a law that α" to make sense of nomic accessibility. Pargetter's response is analogous to Lewis's (1986a) argument that his analysis of possible worlds is not circular. Lewis argues that possible worlds exist and understanding the notion of a possible world does not rely on a previous understanding of possibility, since possible worlds are like the actual world, differing only in what occurs in them. Pargetter (1984) argues likewise that the nomic accessibility relation exists and that one need not have a prior understanding of lawfulness to understand this accessibility relation. Nomic accessibility does not require that all accessible worlds have the same laws; it merely requires that the appropriate generalizations be true in these worlds. Moreover, what this involves is easily understood, since it is analogous to a generalization being true in different parts of the universe. The central problem with this response is that it is uninformative, since it simply treats the accessibility relation as a primitive. (For alternative accounts, see Vallentyne 1988 and Mormann 1994.)

The third difficulty is whether such accounts can make sense of probabilistic laws. Tritium has a half-life of 12.26 years, which means that tritium atoms have a probability of $\frac{1}{2}$ of decaying in 12.26 years. There are typically two ways to understand this probability in terms of possible worlds: One might consider one particular tritium atom and understand the probability for this atom as the proportion of nomically possible worlds (with the same history until now) in which that atom (or its counterpart) decays in the next 12.26 years; alternatively, one might consider *all* tritium atoms in all nomically possible worlds and understand the probability as the proportion of all nomically possible tritium atoms that decay in 12.26 years. In order for such accounts to even get off the ground, an assumption must be made about the likelihood of each possible world—typically that each is equally probable. Of course, if probabilities are grounded in possible worlds, it is unclear what could ground this probability assignment. It might be taken as a primitive, but that would not answer which primitive probability assignment should be used—should they be treated as equally probable, or should some be treated as more likely than others? Moreover, as van Fraassen (1989) has argued, if there are a countable infinity of possible worlds, they cannot be treated as equally likely, and "if they are infinitely many and form a continuum (surely the most plausible idea) then it literally makes no sense to say: the objective chance is *the* measure that treats them all as equally likely" (79).

Perhaps the most serious difficulty faced by possible-worlds accounts is how scientists could ever gain knowledge of which generalizations are laws. It would require knowing not only what goes on in other possible worlds, but also which possibilities are nomically accessible. Knowledge of logic might yield answers to the former, but knowledge of the latter is more problematic. Consider Bigelow and Pargetter's (1990) account that treats possible worlds as complex structural universals. The question is how one could know which complex structural universals are nomically possible and which are not. Perhaps scientists could run experiments to determine which lower-level structural universals are possible. Experiments allow scientists to instantiate possibilities that might otherwise not have

existed; and since actuality implies possibility, this would provide some access to which structural universals are possible. However, since it is impossible to instantiate more than one most complex structural universal, that is, the one that is instantiated by the entire actual world, there is at least one level at which it is in fact impossible to instantiate other possibilities. Moreover, to determine which generalizations are nomically necessary, scientists would have to know what all the nomic possibilities are, or which structural universals are nomically impossible, and it is unclear how instantiating some of the possibilities yields knowledge of which are impossible.

The problem for probabilistic laws seems even worse, since it is unclear what the proportion of possible worlds with a certain type of event implies about the proportion of those events in the actual world (van Fraassen 1989), much less what the proportion of a type of event in the actual world implies about the proportion of events in other possible worlds, which is what knowledge of probabilistic laws would need to rely on. To resolve these difficulties, one might argue that scientists can simply use the methods of inference already used to figure out which generalizations are laws. However, such a response is inadequate, since the question is precisely how these methods could yield reliable knowledge laws, *if* laws are understood as nomically necessary truths. One could argue that this simply shows that laws ought not to be understood as nomically necessary truths, since it is possible for scientists to gain knowledge of which generalizations are laws, and they could not have such knowledge were laws nomically necessary truths.

Universals Accounts

The three main proponents of the universals account (Dretske 1977; Armstrong 1983 and 1997; Tooley 1987) have slightly different formulations, but the general idea is to conceive of laws as relations between universals. Law statements, rather than being universally quantified statements ranging over individuals, are singular statements about the relations between universals. However, not all relations between universals are laws, since accidental generalizations can be described as second-relations of extensional inclusion between universals. Tooley (1987) and Armstrong (1997) differ in their accounts of what makes laws distinct. According to Tooley, statements expressing nomological relations are contingent, irreducibly and purely of order two or higher, and logically entail the appropriate first-order generalization. Probabilistic laws are contingent, irreducible *probabilification* relations between universals, where the relation of probabilification between universals F and G makes it the case (due to logical probability) that, given that x has F, it is probable to degree k that x has G. According to Armstrong, laws are irreducible relations of necessitation (1983) or causation (1997) between universals, and probabilistic laws are probabilistic relations between universals that specify the probability of an instance of one universal necessitating or causing an instance of a second.

Both accounts successfully distinguish laws and accidental generalizations, since the relation of extensional inclusion is reducible to a first-order generalization and is neither a necessitation nor a causal relation between universals. This comes, however, at a price. In particular, it is unclear how such claims could entail anything about what happens in particular instances. Moreover, this problem infects accounts of both deterministic and probabilistic laws. (See van Fraassen 1989 for a discussion of this and other problems, and Armstrong 1997 for a reply.)

Even if this problem can be solved, another difficulty remains. If laws are relations between universals, how could scientists gain knowledge of which generalizations correspond to lawful relations and which are merely accidental? Armstrong argues that scientists can observe causal relations in single instances, draw causal generalizations from these, and then use inference to the best explanation (IBE) to infer that the causal regularity holds due to a lawful relation between the universals instantiated in the causal instances. Leaving aside problems with observing causation in single instances (see Causality), this would not allow scientists to discriminate laws and accidental regularities. For Armstrong, there are two kinds of accidental regularities: causal and noncausal regularities. Assuming scientists could observe causation in single instances, the latter could be excluded. However, there might be accidental causal regularities. The question is how IBE could discriminate an accidental causal regularity from a lawful one.

Similar problems arise for Tooley. Tooley argues that when $(x)(Px \rightarrow Qx)$ survives potential falsification, there is good reason to infer that there is a nomological relation between universals P and Q. In fact, it is only if laws are relations between universals that surviving potential falsification can provide support for the lawful status of a generalization. Otherwise, assuming that the universe is potentially infinite, assigning a nonzero probability

to a universal generalization would be unjustifiable. Of course, since generalizations are supposed to follow from law claims, the law claim cannot be better confirmed than the generalization (Woodward 1992). Moreover, scientists would be unable to discriminate a generalization that is accidental from one that has a nomological relation. Either no accidental generalization can survive falsification (but then Tooley needs to clarify why) or scientists need to determine, prior to (or independently of) the attempted falsification, which generalizations are nomological and therefore ought to be assigned nonzero prior probabilities.

An alternative account that falls broadly into the universals category treats laws as metaphysically necessary truths, much like "Water is H_2O," rather than as contingent relations between distinct universals. The central motivation for such views is the idea that properties are individuated, or perhaps even constituted, by the causal powers they have and, therefore, by the lawful relations in which they stand (e.g., Shoemaker 1980; Swoyer 1982).

Sophisticated Regularity Accounts

There have been numerous attempts to develop sophisticated regularity accounts that conceive of laws as universal truths satisfying some additional functional requirement. The most fully developed of these is the best systems account, according to which laws are those generalizations that function in the appropriate way in the best systematization of the facts. There are various versions of this account that differ in significant respects (Ramsey 1928; Kitcher 1986 and 1989; Lewis 1973) (see also Ramsey, Frank Plumpton). However, the focus here is on Lewis's later (1994) version, according to which laws are those generalizations that are axioms or theorems in the true deductive system that achieves the best balance of simplicity and strength. Simplicity and strength often conflict, so the best system must balance the two. The use of simplicity also requires that the predicates used in the axioms refer to natural kinds. Otherwise, one could use gerrymandered predicates to artificially alter the simplicity of the system. Moreover, there might be different criteria used to measure strength, simplicity, and the balance between them. Lewis's hope is that nature will be kind and there will be only one system that will be best on any standards of strength, simplicity, and balance. If nature is unkind, then there may be nothing deserving the title of 'laws.'

To extend this account to probabilistic laws (or even deterministic laws in a chancy world) the systems must be limited to those that never had any chance of being false (Lewis 1986b). Probabilistic laws are those generalizations about chance that are theorems in the best system, where the best system balances simplicity, strength, and fit, and fit is understood in terms of the degree to which the probabilistic laws conform to the actual course of history. In other words, the chance of the actual history occurring will be higher according to some systems than others; the higher the chance, the better the fit. Since fit is not the only criterion the best system must satisfy, probabilities will not in general be equivalent to actual frequencies. Lewis was initially doubtful that this account of laws would work, since it seemed to lead to a contradiction when combined with his *principal principle* (Lewis 1986b) and ultimately led him to revise it (Lewis 1994). Others have argued that the contradiction need not have arisen in the first place (e.g., Roberts 2001).

This account of laws appears to avoid the epistemic difficulties faced by other accounts. Scientists can justify law claims by determining which universal generalizations are axioms or theorems in the best deductive systems. It is even reasonable to think that scientists already use strength and simplicity as a guide to theory choice. Nevertheless, epistemic problems do arise. A central difficulty is accounting for how scientists could distinguish natural from nonnatural kinds. One common answer to how this is done—that natural kinds are those picked out by the best theories—is not open to Lewis, assuming simplicity plays a role in theory selection. If simplicity guides theory choice (and it must if science is to discover laws, according to Lewis), then science's best theories might fail to pick out natural kinds, since it will be possible to use nonnatural predicates to achieve gains in simplicity. This is precisely why Lewis added this requirement in the first place. (For a discussion of other potential epistemic difficulties, see van Fraassen 1989, 55–59.) Nevertheless, the epistemic problems faced by this account seem, at least on the surface, to be less daunting than those of other accounts. Lewis's account also has the advantage of making sense of the connection between laws and modality, without relying on modal notions to define laws. Nomic necessity is defined in terms of laws, rather than the other way around. A proposition is nomically necessary if and only if it is entailed by the laws of nature. In terms of possible worlds, a world W' is nomically possible relative to another world W if and only if the laws of W are true in W', though they may not be laws in W'. A proposition is nomically necessary if and only if

it is true in all nomically possible worlds. Lewis is also able to distinguish between laws and accidental generalizations, since not all generalizations will be axioms or theorems in the best system. This will presumably apply to such claims as "All pieces of gold have a mass of less than 10,000 kg."

This leads to the fundamental problem faced by such Humean positions: They fail to adequately account for the necessity involved in laws and therefore incorrectly distinguish between laws and accidental generalizations. While Lewis's account does provide for a distinction between laws and accidental generalizations, the question is whether it draws the distinction correctly. Criticisms have generally taken the form of counterexamples that attempt to show that Lewis's account yields the wrong answer about which generalizations are laws (Armstrong 1983; Tooley 1987; Carroll 1994; van Fraassen 1989). While these counterexamples are decisive against Lewis only if one shares the intuitions about which generalizations ought to count as laws or about how laws and modal notions are connected (Loewer 1996), they nevertheless make clear why many find Lewis's account inadequate. One counterintuitive consequence of Lewis's account is that there will be some nomic possibilities compatible with the laws but not compatible with their being the laws. This leads to a revision of the distinction between initial conditions and laws. As a result, Lewis's account carves the distinction between laws and accidental generalizations in a way many find counterintuitive.

Other Approaches and Issues

In response to these difficulties, Carroll (1994) and Lange (2000) argue that it is impossible to give a reductive analysis of laws that does not rely on nomic notions, while van Fraassen (1989) and Giere (1999) argue that there are no laws. Others have argued that there are no strict laws, even in fundamental physics (Cartwright 1983 and 1989). Instead, law statements require *ceteris paribus* clauses or perhaps might be better understood as claims about capacities. Earman and Roberts (1999) disagree with Cartwright about fundamental physics, but, building on an insight of Hempel's (1988), argue that the special sciences can have no strict laws, at least not formulated purely in the language of that science. (For related discussion about psychological laws, see Davidson 1970; for biological laws, see Beatty 1995; for economic laws, see Hausman 1992; and for social science laws, see Kincaid 1990.) The use and nature of laws has also played an integral part in debates about numerous other philosophical issues, such as causation, explanation, reductionism, determinism, confirmation, and induction.

PHILOSOPHY OF LINGUISTICS

Linguists study various topics, ranging from politeness register to the etymology of the word "dude"; but what has caught the attention of philosophers (and what has given rise to interesting questions in the philosophy of science) has been work in generative linguistics as developed by Noam Chomsky (see Chomsky, Noam) and several generations of his students. Generative linguistics per se has a tradition that dates back further than Chomsky (e.g., to work in phonology by Roman Jakobson), but Chomsky was the first to bring serious formal methods to the field and the first to pursue ways of embedding linguistic theory in other more basic sciences, such as biology. The field that has emerged in the wake of this effort has seen its share of empirical successes and continues to show promise, but it has also given rise to a series of interesting debates about the nature of language and scientific practice.

Among the issues that have emerged with the development of generative linguistics are questions about the nature of language and the object of inquiry in linguistics, about the role of reference and language/world relations, and about the plausibility and nature of rules and representations in linguistic theorizing, as well as a cluster of issues surrounding methodology in linguistics (among other things, for example, generative linguistics incorporates an unabashed appeal to intuitions as part of its data). The most radical issue, however, concerns how to understand the object of study itself.

The Object of Study

Most current work in generative linguistics holds that the object of study is not an external abstract language that one comes to acquire, but rather the study of the faculty that underwrites one's linguistic competence. The motivation for this is clear enough: The commonsense notion of a language has been under pressure for some time. Consider Weinreich's contention that a language is a dialect with an army and a navy: Why is Italian a language and Veneto a dialect? It seems to be a purely political decision, not driven by any facts about the linguistic forms themselves. Individuating dialects (or identifying a natural group of "same-language speakers") is no more feasible than separating dialects from languages. Exactly when do two people speak the same dialect? There are differences between the way any two people speak—does that make them speakers of different dialects? In the end, people say that they "speak the same dialect" when they identify with each other enough. Once

again, linguistic identity recapitulates political identity. Even trying to say that a particular agent speaks a single idiolect (his/her own individual language), which might be identified by a series of rules, does not stand up to serious scrutiny. Which set of rules is appropriate for describing one's idiolect? The way one speaks shifts radically depending upon one's age, discourse partners, and context. Is the conversation in a classroom? in a bar? with an interlocutor from a foreign country? What sentences one produces will vary markedly from situation to situation. Then, too, there is the question of errors. One may stutter and stammer or hiccup during a conversation. Are those noises to be counted as part of one's idiolect? If not, then, why not?

The considerations just reviewed provide good reason for being suspicious of language as an abstract external object, whether construed nationally, locally, or individually. But what is to replace this conception? Generative linguists hold that one should focus on the faculty that underwrites linguistic competence. That is, they are not interested in languages so much as the tacit theory that the agent deploys in the production and comprehension of linguistic behavior (or at least in judging the acceptability of certain linguistic forms).

This tacit theory is also enlisted to account for the fact that the data the language learner is exposed to are not sufficient (by themselves) to explain the linguistic competence that the agent comes to have. The language learner faces the problem, familiar in the philosophy of science, that the available evidence radically underdetermines the theory. The sentences that a child hears—and even the explicit corrections and affirmations it receives—when first acquiring a language are compatible with infinitely many, wildly divergent grammars. Nonetheless, the learner apparently manages to select a grammar. And, by and large, learners in similar environments select similar grammars. Infinitely many grammars, perfectly compatible with the evidence the child has access to, are simply ignored. Understanding the nature of the tacit theory that language users employ is one way of illuminating just how it is that agents are able to acquire the linguistic competence they do. Current linguistic and psychological theories suggest that the tacit theory employed by a linguistic agent may be part of human biological endowment and, as a corollary, that the mechanisms under study in linguistic theory will be embedded in human cognitive psychology and ultimately in human biology (see Pinker 1994 for a readable account and defense of this view).

This view about the object of study is not shared by all linguists. For example, Katz (1985) endorsed a Platonist view that takes the object of study in linguistics to be an abstract mathematical object outside of space and time—this would contrast with a position like Chomsky's, in which the object of study is a mental object of some form. The Platonist view has been advanced most visibly by Katz (1981), and it has been at least endorsed by Gazdar et al. (1985). It may be, however, that the position rests on a confusion. Higginbotham (1983) has observed that even if grammars are abstract objects, there is still the empirical question of which grammar a particular agent is employing. George (1989) has further clarified the issue, holding that one needs to distinguish between (i) a grammar, which is the abstract object that an agent knows, (ii) a psycho-grammar, which is the cognitive state that constitutes the agent's knowledge of the grammar, and (iii) a physio-grammar, which is the physical manifestation of the psycho-grammar in the brain. If this picture is right, then the Platonist position in linguistics may be trading on a failure to distinguish between grammars and psycho-grammars.

Perhaps more pressing is the dispute between what Chomsky (1986) has characterized as conceptions of language of *E*-language and *I*-language. From the *E*-language perspective, a natural language is a kind of social object the structure of which is purported to be established by convention (Lewis 1975) (see Conventionalism), and persons may acquire varying degrees of competence in their knowledge and use of that social object. In Chomsky's view, such objects would be of little scientific interest if they did exist (since they would not be "natural" objects), but in any case such objects *do not* exist. Alternatively, an *I*-language is not an external object, but is rather a state of an internal system that is part of the agent's biological endowment. An agent might have *I*-language representations of English sentences, but those internal representations are not to be confused with spoken or written English sentences. They are rather data structures in a kind of internal computational system.

Chomsky understands the *I*-language computational system to be individualistic (see Methodological Individualism). That means that the properties of the system can be specified independently of the environment that the agent is embedded in. Thus, it involves properties like the agent's rest mass and genetic makeup, but not relational properties like the agent's weight and IQ. The difference can be described by analogy to the difference between primate physiology and primate ecology. The former study is "narrow" in that it is concerned with the properties and structure of the primate in isolation (e.g., with bone and muscle

architecture). The latter study is "wide" in that it is concerned with primate/environment relations (e.g., with the role the primate's musculature might play in its interactions with its environment—allowing it to swing from tree to tree, say). In Chomsky's view, linguistic theory is much more analogous to physiology, and is narrow in precisely that sense. Both the claim that *I*-language is individualistic and the claim that it is computational have led to a number of philosophical skirmishes.

The Language Faculty and the External World

One of the immediate questions raised by the idea that *I*-language is individualistic has to do with how semantics could be possible—in particular, how *referential* semantics could be possible, where referential semantics is a theory of the relation between linguistic forms and aspects of the external world. The worry is this: If generative linguistics is a chapter of narrow (individualistic) psychology, and semantics (and indeed meaning) is concerned with relations of language/world (or at least mind/world), then how are the two enterprises to be squared? There are two parts to the question. Is it really the case that meaning involves language/world relations? And, if so, then how can semantics (and the theory of meaning) be reconciled with generative linguistics?

The case for meaning involving language/world relations was put most vividly by Putnam (1975), who offered a number of thought experiments intended to show that the meanings of linguistic utterances (and, indeed, of tokens of mentalese, should there be any) are not determined solely by the internal psychological states of the speaker, but by those states along with the speaker's local environment and social milieu. Consider the example of an agent, Hilary, who has in his lexicon the words *elm* and *beech.* However, all Hilary knows about elms is that they are trees called 'elm,' and all he knows of beeches is that they are trees called 'beech.' He has no knowledge, linguistic or otherwise, that would allow him to identify elms or beeches, or to tell them apart; in particular, there is nothing in his concept *elm* (*beech*) that makes it true of all and only elms (beeches). (The fact that elms are called 'elm' while beeches are called 'beech' will not do: For this to work, Hillary would need to know what '*elm*' and '*beech*' pick out—but this, of course, is exactly what is in question. Kripke [1980] first made this point with respect to the meanings of proper names.) What, then, allows Hilary's uses of '*elm*' to pick out exactly those things that are, in fact, elms? (And likewise for his uses of '*beech.*') Putnam's answer is that the tokens get their reference, in part, from Hilary being a member of a linguistic community that contains experts who *can* identify elms and beeches. And it is these experts who determine the reference of '*elm*' and '*beech*'; Hilary's use of the words is normatively constrained by the expert's use—Hilary means by '*elm*' whatever the experts mean by '*elm.*' So the reference of Hilary's tokens of 'elm' and 'beech' is partly determined by knowledge about how to identify elms and beeches. But this knowledge is not in Hilary's head, it is distributed across Hilary's linguistic community.

Next, consider Oscar. Oscar is a normal English speaker, with the word '*water*' in his lexicon. Oscar's uses of '*water*' refer to the substance with the chemical formula H_2O (this being the substance that the relevant experts identify as water). Now somewhere in the universe, there is a planet, Twin-Earth, that is qualitatively very similar to Earth. In particular, it has "lakes," "rivers," and "oceans" filled with a colorless, odorless liquid that often falls from the sky and is necessary for the life on Twin-Earth. The intelligent inhabitants of Twin-Earth—twin-earthlings—drink large quantities of this liquid, wash their dishes in it, have bubbling fountains of it; in fact, they use it in all the ways Oscar and other earthlings use water. Despite its superficial resemblance to water, however, this substance does not have the chemical formula H_2O, but the formula XYZ. Among the twin-earthlings is Twin-Oscar, a normal Twin–English speaker, with the word '*water*' in his lexicon. Twin-Oscar and the other twin-earthlings use this word to refer to the liquid that plays the same role on Twin-Earth as water does on Earth. But this substance, on Twin-Earth, is not H_2O, but XYZ. So despite having qualitatively identical mental states—and perhaps even qualitatively very similar linguistic communities—Oscar's uses of '*water*' and Twin-Oscar's uses of '*water*' refer to different substances. What Oscar's and Twin-Oscar's uses of '*water*' are about depends crucially on their local environments.

So Hilary and an arborist, despite having different concepts of elms, refer to the same things by tokens of '*elm*'. And Oscar and Twin-Oscar, despite having the same concept associated with '*water*', refer to different things by tokens of that word. Thus, Putnam's examples apparently show that the meanings of words cannot depend entirely on the mental states of the speaker: Meaning depends crucially on facts external to the speaker. Call such an approach to meaning *referential semantics.*

Chomsky (e.g., 1995a and 2000) has launched numerous attacks on referential semantics. The initial worry is that referential semantics conflicts

with the internalist, individualist nature of *I*-language. *I*-language is to be characterized in terms of nonrelational properties of the linguistic agent: It is a "narrow" property (or system) of the agent's mind/brain. Referential semantics, however, deals with relational properties: It is in the business of detailing relations between linguistic items and parts of the world external to the agent.

Chomsky admits that the naturalistic study of *I*-language is not restricted a priori to internalist investigations. The relations that bits of *I*-language (lexemes, phrases, and sentences, conceived of as elements of a mental computation system) bear to the extra-mental world could, *in principle*, be examined naturalistically. Chomsky believes, however, that these relations are, in fact, naturalistically intractable—the relations that linguistic items bear to the external world are asystematic enough that no serious, naturalistically acceptable explanatory theory can be given for them. Chomsky (1995) illustrates this point with the word *water*, which Putnam took to pick out all and only those things with the property of being H_2O (give or take impurities). Suppose Peter fills a cup out of the tap; it is a cup of water. But after a tea bag is dipped in it, it is no longer water—it is tea. Suppose further that, across town, Noam fills another cup from the tap; Noam's tap draws water from a reservoir into which a large quantity of tea leaves has been dumped as part of a purification process. Noam's cup contains water (albeit contaminated), even if what it contains is chemically indistinguishable from what is in Peter's cup. Thus, whether a substance counts as tea or water (containing tea only as an impurity) depends crucially on the particular interests and intentions of the speaker in the context. There simply is no single substance that infallibly serves as the reference of '*water*'.

Any object that could serve as a referent in referential semantics, argues Chomsky, is bound to be so gerrymandered and ill-behaved that it could not plausibly be a real constituent of the world. Is it to be believed that there is some single substance, an "object" in the world, that is what is in Noam's cup—as well as the River Thames, the Pacific Ocean, and bottles of Evian—but not what is in Peter's cup—nor bottles of Windex or cans of Coca Cola? And the complexity that attends '*water*' is entirely typical of natural language. Consider that, during World War II, Dresden was burned to the ground; but it was rebuilt, and it deserves to be proud of its many new buildings. Or that a bank, which raised its interest rates because it hoped to bring in new business, might be destroyed in an earthquake and have to move across the street. What are these things, picked out by '*Dresden*' and '*bank*', that are at once concrete and abstract, apparently intentional, and can survive destruction? Consider, too, that there is likely a flaw somewhere in this paper, or that the average family has 2.3 children. In the simplest referential picture, '*flaw*' refers to flaws and '*the average family*' refers to the average family. But, surely, flaws and average families are naturalistically dubious; it is difficult to imagine a naturalistic inquiry into the nature of flaws. Of course, the surface form of sentences containing '*flaw*' and '*average family*' might be misleading; at the level of logical form, these linguistic items might not be referential—they could instead be adjectival modifiers or adverbials. But natural language is replete with apparent reference to naturalistically suspicious entities; to pass naturalistic muster, referential semantics must contend with each and every case.

Chomsky concludes that there is no relation of reference holding between linguistic items and objects in the world, at least not one about which anything interesting and general can be said. Any account of reference must ultimately advert to intentionality, a subject forever out of reach of naturalistic inquiry (see Intentionality).

Ludlow (2003) mounts a defense of referential semantics for *I*-languages. He suggests that semanticists bite the metaphysical bullet and accept that—perhaps in addition to the substances, objects, and properties catalogued by physical science—there are things exactly like those needed for referential semantics. There are cities and banks that survive destruction and act intentionally; there is a substance, water, the nature of which depends sensitively on its origin and the uses to which it is put; there are, perhaps, even such things as flaws and average families. In this view, metaphysical intuitions—about, say, whether or not a particular substance in a particular context is water—are underwritten by the structure of *I*-language. And if metaphysical intuitions—at least of the sort probed in Putnam-like examples—are by and large correct, semanticists and philosophers are in a position to reason from the structure of *I*-language to the structure of the world and vice versa.

This Kantian view of the nature of referential semantics presents a dilemma, however. If the semanticist insists that the entities and substances invoked as referents really exist, but agrees with Chomsky that such things are not fit for naturalistic study, then referential semantics is nonnaturalistic. It then lies outside the *scientific* study of language and is instead a philosophical epicycle on naturalistic linguistics. If, on the other hand, the entities

and substances of referential semantics are natural objects, it is a serious question as to what place they hold in the vast array of objects posited by the other sciences. How, for example, is the referent of '*water*', water, related to atoms and molecules (objects of chemistry and physics) and to the representational/computational systems of the brain (objects of linguistics, psychology, and neurobiology)? (If Chomsky is correct, any adequate answer will be more complicated than "The referent of '*water*' is identical with H_2O.") This seems tantamount to asking questions about the relation between *I*-language and the world that Chomsky thinks is naturalistically legitimate but also naturalistically intractable.

Questions About Rules and Representations

The idea that linguistic theory involves the investigation of rules and representations (or principles and parameters) of an internal computational system has also led to philosophical questions about the nature of these rules and representations. For example, Quine (1970) has argued that, since many possible grammars may successfully describe an agent's linguistic behavior, there is no way in principle to determine which grammar an agent is using (see Quine, Willard Van). For his part, Chomsky (1980) has argued that, if one considers the *explanatory adequacy* of a grammar in addition to its *descriptive adequacy*, then the question of which grammar is correct is answerable in principle. That is, because the theory of grammar must be consistent with the theory of language acquisition, acquired language deficits, and, more generally, cognitive psychology, then there are many constraints available to rule out competing grammatical theories. To illustrate, two descriptively adequate theories of tense may differ in their assumptions about whether tenses like past and future are more basic, or whether a grasp of terms of temporal order (like 'before' and 'after') are more basic. Acquisition data might shed light on such a standoff if it could be shown that children acquire the use of one set of linguistic items markedly before the other.

Another set of worries about rule following have stemmed from Kripke's (1982) reconstruction of arguments in Wittgenstein (1953 and 1956). The idea is that there can be no brute fact about what rules and representations a system is using apart from the intentions of the designer of the system. Since, when studying humans, there is no access to the intentions of the designer, there can be no fact of the matter about what rules and representations underlie linguistic abilities. The conclusion drawn by Kripke (1982) is that "it would seem that the use of the idea of rules and of competence in linguistics needs serious reconsideration, even if these notions are not rendered meaningless" (1983, 31n, 22).

Chomsky (1986) appears to argue that one can know certain facts about computers in isolation, but Chomsky's current position (1995) is that computers, unlike the human language faculty, are artifacts and hence the product of human intentions. The language faculty is a natural object and embedded within human biology, so the facts about its structure are no more grounded in human intentions than are facts about the structure of human biology.

Kripke's argument is often stated in the form of a problem about justification: Speakers believe they know what they mean by their words; what justifies that belief? Chomsky (1986) responds to this worry by observing that, in the syntactic realm, there is no reason to suppose that speakers have first-person authority with respect to the rules they follow. Speakers produce grammatical sentences effortlessly, but the procedures they use in producing them are highly abstract and can remain obscure even under careful scrutiny. Justification is not available, or necessary, for successful linguistic communication. Scientific inquiry into the nature of those rules, by contrast, is no more or less justified than inquiry into the guiding principles of any system whose operation cannot be directly observed.

Such considerations address the epistemic side of Kripke's argument, but they do not address the metaphysical problem: What is it about someone that makes him or her a follower of rule *R*? One possible response may come from Chomsky's (1965) suggestion that the object of inquiry for syntactic theorizing is "an ideal speaker-listener, in a completely homogeneous speech-community, who knows its language perfectly and is unaffected by such grammatically irrelevant conditions as memory limitations, distractions, shifts of attention and interest, and errors (random or characteristic) in applying his knowledge in actual performance" (3). Such an idealized speaker could in principle produce evidence capable of distinguishing between any two substantively different rule systems. The apparent reliance on the relevant problematic notions ("grammatical," "ungrammatical") in linguistic theory might thus be seen as an artifact of considerations that are appropriately idealized away. This line of response may, however, be susceptible to Kripke's critique of solutions that depend on *ceteris paribus* clauses. In that critique, Kripke argues that there is no non-question-begging

way to decide which features of the system should be idealized away from and which should not.

Perhaps a more promising solution can be found in an argument, due to Soames (1998), that an inability to know what fact about someone makes that person a follower of rule *R* in no way undermines the metaphysical possibility that there is such a brute fact. Soames suggests that Kripke, of all people, should have seen the error here—a conflation of metaphysical and epistemic possibility.

Methodological Issues

If the language faculty is an internal computational/representational system, a number of questions arise about how to best go about investigating and describing it. For example, there has been considerable attention paid to the role of formal rigor in linguistic theory. On this score, a number of theorists (e.g., Gazdar et al. 1985; Bresnan and Kaplan 1982; Pullum 1989) have argued that the formal rigor of their approaches—in particular their use of well-defined recursive procedures—count in their favor. However, Ludlow (1992) has argued that this sort of approach to rigorization would be out of synch with the development of other sciences (and indeed, of branches of mathematics), where formalization follows in the wake of the advancing theory.

Another methodological issue concerns the nature of evidence available to investigations of the language faculty. For generative linguists, evidence from a written or spoken corpus is at best twice removed from the actual object of investigation, and given the possibility of performance errors, is notoriously unreliable at that. Much of the evidence adduced in linguistic theory has therefore been from speakers' intuitions of acceptability, as well as intuitions about possible interpretations. This raises a number of interesting questions about the reliability of introspective data and the kind of training required to have reliable judgments. There is also the question of why one should have introspective access to the language faculty at all. It is fair to say that these questions have not been adequately explored to date (except in a critical vein; see Devitt 1995; Devitt and Sterelny 1987).

A third methodological issue relates to the use of parsimony and simplicity in the choice between linguistic theories (see Parsimony). While tight definitions of simplicity within a linguistic theory seem to be possible (see Halle 1961; Chomsky and Halle 1968; Chomsky 1975), finding a notion of simplicity that allows one to choose between two competing theoretical frameworks is another matter. Some writers (e.g., Postal 1972; Hornstein 1995) have argued that generative semantics and the most recent version of generative linguistics, minimalism (discussed in the next section), are simpler than their immediate competitors because they admit fewer levels of representation. In response, Ludlow (1998) has maintained that there is no objective criterion for evaluating the relative amount of theoretical machinery across linguistic theories. Ludlow offers that the only plausible definition of simplicity would be one that appealed to "simplicity of use," suggesting that simplicity in linguistics may not be a feature of the object of study itself, but rather an ability to easily grasp and utilize certain kinds of theories.

An alternative approach would be to take a leaf from Sober (1975) and argue for a view of simplicity according to which a theory is simpler than another if it is more easily embedded within more basic sciences. In such a view the simpler linguistic theory would be the one that could more naturally be embedded into cognitive psychology or even, following recent work in the minimalist program, into low-level biophysical and mathematical principles.

Issues Raised by the Minimalist Program

Although generative linguistics has gone through a number of permutations over the last 50 years, perhaps the most interesting has been the recent development of the minimalist program, outlined in Chomsky (1995a). Setting aside the technical details of the project, the headline idea is that the core language faculty did not evolve slowly over an extended period of time but was, rather, the result of a sudden mutation that, in effect, wired together two discrete cognitive systems—the conceptual/intentional (C/I), involving meaning and thought; and the perceptual/articulatory (P/A), responsible for speech production and perception. The working hypothesis is that the wiring solution was "optimal" and governed by basic low-level biological and mathematical constraints (such as those that account for the prevalence of recursive and fractal patterns in nature). This speculative hypothesis, if correct, would suggest that the linguistic theory should be looking for very specific kinds of properties and principles linking the C/I and P/A systems—properties that might naturally emerge from low-level biophysical principles (much as the Fibonacci pattern in a sunflower does). While speculative in the extreme, this new research program has shown some surprising successes and clearly calls for further investigation of its basic guiding assumptions. Although the project has yet to be

explored in a formal way by philosophers of linguistics, it should prove a fascinating domain for future investigations.

Conclusion

Although the philosophy of linguistics is not as well explored as the philosophy of physics or of biology, it is certainly no less rich a domain of inquiry. Not only does it involve the usual concerns of scientific methodology (simplicity, the nature and trustworthiness of the data, etc.), but it also deals with kinds of entities (rules and representations) that are not routinely found in the basic sciences and are not well understood. Furthermore, the philosophy of linguistics is concerned with questions of the embeddability of linguistics into more basic sciences (possibly even into low-level biophysical and mathematical systems), as well as which parts of linguistics (if any) involve agent/environment relations and which parts are purely individualistic. For all these reasons, this subdiscipline of the philosophy of science promises to be a fertile area of investigation, plausibly able to illuminate some of the deeper cognate questions being explored in the philosophy of other sciences, as well as the philosophy of science generally.

LEVELS OF SELECTION

See **Biology, Philosophy of; Natural Selection**

LOCALITY

The principle of local action has played an important role in the development of modern physics, and has been taken by many philosophers to be a necessary condition for intelligible causal explanations. However, recent evidence from quantum mechanics and quantum field theory seems to point toward fundamental limitations on the ability to provide locally causal explanations of physical phenomena (see Quantum Mechanics; Quantum Field Theory).

Locality in the History of Philosophy

According to a popular view, the most primitive cause/effect relation is that which holds between two physical objects that make contact in space and time, known as *contact action.* Furthermore, it is supposed that between any cause and effect, there must be a continuous chain of primitive causes by contact action; and if there is no continuous chain in space and time between two events, neither can be a cause of the other. This view has been advocated in one form or another by a number of philosophers of diverse persuasions. For example, Aristotle claims that ''it is evident, therefore, that in all locomotion there is nothing intermediate between mover and moved'' (Aristotle 1941). Similarly, in establishing the foundations for his new physics, Descartes takes it as an a priori principle that causation occurs only by local contact (see Suppes 1954). Moreover, Hume (1978)—the arch-critic of a priori knowledge of causal relations—claims that the concept of causation includes the concept of contiguity:

> [W]hatever objects are consider'd as causes or effects, are *contiguous*; and . . . nothing can operate in a time or a place, which is the ever so little remov'd from those of its existence. (§I.3.2)

Einstein (1948) claims that the principle of local action is a necessary presupposition for the existence of empirically testable natural laws:

> For the relative independence of spatially distinct things (A and B), this idea is characteristic: an external influence on A has no immediate effect on B; this is known as the ''principle of local action'' . . . . The complete suspension of this basic principle would make impossible . . . the establishment of empirically testable laws in the sense familiar to us. (321)

Finally, a number of influential contemporary accounts of causation tie the notion of causal connectedness to a space-time picture (see, e.g., Salmon 1984).

Locality in Modern Physics

The principle of local action was a cornerstone of the mechanical philosophy of Cartesian and neo-Cartesian physics. However, in Newton's theory of gravitation, the inverse square law seems to entail that some causes are spatially separated from their effects. Although numerous attempts, both physical and philosophical, were made to explain nonlocal gravitational forces (see McMullin 1989), a satisfactory resolution was not reached until Einstein supplied a field-theoretic formulation of gravity. Einstein's general theory of relativity was the culmination of a line of development that had

begun in the early nineteenth century with Michael Faraday's introduction of the concept of "lines of force" emanating from a magnet. Faraday's idea was incorporated into Maxwell's dynamical theory of the electromagnetic field, in which electromagnetic field quantities are associated with each point of space, and disturbances in the field propagate through space via wave motion. Problems arising from Maxwell's theory ultimately led to Einstein's special theory of relativity, which grounds the principle of local action in the assumption of the constancy of the speed of light in all reference frames.

According to textbook presentations, special relativity is based on the limit principle: No physical process can propagate faster than the speed of light. If two events cannot be connected by a light signal, then they are said to be *spacelike separated* (i.e., they are simultaneous in some inertial reference frame). Thus, there can be no cause/effect relation between two spacelike separated events. However, the status of the principle of locality in special relativity continues to be a subject of dispute among philosophers. For example, it has been claimed that special relativity is not premised on the limit principle and probably does not entail it (Nerlich 1982). It has also been claimed that the limit principle is a statistical generalization that need not hold for individual processes (Cushing 1996; Maudlin 1994 provides an extended discussion of the role of locality in special relativity) (see Space-Time).

Entanglement and the Einstein–Podolsky–Rosen Result

In quantum mechanics, a pair of spatially separated systems can occupy an "entangled" state in which the values of their dynamical variables are perfectly correlated. In particular, if S_1 and S_2 are spatially separated systems with state spaces H_1 and H_2, then the state space for the composite system $S_1 + S_2$ is the tensor product $H_1 \otimes H_2$. For any $u_2 \in H_1$ and $v_2 \in H_2$, there is a vector $u \otimes v \in H_1 \otimes H_2$ called the "product" of u and v. Product states can be thought of as describing conjunctive states of affairs: $S_1 + S_2$ is in state $u \otimes v$ just in case S_1 is in state u and S_2 is in state v. However, since $S_1 + S_2$ is a quantum system, it also has states that are superpositions of product states. In particular, if u_1, u_2 are distinct states of S_1 and v_1, v_2 are distinct states of S_2, then

$$\psi = \frac{1}{\sqrt{2}}(u_1 \otimes v_1) + \frac{1}{\sqrt{2}}(u_2 \otimes v_2),$$

is a state of $S_1 + S_2$ that cannot be decomposed as a simple product. Such states are said to be *entangled*.

Composite systems in classical physics also have correlated states. But unlike the classical case, an entangled quantum state cannot be taken to represent an ensemble of composite systems each of which is in some definite product state. Indeed, unlike any correlated state in classical physics, entangled states are "pure" (i.e., statistically irreducible) states of the composite system. However, entangled states look mixed to local observers at S_1 or S_2. In fact, there is no pure (vector) state v of S_1 that agrees with ψ on the probabilities assigned to the various propositions about S_1, and similarly for S_2. In general, when $S_1 + S_2$ is in an entangled state, it is impossible to think of S_1 and S_2 as having their own (pure) quantum states.

The entangled state ψ predicts perfect correlations between measurements on the component systems. In particular, there is a measurement M_1 on S_1 that discriminates between the states u_1 and u_2, and there is a measurement M_2 on S_2 that discriminates between the states v_1 and v_2. If $S_1 + S_2$ is in the state ψ, then the two outcomes of M_1 are equally likely, and the two outcomes of M_2 are equally likely. However, outcomes of M_1 and M_2 are perfectly correlated: If M_1 yields an outcome corresponding to u_1, then M_2 will yield an outcome corresponding to v_1; and if M_1 yields an outcome corresponding to u_2, then M_2 will yield an outcome corresponding to v_2.

In their argument against the completeness of quantum mechanics, Einstein, Podolsky, and Rosen [EPR] (1935) made use of an entangled state that predicts perfect correlations between both the positions and the momenta of a pair of particles. They note that if the position of the first particle is ascertained, then the position of the second particle can be predicted with certainty. Similarly, if the momentum of the first particle is ascertained, then the momentum of the second particle can be predicted with certainty. Now, if one assumes (as EPR did) that the principle of local action holds, then a measurement on the first particle can neither alter nor bring into being properties of the second particle. Thus, a *position* measurement on the first particle should be thought of as a means of discovering the preexisting position of the second particle; and a *momentum* measurement on the first particle should be thought of as a means of discovering the preexisting momentum of the second particle. But then the second particle must have had a definite position and momentum before any measurement was performed. Since, however, a quantum-mechanical state never assigns a definite position and momentum to any object, EPR concluded that the quantum-mechanical state does not

provide a complete description of the properties of the second particle.

EPR claimed to have shown that each particle must have a "hidden" state that determines the values of all of its dynamical variables—in other words, there are hidden variables. EPR also assumed that the hidden state of one system cannot be instantaneously influenced by events in distant locations. Nonetheless, neither EPR nor any other similarly inclined physicists were able to find a hidden variable theory that obeys the principle of local action. This failure, it is now known, was inevitable: Bell's theorem (Bell 1964) shows that no local hidden variable theory can explain the correlations described in the EPR experiment.

Bell's Theorem

According to hidden variable theories, quantum states merely provide statistical information about ensembles of systems, each of which has its own definite state (which includes a specification of the values of all relevant dynamical variables). A local hidden variable theory attributes a definite state to each local system and requires that changes in the state of one system cannot instantaneously bring about changes in the state of a distant system. Bell's theorem shows that no such local hidden variable theory can reproduce the predictions of quantum mechanics.

In the thirty years prior to the proof of Bell's theorem, the question of hidden variables had been largely pushed aside, in particular since von Neumann (1932) had supposedly shown that hidden variables are inconsistent with the empirical predictions of quantum mechanics. Few physicists took notice at the time when, in 1952, David Bohm constructed a hidden variable theory that is empirically equivalent to quantum mechanics. As Bell (1982) points out, Bohm's theory is not ruled out by the (mathematically valid) no-go theorems of von Neumann and Kochen-Specker because Bohm's hidden variables are contextual; that is, the hidden state of a system cannot be specified without taking into account its context, including the setting of measurement devices in distant locations. In fact, Bohm's hidden variables are patently nonlocal. Bell's theorem shows that this feature of Bohm's theory holds for any hidden variable theory that reproduces the predictions of quantum mechanics.

Consider the most simple correlation experiment, in which there is a pair of measurement devices situated in distant wings of a laboratory and each measurement device has (at least) two distinct settings. Let L_a denote the event that the left device is in setting a, and let R_b denote the event that the right device is in setting b. Suppose that each experiment has two possible outcomes, denoted by $-$ and $+$. Let $L_a^{\pm}$ denote the event that the device on the left registers a $\pm$ outcome when in setting a, and let $R_b^{\pm}$ denote the event that the device on the right registers a $\pm$ outcome when in setting b. A quantum-mechanical realization of such an experiment is given by a pair of spin-$\frac{1}{2}$ particles in the singlet state:

$$\psi = \frac{1}{\sqrt{2}}(x_1 \otimes y_1 - x_2 \otimes y_2). \tag{1}$$

The measuring devices can be taken to be a pair of Stern-Gerlach magnets, each of which can be oriented at various angles in a plane from a common (arbitrarily chosen) axis. For each possible measurement on each particle, there are two possible outcomes, spin up and spin down. In this case, quantum mechanics supplies the following probabilities:

$$P_{\mathrm{QM}}(L_a^+) = P_{\mathrm{QM}}(R_b^+) = \frac{1}{2}, \tag{2}$$

and

$$P_{\mathrm{QM}}(L_a^+ \cap R_b^+) = \frac{1}{2}\cos^2\theta_{ab}, \tag{3}$$

where θ_{ab} is the difference between the angles of orientation of the magnets on the left and right. If θ_{ab} is not an integer multiple of $\pi/4$, then the left and right measurement outcomes are statistically correlated:

$$P_{\mathrm{QM}}(L_a^+ \cap R_b^+) \neq P_{\mathrm{QM}}(L_a^+) \times P_{\mathrm{QM}}(R + b). \tag{4}$$

Of course, the existence of a correlation between spatially separated events does not necessarily indicate a nonlocal connection, because the two events might have a common cause in the intersection of their past light cones. Suppose then that the quantum state corresponds to a probability distribution P_{HV} over a space Λ of hidden variables. Suppose for simplicity that Λ is finite. Suppose also that the domain of the probability function P_{HV} includes the events L_a, R_b^+ etc.). Let

$$P_{ab} = \sum_{\lambda \in \Lambda} [P_{\mathrm{HV}}(L_a^+ \cap R_b^+ \mid L_a \cap R_b \cap \lambda) \times P_{\mathrm{HV}}(\lambda)], \tag{5}$$

for all a, b, and let

$$P_1 = \sum_{\lambda \in \Lambda} [P_{\mathrm{HV}}(L_1^+ \mid L_1 \cap \lambda) \times P_{\mathrm{HV}}(\lambda)], \tag{6}$$

$$P_3 = \sum_{\lambda \in \Lambda} [P_{\mathrm{HV}}(R_3^+ \mid R_3 \cap \lambda) \times P_{\mathrm{HV}}(\lambda)]. \quad (7)$$

Thus, this hidden variable model reproduces the quantum mechanical probabilities in state ψ just in case $P_a = P_{\mathrm{QM}}(L_a^+)$, $P_b = P_{\mathrm{QM}}(R_b^+)$, and $P_{ab} = P_{\mathrm{QM}}(L_a^+ \cap R_b^+)$.

The hidden variable λ is local just in case it determines the outcomes of measurements on S_1 independently of what is occurring at S_2, and vice versa. That is, once the value of the hidden variable λ and the setting of the measurement apparatus at S_1 is fixed, then the outcomes of measurements on S_1 are determined; and similarly for S_2. (In the more general case of stochastic hidden variables, λ and the setting at S_1 will fix the probabilities for various outcomes at S_1.) This assumption is captured succinctly by Bell's locality condition:

$$P_{\mathrm{HV}}(L_a^+ \cap R_b^+ \mid L_a \cap R_b^+ \cap \lambda) = P_{\mathrm{HV}}(L_a^+ \mid L_a \cap \lambda) \times P_{\mathrm{HV}}(R_b^+ \mid R_b \cap \lambda)]. \quad (8)$$

If Bell's locality condition is conjoined with a "no conspiracy" condition (*viz.,* the event that a certain measurement occurs is probabilistically independent of λ), then Bell's inequality follows:

$$0 \leq P_1 + P_3 + P_{24} - P_{14} - P_{23} - P_{13} \leq 1. \quad (9)$$

Thus, Bell's inequality is satisfied by the statistical predictions of any "reasonable" local hidden variable model of this experiment.

For specific choices of angles for the measurement devices, the quantum mechanical predictions violate Bell's inequality. For example, for the settings $\theta_{24} = \pi/2$, $\theta_{13} = \theta_{14} = \theta_{23} = \pi/6$, the sum of the quantum-mechanical probabilities equals $-\frac{1}{8}$. Thus, the predictions of quantum mechanics cannot be reproduced by any local hidden variable model. Moreover, these predictions have now been verified in a number of different experiments (for a review, see Redhead 1994, 107ff). Thus, the phenomena cannot be explained by a local hidden variable model.

Interpretations of Bell's Theorem

Many philosophers and physicists think that the violation of Bell's inequality points toward some form of nonlocality, whether or not quantum mechanics is a complete theory. However, a small group of dissenters claim that the violation of Bell's inequality has nothing to do with locality but should be seen as a consequence of the use by quantum mechanics of a nonclassical probability theory. Moreover, even among those who think that the violation of Bell's inequality entails nonlocality, there is still widespread disagreement about what exactly this means. Some claim that the violation of Bell's inequality shows that the world is thoroughly interconnected and holistic (or "nonseparable"), but not that the principle of local action is false. Others claim that the violation of Bell's inequality shows that causes can be spatially separated from their effects. The following section examines arguments for these three positions.

Quantum Mechanics Is Local

In a minimalist interpretation of Bell's theorem, the violation of Bell's inequality is due to the fact that local systems have incompatible observables, that is, observables for which there are no joint probabilities. The primary support for this interpretation comes from a theorem by Arthur Fine (1982a and 1982b) that shows that Bell's inequality is satisfied if and only if all joint probabilities are well defined. More precisely, suppose that there are joint probabilities $P(L_a^+, L_b^\pm)$ and $P(R_c^+, R_d^\pm)$ that return the already-given marginal probabilities:

$$P_{\mathrm{QM}}(L_a^+) = P(L_a^+, L_b^+) + P(L_a^+, L_b^-), \quad (10)$$

$$P_{\mathrm{QM}}(R_c^+) = P(L_c^+, L_d^+) + P(R_c^+, R_d^-). \quad (11)$$

Note that these joint probabilities are not supplied by quantum mechanics.

If such joint probabilities exist, then the marginal probabilities must satisfy Bell's inequality (de Muynck 1986). The minimalist will then point out that this derivation of Bell's inequality does not use any locality condition, and so the violation of Bell's inequality does not entail nonlocality. Contrapositively, the minimalist claims that since the existence of joint probabilities entails Bell's inequality, the violation of Bell's inequality shows that joint probabilities do not exist. The minimalist interpretation of Bell's theorem has also been defended within the context of particular interpretations of quantum mechanics. For example, advocates of the *consistent histories* interpretation have argued that "locality is not the only assumption that goes into the proof of the Bell inequalities, and thus their violation by quantum theory is not a proof of nonlocality" (Brun and Griffiths 2000). Furthermore, it has recently been claimed that if quantum mechanics is approached from an information-theoretic perspective, then the theory is "essentially local" (Fuchs and Peres 2000).

However, the minimalist interpretation of Bell's theorem has been criticized on the grounds that it ignores the issue of contextuality (van Fraassen 1991, 102; Shimony 1993, II.9). In particular, in a contextual hidden variable theory, unconditional

probabilities such as $P_{\mathrm{HV}}(L_a^+ \mid \lambda)$ are not physically significant. Rather, the physically significant probabilities are those conditionalized on all relevant measurement settings, for example, $P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b \cap \lambda)$.

However, Bell's inequality cannot be derived for the latter conditional probabilities. In other words, the existence of joint conditional probabilities does not entail Bell's inequality.

Holism and Nonseparability

Some philosophers have argued that the violation of Bell's inequality may entail nonlocality but it does not entail that there is superluminal causation. The main supporting argument for this position draws on Jarrett's (1984) analysis of Bell's locality condition. Jarrett shows that Bell's locality condition is equivalent to the conjunction of two conditions (the labels here are due to Shimony):

1. Outcome Independence:

$$P_{\mathrm{HV}}(L_a^+ \cap R_b^+ \mid L_a \cap R_b \cap \lambda) = P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b \cap \lambda) \times P_{\mathrm{HV}}(R_b^+ \mid L_a \cap R_b \cap \lambda). \quad (12)$$

2. Parameter Independence:

$$P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b \cap \lambda) = P_{\mathrm{HV}}(L_a^+ \mid L_a \cap \lambda), \quad (13)$$

$$P_{\mathrm{HV}}(R_b^+ \mid L_a \cap R_b \cap \lambda) = P_{\mathrm{HV}}(R_b^+ \mid R_b \cap \lambda). \quad (14)$$

According to the orthodox interpretation of quantum mechanics, the quantum state ψ gives maximal information about the system. Thus, the orthodox interpretation can be thought of as the trivial hidden variable theory in which λ supplies no information beyond that supplied by the quantum state. Since the probabilities assigned by the quantum state are insensitive to which measurements are being performed on distant systems, the orthodox interpretation satisfies parameter independence. On the other hand, since distant measurement outcomes are correlated (see equation 4), outcome independence is violated. Moreover, it has been claimed that since outcomes are not determined by the quantum state—and hence cannot be controlled—this nonlocality could not be exploited to send a signal faster than the speed of light. Thus, orthodox quantum mechanics is consistent with special relativity (Shimony 1993, II.10). Proponents of the orthodox interpretation have also claimed that hidden variable theories violate parameter independence and that such a violation allows for superluminal signaling, and therefore hidden variable theories are inconsistent with special relativity. However, advocates of hidden variables have replied by pointing out that superluminal signaling is possible only if the hidden variables could be controlled, and this is not generally possible (e.g., in Bohm's theory).

Action at a Distance

Bell's inequality follows from the conjunction of outcome independence and parameter independence. So, either outcome independence or parameter independence (or both) is false. Bell's theorem by itself says no more. Nonetheless, there have been many attempts over the years to narrow down the interpretive options by deriving Bell's inequality from one of Jarrett's conditions. On the one hand, some argue that Bell's inequality can be derived from the assumption of hidden variables (*viz.,* the existence of joint probabilities), and therefore its violation supplies good evidence against "realism." Others, however, argue that Bell's inequality follows from locality alone, and so its violation entails nonlocality.

Maudlin (1994) argues that quantum-mechanical correlations can be explained only on the supposition of nonlocal causes. For example, he parodies Jarrett's analysis of Bell's locality condition by showing that it is equivalent to the conjunction of two conditions:

$$P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b^+ \cap \lambda) = P_{\mathrm{HV}}(L_a^+ \mid L_a \cap \lambda), \quad (15)$$

$$P_{\mathrm{HV}}(R_b^+ \mid R_b \cap L_a^+ \cap \lambda) = P_{\mathrm{HV}}(R_b^+ \mid R_b \cap \lambda), \quad (16)$$

and,

$$P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b \cap R_b^+ \cap \lambda) = P_{\mathrm{HV}}(L_a^+ \mid L_a \cap R_b^+ \cap \lambda), \quad (17)$$

$$P_{\mathrm{HV}}(R_b^+ \mid L_a \cap R_b \cap L_a^+ \cap \lambda) = P_{\mathrm{HV}}(R_b^+ \mid R_b \cap L_a^+ \cap \lambda). \quad (18)$$

Maudlin (1994) then points out that that it would be appropriate to call the first condition "outcome independence" and the second condition "parameter independence" (95). But now orthodox quantum mechanics violates "parameter independence" but not "outcome independence." The conclusion that should be drawn, claims Maudlin, is that Jarrett's analysis does nothing to show that the nonlocality found in orthodox quantum mechanics is more benign than the nonlocality found in hidden variable theories. (For another

argument that quantum mechanics by itself—i.e., without additional interpretive assumptions—entails nonlocality, see Stapp 1997.)

The Subtleties of Nonlocality

While philosophers have been mainly concerned with investigating the consequences of the violation of Bell's inequality, physicists have also been trying to find ways to use nonlocality as a physical resource (e.g., to speed up computation). In the course of these investigations, it has been discovered that the violation of Bell's inequality is just one of many manifestations of nonlocality in quantum mechanics. Each vector state for a composite system is either a product state, or it is entangled. If a vector state is entangled, then it violates Bell's inequality (Gisin and Peres 1992), and therefore its correlations cannot be reproduced by a local hidden variable model. More generally, an arbitrary (possibly mixed) state ρ of a composite system is said to be separable just in case it is a mixture of product vector states; otherwise it is said to be nonseparable.

It is not difficult to see that separable states satisfy Bell's inequality. (Indeed, the "hidden variables" can be taken to be the quantum product states that are mixed together to form the separable state.) Werner (1989), however, shows that not all nonseparable states violate Bell's inequality. In particular, consider the mixture

$$W_n = \frac{1}{2} M_n + \frac{1}{2} P_s, \qquad (19)$$

where $M_n = (1/n^2)(I \otimes I)$ is the maximally mixed state of $\mathbf{C}^n \otimes \mathbf{C}^n$, and P_s is any maximally entangled, symmetric, pure state of $\mathbf{C}^n \otimes \mathbf{C}^n$. (For example, when $n = 2$, P_s could be the singlet state.) Werner uses an ingenious argument to show that W_n is nonseparable. However, he then goes on to construct a local hidden variable model for the correlations of W_n in Bell-type experiments. So, is W_n local or nonlocal?

There are at least two good reasons for thinking that the Werner state is nonlocal. First, a local hidden variable model, in Bell's sense, need account for the outcomes of only a certain special class of measurements; there might be other measurements whose statistics in W_n cannot be reproduced by such a model. In fact, Popescu (1995) shows that (for $n \geq 5$) a local observer can select a subensemble from W_n that violates Bell's inequality. That is, after an initial preparatory measurement on W_n is performed, then a Bell-type measurement can be performed that yields manifestly nonlocal results. Since the initial preparatory measurement is purely local, it cannot create entanglement where none already existed. Therefore, it seems plausible to say that the original state W_n was already nonlocal (although its nonlocality was "hidden").

Second, the Werner state permits a teleportation scheme with higher fidelity than any classical communication channel (see Popescu 1994). Suppose that an observer O_1 has a particle P_1 in some unknown quantum state ψ, and O_1 wants to supply enough information to a second observer O_2 so that O_2 can prepare a particle in an identical state. On the one hand, if O_1 has access only to classical means of communication, the best O_1 can do is to make a measurement on P_1 (which can supply only partial information about its state), and then report the outcome to O_2. On the other hand, suppose that O_1 and O_2 share a pair (P_2, P_3) of particles in the Werner state. Suppose also that O_1 makes a measurement on the pair (P_1, P_2) and reports the outcome of this measurement to O_2. It can then be shown that O_2 is more likely to infer correctly the initial state ψ of P_1 than would be possible if O_2 had access to only classical communication from O_1. Thus, the Werner state allows for the transmission of more information than any classical procedure. Whether this improved communication ability amounts to superluminal information transfer is a matter of dispute.

Nonlocality in Relativistic Quantum Field Theory

The special theory of relativity (at least according to its most popular interpretation) prohibits action at a distance, while quantum mechanics seems to require it. Surely this poses a serious problem of consistency: How can two theories be true (or at least approximately true) when their most basic principles contradict each other? Philosophers have often confronted this apparent contradiction by looking for creative ways to reinterpret relativity and quantum mechanics; some have even concluded that special relativity must be false. And yet, there already is a theory, *viz.,* relativistic quantum field theory, that is both relativistic and quantum mechanical. Although relativistic quantum field theory has been immensely successful in applications (in fact, it forms the basis for all of contemporary particle physics), philosophers have hardly begun to investigate how it manages to combine relativistic causality and quantum nonlocality (see Quantum Field Theory).

There are two structural features of relativistic quantum field models that mark them as distinctively

relativistic. First, if A and B are spacelike separated regions, then any observable that can be measured in A is compatible with any observable that can be measured in B. This compatibility relation ensures that (nonselective) measurements performed in A cannot influence the statistics of measurements performed in B, and vice versa. Second, in relativistic quantum field models the spectrum of the four-momentum observable (i.e., the set of its possible measurement outcomes) is contained in the forward light cone. Thus, any measurement of the four-momentum will yield a result consistent with the predictions of special relativity; in particular, there can be no detectable energy-momentum transfer faster than light.

However, recent investigations have shown that these relativistic features of quantum field models do not preclude them from having nonlocal states. In fact, it has been shown (roughly speaking) that the percentage of nonlocal states grows in proportion to the dimension of the state space of the system. Thus, while systems with low-dimensional state spaces (e.g., spin-$\frac{1}{2}$ particles) have relatively few nonlocal states, systems with infinite-dimensional state spaces (e.g., field theories) have a very high percentage of nonlocal states. More specifically, for any two spacelike separated regions A, B, the set of field states that are Bell correlated across A and B is everywhere dense in the state space (Halvorson and Clifton 2000). Furthermore, every field state is maximally Bell correlated across unbounded tangent space-time regions, that is, "Rindler wedges" (Summers and Werner 1988). Finally, the vacuum state is non-separable across any pair of space-like separated regions, no matter how distant (Halvorson and Clifton 2000).

LOGICAL EMPIRICISM

Logical empiricism dominated philosophical thinking about science from the late 1930s through the 1970s, so much so that nearly all philosophical writing about science in this period located itself, quite consciously, either within the fold of or in opposition to logical empiricism. Middle ground was, for a time, not easily found, and to ignore logical empiricism was to betray a profound ignorance of professional philosophy of science. Indeed, for many, the distinctly professional philosophy of science that emerged in the 1950s and 1960s had been made possible by—and was, perhaps, even identical to—logical empiricism. It is the task of this article to convey the main ideas and development of this profoundly influential philosophical movement.

Logical Positivism Versus Logical Empiricism

'Logical empiricism' is often used to refer to a philosophical school thought to be developed from *logical positivism*, whose more stringent *verifiability* criterion of cognitive meaning was replaced by a looser *confirmability* criterion; and an endorsement of scientific realism replaced logical positivism's rejection of the very question of whether the terms of a scientific theory refer to or of whether a successful theory's main claims should be taken to be, approximately true (see Cognitive Significance; Scientific Realism; Verifiability). (For the distinction between logical positivism and logical empiricism in this form, see Salmon 1999, 334.) But the notion that 'logical empiricism' suggests an identifiable, discrete, and conscious departure from something called logical positivism is tantamount to historical falsehood. In fact, logical empiricism, logical positivism, and *wissenschaftliche Philosophie* (scientific philosophy) had no fixed referents even in their heyday, and for good reason: What was usually behind these terms was an *attitude* or *approach,* rather than a theory or doctrine (a study of the terms used by participants themselves might suggest *wissenschaftliche Philosophie* as the most apt general term for the movement). And for this reason, current historical work should resist any urge to fix these terms' referents retrospectively (Hardcastle and Richardson 2003); logical positivism thus is not best described as having turned into, or given rise to, any particular successor movement, let alone one that embraced relaxed criteria of cognitive significance or scientific realism. It is worth noting that in contrast to 'logical positivism,' a term introduced in Blumberg and Feigl (1931), the provenance of 'logical empiricism' is murky.

On the other hand, insofar as logical empiricism denotes something like an intellectual development from and reaction to the main texts of logical positivism, the term is both useful and historically appropriate. Accordingly, this article on logical empiricism will present the tenets of logical positivism and the subsequent intellectual efforts that related themselves, directly and, on occasion, in opposition to these tenets; logical empiricism is really the story of the *development* of themes articulated within logical positivism. Following a discussion of five of logical positivism's main themes, then, logical empiricism will be described as it was reflected in ensuing philosophical work on analyticity, cognitive significance, holism, explanation, and the proper attitude toward scientific theories (see Analyticity; Cognitive Significance; Explanation; Theories).

Logical empiricism developed alongside intellectual projects with which it conflicted (socially and politically, as well as intellectually). The account of logical empiricism given here describes these conflicts without the typical "mortality" metaphor, in which philosophical views are born, mature, age, and die, becoming then objects of historical study. Instead, logical positivism is presented as the *distillation* of a particular scientific/philosophical ethos, and logical empiricism as the gradual, but detectable, *dilution* of that ethos over several decades and across several realms. This alternative metaphor presents logical empiricism as not a dead philosophical idea of mere historical interest, but as a set of identifiable traces left by the problems, approaches, and thinking associated with logical empiricism—problems, approaches, and thinking that animate and explain philosophy of science in the twenty-first century.

Distillation: Central Themes of Logical Positivism

The central themes of logical positivism are:

1. Antimetaphysics
2. A close relation to the natural sciences
3. Logic

At logical positivism's heart is antimetaphysics, or, to put it positively, a "spirit of enlightenment and anti-metaphysical factual research" (*geist der Aufklärung und der antimetaphysischen Tatsachenforschung*) (Hahn, Carnap, and Neurath [1929] 1973, 301). Indeed, it is important to express this central theme positively, since the image of logical positivism (and logical empiricism) as a negative, even destructive, movement is an egregious misrepresentation. The clearest expression of logical positivism's spirit of enlightenment is the 1929 pamphlet *The Scientific Conception of the World: The Vienna* Circle [*Wissenschaftliche Weltauffassung: Der Wiener Kreis*] (hereafter SCW), the 64-page "manifesto" of the Vienna Circle, the group of scientists, mathematicians, and like-minded thinkers that gathered around Moritz Schlick in Vienna in the 1920s, including Rudolf Carnap, Herbert Feigl, Philipp Frank, Hans Hahn, Otto Neurath, and Friedrich Waismann (see the listings for many of these figures in this volume, along with Vienna Circle). The pamphlet's author was listed simply as the "Wiener Kreis," but Neurath in fact wrote the bulk of the text, with contributions from Hahn and Carnap (Neurath 1973). The document announced to the European intellectual world the Circle's "scientific world-conception," which, it made clear, was characterized not so much by theses of its own, but rather by its basic attitude, its points of view, and direction of research:

> Neatness and clarity are striven for, and dark distances and unfathomable depths rejected. In science there are no 'depths'; there is surface everywhere: all experience forms a complex network, which cannot always be surveyed and can often be grasped only in parts. Everything is accessible to man; and man is the measure of all things. . . . The scientific world-conception knows no *unsolvable riddle*. Clarification of the traditional philosophical problems leads us partly to unmask them as pseudo-problems, and partly to transform them into empirical problems and thereby subject them to the judgment of empirical science. The task of philosophical work lies in this clarification of problems and assertions, not in the propounding of special 'philosophical' pronouncements. (Hahn et al. [1929] 1973, 305–306; cf. Carnap 1963, 20–34)

To what was this "spirit of enlightenment" directed? In practice, logical positivism directed itself toward questions concerning the logical structure of the sciences—the "clarification of problems and assertions" in them. The SCW summarized, for example, various "fields of problems" still to be addressed at "the foundations" of arithmetic, physics, geometry, biology, psychology, and the social sciences. Significantly, though, the scientific world-conception also addressed "questions of life" (304–305) in an enlightened manner, and thereby linked the Vienna Circle and logical positivism with political and social sensitivity, if not activism. As the SCW declared:

> [E]ndeavors toward a new organization of economic and social relations, toward the unification of mankind, toward a reform of school and education all show an inner link with the scientific world-conception; it appears that these endeavors are welcomed and regarded with sympathy by the members of the Circle, some of whom indeed actively further them. (Hahn et al. [1929] 1973, 305; cf. Carnap 1963, 20–26)

The later impression that logical positivism, and thus logical empiricism, consisted mainly in the systematic *rejection* of various philosophical traditions and methods as (worthless) "metaphysics" is owed largely to A. J. Ayer's *Language, Truth, and Logic*, an early, popular, and polarizing report on the Vienna Circle (see Ayer, Alfred Jules). The young Ayer visited the Circle from late 1932 through March of 1933 and managed to grasp its opposition to metaphysics, but little of its positive program. Nevertheless, *Language, Truth and Logic*'s infamous first line—"The traditional disputes of philosophers are, for the most part, as unwarranted as they are unfruitful" (Ayer 1936, 33)—fixed for the next three decades an image of logical positivism and empiricism. (In fairness, Blumberg and Feigl's [1931] earlier but less influential English presentation of logical positivism also failed to convey logical positivism's enlightenment theme.) Ayer's employment of logical positivism's verifiability criterion as a test for cognitive meaningfulness, and thus as a means to attack metaphysical claims, will be taken up below.

The second theme of logical positivism, one subsequently prominent in logical empiricism, is its close relationship to the natural sciences. Indeed, the distance between Ayer's understanding of logical positivism and logical positivism itself is clearest at the very end of *Language, Truth, and Logic*, where Ayer calls for the "philosopher to become a scientist. . . if he is to make any substantial

contribution towards the growth of human knowledge'' (Ayer 1936, 153). Ayer took himself to be calling for an unrealized philosophical future, but in fact logical positivism was already steeped in science. Its adherents aspired in their philosophical work to the sobriety and clarity of science, as represented particularly in relativistic physics (see Conventionalism; Space-Time). And its practitioners in Vienna, Berlin, and Prague were themselves adept at relativistic and quantum physics; the Circle's Philipp Frank, in fact, succeeded Einstein in Prague in 1912 when Einstein went to Berlin. Yet Ayer's insulation from actual science, combined with his authorship of *Language, Truth, and Logic*, led to the unfortunate, mistaken, and ironic impression that logical positivism was actually *detached* from contemporary science.

Steeped in science, logical positivism nevertheless distinguished itself from science, although what sort of project it *was* exactly would be subject to continued debate. The distinction between logical positivism and science itself was reflected most clearly in the fact that the former attended not to particular domains of experience (that was the focus of the various separate sciences) but to experience, and its *logical* structure, *as a whole.* Logic—the study of the *form* of scientific statements and the experience they describe—emerges as a third theme of logical positivism. And it is in this context that logical positivism's verifiability criterion is best appreciated. In SCW the criterion can be glimpsed as the claim that ''for us, *something is 'real' through being incorporated into the total structure of experience*'' (Hahn et al. [1929] 1973, 308, emphasis in original; see also Schlick [1930–1931] 1959). A claim or entity that could *not* be incorporated into the ''total structure of experience'' was therefore not real, in the strongest sense, and thus not even describable. Attempts to express such a claim or describe such an entity were at best confused and at worst disingenuous: metaphysics in the most damning sense (see, e.g., Blumberg and Feigl 1931; Carnap [1932] 1959, esp. §7).

Logic, particularly the quantificational logic articulated by Gottlob Frege and developed in 1910 by Whitehead and Russell (1963) and in 1921 by Wittgenstein (1961), was thus of enormous use to logical positivism. Indeed, the Circle read Wittgenstein's *Tractatus* painstakingly (Feigl 1969, 634). Moreover, the logical positivists' view of logic allowed for a statement to be true in a language purely by virtue of the meaning of its terms, that is, to be *analytically* true; such sentences provided an essential component of their epistemological account of mathematics and the formal sciences generally (see Analyticity). If mathematical statements were ultimately analytic statements of logic, and if logical statements were truths that could be produced at will, as it were, by the articulation of a language (perhaps an artificial language) in which they always came out true, then the truth of a mathematical sentence could be explained by reference to nothing more puzzling than a simple convention—a decision, freely taken, to render the sentence in question true (see Conventionalism). Knowledge of the truths of mathematics, *qua* sentences of logic, would then be as transparent or obvious as the language itself. Such a result embodied the enlightenment ethos of the scientific world-conception, and, correspondingly, challenges to it (as well as to, more generally, the view of logic at the heart of logical positivism) carried particular weight.

It remains to recognize two further important themes of logical positivism. One, implicit in the *generality* of logic, is the unity of science (*Einheitswissenshaft*) (see Unity and Disunity of Science; Unity of Science Movement). The SCW duly sounded the unity-of-science theme, which would become central to logical empiricism in the United States: ''The goal ahead,'' the SCW stated, ''is *unified science*. . . .The endeavor is to link and harmonize the achievements of individual investigators in their various fields of science'' (Hahn et al. [1929] 1973, 306). Sciences, that is, were not to be distinguished on the basis of different methods, subject matters, or attitudes; their attitudes and methods did not differ, and differences in subject matter reflected merely pragmatic divisions of labor. Just beneath the surface of the unity-of-science theme was the denial of a division between the natural and social sciences, that is, between *Natur-* and *Geisteswissenschaften*; this denial had substantial political import for logical empiricism (Reisch 2004).

Finally, emphasis on the unity of science served to underscore a final theme implicit in the other three, *viz.,* the question of logical positivism's own place in the realm of inquiry or knowledge. In the 1920s and 1930s, the logical positivists struggled to describe their work in its own terms, that is, to describe their perspective as a philosophy informed by but not identical to science and its world-conception. Some, such as Schlick, subscribed to Wittgenstein's apparent view that the propositions of philosophy, properly understood, were themselves meaningless (Wittgenstein 1961; Schlick [1930–1931] 1959). Against Schlick's view, Carnap (1934) argued that a sufficiently rich metalanguage allowed for the expression of truths about the logical structure of science, including truths about that

metalanguage itself. This was a matter within logical positivism that was not resolved and, indeed, became a central question for logical empiricism.

Dilution of Logical Empiricism: Analyticity and Cognitive Significance

World War II's significance to the development of logical empiricism is enormous, and at present only partly understood and appreciated (Reisch 2004). The war interrupted work within scientific philosophy in the obvious, material, way, but significantly also by virtue of logical positivism's perceived peripheral significance compared with the war effort. After World War II, scientific philosophy—now a distinctively North American endeavor, with Carnap, Hempel, Feigl, Frank, and Hans Reichenbach having emigrated to the United States—resumed work put aside in the late 1930s and early 1940s, although it did so in a very different cultural and political climate (see Carnap, Rudolf; Hempel, Carl Gustav; Reichenbach, Hans).

The result, by the early 1950s, consisted of three papers that would each have, for decades to come, a profound effect on philosophical thinking about science, challenging many (but, importantly, not all) of the themes associated with logical positivism. These papers were Quine's (1951) *Two Dogmas of Empiricism* and two essays published by Hempel in the early 1950s (Hempel 1965) (see Hempel, Carl Gustav; Quine, Willard Van). The former argued against the widely accepted view that certain truths were to be accounted for as true by virtue of the meanings of their terms (and, indeed, the article rejected as dogma the doctrine that there *were* analytic truths in this sense), while Hempel's two papers taken together reviewed and eventually rejected the notion that statements on their own had cognitive significance, by which was meant empirical meaning (see Analyticity; Cognitive Significance). Together the line of argument in these works pointed scientific philosophers sympathetic to logical positivism toward a holism about the meaning of statements and a pragmatism about any separation between science and metaphysics. The result, ultimately, was a nearly complete dilution, by the 1960s, of logical empiricism. An examination of these papers (each of which, incidentally, summarized discussions and work of several previous years) will illustrate this development.

Two Dogmas of Empiricism ostensibly takes up the following question: In virtue of what, precisely, are certain "analytic" sentences, the truth of which seems to be unavoidable, true? (Quine's example is "All bachelors are unmarried men.") Recognizing that the logical positivists' answer appealed to the meaning of the nonlogical terms in such sentences ('bachelor' and 'unmarried men'), Quine presses the question of how, precisely, the meaning of these terms manages to accomplish such a feat (see Analyticity). A good portion of *Two Dogmas of Empiricism* is given over, then, to showing how successive versions of the putative semantic relations between terms, and between sentences and a language, fail to provide the needed explanation of the analytic truths in question, typically because the purported explanation rests on concepts as much in need of clarification as meaning itself (Quine considers, specifically, definition, interchangeability *salva veritate*, semantic rules, and verificationism). Having presented a comprehensive, if not exhaustive, list of potential accounts and found them all wanting, Quine proceeds to doubt the presumption of the question, doubting, that is, that so-called analytic sentences are true by virtue of meaning. He then offers an alternative view. The single exception Quine recognizes to his list of failed accounts of analyticity, though, is telling. Quine allows that truths arising from the "explicitly conventional introduction of novel notations for sheer abbreviation" *does* suffice to account for some analytic truths, for here the definiendum becomes synonymous with the definiens simply because it has been created expressly for this purpose: "Here we have a really transparent case of synonymy created by definition; would that all species of synonymy were as intelligible" (26). Such "explicitly conventional" definition is rejected simply because it in fact is at the root of very few, if any, of the *actual existing* instances of analytic statements *in the present language*. Radically revising, or even discarding, present language, or more generally present theories, is not a live option.

Quine's rejection of explicitly conventional definition in *Two Dogmas of Empiricism* reflects not just his own conservatism but, significantly, that of the philosophy of science from the early 1950s on (see Quine, Willard Van). The enlightenment optimism of the SCW was no longer seriously considered; a departure from the past by means of the adoption of a new, modern, scientific attitude and the creation of a new, transparent language suitable to modern needs was simply dismissed.

Quine's critical treatment/rejection of various explanations of analytic truth is followed by his own account of those truths. His alternative is at once novel and conservative:

> The totality of our so-called knowledge or beliefs, from the most casual matters of geography and history to the

> profoundest laws of atomic physics or even pure mathematics and logic, is a man-made fabric which impinges on experience only along the edges . . . . A conflict with experience at the periphery occasions readjustments in the interior of the field . . . . But the total field is so underdetermined by . . . experience that there is much latitude of choice as to what statements to reevaluate in the light of any single contrary experience . . . . If this view is right . . . it becomes folly to seek a boundary between synthetic statements, which hold contingently on experience, and analytic statements, which hold come what may. Any statement can be held true come what may, if we make drastic enough adjustments elsewhere in the system . . . . Conversely . . . no statement is immune to revision. (42–43)

Analytic statements, then, are simply those abandoned last, if ever, in the face of experience. Contained in this influential metaphor, which would come to be known as the web of belief, is a powerful challenge to several of logical positivism's central themes (see Duhem Thesis). Quine's holism—reflected particularly in his insistence that present and future language and theory be continuous with past theory and language—is in considerable tension with the progressiveness of the Vienna Circle (a tension embodied, indeed, in the work of Neurath (1973) (see Neurath, Otto). Further, Quine's (1951) pragmatism, displayed above in his recognition of several different but acceptable reactions to "contrary experience," "blurs," as he puts it, the "supposed boundary between speculative metaphysics and natural science" (10).

The effect of *Two Dogmas of Empiricism* was dramatic, and was only heightened when an analysis from a somewhat different starting point led to a very similar set of recommendations. Hempel's *Empiricist Criteria of Cognitive Significance: Problems and Changes,* which in many ways continued work begun by Carnap (1936–1937), reviewed and ultimately abandoned the thesis that there existed a "sharp dividing line . . . between those sentences which do have cognitive significance and those which do not," or, for that matter, between significant and insignificant, or metaphysical, *systems* or *theories* (see Cognitive Significance; Hempel, Carl Gustav). Posing the problem in terms of a search for a formal relation between putatively cognitively significant statements and "observation sentences" (which contain only observational terms and are thus empirically unobjectionable), Hempel examined and rejected both verificationism (construed as the thesis that a cognitively significant sentence must be entailed by a consistent finite set of observation sentences) and falsificationism (that its negation be so entailed), as well as closely related proposals, on the grounds that each criterion either admitted clearly insignificant claims or, alternatively, barred clearly significant ones.

Pursuing the different tack of isolating the cognitive significance of *terms* (on the basis of "observation" terms), Hempel (1965) established first the inadequacy of the reductionist strategy Carnap (1936–1937) had outlined for theoretical terms, and then endorsed the semantic holism Quine also forwarded:

> It is not correct to speak . . . of the "experiential meaning" of a term or a sentence in isolation. [A] single statement usually has no experiential implications . . . . [T]he occurrence of certain observable phenomena can be derived from it only by conjoining it with a set of other, subsidiary, hypotheses . . . [that] will usually be observation sentences [and] accepted theoretical statements. (112)

More significantly, Hempel was led from this holism to philosophical morals that, again, echo Quine's. After a failed search for criteria to separate cognitively significant from cognitively insignificant systems or theories (by way of barring those containing "isolated" sentences, that is, those without "experiential bearing"), Hempel (1965) cautiously suggests that "it is not possible to formulate . . . criteria which would separate those . . . systems whose isolated sentences . . . have a significant function from those in which the isolated sentences are . . . mere useless appendages. (117)

Rather,

> [C]ognitive significance . . . is a matter of degree: Significant systems range from those whose entire extralogical vocabulary consists of observation terms, through theories whose formulation relies heavily on theoretical constructs, on to systems with hardly any bearing on potential empirical findings. (117)

As with Quine's conclusion in *Two Dogmas of Empiricism,* such a claim constitutes (and was understood at the time to constitute) an abandonment of the *spirit* of the verifiability criterion, and of logical positivism. Moreover, here, as again with Quine (1951), logical empiricism took direction from Hempel's conclusion, which (like Quine's) revealed a certain conservatism in opposition to logical positivism's "spirit of enlightenment and anti-metaphysical factual research." For example, Hempel's critique of cognitive significance relied upon the appeal to the value of theory, even (indeed, especially) theory disconnected from experience or practice. As Hempel (1965) put it:

> The history of scientific endeavor shows that if we wish to arrive at precise, comprehensive, and well-confirmed

> general laws, we have to rise above the level of direct observation . . . . In following . . . a narrowly phenomenalistic or positivistic course, we . . . deprive ourselves of the tremendous fertility of theoretical constructs, and we . . . often render the formal structure of the expurgated theory clumsy and inefficient. (116)

Hempel's brief for empirically isolated theory contrasts deeply with the antimetaphysical spirit of logical positivism, and would shape logical empiricism in many ways, for decades.

Dissolution of Logical Empiricism: Unity, Realism, and the Philosophy of Science

It is important to recognize that the challenges to logical empiricism posed by Quine and Hempel, among others, as deep as they were, remained in a broadly scientific philosophical context. In other respects, logical empiricist themes were endorsed and elaborated. This is the case, for example, regarding the unity of science, which figured in logical empiricism in two significant ways.

Hempel's studies of cognitive significance were undertaken at nearly the same time as studies of what Hempel called the "logic of explanation," the attempt to characterize, as with cognitive significance, the formal relation obtaining between an event or a regularity to be explained, an *explanandum,* and that which explains the explanandum, the *explanans* (see Explanation). Hempel was motivated to pursue a logic of explanation in order to counter the view that methodology within the social sciences, notably history, differed in kind from what was found in the natural sciences. Both, Hempel urged, accomplish explanation by showing how the explanandum was to be expected given the laws inevitably cited in the explanans. In his first discussion of explanation, *The Function of General Laws in History,* Hempel (1942) argued that historical explanation "aims at showing that the event in question was not 'a matter of chance,' but was to be expected in view of certain . . . conditions. The expectation referred to is not prophecy or divination, but rational scientific anticipation which rests on the assumption of general laws" (39).

Hempel later attempted to extend the fundamental idea contained in his account of explanation—that explanation consisted in subsuming the explanandum under general laws—to both the use of statistical laws to explain particular facts and the explanation of the laws themselves. The explication of scientific explanation in all its guises emerged as a research project of great fecundity in the 1950s and 1960s, as philosophers such as Braithwaite (1953) and Nagel (1961) pursued the essentially Hempelian project of providing a single explication of scientific explanation in all its guises, including, notably, explanations that made use of functions, particularly within a biological context. In this respect, Nagel's (1961) account of functional explanation came to exercise particular influence (see Function). This research project remained both popular and fruitful through the 1980s, as exemplified by Kitcher and Salmon (1989). Its roots, however, lay in the unity-of-science thesis. (For an authoritative overview of research on explanation, see Salmon 1990 and 1998.)

Hempel also pursued a parallel, and equally fecund, project with respect to confirmation; the effort here was to express the single relationship between evidence and hypothesis as it was to be found across all the sciences (Hempel 1965) (see Confirmation Theory). Hempel's efforts to capture the confirmation relation syntactically were dealt a fatal blow by Goodman (1955) (see Induction, Problem of), although valuable and influential work in this direction continued under the heading of inductive logic in the hands of Carnap, who made extensive use of the logical (as opposed particularly to a frequentist) interpretation of probability (Carnap 1950 and 1952) (see Inductive Logic; Probability).

In another, different guise, the unity of science proved far less successful. The Unity of Science movement, an official collaboration of Neurath, Carnap, and Charles Morris, had begun in Europe in 1934 with enormous ambition and promise (see Unity of Science Movement). It included international congresses, the *Journal of Unified Science* (a reincarnated version of the earlier logical positivists' organ *Erkenntnis*), and a separate Library of Unified Science, containing, in one vision, two hundred separate monographs (Neurath, Carnap, and Morris 1971). But World War II, a series of personal disputes between the collaborators, and, possibly, increasing (and justified) association of the Unity of Science movement with socialism and communism during the onset of the Cold War in the United States resulted in the nearly complete disintegration of the enterprise by the early 1950s. Thus the idea of scientific unity survived, even thrived, in the search for universal formal accounts of explanation and confirmation, while it languished in the cultural forum that had previously identified it with political aims—specifically, progressive socialism (Reisch 2004).

Hempel's welcoming of theoretical terms and entities disconnected from observation, as well as Quine's appeal to purely pragmatic criteria for preferring certain ontologies to others in an account of

the world, contributed significantly to the consideration of the question of under what conditions, if any, the success of a scientific theory warranted belief that its central claims were in fact true or that the entities it mentioned in fact existed. Scientific realism—the position that success did warrant actual belief in, rather than mere acceptance of, a theory—was subsequently the focus of much debate from the late 1950s on, leading in turn to careful attention to the distinction between observable and nonobservable entities and the nature of success for scientific theories (see Scientific Realism). The debate itself, quite apart from any resolution it reached, demonstrated the intellectual distance logical empiricism had come from the attitude heralded in the SCW.

Thus by the late 1950s, logical empiricism embodied a tension between the historically oriented holism suggested by Quine and (less so) Hempel and the pursuit of general, unified accounts of science by way of specifying formal relations definitive of explanation or confirmation. This tension provides one (but hardly the only) means to understand the reaction to Thomas Kuhn's (1962/1970) profoundly influential *The Structure of Scientific Revolutions,* an essay that pitted an image of science that Kuhn understood to be logical empiricism against another image garnered from a close reading of scientific changes and the texts surrounding them (see Kuhn, Thomas; Scientific Revolutions). The latter image, Kuhn argued, engaged on its own terms, would transform the former and possibly lead to a rejection of both the unity-of-science thesis and the notion that science itself was a social institution with epistemic authority and privilege that it had earned. Yet, while *The Structure of Scientific Revolutions* was offered (and is now perceived) as an attack on logical empiricism, in fact several logical empiricists (most notably, Carnap) endorsed it. Such were the tensions within logical empiricism by the early 1960s.

Logical empiricism, understood as the reexamination, modification, and (alternatively) rejection and endorsement of the themes of logical positivism, is perhaps no more detectable within philosophy of science in the early twenty-first century than in current discussions of the nature and place of the philosophical examination of science, a topic, as mentioned above, that exercised the Vienna Circle. A good number of logical empiricists or their heirs subscribe to some version of Carnap's understanding of philosophy as the analysis of the logical structure of the concepts of science; work on confirmation, explanation, and other general concepts proceeds on several fronts. Others take up Quine's development of his own holism in his call for continuity between science and philosophical thought *about* science; Quine's "naturalized" account of epistemology describes philosophy of science as science itself. So motivated, philosopher-scientists have contributed to a number of scientific fields since the late twentieth century, most notably biology and physics. Finally, a felt need to connect philosophy of science in either guise to social and political matters, as well as study of the traditional aims and history of logical positivism and empiricism, has reopened discussion of the social and political dimensions of the philosophy of science and informed, for example, the *Institut Wiener Kreis,* an especially active institute of the University of Vienna dedicated to promoting historical study and understanding of the Vienna Circle and its aims. The perspective of logical empiricism thus informs the best philosophy of science done today.

M

ERNEST MACH

(18 February 1838–19 February 1916)

Mach was a physicist, psychologist, philosopher, and historian of science, as well as a political figure (for biographical detail, see Blackmore 1972). He studied physics at the University of Vienna from 1855 to 1861, continuing there as a lecturer until 1864. After spending three years as professor of mathematics at Graz, he received a chair at Prague, where he stayed until 1895. For the next six years, Mach occupied a chair in the History and Philosophy of the Inductive Sciences at Vienna. He suffered a stroke in 1898 and retired in 1901.

Mach's Influence

As a political figure, Mach served in the Austrian parliament and was so influential amongst the Austrian and Russian left that Lenin wrote *Materialism and Empirico-Criticism* as a criticism of Mach's anti-materialism. In physics, he was the first to understand supersonic shock waves and was a major influence upon a generation of physicists, including Einstein (who credited Mach for being a philosophical forerunner of relativity theory), Schrödinger, Planck, and Heisenberg. In psychology, Mach was a founder of Gestalt theory and made numerous contributions to sense physiology (see Psychology, Philosophy of). His research on Mach bands anticipated the modern understanding that the senses have neural nets that preprocess information before sending it to the brain. In philosophy, he was a major influence on the Vienna Circle (especially Frank, Hahn, and Carnap) and remains an inspiration to empiricist conceptions of science (see Vienna Circle). He was one of the most influential intellectuals in Vienna at a time when Vienna was the center of Western intellectual activity.

Mach's Psychology and Biology

Although he received his degree in physics, Mach attended many classes in physiology, and from the beginning of his career the majority of his research was not in physics but in the physiology of the senses. His central project, developed most extensively in his *Analysis of Sensations*, was to understand the relationship between sensations (the actual phenomenal experience) and the physical stimuli that trigger them (Mach [1914] 1984).

How, for instance, do eyes convert light particles into three-dimensional visual fields, when those particles themselves contain no information about their point of origin?

Although an empiricist in many regards, Mach held a strong notion of the a priori, maintaining that three-dimensional space is biologically innate (Banks 2003). Mach differed from the Kantian tradition by holding that the a priori is formed through evolution and development. Thus, there is nothing necessary about the current human spatial intuition; had humans evolved differently, they would perceive space differently. A similar account is given for other aspects of cognition, such as the understanding of matter, time, color, and even mathematics. The current human condition is historically contingent upon the particular evolutionary pathway humans accidentally took, and thus the world known through human senses should not be confused with the actual world.

Mach was strongly influenced by Darwin and by a variety of evolutionary ideas that are rejected today but were prominent within nineteenth-century German culture (see Evolution). Borrowing from the latter, Mach saw humans as nature's way of understanding itself, almost a waking up of nature. Science was a continuation of this process in that it was the "waking up" of humans. Evolution in prescientific times was an unconscious adaptation of organisms to their physical environments. The selection pressure was on survival and not on truth or higher social ideals. Humans thus adapted to convenient local minima and have come to misinterpret the human view of the world for the world itself. Thus there is a confusion between biological programming and reality. It is the biological purpose of science to lift humans out of this condition by understanding the nature of our psychological programming, and to provide us with a stable environment for future cognitive growth. It was an optimistic outlook; Mach's brand of positivism held out the hope that psychology embedded within an evolutionary framework would change the way humans saw the world, and thus lead not only to knowledge but, more importantly, to social-political harmony.

Mach's Philosophy of Physics

Two central areas dominate Mach's philosophy of physics: his opposition to atomism and his opposition to Newton's conception of absolute space and time. Both arise from his antimetaphysical attitude, which in turn derives from his placing physics within a biopsychological framework.

His opposition to atomism arose from his biological conception of the purpose of science. For Mach, the social-political value of a scientific worldview is that it is nonmetaphysical and stable, and thus can provide a basis for positive scientific and social progress. Science should be nonmetaphysical so that all humans can agree to it. Furthermore, a nonmetaphysical science is stable in that it is not grounded in speculation but in description. This led him to favor a view of physics that emphasized description of the phenomena over the positing of ontologies and theories. Descriptions are simply more stable and less likely to be overthrown by future science, and thus provide a stable environment for cognitive change.

Turning to Mach's theories of space and time, it is important to note that Mach writes far more on the *psychology* of space than on the physics of space. In particular, his research on Mach bands develops the idea that even at a sensory level, one experiences only relations between things, and not the things themselves (Ratliff 1965). Mach's critique of Newton's theories of absolute space and time (which in turn influenced Einstein) was thus derivative of this psychological outlook. The history of physics thus owes a small but important debt to psychology. This is still controversial. What is agreed upon is that Mach rejected the mechanical view of physics and developed an influential alternative in which space, time, and matter were redefined as relations. For instance, he defined matter in terms of its relational interactions with other matter, that is, how much acceleration two objects impart to each other. With space and time, Mach similarly argued for a relational view. Humans have no psychological access to what space and time "are," so physics should simply mathematically describe the relations between objects.

In his influential *Science of Mechanics*, he argues that space and time cannot be used to measure the absolute changes of objects, as the very concepts of space and time are arrived at by observing the changes in objects (Mach [1893] 1960). That is, an intuition of space and time is prerequisite to measuring motion. Thus one cannot claim after measuring a motion that one has measured 'space' and 'time.' All one can do is give mathematical accounts of the spatial–temporal relationships of things. Mach, then, was a radical naturalistic epistemologist who turned to biology and psychology to give a naturalistic account of the entire human condition, including physics.

MATERIALISM

See **Physicalism**

MECHANISM

Interest in mechanisms has experienced a recent upsurge in the philosophy of science generally (e.g., Salmon 1984; Glennan 1996) and in the philosophy of biology and neuroscience in particular (see e.g., Bechtel and Richardson 1993; Craver and Darden 2001; Machamer, Darden, and Craver 2000). Scientific explanation often involves identifying the mechanism responsible for a phenomenon of interest. This entry provides a generic account of what mechanisms are and how they are appealed to in explanations and then turns to the question of how scientists discover them. What are mechanisms?

Four Aspects of Mechanisms

The notion of mechanism has four aspects: (i) a phenomenal aspect, (ii) a componential aspect, (iii) a causal aspect, and (iv) an organizational aspect. Mechanisms can differ from one another in each of these aspects. Consider them in turn, first using a common mousetrap as an example and then considering the more complicated mechanism of action potential generation in neurons:

The Phenomenal Aspect

Mechanisms do things; they are the mechanisms *of* the things that they *do*. A mousetrap traps mice, and the mechanism for generating action potentials generates action potentials. These tasks performed by the mechanism as a whole are the *phenomena* explained by the working of the mechanism. There are no mechanisms *simpliciter*—only mechanisms *for* phenomena. A mechanism's phenomenon partially determines the mechanism's boundaries (i.e., what is "in" the mechanism and what is not). As Kauffman (1971) clearly emphasized, an item is considered "part of" the mechanism only if it is relevant to a mechanism's phenomenon.

The Componential Aspect

Mechanisms have components, or working parts. Mechanisms all have at least two components. The old-fashioned mousetrap has six: a platform, a trigger, a latch, a catch, a spring, and an impact bar (see Figure 1). Trivially, the components are proper parts of the mechanism as a

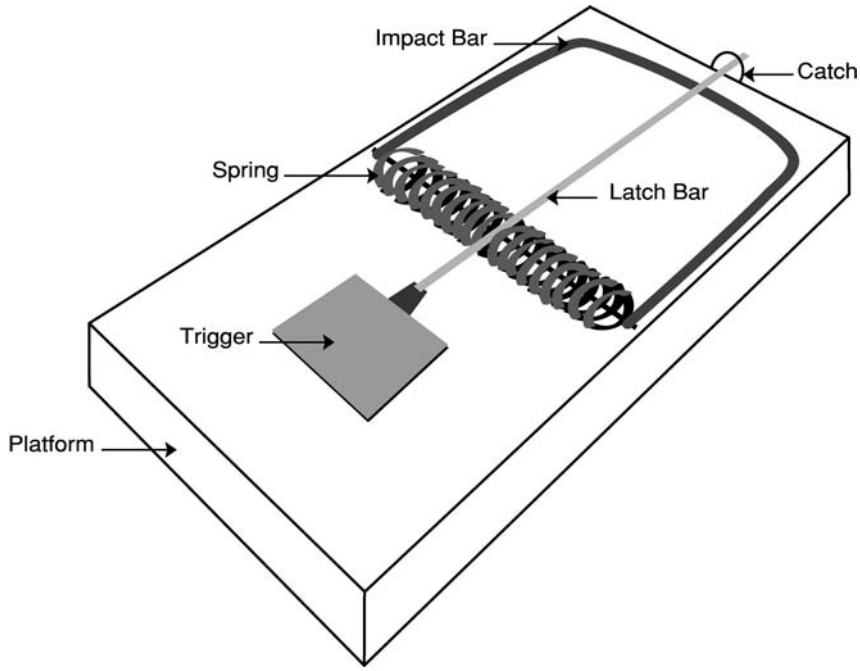

Fig. 1. The Mousetrap.

whole. More restrictively, as just noted, the parts of a mechanism are those that are relevant to the phenomenon explained by the mechanism. The parts are relevant to the phenomenon by virtue of certain of their properties (and not others). But for the rigidity of the bar and the tension on the spring, a mousetrap would catch no mice. The buoyancy of the platform, in contrast, is not properly included in the mechanism for catching mice.

The Causal Aspect

The components of mechanisms act and interact with one another. If they did not, they would not do anything. *Pressing* the trigger *releases* the catch, *allowing* the spring to *launch* the impact bar. The verbs in this description of the mousetrap refer to the relevant causal relations among the component parts. Talk of causal relations is a schematic placeholder to be filled in with one or more appropriate accounts of the kinds of causing exhibited in a given case. Philosophical attempts to develop univocal analyses of such causal relationships have yet to garner widespread acceptance. Yet the intransigence of the causal relation to a single uniform philosophical analysis should not distract attention from the central role that causal relations play in mechanistic explanations.

The Organizational Aspect

The components of mechanisms and their causal relations are organized spatially and temporally in the production of the phenomenon. The *spatial organization* of a mechanism includes the relative locations, shapes, sizes, orientations, connections, and boundaries of the mechanism's components. In the mousetrap, the trigger and the catch have to be so located with respect to one another that a small amount of pressure on the trigger moves the trigger bar enough to dislodge from the catch. The catch is circular and accommodates the size of the trigger bar. When the mechanism is loaded, the parts are connected to one another: The trigger bar restrains the blunt bar because it is stuck in the catch. As the mousetrap "fires," temporal organization takes center stage. The temporal organization of a mechanism includes the order, rates, durations, and frequencies of the activities in the mechanism. If a mousetrap is to work, it should work quickly, it should not discharge until there is pressure on the trigger, and there should not be significant delays between the steps of its working. Spatial and temporal organization are two important varieties of mechanistic organization. There are familiar patterns of mechanistic organization that can be found in different mechanisms for different phenomena. Some mechanisms are feed-forward, with

each step following upon its predecessor without forks, joins, or cycles (like the common mousetrap); others may work in parallel or have significant feedback connections.

A Neurobiological Example: The Mechanism of the Action Potential

Mousetraps fire, and so do neurons. The firing of a neuron is known as an action potential. Action potentials are changes in the electrical potential difference across the cell membrane that propagate along the length of the neuron. This difference, known as the membrane potential (V_m), consists of the separation of charged ions on either side of the membrane. In the neuron's resting state, positive ions line up against the membrane's extracellular surface, and negative ions line up on the intracellular side, producing a polarized resting potential (V_{rest}) of roughly -60 mV. The action potential (as indicated in Figure 2) consists of (I) a rapid rise in V_m (reaching a maximum value of roughly $+20$ mV), followed by (II) an equally rapid decline in V_m to values below V_{rest}, and then (III) an extended hyperpolarized afterpotential during which the neuron is less excitable. These three features characterize the phenomenon to be explained by the action potential mechanism.

The components of this mechanism include the cell membrane, positively charged sodium (Na^+) ions, positively charged potassium (K^+) ions, and two types of voltage-sensitive ion channels that selectively allow, respectively, Na^+ or K^+ ions to diffuse through the membrane. It is the temporally organized activities of these channels that produce the action potential phenomenon.

The mechanism of the action potential starts with a cumulative depolarization of the cell body (i.e., V_m becomes greater than V_{rest}), typically through the effect of neurotransmitters on ion channels in the cell's dendrites (the "receiving" ends of the neuron). Action potentials are generated in the axon hillock, an ion-channel-dense region of membrane at the interface of the cell body and the axon (the "sending" end of the neuron). Depolarization of the cell body opens voltage-sensitive Na^+ channels (increasing membrane conductance to Na^+), allowing Na^+ to diffuse down its concentration gradient from the Na^+-rich extracellular fluid into the relatively Na^+-poor intracellular fluid (illustrated by the membrane conductance curve for Na^+ in Figure 2). The resulting flood of Na^+ drives the voltage of the cell toward the Na^+ equilibrium potential (E_{Na}; roughly $+55$ mV), accounting for the rapid rising phase of the action potential (I).

This rapid depolarization of the membrane has two consequences that account for the declining phase of the action potential (II). The first is the inactivation of the Na^+ channel, which slows and eventually stops the ascent of V_m toward E_{Na}. The second is the delayed activation of voltage-sensitive K^+ channels, increasing the K^+ conductance of the membrane and allowing K^+ to diffuse down its concentration gradient from the K^+-rich intracellular fluid into the K^+-poor extracellular fluid. This diffusion of K^+ drives the membrane potential back down toward the K^+ equilibrium potential (E_K; roughly -75 mV) and even below the resting potential of the membrane.

Thus begins the final, afterpotential phase of the action potential (III), which is characterized by both the hyperpolarization of the membrane (i.e., V_m is

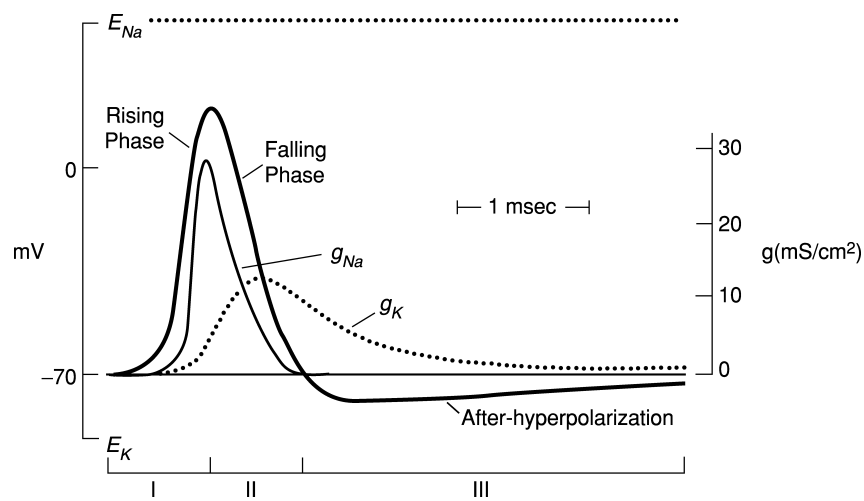

Fig. 2. The Action Potential.

lower than V_{rest}) and a period of reduced excitability. The membrane hyperpolarizes after the action potential because K^+ channels are slow to return to their resting closed state. The residual K^+ conductance tugs V_m away from V_{rest} and toward E_K.

The parts in the mechanism for generating action potentials are the membrane, the ions, and the ion channels. These parts are causally connected; they act and interact in regular ways to produce the action potential. These activities depend crucially upon the spatial organization of the components; ion channels *span* the membrane, allowing ion *movement* between the intracellular and extracellular fluids. Spatial organization is also fundamental to understanding the molecular mechanisms of channel activation and inactivation and for understanding the propagation of action potentials along axons. Yet, it is temporal organization that is most evident in the mechanism of the action potential; it is the relative orders and durations of the activation and inactivation of Na^+ and K^+ channels that explain the characteristic waveform (I, II, and III) of the action potential.

Levels of Mechanisms

Often mechanisms are nested within mechanisms. In such cases, some phenomenon (ψ) of a mechanism (M) is explained by the organized activities (ϕ) of lower-level components (X) that can themselves be taken as phenomena to be explained by the activities (ρ) of still lower level components (Z). Thinking about mechanisms provides a straightforward way to think about levels (see Craver 2001b). In this case, the relationship between lower and higher mechanistic levels is a compositional relationship with the additional restriction that the lower-level parts are components of (and hence organized within) the mechanism at the higher level. The requirement that lower-level parts be organized (at least spatially and temporally) within the higher-level mechanism distinguishes mechanistic levels from mere aggregates, such as piles of sand (Wimsatt 1986); from mere collections of improper parts, such as the cubes into which a television might be arbitrarily sliced (Haugeland 1998); and from mere inclusive sets, such as the collected songs of the Ramones. Lower mechanistic levels are entities and activities organized to exhibit the behavior of the mechanism as a whole.

Mechanistic levels should not be confused with intuitive ontic levels (e.g., Oppenheim and Putnam 1958), which map out a monolithic stratigraphy of levels across theories, sciences, and types of entities. Just as there are no mechanisms *simpliciter*, there are no mechanistic levels *simpliciter*. Mechanistic levels, instead, are defined only with respect to some highest-level mechanism M and its phenomenon ψ (pronounced "psi"). This, however, does not mean that the investigator cannot move upward, treating M as part of a yet higher level mechanism that generates its own phenomenon. Different levels of a mechanism involve different entities and activities. Accordingly, different vocabularies are typically used to describe mechanisms at different levels (Bechtel 1995). Exactly how many levels there are and how they are to be individuated are empirical questions that are answered differently for different phenomena.

Representing Mechanisms

There are many conventions for describing and representing mechanisms. Verbal accounts are generally insufficient to convey an understanding of a mechanism, especially if there are any nonlinearities in its behavior. Accordingly, verbal descriptions are often accompanied by diagrams representing the components, their activities (often depicted with arrows), and the relevant features of their organization (see Figure 1 above). Temporal relations are often represented spatially, either with labeled events conjoined by arrows or in separate frames. Diagrams afford the viewer the opportunity to follow through the parallel sequences of activities within the mechanism in one glance. With increasing frequency, the working of a mechanism may be represented in animated shorts. Extremely complicated mechanisms, however, frequently require the viewing time afforded by static two-dimensional representations so that aspects of the mechanism can be taken in piecemeal.

Descriptions of mechanisms, whether verbal or pictorial, may be more or less gappy, with holes or question marks to be filled in as details of the mechanism are discovered. Sometimes these are appreciated by the person portraying the mechanism, but many times the gaps are not even recognized until, for example, another component is discovered and researchers try to figure out what it contributes. Descriptions of mechanisms may also be more or less abstracted from the details of the operation of any particular mechanism, highlighting broad patterns of organization (e.g., with equations) or exhibiting precisely the spatial, temporal, and hierarchical organization of the components and activities of the mechanism.

Often the activities within a mechanism are characterized mathematically. For example, in describing the action potential mechanism, equations

are advanced describing the changes in magnitude of Na^+ concentrations over time. Once such equations are developed, mathematical models of the overall operation of the mechanism can be advanced.

Mechanistic Explanations

Since mechanisms are often responsible for generating phenomena for which explanations are sought, it is not surprising that scientists frequently advance accounts of mechanisms as explanations. That is, to explain an action potential, they proceed much as in the example above—identifying the components of the responsible mechanism, describing the activities performed by the components, and showing how these components and activities are organized. They frequently present this information in diagrams, and often the account offered is gappy. Presenting a mechanism as an explanation, however, does not fit the standard deductive-nomological account of explanation, according to which explanation involves deriving a statement of the phenomenon to be explained from laws and relevant initial conditions. It is not laws that do the explanatory work but the account of the operation of the mechanism.

One might try to reconcile the two accounts of explanations by insisting that there is a law characterizing each mechanism. Typically, however, there is too much variability in a given mechanism (e.g., in the generation of action potentials in different neurons) for this to be plausible. It is better to recognize mechanistic explanation as an alternative model of explanation. Its prevalence in a variety of sciences such as physiology and neuroscience may account for the fact that these sciences have not been the primary source of examples of deductive-nomological explanation and have been relatively neglected by philosophers of science. Once mechanisms are recognized for their explanatory role in these sciences, though, we can also identify a number of philosophical issues to be pursued. One of these concerns their discovery.

How Are Mechanisms Discovered?

Characterizing the Phenomenon

One of the first tasks in discovering mechanisms is identifying the phenomenon—determining what it is that the mechanism does. The world does not come obviously prepackaged in terms of phenomena. How one characterizes the phenomenon critically affects how one goes about trying to discover the responsible mechanism and whether that quest will prove successful. Accordingly, characterizations of phenomena prove controversial and frequently are revised in the course of inquiry as one discovers that the mechanism does something different than one thought.

Phenomena are often subdivided, consolidated, or reconceptualized entirely as the discovery process proceeds. Researchers may recognize the need to subdivide a phenomenon into many distinct phenomena, as when learning and memory researchers were forced to recognize that there were many different kinds of memory requiring more or less distinct mechanisms to explain them. Alternatively, researchers may be forced to consolidate many different phenomena into a single phenomenon, as when it became understood that burning, respiring, and rusting were all due to a common mechanism and thus are examples of one phenomenon, oxidation. Finally, investigators may need to reconceptualize the phenomenon to be explained entirely. For example, early physiologists focused on the fact that animals burn foodstuffs and release heat. But after further investigation, researchers recharacterized this phenomenon as transforming energy into usable forms (e.g., ATP bonds).

Identifying Components

The discovery of mechanisms also involves identifying the components of the mechanism and their activities. Bechtel and Richardson (1993) used the term *decomposition* to describe analysis of a phenomenon into activities that, when properly organized, exhibit the phenomenon. In one of their main examples, they describe how the biological process of fermentation, over three decades of research, was decomposed into a set of more basic chemical reactions (oxidations, reductions, phosphorylations, etc.). This is *functional decomposition*. But frequently the process of decomposition begins by breaking the mechanism apart into component entities and only then investigating what the components do. This is *structural decomposition*. Ultimately, one measure of the adequacy of either form of decomposition is that it maps onto the other so that specific components are related to particular activities. Bechtel and Richardson call this identification of activities with components *localization*.

Often the search for the components of a mechanism is guided by an accepted store of components and activities that are reasonably well understood by a science at a particular time and that are available for use in thinking about how a mechanism works (Craver and Darden 2001). In the early stages of mechanism discovery, there may be no

such store; there is either no idea of, or considerable controversy over, what the components and activities might be. The brain provides a useful example (Mundale 1998). There has been considerable controversy, for example, about what counts as a brain region, with different investigators using different criteria to divide the brain into parts at different times. Early attempts to map brain areas focused on the sulci and gyri resulting from the folding of cortex. Although prominent features of the brain, these tend not to be closely linked to component activities. With the identification of different types of neurons and the existence of cortical layers of varying thicknesses, numerous early-twentieth-century scientists, including Korbinian Brodmann, used these cytoarchitectural features to demarcate brain areas. Brodmann explicitly thought that different areas were likely to perform different operations, but he lacked any means for linking the regions he differentiated with function. More recent brain mappers have invoked yet additional criteria such as connectivity to other regions to identify brain areas. A major reason for controversy over these is that researchers are interested in components that perform the activities that generate the relevant phenomena. As the sulci and gyri of the brain illustrate, it is possible to differentiate structures within a mechanism that are not working components, that is, parts that carry out the relevant activities. In the relevant sense, these are not components of the mechanism. Similar challenges arise in functional decomposition—one may propose a decomposition into activities but not ones performed by any of the mechanism's components. Moreover, as hinted above, the search for components and for activities is interdeterminate—conceptions of the activities thought to be performed guide the identification of components, and vice versa.

How do scientists arrive at satisfactory decompositions that describe mechanisms in terms of their organized parts and activities? Often scientists begin the discovery process by proposing that there is a single component in the mechanism that alone is responsible for the phenomenon (e.g., attributing pleasure to activation of the brain's pleasure center). Sometimes this claim is correct, but even when it is, the task of identifying the mechanism that generates the phenomenon awaits decomposition of that component itself.

True decomposition is frequently guided either by the available store of components or by the available tools for investigating these components. Often scientists, functioning much like engineers, attempt to organize known components and activities in such a way that they might possibly produce the phenomenon. This process may involve reasoning analogically from other mechanisms (discovered in nature or human artifacts) and the activities performed in them. Such "how possibly" reasoning is, of course, fallible, since even two phenomena that are very similar may be generated by two very different mechanisms. In fact, sometimes the discovery process is slowed dramatically by pursuit of false leads generated by this engineering heuristic. On the other hand, even an erroneous proposal often advances the inquiry, since now experimental evidence can be generated that points to a more adequate decomposition. Experimental strategies for decomposing a mechanism are discussed further below.

Discovering the Organization of a Mechanism

Beyond delineating the phenomenon and revealing the components, a third major goal in the discovery of a mechanism is to determine how these components and activities are organized in the mechanism. Typically there are both spatial and temporal aspects to the organization of a mechanism. For example, the rate and duration of the phenomenon places time constraints on the activities of the components, and uncovering the order, rate, and duration of the steps in a mechanism often provides important clues into how the mechanism works. Likewise, discovering aspects of the spatial organization of a mechanism (the size, shape, position, orientation, etc., of the components) is often crucial for suggesting possible mechanisms and for ruling out others (see Craver and Darden 2001).

The relative importance of spatial and temporal organization varies from mechanism to mechanism. Spatial organization is of fundamental importance in, for example, the mechanisms of enzyme degradation because enzymes that can break down cellular substances need to be kept separate from other cellular substances that are not to be broken down. Spatial organization also helps provide efficiency in production mechanisms in which intermediate products are literally passed from one activity to the next (as in the Kreb's cycle).

If a phenomenon involves a change from one state or set of conditions to another (e.g., from glucose to alcohol, from sensory stimulus to recognition), it is common to think of that change as being executed by a linear sequence of steps. In part this is common because human conscious cognitive activities are serial—humans proceed from thinking of one thing to thinking of another. But, for very good reasons, such as ensuring proper regulation of a process, many natural mechanisms

are not organized linearly. As a result, they are difficult for humans to conceptualize, at least without the aid of external representations such as diagrams in which one can represent backward as well as forward linkages.

The naturalness of linear organization means that in trying to fit multiple parts and activities together into a coherent description of a mechanism, researchers often begin by trying to organize them linearly. Often researchers begin to appreciate more complex modes of organization only when these attempts fail to account for the phenomenon. In modeling a chemical process, for example, one may find that there is no way to link together known basic reactions to get from the initial input to the product. This often leads to the exploration of more complex modes of organization such as a cycle. Thus, one common pattern in the process of discovering mechanisms is to begin with linear organization and then add complexity as required.

Experiments in Mechanism Discovery

Typically, the components, activities, and organization of a mechanism cannot be understood without the aid of well-designed experiments. Experimentation figures not just in the testing of models of mechanisms that have been hypothesized independently, but in the very process of discovering the mechanism.

Experimentation requires some means of intervening in the operation of the mechanism as well as a means of recording the effects of those interventions. Sometimes interventions into a mechanism are performed "by nature," through accidental damage, disease, or genetic mutation or variation. Other times the interventions are intentional and designed by the researcher to perturb some isolated aspect of the phenomenon or some component or activity in the mechanism.

A taxonomy of experimental approaches to developing and testing descriptions of mechanisms can be developed by focusing on where the intervention and recording techniques are applied (Bechtel and Richardson 1993; Craver 2001a). In the sense discussed above, a phenomenon and the mechanism that produces it are at two mechanistic levels, the phenomenal level (L_P) and the level of the mechanism (L_M) (see Figure 3). As illustrated in Figure 3, experiments may intervene and record entirely at the phenomenal level, bridge phenomenal and mechanistic levels, or intervene and record entirely within the mechanistic level.

First, both the intervention and the recording may be conducted at L_P without going down to L_M (see Figure 4). For example, one can intervene to vary the inputs to a mechanism or the conditions under which it operates (e.g., temperature) and record variations in the phenomenon. Much experimentation in cognitive psychology (e.g., requiring subjects to perform a task under varying conditions, such as cognitive load, and using reaction time as the measure of the effect) is of this sort and, when done well, can provide abundant information about the internal design of the mechanism. For example, evidence that two tasks interfere with each other provides further evidence that some component or components may be involved in both tasks. A great deal can also be learned about a mechanism by determining the range of input conditions under which it works properly and under which it fails or malfunctions.

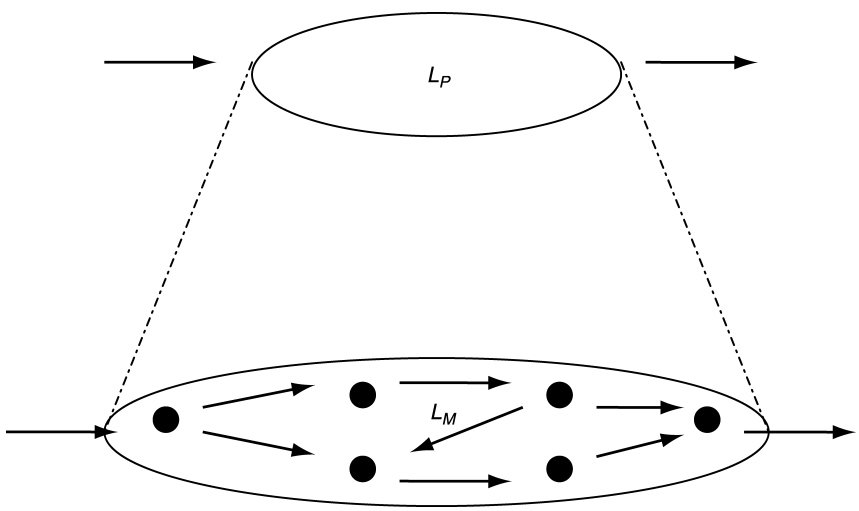

Fig. 3. Phenomenal Level (top) and Mechanism Level (bottom).

Second, experiments may bridge L_P and L_M. (Many experiments bridge several such levels at once.) Such experiments may be top-down (intervening at L_P and recording at L_M) or bottom-up (intervening at L_M and recording at L_P), and the experimental intervention may be either excitatory (somehow stimulating the target of the intervention) or inhibitory (somehow removing or impairing the target of the intervention). Top-down excitatory experiments are prevalent in cognitive neuroscience, where researchers intervene to engage an organism in some cognitive task while recording the activities of component brain regions, neurons, or molecules. Bottom-up excitatory experiments are also common. Neural stimulation studies, for example, use electrodes to excite individual neurons, and the effects are recorded for the cognitive phenomenon in which those neurons are involved. Additionally, bottom-up inhibitory experiments are a staple of most sciences that search for mechanisms. In neuroscience, for example, one may intervene to remove a brain region, a receptor molecule, or a neurotransmitter and record the effects on the phenomena in which those components are putatively involved. It is not uncommon for researchers to find a way to impair the activity before they figure out what the relevant components are or which are being affected. For example, one can discover a chemical poison that impairs a metabolic process but not know what component of the mechanism the poison is acting upon.

Third, inhibitory and excitatory techniques can also be applied within L_M. In this case, one intervenes to excite or inhibit some component or activity in the mechanism and then records the results of that intervention elsewhere in the mechanism. This form of experiment is especially important for determining how the components of the mechanisms are organized together in the production of the phenomenon.

There are significant epistemological challenges in interpreting the results of excitatory and inhibitory interventions into the working of the mechanism. Bottom-up inhibitory experiments may be foiled by redundancy, reorganization, and failures of specificity in the intervention. Intervention to remove or inhibit a component or activity may result in little or no change to the phenomenon if the removed or inhibited component is redundant (like the human kidney). Likewise, the mechanism may reorganize in the face of a loss of its component, leaving the phenomenon intact or only mildly transformed. In general, in removing a part of a mechanism and observing the behavior of the mechanism as a whole, researchers learn not what the removed part does but rather what the rest of the mechanism can do in its absence. Finally, the intervention may have nonspecific effects on other components in the mechanism, thereby indirectly altering the phenomenon and foiling the inference from the recorded changes to the function of the inhibited part. This problem is often exacerbated in "natural

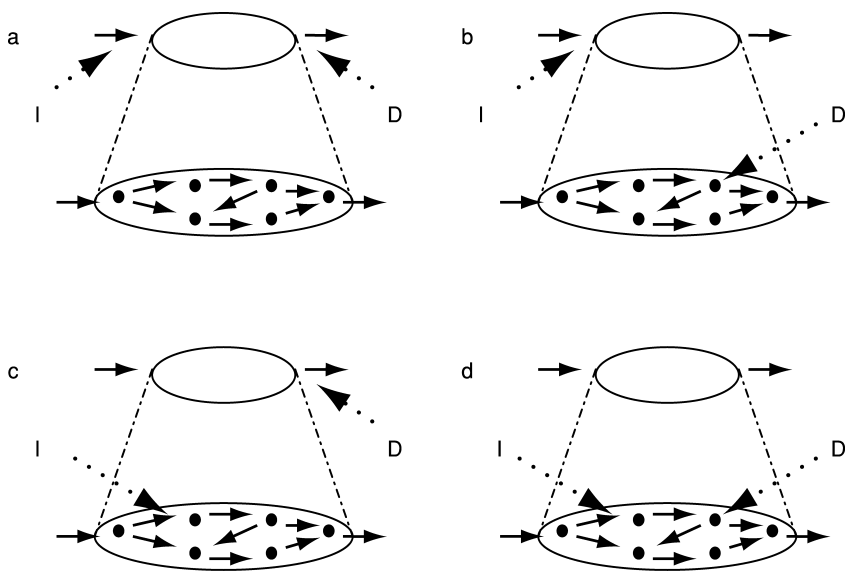

Fig. 4. Points of intervention and recording in experiments. Experiments may (a) both intervene and record at the phenomenal level, (b) intervene at the phenomenal level and record at the mechanistic level, (c) intervene at the mechanistic level and record at the phenomenal level, or (d) both intervene and record at the mechanistic level.

experiments'' in which the intervention has not been tightly controlled by an investigator and so may have had a rather nonlocal impact on the components of the mechanism.

Similar epistemological difficulties attend the use of top-down excitatory experimental strategies. One example of such an experiment is to provide a stimulus to an organism and record from individual neurons in its brain or to use neuroimaging to record where there is increased blood flow in the brain. The epistemic challenges here are no less than when the intervention is within the mechanism. Activity in a part of a mechanism when the whole mechanism has been stimulated shows only that the component in question does respond to the stimulation. It does not yet show what activity it performs. Many neurons in the brain, for example, will respond when the organism is presented with a visual stimulus. One can gain more of a clue as to what a component is contributing by varying the intervention and determining the range of interventions to which the component is responsive (e.g., that it is only responsive to visual stimuli moving to the left). Even so, a given active neuron may perform an activity that is largely incidental to the phenomenon one is investigating (e.g., how objects are identified).

One way investigators begin to acquire confidence in their physical and functional decompositions is by drawing upon multiple modes of investigation, especially by invoking both inhibition and excitatory interventions. If lesioning a component eliminates the phenomenon of interest and exciting it produces the phenomenon, compelling evidence is provided that the component figures in generating that phenomenon. But just what does it contribute? Often answering that question depends on formulating a hypothesis about what many different components are contributing, and developing an account of how the components together produce the phenomenon. For example, researchers working on how the brain recognizes objects identified different brain regions in which individual cells would respond to different aspects of a stimulus—some responded whenever a given color was present, another when a given shape was present, and yet others when a particular object was present. By also knowing how these various brain regions were connected to each other, researchers began to piece together an account of the overall mechanism (Bechtel 2001).

As researchers reach the stage of reasonably worked out hypotheses about what different components contribute, additional tools can be invoked to help figure out the mechanism. For example, researchers often begin to build models, including computational ones, that characterize what each component is thought to contribute and to simulate their interaction. To the degree that the model predicts the phenomenon, one acquires confidence that one's account is at least close to correct. (The fit between a model and the phenomenon is often a matter of degree, and the degree of fit deemed sufficient often changes as research on the mechanism proceeds.) But failures are equally informative, since they often lead researchers to posit yet unidentified components and activities and begin to seek evidence for them.

Not surprisingly, there is no foolproof procedure for discovering mechanisms. But there are a range of strategies that can be identified by careful examination of actual science.

Conclusion

Four aspects of mechanisms have been identified: (i) the phenomenal, (ii) the componential, (iii) the causal, and (iv) the organizational. The generation of a phenomenon is often the product of a mechanism, and describing the mechanism provides an explanation of the phenomenon. The sciences concerned with identifying mechanisms have developed a variety of conceptual and experimental tools for this purpose. The philosophical analysis of mechanisms and their discovery is still in a relatively early stage but has advanced far enough that it is safe to predict that careful attention to mechanisms and mechanistic explanation is likely to yield significant advance in the philosophical understanding of science.

METHODOLOGICAL INDIVIDUALISM

Methodological individualism (MI) is a set of related but distinct theses about how the social sciences should proceed. Drawing inspiration from the atomist program in natural science, MI holds that all social explanation should be in terms of individuals. Classic figures in the history of the social sciences such as Weber advocated some version of the doctrine, which is espoused by major schools of thought in economics and elsewhere in the social sciences (Blaug 1992; Gordon 1991). It is opposed by the holist tradition that began with the founders of sociology (Durkheim 1965) and continues to this day throughout the social sciences. While it has been usually treated as a conceptual or philosophical thesis, MI is probably best thought of as a series of more or less empirical theses.

Most individualist claims can be classified under one of the following four types (Kincaid 1996 and 1997):

1. Ontological claims:
   (i) Societies are composed of individuals.
   (ii) Societies do not act independently of individuals.
   (iii) Social entities do not exist.
2. Claims about theory reduction:
   (iv) Any social theory is in principle reducible to a theory referring entirely to individuals. (see Reductionism)
3. Claims about explanation:
   (v) Theories referring only to individuals can fully explain all social phenomena.
   (vi) Individualist mechanisms are a necessary condition for social explanation. (see Explanation)
4. Claims about confirmation:
   (vii) No social theory without individualist mechanisms can be well confirmed; and
   (viii) Searching for individualist theories is the best route to successful social science (see Confirmation Theory)

There are, of course, various real and alleged interconnections among these claims.

Perhaps the most common and logically central claim is the reductionist one. To reduce one theory to another is to show that the reducing theory can do all the explanatory work of the reduced theory, which is only a special case of the reducing theory. Since different theories have different vocabularies, theory reduction requires systematic linkages between the categories of the two theories. Individualism in its reductionist guise thus claims that the concepts of the social sciences can be equated with descriptions of individual behavior in such a way that all social science explanations can be put in individualist terms.

Many have claimed that this reductionist thesis follows from the ontological truism that society is made of and does not act independently of

individual people (Watkins 1973). That conclusion does not follow, however. Chairs are made of molecules, but there are so many ways of making a chair that it is unlikely that a systematic connection will be found that would allow the replacement of the category 'chair' with some molecular description, however complex. Social entities such as corporations or states may have a similarly loose relation to the individual behaviors constituting them. Whether that is the case is an empirical issue that is unlikely to have any general answer across all domains of social research.

While the ontological claim that society does not exist and act independently of individuals is quite plausible, the presumed failure of theory reduction mentioned above argues against the further ontological claim that societies do not exist. If there are successful theories that make essential reference to social entities, that is one good reason to countenance their existence.

Of course the methodological individualist might deny the assumption that social explanations—explanations in terms of social entities—ever succeed in the first place. Two versions of this claim were identified above: No explanation is adequate unless it is entirely in terms of individuals (claim [v]) and some reference to individuals is necessary (claim [vi]). The latter, logically weaker claim is usually put as a claim about mechanisms: explanations in terms of social entities are only acceptable if the individualist mechanisms bringing them about are provided (see Mechanism).

To be interesting, these theses should be independent of assertions about theory reduction. It is unclear, however, that the stronger of the two is independent. If an individualist theory can fully explain everything that a nonindividualist theory can, then it can state those explanations only if it can relate the categories of the nonindividualist theory in every case to its own. But this goes back to the requirements for reduction.

The claim that individualist mechanisms are needed for explanation is widespread (Elster 1985; Little 1989). It is often defended as an instance of the general truth that all explanations require citing the mechanism involved. The general principle is implausible and of dubious value. It is implausible because one seemingly explains one macroscopic physical event by a previous one without any idea of the mechanism—"the crash of the plane caused the collapse of the building" is explanatory even without describing how it did so. The general principle is of dubious value because 'mechanism' is ill-defined. There can be mechanisms at many different levels of detail, so a demand for mechanisms is ambiguous. Individualists need to show that the mechanism cannot be social—as when competition between firms is cited to explain prices—and that it must be about individuals instead of neurons or genes.

Even if individualist mechanisms are needed to explain, this may not be much of a victory for methodological individualism. The mechanisms in question are likely to invoke the role individuals play and the constraints they face in institutions. Many game-theoretic and rational choice accounts provide individualist explanations, but they take norms, rules of the game, institutional constraints, and other such nonindividualist explainers as givens (see Game Theory).

Another motivation for individualist mechanisms is confirmation. The basic idea is that mechanisms are needed to rule out confounding cases. Aside from the question of levels raised above, this rationale suffers from the obvious fact that scientific claims can be confirmed without mechanisms. Newton's laws of motion were predictively very successful for a long period of time without any account of the underlying cause of gravity; Darwin had a similar success in describing evolution with an incorrect mechanism of genetic transmission. No doubt mechanisms play a useful role in confirming and explaining. But when, where, and at what level of detail they are useful is an empirical question that depends on the context.

MOLECULAR BIOLOGY

The term 'molecular biology' was introduced by Warren Weaver in 1938 in an internal report of the Rockefeller Foundation: "And gradually there is coming into being a new branch of science—molecular biology . . . in which delicate modern techniques are being used to investigate ever more minute details of certain life processes" (as quoted in Olby 1974, 442). What Weaver may have only dimly foreseen is that these new techniques would ultimately transform the practice of biology in a way comparable only to the emergence of the theory of evolution in the nineteenth century. At the beginning of the twenty-first century, molecular biology has become most of biology, either *constitutively,* insofar as biological structures are characterized at the molecular level as a prelude for further study, or at least *methodologically,* as molecular techniques have become a preferred mode of experimental investigation of a domain. Recent biological work at the organismic and lower levels of organization (cytology, development, neurobiology, physiology, etc.) increasingly fall under the former rubric. Work in demography, epidemiology, and ecology falls under the latter, with ecology perhaps being the subdiscipline within biology that has most resisted molecularization. Work in evolution falls under both: constitutively, when the evolution of molecules and molecular structures forming organisms is studied for its own sake, and methodologically, when molecular techniques (most notably, DNA sequencing) are used to reconstruct evolutionary history. This article will be largely restricted to the constitutive aspect of molecular biology, since that is what has so far (perhaps deservedly) commanded most philosophical attention.

The decade following Weaver's introduction of molecular biology saw the steady increase in the use of "delicate" molecular techniques, in particular, x-ray crystallography, to study biological macromolecules "minutely," increasingly with an emphasis on proteins. The central problem was the elucidation of the three-dimensional structures (the relative positions of the atoms) of biological macromolecules. The structure of proteins was supposed to explain their behavior. Proteins were singled out because they were believed to be the most important of these macromolecules. In particular, since the establishment of biochemistry as a discipline in the 1920s, enzymes and their interactions had been held to be the key to understanding *metabolism* (the catchall term for the complex chemical reaction systems that characterize life). All enzymes are proteins. Until the early 1940s, it was believed that the hereditary material (the genes) was also likely to be proteins. The nucleic acids, constructed out of only four nucleotide base types (adenosine [A], cytosine [C], guanine [G], and thymine [T]), were believed to be insufficiently complex to be able to specify the immense variety of known genes.

However, experimental work starting in the early 1940s showed that the hereditary substance—specifying 'genes' (see Genetics)—was deoxyribonucleic acid (DNA). Attention then shifted to deciphering the physical structure of DNA, a problem that was solved by Watson and Crick (1953)

with their double-helix model. The construction of this model and its subsequent confirmation marks a development of signal importance for modern biology (Sarkar 2005, Ch. 1). It ushered in the "classical" age of molecular biology (see the next two sections) with an intriguing informational interpretation of biology (see Biological Information). Important conceptual innovation also came from Monod and Jacob in the early 1960s, who constructed the allostery model to explain cooperative behavior in proteins and the operon model of gene regulation (Monod 1971; Jacob 1973; see below). Genes were interpreted as DNA sequences either specifying proteins (the *structural* genes) or controlling the action of other genes (the *regulatory* genes). Perhaps the most important development in classical molecular biology was the establishment of a genetic "code" delineating the relation of DNA sequences to amino acid residue sequences in proteins. (Both DNA and protein are linear molecules in the sense that they consist of units connected in a chain through strong [covalent] chemical bonds.) Gene *expression* took place by the *transcription* of DNA to ribonucleic acid, RNA, at the chromosomes (in the nucleus), and the *translation* of these transcripts into protein at the ribosomes (in the cytoplasm). The one gene–one enzyme credo of classical genetics was transformed into the one DNA segment–one protein chain credo of molecular biology (see Genetics).

Crucial to the program of molecularizing biology was the expectation—first explicitly stated by Waddington (1962)—that gene regulation explained tissue differentiation and, ultimately, morphogenesis in complex organisms. Genetic reductionism, the thesis that genes alone can explain organismic features, long predates molecular biology (Sarkar 1998). However, the molecular interpretation of the gene allowed the general explanatory success of molecular biology to be co-opted as a success of molecular genetics. In such a context, Waddington's thesis was positively received and helped usher in an era dominated by *developmental genetics,* according to which organismic development was to be understood through the action of genes. Mayr (1961) and others introduced the metaphor of the genetic program to characterize the putative relation between genomic DNA and organismic features. As molecular genetics began to dominate the research agenda of molecular biology in the 1970s, the emergence of organismic features came to be viewed as determined by "master control genes" (Gehring 1998). This view was initially supported by the demonstration that some DNA sequences (such as the homeobox) were conserved across a wide variety of species. DNA came to be viewed as the molecule "defining" life, a view that helped initiate the massive genome sequencing projects of the 1990s, which were supposed to produce a gene-based complete biology that delivered on all the promises of molecular developmental genetics. In general, because of the presumed primacy of DNA in influencing organismic features, starting in the early 1960s, molecular genetics began to dominate research in molecular biology.

Genetics and development were the earliest biological subdisciplines to be redefined by molecular biology. In the case of evolutionary biology, as early as the 1950s, Crick (1958) pointed out that the genotype/phenotype relation could be reinterpreted as the relation between DNA and protein, with proteins constituting the subtlest form of the expression of a phenotype of an organism. Consequently, the evolution of proteins (and, later, DNA sequences), especially the question of what maintained their diversity within a population, became a topic of investigation—in the 1960s, these studies led to the neutralist challenge to the received view of evolution (see Evolution). More importantly, changes at the level of DNA sequences, provided that these were selectively neutral, permitted the construction of a "molecular clock" that could be used to reconstruct evolutionary history more accurately than could be achieved by traditional morphological methods (see Population Genetics).

Meanwhile, biochemistry and immunology were reconstituted by the new molecular biology in ways that were not unexpected. That enzyme interactions and specificity would be explained in molecular terms was no surprise (see "Classical Molecular Biology" below). However, immunological specificity was also believed to be explainable by the same mechanism. This model of immune action was coupled to a selectionist theory of cell proliferation to generate the clonal theory of antibody formation, which combined molecular and cellular mechanisms in a novel fashion (see Immunology). In both biochemistry and immunology, what was largely at stake was the development of models that could explain the observed specificity of interactions: Enzymes reacted with only very few substrates; antibodies were highly specific to their antigens.

By the late 1970s, it became clear that the simplicity of the picture of genetics inherited from the 1960s was being lost. The initial picture was generated from an exploration of the genomes of prokaryotes (single-celled organisms without a nucleus), especially the bacterium *Escherichia coli*. In prokaryotes, every piece of DNA has a structural

or regulatory function. In the 1970s, it was discovered that the genetics of eukaryotes (organisms with cells with nuclei) turned out to have an unexpected complexity. In particular, large parts of the genomic DNA sequences apparently had no function: These segments of "junk" DNA were interspersed between genes on chromosomes and also within genes. After RNA transcription, noncoding segments within genes were *spliced out* before translation. Gene regulation in eukaryotes was qualitatively different and more complicated than in prokaryotes. Some organisms used nonstandard genetic codes and other alternatives (see Sarkar 1996 for a detailed account.)

Subsequent work in molecular biology has only added to this picture of complexity, so much so that it is reasonable to suspect that the classical picture is breaking down. RNA transcripts are subject to *alternative splicing,* with the same DNA gene corresponding to several proteins. RNA is edited, with bases added and removed, before translation at the ribosome, to such an extent that it is sometimes difficult to maintain that some gene actually does code for a given protein. There is no obvious relation between the number of genes in an organism and its morphological or behavioral complexity. Most importantly, it now appears that a fair amount of the DNA thought to be junk is transcribed into RNA though not translated. Thus, presumably, much of the so-called junk DNA is functional, though the nature of these functions remains controversial.

This article will concern both classical molecular biology and the postgenomic molecular biology of the modern era. It will not only discuss issues in the philosophical interpretation of the classical era, which are fairly well characterized, but also include more speculative discussions of issues raised by recent developments.

Classical Molecular Biology

Classical molecular biology can be viewed in continuity with both the genetics and the biochemistry of the era that preceded it. From biochemistry—in particular, the study of enzymes in the 1920s and 1930s—early molecular biology inherited the mechanistic proposal that the function or behavior of biological molecules was "determined" by its structure, an idea that went back to Ehrlich's "side-chain" theory in the late nineteenth century. In the 1950s, structural modeling of biological macromolecules, especially proteins, was pioneered by Pauling and his collaborators using data from x-ray crystallography (see, e.g., Pauling and Corey 1950). By the early 1960s, a handful of such structures were fully solved. These structures, along with the structure of DNA, seemed to confirm the hypothesis that structure explains behavior. Perhaps more surprisingly, it was found that structural interactions seemed to be mediated entirely by the shape of active sites on molecules and that the sensitive details of structure and shape were maintained by very weak interactions.

These experimental observations led to four seemingly innocuous rules about the behavior of biological macromolecules, which in the 1960s and 1970s formed the theoretical core of molecular biology (Sarkar 1998, 149–150):

1. The weak interactions rule: The interactions that are critical in molecular processes are very weak.
2. The structure-function rule: The behavior of biological macromolecules can be explained from their structures, as determined by techniques such as crystallography.
3. The molecular shape rule: These structures, in turn, can be characterized entirely by molecular size, external shape (especially), and some general properties (such as hydrophobicity) of the different regions of the surfaces;
4. The lock-and-key fit rule: In molecular interactions, molecules interact only when there is a lock-and-key fit between the two molecular surfaces. There is no interaction when these fits are destroyed.

A lock-and-key-fit thus based on shape is an obvious way of achieving stereospecific capacity, thus resolving the critical problem for classical molecular biology. Because they are most intimately involved in the explanation of specificity, the molecular shape and lock-and-key-fit rules are the most important in this respect. In what follows, these will be called the rules of classical molecular biology.

In the 1960s and 1970s, these rules were deployed with remarkable success. As noted earlier, enzymatic and immunological interactions were among those that were immediately brought under the aegis of the new molecular biology. Two other cases are even more philosophically interesting:

- The allostery model explains why some molecules such as hemoglobin show *cooperative* behavior. In the case of hemoglobin, there is a nonlinear increase in the binding of oxygen after binding is first initiated. This is explained by conformational—shape—changes in the molecular subunits of hemoglobin; and

- The operon model explains *feedback*-mediated gene regulation in prokaryotes: The presence of a substrate activates the production of a protein that interacts with it, and its absence inhibits that production (see Monod 1971 for an accessible accurate account of these two examples and a conceptual summary of theoretical reasoning in early molecular biology).

Both cooperativity and feedback phenomena formed part of the traditional repertoire of holists in biology (see the next section, which will discuss the philosophical significance of the success of such structural explanation in molecular biology).

However, the 1950s also saw the elaboration of a radically different model of biological specificity, based on the concept of *information*, which was introduced into genetics only in 1953 (Sarkar 1996). This concept soon came to play a foundational role in molecular genetics. DNA was supposed to be the repository of biological information, a genetic ''program'' was supposed to convert this information into the adult organism, and new information was supposed to result from random mutation (and be maintained by selection) and never incorporated into the genome from the environment. Crick (1958) enshrined these assumptions in what he called the central dogma of molecular biology:

> This states that once ''information'' has passed into protein *it cannot get out again.* In more detail, the transfer of information from nucleic acid to nucleic acid, or from nucleic acid to protein may be possible, but transfer from protein to protein, or from protein to nucleic acid is impossible. (153) (emphasis in original)

Information, according to Crick, was the sequence of nucleotide bases in DNA or the sequence of amino acid residue in protein molecules. Note the contrast here with the stereospecific physical model of specificity. The dogma has continued to be an important regulative principle of molecular biology in the sense that it is presumed for further theoretical reasoning: Whether it survives recent developments will be discussed later in this essay.

However, the complexities of eukaryotic genetics, as discovered in the 1970s and 1980s, already began to challenge the central dogma (but see Thiéffry and Sarkar 1998). Much of this work was made possible by the development of technologies based on the polymerase chain reaction in the 1980s. There were five salient discoveries that challenged the simple picture inherited from prokaryotic genetics (Sarkar 2005, Ch. 8) (see Genetics):

1. The genetic code is not fully universal, the most extensive variation being found in mitochondrial DNA in eukaryotes. However, there is also some variation across taxa (see Fox 1987 for a review).
2. DNA sequences are not always read sequentially in blocks. There are overlapping genes, genes within genes, and so on (Barrell, Air, and Hutchison 1976). Thus, two or more different proteins could be specified by the same gene.
3. As noted earlier, not all DNA in the genome is functional. Intervening sequences—within and between structural genes—must be spliced out from transcripts (Berget, Moore, and Sharp 1977; Chow et al. 1977). This discovery helped resolve the so-called C-value paradox (Cavalier-Smith 1978), that is, the absence of any obvious correlation between the size of the genome and the morphological and behavioral complexity of an organism.
4. The same transcript may be spliced in different ways (Berk and Sharp 1978). One consequence of such alternative splicing is that, as with overlapping genes, two or more different proteins could be specified by the same gene.
5. Besides splicing, RNA is sometimes subject to extensive editing before translation at the genome (Cattaneo 1991).

These developments have led to skepticism of the relevance of the coding model of the DNA/protein relationship and of the informational model of specificity (see the next section). Though philosophers (and some biologists) have been slow to recognize this, the credo of one DNA segment–one protein chain has long become irrelevant in molecular biology. The modern era presents even more significant challenges, as later sections of this essay will underscore.

Philosophical Interpretations

Philosophy of biology only emerged as a recognizable part of philosophy of science only in the late 1960s. In the early years, considerable attention was paid to molecular biology, especially with respect to the issue of reductionism, but starting in the late 1970s, attention within philosophy of biology began to be concentrated solely on evolutionary theory, much to the detriment of the field. Attention shifted back to molecular biology in the 1990s, with some work now being done on the question of biological information besides reductionism. Since then, classical molecular biology has

been increasingly scrutinized by philosophers, though not as much as it deserves. This section will focus on reduction and information. However, important philosophical work has also been done on other forms of conceptual change in molecular biology and, lately, experimentation in the field (Culp 1995; Rheinberger 1997).

Reduction

The first question about molecular biology that interested philosophers was whether it could be interpreted as a reductionist enterprise in the same way as the kinetic theory of matter was reductionist within classical physics (see Reductionism). The model of reduction then in vogue was due to Nagel (1961) with some modification by Schaffner (1967): It viewed reduction as a deductive-nomological explanation but with the reduced laws as the explanada (see Explanation; Nagel, Ernest). The debate soon centered on the question of whether molecular genetics was reducing or replacing Mendelian genetics. While Schaffner (1967) made the case for successful reduction, this position was attacked by Hull (1972) on the grounds that molecular biology did not have laws and theories (as logical empiricists envisioned those entities). Subsequently, an antireductionist consensus developed (also influenced by Kitcher [1984]).

This consensus was subsequently challenged by Sarkar (1989 and 1998), Waters (1990), and others, but only by rejecting the Nagel-Schaffner formal model as being relevant to substantive questions about reduction. (Even earlier, Wimsatt [1976] had argued against the relevance of the Nagel-Schaffner model.) In these analyses, what is at stake is that properties of wholes are being explained by properties of parts interacting locally. The allostery and operon models are philosophically critical exemplars of this approach because the former explains cooperativity and the latter feedback, both of which formed part of the conceptual repertoire of traditional holists (see Emergence). Enzymatic and immunological specificity provide more mundane examples. However, most of these cases are much simpler than that of providing fully reductionist explanations of quintessentially Mendelian genetic phenomena such as the segregation or assortment of alleles. In these cases—central to the question of reducing Mendelian genetics to molecular genetics—reductionist explanation remains piecemeal and, in many ways, incomplete. However, there is every reason to believe that the relevant lacunae will be filled without requiring new conceptual or theoretical resources.

Nevertheless, even during the classical era, a few anomalies remained, though none serious enough to call into question the viability of the reductionist project. In particular, there has never been a successful parts-whole account of dominance (that is, the dominance of one trait or allele over another) (see Genetics). There is some reason to believe that explaining dominance at the molecular level will require appeal to topological properties of networks, but such a move would take explanation beyond the reductionist realm (see ''Philosophical Speculations'' below).

Information

Though it is commonplace to talk of biological information, no successful formal definition of the concept in the context of molecular biology has ever been given. Because of difficulties that the concept of information encountered in the late 1980s and 1990s, this failure led Sarkar (1996) to suggest that information in molecular biology was a metaphor masquerading as a theoretical concept (Griffiths 2001) (see Scientific Metaphors). For Crick (1958), information consisted of sequences, of DNA or protein. Informally, this is what 'information' is probably taken to mean in most contexts. The first point to note is that any such definition would require that the concept of information being used *not* be Shannon's (1948) communication-theoretic notion of information, which requires the estimation of the frequency of symbols drawn from a set. Thus, mathematical information theory based on Shannon's concept simply becomes irrelevant in this context (for a contrary position, see Yockey 1992). At the very least, any usable concept of biological information must refer to individual sequences and be symbolic, semantic, or semiotic, in the sense that it must capture the idea that the sequence is a ''sign'' for something else (Sarkar 2005, Ch. 10). As such, it must account for biological specificity.

The concept was central to two related theoretical interpretations within molecular biology:

(a) that the DNA/protein relation is a genetic code, typically extended to suggest that all phenotypic traits are encoded in the DNA of the genome; and
(b) that the genome constitutes a genetic program for the organism.

As discussed earlier, developments within eukaryotic genetics began to limit the scope of the genetic code in the 1970s. Any claim of the existence of a genetic program at the very least constitutes a claim of genetic reductionism, and at the

very worst a claim of genetic determinism. Genetic reductionism must be clearly distinguished from physical reductionism (the physical explanation of properties of wholes from properties of parts, which was discussed earlier). Genetic reductionism is the claim that organismic features are satisfactorily explained by appeal to properties of genes or DNA (without recourse to properties of other molecules). It is, for instance, central to the project of developmental genetics. Such a reductionism was never very plausible; consequently, the metaphor of a genetic "program" was always troubled (Keller 2000). Nevertheless, the "program" metaphor was quite influential during the heyday of developmental genetics. As the next two sections will underscore, it does not survive even in a mitigated form in the postgenomic era. The failure of genetic reductionism makes any stronger claim of genetic determinism irrelevant.

Viewing information as sequence, Crick (1958) also proposed the *sequence hypothesis:* that the sequence of amino acid residues in a protein (also called its *primary* structure) determines its three-dimensional conformation (also called its *tertiary* structure). Attempting to show how this comes about came to be called the protein folding problem. It has never been successfully solved, and not for lack of effort (Sarkar 1998). Moreover, for many proteins, it is known that sequence alone is insufficient for specifying three-dimensional conformation. It may even be the case that the same sequence can lead to several different conformations. This failure casts additional doubts on the utility of the concept of biological information stored in the genome, at least in the sense Crick intended it. Even if the genetic code were as exceptionless and predictively successful as was believed in the 1960s, all that it would allow is the inference of an amino acid residue sequence from the DNA. If the protein sequence does not determine its conformation, ipso facto, the DNA sequence cannot. It follows that the information within the DNA cannot specify phenotypes even further removed from the genome.

To the extent that the genetic code still remains useful, a proper explication of the concept of biological information remains an unaccomplished philosophical task of some importance (see Biological Information).

The Modern Era

By the "modern era" of molecular biology is meant the period beginning with the production of large genomic sequences in the 1990s. It is also referred to as the Genomic, Postgenomic, or, less accurately, Proteomic era ("proteomic" is less accurate because, to date, there has been limited progress in proteomics; see below). What marks this era is the study of large genomic sequences, and not individual alleles that had been previously identified by their phenotypic effects.

Genomics and Postgenomics

Genomics was ushered in by the decision to sequence the entire human genome as an organized project (the Human Genome Project [HGP]), involving a large number of laboratories in the late 1980s. Subsequently, similar projects were established to sequence the genome of many other species. To date, genomes of over 150 species have been sequenced. Almost every month sees the announcement of the completion of sequencing for a new species. The sheer volume of sequence information that has been produced has spawned a new discipline of "bioinformatics" dedicated to the computerized analyses of biological data.

When the HGP was first proposed, there was considerable controversy among biologists about its wisdom (Tauber and Sarkar 1992; Cook-Deegan 1994). There were:

(i) doubts about its ability to deliver on the bloated promises made by proponents of its scientific and, especially, medical benefits;
(ii) questions whether such organized "Big Biology" projects were wise science policy because of their potential effect on the ethos of biological research; and
(iii) worries that society would be legally and medically ill-prepared to cope with the results of sequencing that came too rapidly, in contrast to the normal slower accumulation of human genomic sequence information. It was feared that legislation protecting genetic privacy and preventing genetic discrimination would not be in place; there would be a shortage of genetic counselors; and so on.

In one important respect, the critics were correct: There have been few immediate medical benefits from the HGP, and no significant such innovation seems forthcoming. Instead, recent work underscores the importance of gene/environment interactions that critics had routinely invoked to criticize the claims of the HGP (see Heredity and Heritability). However, in another sense, even the most acerbic critics should now accept that the scientific results of the sequencing projects, taken together, have been breathtaking.

Contrary to the expectations of the HGP's proponents, few successful predictions about organismic development have come from sequence information alone (Stephens 1998). However, genomic research is persistently throwing up surprises:

1. The most important surprise from the HGP is that there are probably only about 30,000 genes in the human genome, compared with an estimate of 140,000 as late as 1994 (Hahn and Wray 2002). In general, plant genomes are expected to contain many more genes than the human genome. Morphological or behavioral complexity is not correlated with the number of genes that an organism has. This has been called the G-value paradox (ibid).
2. The number of genes is also not correlated with the size of the genome, as measured by the number of base pairs. The fruit fly *Drosophila melanogaster* has 120 million base pairs but only 14,000 genes; the worm *Caenorhabditis elegans* has 97 million base pairs but 19,000 genes; the mustard weed *Arabidopsis thaliana* has only 125 million base pairs and 26,000 genes; while humans have 2,900,000,000 base pairs and 30,000 genes (Hahn and Wray 2002).
3. At least in humans, the distribution of genes on chromosomes is highly uneven. Most of the genes occur in highly clustered sites. Most of these genes are expressed in many tissues—the so-called "housekeeping" genes (Lercher, Urrutia, and Hurst 2002). However, the spatial distribution of cluster sites appears to be random across the chromosomes. (Cluster sites tend to be rich in C and G, whereas gene-poor regions are rich in A and T.) In contrast, the genomes of arguably less complex organisms, including *D. melanogaster*, *C. elegans*, and *A. thaliana,* do not have such pronounced clustering.
4. Only 2% of the human genome codes for proteins, while 50 % of the genome is composed of repeated units. Coding regions are interspersed by large areas of noncoding DNA. However, some functional regions, such as *HOX* gene clusters, do not contain such intervening sequences.
5. Scores of genes appear to have been horizontally transferred from bacteria to humans and other vertebrates, though apparently not to other eukaryotes. However, this issue remains highly controversial.
6. Once attention shifts from the genome to the proteome, or the protein complement of a cell (see below for more detail), a strikingly different pattern emerges. The human proteome is far more complex than the proteomes of the other organisms for which the genomes have so far been sequenced. According to some estimates, about 59% of the human genes undergo alternative splicing, and there are at least 69,000 distinct protein sequences in the human proteome. In contrast, the proteome of *C. elegans* has at most 25,000 protein sequences (Hahn and Wray 2002).
7. It now appears that noncoding DNA is routinely transcribed into RNA but not translated in complex organisms (Mattick 2003). It seems that these RNA transcripts form regulatory networks that are critical to development. Interestingly, the amount of noncoding DNA sequences in organisms appears to grow monotonically with the morphological complexity of organisms.
8. At least in *A. thaliana*, there is evidence of genome-wide non-Mendelian inheritance during which specifications from the grand-parental, rather than parental, generation are transmitted to organisms (Lolle et al. 2005).

An important task of modern molecular biology is to make sense of these disparate unexpected discoveries. One conclusion seems unavoidable: Any concept of the gene reasonably close to that in classical genetics will be irrelevant to the molecular biology of the future (see Genetics).

Proteomics

The term "proteome" was introduced only in 1994 to describe the total protein content of a cell produced from its genome (Williams and Hochstrasser 1997). Unlike the genome, the proteome is not even approximately a fixed feature of a cell (let alone an organism), but changes over time during development. Deciphering the proteome, and following its temporal development during the life cycle of each tissue of an organism, has emerged as the major challenge for molecular biology in the postgenomic era. This project has been encouraged by the discovery of unexpected universality of developmental processes at the level of cells and proteins (Gerhart and Kirschner 1997). For instance, even though hundreds of genes are known to specify molecules involved in transport across cellular membranes, there are only about twenty transport mechanisms in all living systems. The emergence of proteomics in the wake of the various sequencing projects signals an acceptance of the position that studying

processes largely at the DNA level will not suffice to explain phenomena at the cellular and higher levels of organization. Even genomics did not go far enough; a sharper break with the past will be necessary.

Nevertheless, in one very important sense, the emergence of proteomics recaptures the spirit of early molecular biology, when all molecular types, but especially proteins, were the foci of interest, and the deification of DNA had not replaced a pluralist vision of the molecular basis for life. In the late 1960s, Brenner and Crick proposed "Project K, the complete solution of *E. coli.*" *E. coli* (strain K-12) was selected as a model organism because of its simplicity (as a unicellular prokaryote) and ease of laboratory manipulation. Project K included: (i) a "detailed test-tube study of the structure and chemical action of biological molecules (especially proteins)"; (ii) completion of the models of protein synthesis; (iii) work on the structure and function of cell membranes; (iv) the study of control mechanisms at every level of organization; and (v) the study of the behavior of natural populations, including population genetics. Once *E. coli* was solved, and biology was supposed to move on to more complex organisms (Crick 1973, 67).

Notice that DNA receives no preferential attention at the expense of other molecular components in Project K and that the centrality of proteins as the most important active molecules in a cell is recognized. Project K accepts that there is much more to the cell than DNA; it accepts that no simple solution of the cell's behavior can be read from the genomic sequence. After a generation of infatuation with DNA and genetic reductionism, the aims of proteomics return in part to the vision of biology incorporated in Project K. However, at least in one important way, that project went even beyond proteomics as currently understood: It emphasized all levels of organization, whereas the explicit aims of proteomics are limited to the protein level. The future will probably require further expansion.

Meanwhile, work on proteins has also generated unexpected challenges. In particular, the four rules of classical molecular biology have not survived intact, and at least the last three will require some modification. It now appears—though the essential idea goes back to the 1960s—that the fit between interacting sites of protein molecules is more dynamic than in the classical model, with the active site often "inducing" an appropriate fit (see e.g., Koshland and Hamadani 2002). It also appears that a more complicated model than the original allostery model will be required to account for many cases of cooperativity. A systematic philosophical appraisal of these developments is yet to be undertaken.

Philosophical Speculations

The developments described in the last section are so recent that any attempt to interpret their philosophical significance must remain partly speculative. Some of the empirical generalizations noted will undoubtedly be challenged by further work in the near future—if the recent past of molecular biology is any guide to its future. Moreover, there has been very little philosophical attention to these developments.

Beyond Reduction?

That the four rules of classical molecular biology are being challenged, at least to some extent, is not reason enough to generate any new skepticism about the reductionist interpretation of explanation in molecular biology. They do not bring the physical explanation of wholes by parts into question. However, if an RNA-based (or other) regulatory network turns out to be crucial to explaining development (and evolution, as Mattick 2003 argues), the reductionist interpretation may be in trouble. If network-based explanations are ubiquitous, it is quite likely that what will often bear the explanatory weight in such explanations is the topology of the network. As noted earlier, some classical phenomena such as dominance have already been known to resist straightforward reductionist explanation (Sarkar 1998).

Topological explanations have not received the kind of attention from philosophers they deserve, even though networks have lately entered the center stage of scientific attention (Mattick and Gagen 2005). Here "topology" refers to the connectivity properties of systems such as networks, which, without loss of generality, can be modeled as directed graphs. The vertices of such a graph represent components of a system, and edges (between vertices), with appropriate directionality and weights, represent interactions between such vertices. How topological an explanation is becomes a matter of degree: The more an explanation depends on individual properties of a vertex, the closer an explanation comes to traditional reduction (the components matter more than the structure) (see Reductionism). Conversely, the more an explanation is independent of individual properties of a vertex, the less reductionist it becomes. In the latter case, if explanations invoke properties of a graph that measure its connectivity, then these are

topological explanations. Such connectivity measures include the number of edges in the graph, the distribution of edge degree between vertices (the "degree" of a vertex being the number of edges incident on it), and so on. (For a review of network theory, see Newman 2003). If topological explanations become necessary in molecular biology, it will mark a serious philosophical break with the reductionist classical era.

Beyond DNA Information?

As noted earlier, there is as yet no fully satisfactory account of biological information that is appropriate for molecular biology. However, the developments within eukaryotic genetics and, especially, genomics strongly suggest that the view that DNA is the sole carrier of information, however it is characterized, cannot be sustained at least for organisms more complicated than prokaryotes and perhaps not even for them. Most of the critical interactions that determine the future behavior of a cell seem to occur at the level of RNA: splicing, RNA editing, and so on. Because of this feature of cellular interactions, Sarkar (2005, Ch. 14) has speculated that the DNA genome consists of a relatively static set of sequestered modular templates (resulting in the "SMT model" of the cell), far from the classical view of the genome coding a program for development. The failure of the sequence hypothesis for many proteins only increases skepticism about the classical picture.

The routine generation of untranslated RNA transcripts from the genome also suggests that should cellular processes be viewed informationally, RNA networks form a parallel information-processing system partly independent from the genomic DNA (Mattick 2003). At present, it is unclear whether such information must also be viewed semiotically, though it seems likely, since the simplest way in which RNA sequences can be viewed as carriers of information is by the specification of information by the RNA sequences.

Similarly, the discovery of ubiquitous non-Mendelian genetic specification in *A. thaliana* (Lolle et al. 2005) also suggests that there is yet another parallel system of heredity that can also potentially be viewed informationally and, once again, is not specified through DNA. It is also possible that all such phenomena are best interpreted not informationally but using the more traditional—generally structural—conceptual apparatus of physics and chemistry. However, the distinction between the two frameworks becomes blurred in the case of RNA because the relation between the sequence and three-dimensional conformation seems to be relatively straightforward, at least much more so than in the case of proteins.

Finally, in these discussions of biological information, two issues should be distinguished:

- whether an informational framework for molecular biology is of any use; and
- whether, within any such framework, DNA (or, more restrictively, genomic DNA) is the sole repository of that information.

The problems mentioned here provide a forceful argument against the second claim, leaving open the status of the first.

Toward a Dynamic Account of the Organism

One problem with informational interpretations of molecular biology is that they have always been static: Time does not enter explicitly into accounts of biology based on the transfer of information, though, implicitly, such transfer must take place during some time interval. Recall that the proteome is not a static feature of the organism, let alone the cell: Proteomics requires a commitment to the characterization of cellular and organismic change over time. Moreover, the recent discoveries of potentially ubiquitous RNA network-based regulation also underscore the importance of dynamic accounts explicitly taking time into consideration. Moreover, new microarray techniques and their extensions are increasingly making temporal stages of cellular changes empirically accessible. The challenge remains to develop a theoretical framework to interpret the empirical information.

Any such framework can begin with either a physicalist or an informational characterization of cellular processes or a mixture of both, though prospects for a physicalist account do not seem particularly promising because of the sheer complexity of the molecular networks involved (Sarkar 2005, Ch. 10). But a dynamic informational account also leads to uncharted territory. In retrospect, what seems surprising is how successful the static framework for classical molecular biology has been, given that organisms are obviously dynamic entities undergoing development over time.

Conclusions: An Invitation

Molecular biology has not received the extent of philosophical attention it deserves, and the little it has received has been limited to the classical period (see Darden and Tabery 2005 for a more detailed summary than what has been presented here).

There are at least two reasons why philosophers should invest more work on the subject:

- Without at least a partial methodological commitment to molecular concepts and techniques, any subdiscipline within biology will likely soon be relegated to irrelevance. Philosophy of biology that does not take molecular biology into account will remain incomplete.
- Modern molecular biology raises fundamentally new epistemological questions, especially about the relevance of physical and semiotic informational accounts that have dominated discussions of biology for the last century. The deployment of philosophical (particularly formal) techniques may contribute significantly to the advancement of the field.

The most important task in the philosophy of biology for the next few decades will be to conceptualize the functional role of DNA within the cell so as to explain the surprising organization and other properties of the genome that were discussed earlier. Physical and informational accounts will probably have to interact in order to create a consistent satisfactory picture. As the last section indicates, any such attempt must necessarily begin with a clearer account than what is currently available of what 'information' means in a biological context. This is probably where philosophers have the most to contribute to the future of molecular biology (see Biological Information). Perhaps techniques from formal epistemology or semantics will enable progress where traditional biological tools have largely failed.

N

ERNEST NAGEL

(16 November 1901–20 September 1985)

Nagel was born in Bohemia and came to the United States when he was ten years old. He became a naturalized citizen of the United States in 1919. In 1923, he received a B.A. from the College of the City of New York, in 1925, a master's degree in philosophy from Columbia University, and in 1931, a Ph.D. in philosophy from Columbia. Most of his academic career was spent at Columbia, beginning with his appointment in 1931 and ending with his retirement in 1970. During his last three years at Columbia, he held the position of university professor. He died in New York City.

Nagel received many honors. He was a Guggenheim Fellow in 1934–1935 and 1950–1951. In 1954, he was elected to the American Academy of Arts and Sciences, and in 1962 to the American Philosophical Society. He was elected to the United States National Academy of Sciences in 1977.

During his more than forty years of active intellectual life at Columbia—he continued to participate in seminars and other activities after his retirement—Nagel played a central role in the intellectual life of Columbia and, in a more general way, of New York City. For several generations of students and colleagues, his critical philosophic spirit and his detailed attention to scientific methods made him an exemplar of how philosophy could be related to the sciences, both natural and social. His lecture courses and seminars were attended not merely by students of philosophy, but by a wide-ranging mixture of students from the natural and social sciences, as well as professional disciplines. These activities extended to a series of famous seminars with colleagues in other disciplines. Perhaps the best known was his long-standing seminar with Paul Lazarsfeld on methodology in the social sciences.

Nagel's own intellectual mentors were primarily Morris R. Cohen and John Dewey. Dewey was jointly appointed in philosophy and education at Columbia and was active there during the first decade or so of Nagel's years at Columbia. With Cohen, Nagel wrote what was probably the most influential textbook in logic and scientific method in the United States published in the first half of the twentieth century.

Major Works

The textbook that Nagel coauthored with Cohen was *An Introduction to Logic and Scientific Method* (Cohen and Nagel 1934). Nagel's (1939a) "Principles of the Theory of Probability," which was a contribution to the *International Encyclopedia of Unified Science* (Neurath, Carnap, and Morris 1939), was published separately (see Unity of Science Movement). Collections of Nagel's articles were published under the titles *Sovereign Reason* and *Logic without Metaphysics* (Nagel 1954 and 1956). His most important work was *The Structure of Science* (Nagel 1961); then, much later, *Teleology Revisited* (Nagel 1979) was published. What is important about his career is not only his teaching at Columbia and his role in New York City's intellectual life, but also the very large number of articles he published on a great variety of philosophical topics and, perhaps equally important, the extensive critical reviews, published mainly in the *Journal of Philosophy,* of many major philosophical works in the philosophy of science.

Some extended major critical analyses are to be found in his articles on Russell's philosophy of science (Nagel 1944; Russell 1944), Dewey's theory of natural science (Nagel 1950), and Carnap's theory of induction (Nagel 1963). In these three articles, Nagel shows many philosophical sympathies. But the striking thing about his approach is the carefulness of his critical appraisal of significant issues.

Criticism of Carnap

Nagel's critical spirit is reflected in his analysis of Carnap's use, in one form or another, of Laplace's ([1812] 1952) classical principle of indifference (see Carnap, Rudolf; Inductive Logic; Probability).

> I wish next to raise an issue that concerns not only c^* but also the whole continuum of inductive methods Carnap regards as possible candidates for explicating the notion of evidential support. Among the conditions he lays down which any reasonable c must satisfy, there are two that bear considerable resemblance to the notorious Principle of Indifference, often regarded as the Achilles heel of the classical theory of probability. The first of these stipulates that all the individuals are to be treated on par, the second introduces a similar requirement for the primitive predicates. (Nagel 1963, 797)

Here is Carnap's response:

> Nagel expresses doubts about the validity of those principles of my theory which are related to the classical principle of indifference. . . . Nagel raises objections especially against A7 [axiom of indifference] and in this context uses an illustration which refers to samples of water, taken either from different sources or from the same reservoir which is known to be homogeneous, and the like. What Nagel says about these situations and the attitude a scientist would take with respect to such samples is certainly correct, but it is no argument against A7. If the scientist X knows anything about the individuals a_1, a_2, a_4, a_5 other than that they come from the same reservoir, and if he knows either that the water in that reservoir is homogeneous or that it is not, then the knowledge of X is much stronger than the evidence e to which A7 refers. The special case of A7 formulated by Nagel is applicable only if, first, X does not know anything about the individuals a_1, a_2, a_4, a_5 other than that they have the property M and if, second, he does not know with regard to any other individual whether or not it has the property M. Nagel's error here is a case of what I shall later call the fallacy of incomplete evidence. (Carnap 1966, 991)

What is perhaps most interesting about Carnap's response to Nagel is that he does not say how to proceed if his axiom A7 of invariance is violated. Nagel, on his part, is not really suggesting a detailed alternative solution but is proposing a course of prudence in not endorsing too easily the principle of indifference.

Major Articles

Also to be mentioned is Nagel's (1955) presidential address to the American Philosophical Association, published as "Naturalism Reconsidered." It is equally worth mentioning some of the important and later much cited articles of Nagel. A reflection of his wide-ranging historical interests, as well as philosophical ones, is his influential article on the relation between the development of modern logic and the development of axiomatic methods in the nineteenth century (Nagel 1939b). Equally important is his still much cited, informal, but detailed, argument on how physicists conceive of the reduction of thermodynamics to statistical mechanics (Nagel 1949) (see Reductionism). This is a subject of great technical complexity. Nagel provides a clear analysis, showing the main ideas of the reduction, without losing the reader in the inevitable and complicated technical details. Other important works dealt with psychoanalytic theory (Nagel 1959), a much-debated topic at the time, and historical determinism (Nagel 1960).

The Structure of Science

General Issues

Nagel's (1961) most important work was his magisterial book on the philosophy of science,

The Structure of Science. It is a mark of the depth and importance of this work that more than forty years later it is still a primary reference for students in the philosophy of science. In the introductory chapter, three broad areas are identified as those of major importance for analysis. They are the

1. Logical patterns exhibited by explanations in the sciences,
2. Construction of scientific concepts, and
3. Testing and validation of scientific inferences and their conclusions.

The next four chapters are general ones. Chapter 2 concentrates on patterns of explanation; Chapter 3 on the deductive pattern of explanations, in terms of both individual events and of laws; Chapter 4 focuses on the character of scientific laws, especially the questions of their universality and necessity, a topic that has a long history in philosophy, reaching back to Aristotle. Chapter 5 is concerned with experimental laws and theories. Nagel identifies three major components of theories. The first component is the abstract or systematic calculus; the second is a set of rules that assign an empirical content to the concepts of the abstract system; and the third is an interpretation or model for the abstract calculus. What is important about Nagel's treatment of these matters is that he provides many more detailed scientific illustrations than will be found in many comparable works. In this chapter he also provides a detailed treatment of the rules of correspondence for moving from the theory and its concepts to experimental data. Chapter 6 deals with the cognitive status of theories. What is important is the contrast between three views—the descriptive view, the instrumental view, and the realist view of theories. There is here, and in many other parts of Nagel's work, an important tension between the instrumental view, in which he is influenced by Dewey, and the realist view, which he sees as close to much of the language and thought of scientists.

Foundations of Physics and Biology

In broad terms, Chapters 7–11 deal with the foundations of physics. Chapter 7 focuses on the science of mechanics and is important in providing a clear account of why mechanical explanations have played such a prominent role in scientific thinking. Chapter 8 is on space and geometry, with reference to space in Newtonian or classical physics especially. Chapter 9 is on geometry in physics, particularly on the transition from classical physics to the geometric approach of general relativity theory. Chapter 10 focuses on causality and indeterminism in physical theory. Nagel gives a detailed analysis of the language, concepts, and laws of quantum mechanics. In this chapter, he also gives a careful and nuanced account of the way in which quantum mechanics is indeterministic, and also of the way in which it is not. Here is a good passage about the way in which quantum mechanics is deterministic:

> [A]n examination of the fundamental equations of quantum mechanics shows that the theory employs a definition of state quite unlike that of classical mechanics, but that relative to its own form of state-description, quantum theory is deterministic in the same sense that classical mechanics is deterministic with respect to the mechanical description of state. However, the state-description employed in quantum theory is extraordinarily abstract; and, although its formal structure can be readily analyzed, it does not lend itself to an intuitively satisfactory nontechnical exposition. (Nagel 1961, 306)

Chapter 11 is on the reduction of theories, and Nagel returns here to his well-known formulation of the reduction of thermodynamics to statistical mechanics. Important sections are added on emergence and wholes and sums and organic unities, which take us well beyond considerations of thermodynamics. The last section contains one of the most extensive discussions of scientific psychology in the book, with critical attention to the claims of Gestalt psychologists. The careful analysis of holism in this chapter is rightly regarded as one of the classical examples of critical thought in modern philosophy of science (see Emergence). The section begins by distinguishing eight senses of 'whole' and 'part.' Toward the end of the section, Nagel has this to say about organic unities:

> [L]et us turn to . . . what appears to be the fundamental issue in the present context. That issue is whether the analysis of ''organic unities'' necessarily involves the adoption of irreducible laws for such systems, and whether their mode of organization precludes the possibility of analyzing them from the so-called ''additive point of view.'' The main difficulty in this connection is that of ascertaining in what way an ''additive'' analysis differs from one which is not. The contrast seems to hinge on the claim that the parts of a functional whole do not act independently of one another, so that any laws which may hold for such parts when they are not members of a functional whole cannot be assumed to hold for them when they actually are members. An ''additive'' analysis therefore appears to be one which accounts for the properties of a system in terms of assumptions about its constituents, where these assumptions are not formulated with specific reference to the characteristics of the constituents as elements in the

> system. A ''nonadditive'' analysis, on the other hand, seems to be one which formulates the characteristics of a system in terms of relations between certain of its parts as functioning elements in the system.
>
> However, if this is indeed the distinction between these allegedly different modes of analysis, the difference is not one of fundamental principle. We have already noted that it does not seem possible to distinguish sharply between systems that are said to be ''organic unities'' and those which are not. Accordingly, since even the parts of summative wholes stand in relations of causal interdependence, an additive analysis of such wholes must include special assumptions about the actual organization of parts in those wholes when it attempts to apply some fundamental theory to them. There are certainly many physical systems, such as the solar system, a carbon atom, or a calcium fluoride crystal, which despite their complex form of organization lend themselves to an ''additive'' analysis; but it is equally certain that current explanations of such systems in terms of theories about their constituent parts cannot avoid supplementing these theories with statements about the special circumstances under which the constituents occur as elements in the systems. (Nagel 1961, 394–395)

Chapter 12 is on mechanistic explanation in biology. This chapter anticipates the contents of Nagel's John Dewey lectures, which were delivered at Columbia in 1977 and published in the *Journal of Philosophy* in the same year, and also in Nagel's 1979 book, *Teleology Revisited.* This chapter and the later lectures provide a careful account of the importance of a scientific notion of teleology in biology, with a particular emphasis on the structure of teleological explanations. In the last part of the chapter Nagel clears a critical path between the rhetorical excesses of some organismic biologists and the unsupported dogmatism of some mechanistic biologists.

Social Sciences and History

Chapter 13 is on methodological problems in the social sciences, with an emphasis on work in sociology, but with comments as well on issues in psychology, economics, and anthropology. A notable feature of this chapter is Nagel's critique of the well-known view of John Stuart Mill that experimentation in the social sciences is not possible. Nagel shows that in fact Mill was not at all successful in trying to draw a sharp line between the possibility of experimentation in the natural sciences and in the social sciences. Chapter 14 is on explanation and understanding in the social sciences. Nagel concentrates on three important issues. The first is why statistical generalizations are to be expected as appropriate explanations of many social phenomena. The second is what the scientific status of functionalism is in the social sciences. Here ''functionalism'' refers to the doctrine that every social aspect of a culture of society has some purposive role to play, much in the spirit of teleological approaches in biology. The third issue concerns whether or not methodological individualism is the correct way to think about the methods and aims of the social sciences. One too simple view is that sociology should be reducible to psychology, group behavior to individual behavior. Nagel's detailed analysis of the subtle aspects of this controversy is among the best in the extensive literature. The final chapter, Chapter 15, is on problems in the logic of historical inquiry. Much of the focus is on philosophical problems of the nature of history that have been current for a very long time but remain controversial. To provide insight into how Nagel approaches these matters, two extensive quotations are cited. The first is on the selective character of historical data and the accompanying analysis:

> It is a platitude that research in history as in other areas of science selects and abstracts from the concrete subject matter of inquiry, and that however detailed a historical discourse may be it is never an exhaustive account of what actually happened. Curiously enough, although natural scientists have rarely been agitated by parallels in their own branches of study to these obvious features of historical inquiry, the selective character of historical research continues to be a major reason historians give for the sharp contrast they frequently draw between other disciplines and the study of the human past, as well as the chief support for the skepticism many of them profess concerning the possibility of achieving ''objective'' historical explanations. . . . Were this doctrine sound, every historical account that could be constructed by a finite intelligence would have to be considered a necessarily mutilated version of what actually happened; indeed, all science and all analytical discourse would have to be condemned in an identical manner. But the claim that all historical explanations are inherently arbitrary and subjective is intelligible only on the assumption that *knowledge* of a subject matter must be *identical with* that subject matter or must *reproduce it* in some fashion; and this assumption, as well as the claim accompanying it, must be rejected as absurd. Thus, a map cannot be sensibly characterized as a distorted version of the region it represents, merely because the map does not coincide with the region or does not mention every item that may actually exist in that region; on the contrary, a ''map'' which was drawn to scale and which omitted nothing would be a monstrosity utterly without purpose. (Nagel 1961, 576–577)

Nagel's vivid map analogy is a characteristic feature of both his lectures and his writing—finding

something concrete and familiar, but serious, to illuminate the argument.

The second problem concerns historians' use of counterfactuals:

> [N]o mention has thus far been made of a familiar special form in which historians frequently assign an order of relative importance to events, namely, when they assert contrary-to-fact conditionals about the past. . . . To cite a famous example, many historians believe that the battle of Marathon in 490 B.C. was one of the decisive military conflicts in human history; and they support this belief by the contrary-to-fact judgment that, had the Persians been victorious, an Oriental theocratic-religious culture would have been established in Athens, with the consequence that Greek science and philosophy, in which Western civilization has its roots, would not have been developed. . . . Contrary-to-fact judgments are unavoidable except by eschewing all judgments of relevance and all attempts at explaining what has happened. We had occasion to note much earlier [in chapter 4] the intimate connection between scientific laws and counterfactual statements; and, since historical explanations require at least the tacit use of general assumptions, such explanations thereby assert at least by implication contrary-to-fact conditionals. . . . Nevertheless, it is in general by no means an easy task to provide reasonably firm grounds for contrary-to-fact judgments in human history. The task is undoubtedly more difficult than the analogous task in many other disciplines, partly because (as has so often been noted) it is impossible to perform experiments on nonrecurrent events, but in large measure because of the paucity of relevant data on most of the questions about which historians make such judgments. Despite these disadvantages, the task is not quite so hopeless as is frequently claimed. (Nagel 1961, 588–589)

Nagel's way of doing philosophy is nicely illustrated by this quotation. He is skeptical of bold philosophical claims of absolute distinctions—for example, between the methods of physicists and those of historians. But he is happy to focus on distinctions or similarities that have serious conceptual or empirical support. It is sweeping, overly general pronouncements about science, its methods or its structure, that spur his critical spirit to dig into the details whatever the subject matter, be it motion of atoms or battles of the past.

The sweep of this work, with detailed analysis ranging from quantum mechanics to history, is unique among major works in the philosophy of science published in the second half of the twentieth century. In considering mathematically developed parts of science, such as quantum mechanics, he was usually, but not always, successful in conveying a definite sense of the major conceptual issues without using explicitly the mathematical concepts on which specific results depended. The goal, with philosophical readers in mind, was to talk about details but to minimize mathematical formulations and computations. How Nagel felt about the desirability of entering into the intricacies of any scientific discipline on which one wished to make philosophical remarks is well exemplified by the following quotation on the theory of natural science by Dewey, a philosopher whom Nagel admired but of whom he was appropriately critical:

> But there are also less external reasons for the hesitations which even those in full sympathy with Dewey's aims and over-all conclusions have experienced with his account of natural science. The great William Harvey is reported to have said of Francis Bacon that he wrote about science like a Lord Chancellor. Of Dewey it can be said with equal justice that he writes about natural science like a philosopher, whose understanding of it, however informed, is derived from second-hand sources. With rare exceptions, the illustrations he supplies for his major theses on the nature of physical science and its methods come from everyday inquiries of a fairly elementary kind, or from popularized versions of the achievements of theoretical physics. It is indeed curious that a thinker who has devoted so much effort to clarifying the import of science as has Dewey, should exhibit such a singular unconcern for the detailed articulation of physical theory. (Nagel 1950, 247)

Writing this summary of *The Structure of Science*, almost a half a century after it was first published, it seems appropriate to end by some comments on aspects of science and the philosophy of science that were not so evident in that earlier period but are now salient.

The first is that the treatment of causality by Nagel is too centered on determinism. At the time he was writing, one could scarcely find mention of the word *cause* in a standard statistical analysis of data, even if that were implicit in the design of the experiment from which the data arose. The situation is very different now. There is a large and complicated literature on probabilistic causality, but much of what Nagel has to say about causality is not affected by this move from deterministic to probabilistic conceptions.

The second and related point is that the discussions of statistical laws and statistical generalizations, especially in the social sciences, seem too purely empirical after half a century of building probabilistic or stochastic models of all kinds of psychological, economic, and social behavior. The origin of such models can be traced back to before the second half of the twentieth century, but the renaissance certainly did not occur until then.

Their impact has been profound and has made probabilistic modeling and ways of thinking an integral part of the social sciences and also, at the beginning of the twenty-first century, of biology. But there is little in this new emphasis that goes against any fundamental tenets of Nagel's view of the structure of science or the place of probability in it. If it had happened earlier, it is a move he would have applauded.

Third, the various chapters on the social sciences, with their emphasis on sociology, anthropology, and history, seem, in many ways, out of kilter with the main theoretical developments in the social and behavioral sciences over the past several decades. These developments have centered on the increasing use of mathematically formulated models and theories, in economics especially, and also, to a lesser degree, in psychology. If new chapters were to be added, one on the structure of modern theories of economics and another on psychology, it would be very appropriate. In terms of the most recent events, the one on psychology would also move, in a detailed way, toward the intimate involvement with the neurosciences, which will, in the rest of this century, surely have a profound impact on our scientific conception of human nature, and on the way that psychologists formulate their theoretical ideas and philosophers of science modify their conceptions about the nature of language and mental representation. But, again, Nagel would be the last to be surprised at such developments, and they would not disturb, in a deep way, his insistence that what he was after in *The Structure of Science* was to give the general framework of the scientific method, not the current details of specific disciplines.

NATURAL SELECTION

In modern evolutionary biology, a set of objects is said to experience a selection process precisely when those objects vary in *fitness* (see Fitness). For example, if zebras that run fast are fitter than zebras that run slow (perhaps because faster zebras are better able to avoid lion predation), a selection process is set in motion. If the trait that exhibits variation in fitness is *heritable*—meaning, in our example, that faster parents tend to have faster offspring and slower parents tend to have slower offspring—then the selection process is apt to change trait frequencies in the population, leading fitter traits to increase in frequency and less fit traits to decline (Lewontin 1970). This change is the one that selection is "apt" to engender, rather than the one that must occur, because evolutionary theory describes processes other than natural selection (e.g., mutation, recombination, migration, drift, inbreeding) that can change trait frequencies and can nullify the effects that selection is disposed to bring about (see Evolution). This is why heritable variation in fitness is neither necessary nor sufficient for evolution (Brandon 1990).

The logical schema just described is very abstract; the zebra example involves conspecific organisms, but it also is possible that the "objects" in a selection process might be genes, or groups of conspecific organisms, or communities of organisms from different species. The schema also leaves open how often selection actually brings about the effects that it would cause if there were no counteracting forces. Thus, the question of how the schema applies to the living world gives rise to many empirical questions, some of which have interesting philosophical dimensions.

Adaptationism

At the close of his introduction to *On the Origin of Species*, Darwin [1859] 1964, 6 says that natural selection is "the main but not the exclusive" cause of evolution. In reaction to misinterpretations of his theory, Darwin felt compelled to reemphasize, in the book's last edition, that there was more to evolution than natural selection. It remains a matter of controversy in evolutionary biology how important natural selection has been in the history of life. This is the point of biological substance that presently divides adaptationists and anti-adaptationists. The debate over adaptationism also has a separate methodological dimension, with critics insisting that adaptive hypotheses be tested more rigorously (Gould and Lewontin 1979; Sober 1993).

Although it is widely agreed that natural selection has been an important cause of the similarities and differences that characterize the living world, the question remains of how important nonselective processes have been. For example, the underlying genetic system can "get in the way" of natural selection, preventing the fittest of the phenotypes found in a population from evolving to fixation. The simplest example of this is heterozygote superiority: If there are three genotypes at a locus and the heterozygote is the fittest, the genetic system will prevent that genotype and its associated phenotype from evolving to 100% representation. Adaptationists tend to minimize the practical import of this theoretical possibility (saying, for example, that heterozygote superiority is rare), whereas anti-adaptationists often take it very seriously indeed.

Gould and Lewontin (1979) criticized adaptationists for inventing "just-so stories," in which claims about adaptive significance are accepted only because they seem intuitively plausible. They also complained that adaptationism was unfalsifiable, since a new adaptive explanation could be invented if an old one were empirically disconfirmed; unfortunately, this point also applies to the pluralism about evolutionary processes that anti-adaptationists have favored. Gould and Lewontin also criticized adaptationists for taking a naively atomistic approach to how traits are individuated. Although few biologists would regard five fingers on the left hand as a different trait from five fingers on the right (because they do not evolve independently), adaptationists have argued that female orgasm in humans evolved independently of male orgasm, subject to its own selection pressures. It is a characteristic anti-adaptationist suggestion that female orgasm is to male orgasm as male nipples are to female nipples; the traits in each pair are products of the same developmental processes. Both evolved because there was selection in one sex for the trait, and the trait emerged in the other as a correlated consequence (Lloyd 2003).

Adaptationists have replied to these criticisms in several ways. One reply has been to insist that the idea of natural selection is an indispensable tool for biological investigation (Dennett 1995). A second has been to assert that selection is the only natural process that can account for adaptive complexity (Dawkins 1982). It is noteworthy that these adaptationist replies do not address the methodological objections that the critics advanced.

One positive outcome of the controversy has been the development of more rigorous methods for testing adaptive hypotheses—for example, controlling for the influence of nonselective processes (Harvey and Pagel 1991; Orzack and Sober 2001). It is to be hoped that biologists will recognize that global affirmations or denials of the importance of natural selection are not required *before* one studies the evolution of a particular trait in a particular group of organisms. Adaptationism and anti-adaptationism, as general biological claims, are summary *conclusions* that might be drawn after the evolution of a range of traits is understood; they are not needed as *premises.*

The Units of Selection Problem

Although Darwin usually thought of natural selection in terms of different organisms in the same species competing with each other, he also thought there were traits in nature that should be explained by postulating a process of *group selection*, wherein different groups in the same species compete with each other. This idea came in for severe criticism during the 1960s, and it remains controversial to this day (see Altruism). The logical schema for the process of evolution by natural selection also has been applied to the genes that exist in a single organism; this is the process of *intragenomic conflict.* The genes in a single organism often sink or swim together—they are equal in fitness, in that each has the same chance of finding its way to the next generation. However, genes in the same organism sometimes compete. For example, in the process of *meiotic drive*, heterozygotes produce gametes that bear one allele disproportionately more than the other. *Multilevel selection theory* (Sober and Wilson 1998) is the idea that there are different "units of selection"—that natural selection occurs among genes in the same organism, among organisms in the same group, among groups in the same species, and perhaps even among species in the same monophyletic taxon (Gould 2002). This idea contrasts with the doctrine of the *selfish gene*, which says that natural selection should be thought of as a process that exists exclusively at the genetic level (Dawkins 1976; Sterelny and Kitcher 1988).

When Darwin discussed the evolution of altruistic characteristics, he saw that there could be a conflict of interest between what was good for the individual and what was good for the group. More recent work has shown that this type of conflict can arise at levels of organization that Darwin was unable to consider. For example, driving genes in the house mouse are favored at the intragenomic level but are selected against at the level of whole organisms, since they render males sterile when found in double dose. There also is selection against the driving gene at the group level, since groups whose males are all homozygotes go extinct, and the copies of the gene found in females are thereby taken out of circulation (Lewontin 1970). It is intuitive to think of selection processes at different levels as component vectors that serve to increase or reduce the frequency of a trait; the net effect of selection at all levels is the result of combining these vectors into a single resultant.

Gradualism

Darwin thought of natural selection as acting on variations that have small effects—a complex adaptation, like the vertebrate eye, does not appear all at once. This point pertains to the question of how a trait first originates in a single individual—whether its parents had 99% of an eye, or no eye at

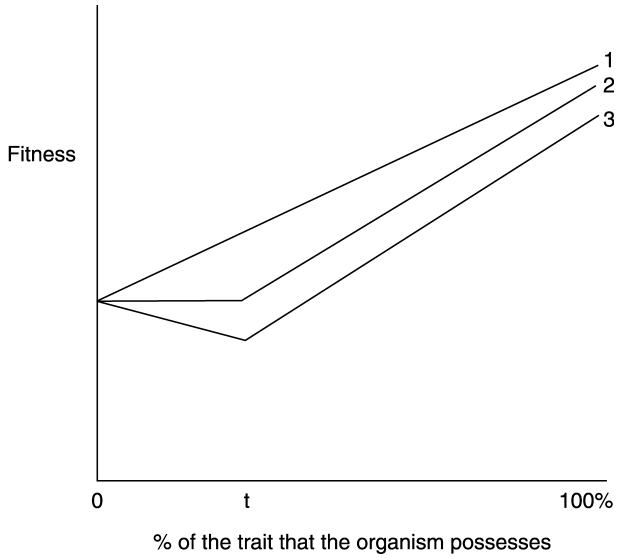

Fig. 1 What are the fitness consequences of having n% of a wing or an eye, as opposed to having $(n-1)$%? According to line 1, each small increase represents an increase in fitness. According to line 2, having more of the trait makes no difference in fitness until a threshold (t) is crossed. Line 3 also depicts a threshold effect, but here having more of the wing or eye is deleterious, not neutral, until the threshold is crossed. Evolution via the pure process of Darwinian gradualism requires the monotonic increase that line 1 exhibits and cannot occur if the fitnesses are those represented by lines 2 or 3. However, evolutionary theory countenances processes additional to that of "pure Darwinian gradualism," so, in fact, the theory says that it *is* possible for a trait to evolve under all three scenarios.

all. In either case, once the complex trait is found in a single individual, the question must be faced of how the trait is to become common in the population. Both saltationists (those who believe that evolution involves "jumps") and gradualists may want to invoke the process of natural selection to account for this. Saltation, therefore, is not an alternative to natural selection. Although Darwin did not know about Mendelian genes, much subsequent work in genetics has vindicated his gradualism. However, recent work indicates that single mutations sometimes produce large effects—for example, the *HOX* gene can cause a leg to appear on the head of a fruit fly. Contemporary biologists usually do not see this as diminishing the importance of natural selection.

If Darwinian gradualism, strictly construed, is to transform an ancestral population in which the organisms have no eyes at all into a descendant population in which all organisms have 100% of an eye, it is essential that n% of an eye represent an advantage compared with $(n-1)$%. In terms of the fitness functions depicted in Figure 1, Darwinian gradualism can occur when the fitnesses obey the pattern in line 1, but not when they conform to lines 2 or 3. However, recall that contemporary evolutionary theory describes processes other than strict Darwinian gradualism (for example, drift, to be described later, allows a less fit trait to replace one that is fitter), and so the evolution of traits whose fitness profiles conform to lines 2 and 3 is by no means impossible.

In thinking about whether a trait can evolve in conformity with the rules of Darwinian gradualism, it is important to consider the possibility that a trait might start evolving for one reason and then continue evolving for another. Perhaps rudimentary and complex eyes both evolved for the same adaptive reason, because they help the organism process information about the environment that is contained in light (Dawkins 1996). However, this pattern seems less plausible for the case of wings. Even if later wing evolution was driven by the usefulness of flying, it is hard to see how the evolution of rudimentary wings could have proceeded in this way, since 5% of a wing provides no lift at all; being able to fly is a threshold effect. Kingsolver and Koehl (1985) argue that insect wings began evolving as devices for regulating temperature and continued to evolve as devices for flying.

Progress

Is the process of natural selection an instrument of progress? This question must be divided in two, distinguishing the issue of moral progress from that of improvement in fitness. With respect to the former, Darwin clearly recognized that the process of natural selection involves a mountain of suffering and death; indeed, he sometimes expressed revulsion at the adaptations that natural selection produces. One grisly example that repeatedly drew his attention was the ability of parasitic wasps to paralyze their hosts and lay eggs in them; when the eggs hatch, the young feed on the living caterpillar, leaving its brain for last (Gillespie 1979). At the same time, Darwin often expressed approval of the changes that selection brings about in nature, and he often did so as well in connection with the workings of selection in human evolution. Whatever moral ambivalence Darwin may have felt about natural selection, it is interesting that Darwin's "bulldog," Thomas Henry Huxley (1893) thought that there was a profound conflict between what is good for us in terms of fitness and what is good for us in terms of morality, with morality obliging us to control the instincts that natural selection has put in place. These critical assessments of the moral

significance of natural selection contrast starkly with the wholesale endorsement of the process that the political movement called Social Darwinism supplied. Social Darwinism used Darwin's theory to construct a moral justification for ruthless capitalism, according to which the weak had to be crushed to make way for the strong. Many modern biologists, sobered by the political misuses of Darwinism, now draw back from this ideological endorsement. They want their science to be *value free;* that is, a scientific theory has the job of saying what changes occur in nature and why, but it is not a scientific problem to say whether those changes represent good news or bad. (See Ruse 1997 for more on how the concept of progress figures in the thinking of different evolutionists.)

With respect to the second sort of progress—the effect of selection on fitness—Darwin thought of the process as an improver. He says that "as natural selection works solely by and for the good of each being, all corporeal and mental endowments will tend to progress towards perfection" (Darwin 1859, 489). Modern evolutionary theory makes it clear, however, that the process of natural selection need not improve the fitness of organisms. Quite apart from whether improving fitness is a good thing, selection can reduce the average fitness of the organisms in a population, even when the physical environment is static. If altruists compete against selfish individuals in a single persisting population, selfishness will go to fixation, with the result that the individuals in the population at the end of the process are less fit than their ancestors were when the process began. Adam Smith's optimistic picture of an invisible hand increasing the wealth of nations has been supplemented (though not replaced) by the pessimistic picture of the tragedy of the commons. Selection can improve average fitness, but it also can reduce it (Sober 1993, 97–99).

The Propensity Interpretation of Fitness

Alfred Russel Wallace, the codiscoverer of the theory of evolution by natural selection, suggested to Darwin that he drop the expression "natural selection" because it misleadingly suggested conscious choice; Wallace preferred Herbert Spencer's phrase "the survival of the fittest" to characterize the theory (Hodge 1992). Darwin embraced this summary slogan; however, it gave rise to the criticism that the theory is a tautology. If the fit are defined as those who survive, one cannot explain why one set of organisms survived to reproductive age while another did not by saying that the former were fitter. The first step in replying to this criticism is provided by the propensity interpretation of fitness (Mills and Beatty 1977; Brandon 1990; Sober 1984). Fitness is to reproductive success as solubility is to dissolving—fitness is a dispositional property. In particular, it is a probabilistic disposition, a propensity. A fair coin is disposed to land heads more often than one that is biased in favor of tails. If one organism is fitter than another, then the first will *probably* be more reproductively successful. The natural way to represent this mathematically is in terms of the idea of a probabilistic expectation. If an organism has a probability p_i of having exactly i offspring ($i = 0, 1, 2, 3, \ldots$), then its expected number of offspring is $\sum i(p_i)$. The expected number of offspring is not the exact number one should expect the organism to have; rather, it is the average number the organism would have if it got to live its life again and again under identical circumstances. Thus, the first line of reply to the charge that the statement "a is fitter than b if and only if a is more reproductively successful than b" is a tautology is to point out that the statement is not even true. If the rejoinder comes that it is then a matter of definition that "a is fitter than b if and only if a has a higher expected number of offspring than b," the reply here is that every theory contains definitions. Even if this is the proper definition of fitness, it does not follow that the entire theory is tautologous; evolutionary biology is full of empirical claims. (For discussion of whether fitness should be defined as a probabilistic expectation, see Sober 2001.)

Chance in Evolution

One reason that fitness should be understood as a probabilistic quantity and not as an organism's actual degree of reproductive success is that evolutionary theory describes a nonselective process that can lead organisms to enjoy different degrees of reproductive success. This is the process of random genetic drift, which Motoo Kimura (1983) developed to explain the huge amounts of molecular variation observed in natural populations. Drift occurs when traits change frequency by random walk; this occurs when they are identical, or nearly identical, in fitness. Here we find a disanalogy with a deterministic propensity like solubility: If a and b are both immersed and a dissolves while b does not, then a must have been soluble and b must have been insoluble. But if a is more reproductively successful than b, it is not inevitable that a was fitter than b.

When should a difference in reproductive success be attributed to natural selection? If two identical

twins are on a mountaintop and one is killed by a lightning strike while the other is not, should we conclude that the second twin was fitter (Beatty 1991)? One way to answer this question in the negative is to argue that there is no phenotypic difference between the two twins that could form the basis for saying that they differed in fitness. This brings out another feature of the propensity interpretation—just as a tossed coin has a given propensity to land heads by virtue of its physical makeup, so an organism has whatever degree of fitness it has in a given environment by virtue of its genetic and phenotypic characteristics. However, the fact remains that the first twin was standing in one place while the second was standing in another when the lightning struck. Is this not a phenotypic difference? It is not relevant that the property of standing in a given place on a given day is not heritable; selection does not require heritability, though evolution by natural selection does. A different approach to the twins problem is to think of it statistically. If two coins are each tossed once, and the first lands heads and the second tails, standard statistical practice does not allow one to reject the null hypothesis, which says that they are identical in their probabilities of landing heads. A similar conclusion can be drawn about the twins. Notice that it does not matter that the two individuals happen to be genetically identical.

To understand the relationship between selection and drift, it is important to distinguish process from product. Evolution in finite populations always includes the process of drift, whatever change in trait frequencies may result. In similar fashion, the possibility of sampling error exists when a fair coin is tossed ten times, regardless of whether the outcome is nine heads and one tail or five of each. And no matter which outcome occurs, it is a mistake to ask "how much" of the outcome was due to the coin's fairness and how much was due to finiteness of sample size. It is useful to have both selection and drift in evolutionary theory because both categories are needed to describe relevant similarities and differences. Two populations may be characterized by the same suite of trait fitness values even though they differ in size, and two populations may have the same size even though they are characterized by different suites of fitness values.

Chance is said to enter evolutionary theory in two ways. First, mutations are said to occur "by chance." Second, random genetic drift is described as a "chance process." The term "chance" has different meanings in these two remarks. The point about mutations is just that they do not arise because they would be useful. This has nothing to do with whether mutations are deterministically caused or arise by an irreducibly probabilistic process. The relation of random genetic drift to the possibility of an underlying determinism raises issues that are more subtle. When we talk about different organisms having different probabilities of surviving and different expected numbers of offspring, how are these probabilities to be interpreted? Reasoning about Newtonian theory, Laplace ([1814] 1951) famously opined that if determinism is true, then probabilities (other than 0 and 1) are merely subjective—they reflect an agent's lack of information, not the objective chanciness of events. If this is right, then interpreting the probabilities used in evolutionary theory depends on facts about microphysics (Rosenberg 1994). However, it is worth contemplating a possibility not dreamt of in Laplace's philosophy. Perhaps nonextreme probabilities at the macro level can be objective even if determinism is true at the micro level. The actual relative frequency interpretation of probability allows for this possibility, although it is inadequate in other respects as an interpretation of the probability concepts used in science. Perhaps other, more adequate, interpretations of probability can allow macroprobabilities to be both objective and independent of whether microdeterminism is true.

What Does Natural Selection Explain?

If selection (in the form of lion predation) over many generations has favored fast zebras over slow ones, selection can explain why all present-day zebras run fast. But does it explain, in addition, why this or that individual runs fast? Sober (1984) answered this question in the negative: Selection explains only the frequencies of traits in a population, not why individuals have the traits they do. Selection is like an entrance exam—if you are required to speak English to gain admission to a room, the test explains why the room is composed entirely of English speakers. However, the test does not explain why the individuals in the room (Sam, Aaron, etc.) speak English. The phenotypes that individuals develop are to be explained by their genes and environment, not by the process of natural selection. Neander (1995) criticized this position on a number of grounds. One criticism involves an appeal to transitivity: If selection can explain why all the individuals in a given generation have a trait, and if the individuals in the next generation have the traits they do because they inherited them from the previous generation, then by transitivity, selection helps explain why the offspring have the traits they do.

Are There Laws in Evolutionary Biology?

Beatty (1991) argued that biological regularities hold only because this or that contingent event occurred in the evolutionary process. For example, if a population obeys Mendel's "law" of assortment, which says that *Aa* heterozygotes produce equal numbers of *A*- and *a*-bearing gametes, this is because there has been sufficiently strong selection against meiotic drive in ancestral populations for this fair Mendelian mechanism to evolve. However, it is a historical contingency that this type of selection pressure actually occurred. Sober (1997) replied that even if a regularity of the form "All *H*s are *F*" is a contingent consequence of the earlier evolutionary event *E*, it still can be the case that "if *E* is true earlier, then it will be true later on that all *H*s are *F*" is an evolutionary law. Rosenberg (1994) develops a different set of reasons for thinking that there are no biological laws other than the principle of natural selection. A separate puzzle about the status of laws in evolutionary biology concerns the fact that they appear to be a priori mathematical truths when spelled out carefully (Sober 1984). This distinguishes them from physical laws like the law of universal gravitation, which is empirical. A possible explanation for why the dynamical laws of evolution should be a priori may be found in the fact that fitness and other biological properties are multiply realizable (see Sober 1999 for discussion).

JOHN VON NEUMANN

(28 December 1903–8 February 1957)

It is widely acknowledged that John von Neumann was a unique scientific genius. His contributions covered the most diverse domains of pure and applied mathematics: from the axiomatization of set theory to the numerical analysis of nonlinear partial differential equations using computers. He chiefly influenced the style of modern mathematical physics and laid the mathematical foundations of quantum physics; his work on game theory opened up a whole new branch of mathematical economics; he played a major role in the design and theoretical understanding of the first computers; and his last writings have stimulated debates in artificial intelligence. During and after the Second World War, in particular under the Eisenhower presidency, von Neumann played an increasingly important role on a large number of military advisory committees.

Von Neumann's importance for philosophy of science, both historically and systematically, emerges from the foundational nature of some of the theories he developed, the universal outlook of his writings, the philosophical significance of a mathematically rigorous analysis of basic theoretical concepts, and a few explicitly methodological papers. Philosophers have often been intrigued by the visionary or utopian nature of some of his ideas. Yet these utopias were typically coined in rather precise mathematical terms, so that they amounted to highly motivating mathematical conjectures of the greatest possible scope. No wonder that the organizers of the 1954 International Congress of Mathematicians invited von Neumann to deliver "an address of the same nature as Hilbert's famous address in 1900" because they considered him as "probably the only active mathematician in the world who is master of mathematics to such a degree" (Rédei and Stöltzner 2001, 227). Von Neumann's answer was simultaneously modest and

utopian. Instead of twenty-three problems, he mentioned a single field close to his heart—the role of operator theory in quantum mechanics—and he developed it into a quest for a new relationship between logic and probability.

In his later years, von Neumann's far-reaching optimism about the role of mathematics in the sciences—from numerics to Hilbert's axiomatic method—was complemented by the then widespread idea that technology was able to control practically all aspects of politics and society. In this vein, he advocated game theory as a tool for strategic analyses and contemplated the idea of global weather control (von Neumann 1955).

From Mathematical Wunderkind to Military Strategist

Von Neumann usually impressed his company by his exceptional calculational powers and his encyclopedic memory, which reached far beyond his scientific interests. It has often been observed that his greatest pleasure was simply thinking.

János (Jáncsi) Neumann was born in Budapest as the first of three brothers into the family of the banker Max Neumann, who was given a title by the emperor Franz Josef I in 1913. At first educated privately, above all in foreign languages, he entered the Lutheran gymnasium, where his extraordinary mathematical abilities prompted his teacher to arrange tutoring by university professors. Still at school, he coauthored his first mathematical paper. Of great importance to the young von Neumann were the table conversations in his father's house, where he came to meet eminent Budapest scientists, artists, and businessmen (cf. Macrae 1992; Vonneumann 1987).

In addition to his mathematical studies at Berlin, Göttingen, and Budapest (until 1926), von Neumann took a degree in chemical engineering at the Technical University in Zurich (in 1925). Apart from the Budapest mathematicians, he was influenced by Erhard Schmidt, Weyl, and the Hilbert school. In 1927 he was appointed as a Privatdozent at the University of Berlin, where he interacted with Schrödinger. In 1929, he moved to Hamburg, but he began to believe that his prospects to obtain a chair in Germany, let alone in Hungary, were dim. After visiting Princeton University in the United States the following year, he was offered a professorship there. In 1933, von Neumann became one of the four founding permanent faculty members of the Institute for Advanced Study and remained there until his untimely death from bone cancer.

Shortly after his naturalization as a United States citizen in 1937, von Neumann became actively involved in military research into problems of ballistics, explosion shock waves, the implosion bomb, the hydrogen bomb, and nuclear missiles, among others. The respective nonlinear problems occupied the various computer projects he was associated with. In 1943, he arrived at Los Alamos to work on the Manhattan Project. He was also spending most of his time on an increasing number of advisory committees. In 1954, President Eisenhower appointed him to the Atomic Energy Commission. In 1956, some of the military leaders of these committees gathered around his bed in Walter Reed Hospital.

Among the reasons for this striking influence, his friend Ulam counts his ability "to commune with the physicists, understand their language, and to transform it almost instantly into a mathematician's schemes and expressions. Then, after following the problems as such, he could translate them back into expressions in common use among physicists" (Oxtoby, Pettis, and Price 1958, 37). Admiral Elliott B. Strauss praised his "invaluable faculty of being able to take the most difficult problem, separate it into its components, whereupon everything looked brilliantly simple, and all of us wondered why we had not been able to see through to the answer as clearly as it was possible for him to do" (Oxtoby et al. 1958, 4). During the Cold War years, von Neumann, appalled by Stalinism and totalitarianism, advocated a strategy of military strength; he criticized the opinions of those of his former colleagues on the Manhattan Project who campaigned for global disarmament.

Set Theory and the Foundational Program

Von Neumann's (1925 and 1928) first major breakthrough was his axiomatization of set theory. While Zermelo-Fraenkel (ZF) set theory used an axiom scheme that generated infinitely many axioms, von Neumann made do with finitely many. Unlike Zermelo, von Neumann held that the naive intuition of a set was of minor importance for the choice of the proper axiomatization.

Basic to von Neumann's axiom system were the concept of class and the element relation. This was in contrast to the program of naive set theory advocated by Cantor and by Hausdorff, for whom all predicate-extensions were considered as sets. Von Neumann's axiom system avoided the set-theoretic antinomies because the classes formed in them need not be sets. Thus von Neumann did not restrict the scope of predicate-extensions but allowed certain predicates to specify only classes. His works also

motivated the set theories of Bernays and Gödel (with classes and sets as two different entities), which are intimately related in the sense that either all three are consistent or none is. The theory of classes is only a conservative extension of ZF, and no axiomatization of naive set theory has yet been given—as, for instance, Quine's New Foundations intended.

A crucial step in Hilbert's axiomatic method was to prove the consistency of an axiom system, be it set theory or relativity theory, relative to the consistency of arithmetic (see Hilbert, David). In order to establish the latter, and thus to provide an absolute justification for mathematical knowledge, Hilbert developed a new proof theory, which he called *meta-mathematics.* Von Neumann (1927a) wrote a long paper that discussed the general aspects of this program and brought some new rigorous results. Seen in retrospect, some of them came close to indicating the actual limits of Hilbert's original program.

At the 1930 Königsberg meeting organized by the Vienna Circle, von Neumann (1931b) acted as the advocate of Hilbert's formalism. When in discussions there, Gödel first mentioned his incompleteness result in public, and von Neumann quickly admitted that Hilbert's foundationalist program in its original form had become infeasible, though not based on wrong intentions. However, Gödel's results, which von Neumann quickly reproduced and extended, did not tarnish the value of the axiomatic method in mathematics and the empirical sciences because, as von Neumann (1947) would put it, the concepts of classical mathematics, "stood on at least as sound a foundation as, for example, the existence of the electron. Hence, if one is willing to accept the sciences, one might as well accept the classical system of mathematics" (6). Mathematics did not amount to just abstraction and absolute rigor. It was instead characterized by its peculiar relationship to the empirical sciences. "Some of the best inspirations of modern mathematics (I believe, the best ones) clearly originated in the natural sciences" (2). In virtue of this intimate connection, mathematics and the empirical sciences shared many pragmatic criteria of success, among them unificatory power and simplicity, but mathematics additionally required "elegance" in its "'architectural," structural makeup (Stöltzner 2001).

Quantum Physics

In a 1954 questionnaire for the National Academy of Sciences, von Neumann listed as his three most important contributions: operator theory, the foundations of quantum mechanics (QM), and the ergodic theorem. The first two originated in his 1927 works with Hilbert and Nordheim and were elaborated in the 1932 book *Mathematical Foundations of Quantum Mechanics.* On the surface, the book's aim was to give a mathematically satisfactory formulation of QM in terms of operators in Hilbert space without resorting to Dirac's then ill-defined delta functions. But its lasting importance was to supply a concise and mathematically rigorous reference frame for subsequent debates about the interpretations of quantum mechanics.

Most influential were the "no-hidden-variable theorem" and the theory of measurement. Taking causality as tantamount to complete determination, von Neumann phrased the notorious causality problem of QM as a question of fact that could be resolved mathematically, accepting certain axioms. Since the dispersion of quantum mechanical ensembles was beyond doubt, the only way to restore causality was to posit hidden parameters, not contained in QM, that permitted a further subdivision of the ensembles. All such attempts contradicted the axioms assumed by von Neumann, and he consequently surmised that any causal modification of QM would amount to a drastically different theory of atomic phenomena. Contrary to his expectations, such modifications can recover quantum mechanical predictions, and Bell's analysis (1966) pinpointed the part of von Neumann's axiom system that prevented this from happening (see Locality). It was too restrictive to assume that if the physical quantities $R, S, \ldots$ have the operators $\boldsymbol{R}, \boldsymbol{S}, \ldots$, then the quantity $R + S + \ldots$ has the operator $\boldsymbol{R} + \boldsymbol{S} + \ldots$ Physically, this was reasonable when results of measurement were identified with properties of isolated systems, but "quite unreasonable when one remembers with Bohr 'the impossibility of any sharp distinction between the behaviour of atomic objects and the interaction with the measuring instruments which serve to define the conditions under which the phenomena appear'" (Bell 1966, 447).

Von Neumann's theory of measurement was based on the distinction between the irreversible measurement process and the deterministic unitary time evolution in between. Let I be the object system, II the measuring device, and III the observer. Von Neumann showed that the boundary, the Heisenberg cut, could be placed either between I+II and III or between I and II+III. Von Neumann emphasized that III remains outside any calculation:

> [f]or, subjective perception leads us out of the latter, or more precisely: it leads into the intellectual inner life of

> the individual, which is uncontrollable since it must be taken for granted by any attempt of [empirical] control. . . . Nevertheless, it is a fundamental requirement of the scientific world view—the so-called principle of the psycho-physical parallelism—that it must be possible so to describe the (in reality) extra-physical process of the subjective perception as if it would occur in the physical world, i.e., to assign to its parts equivalent physical processes in the objective environment, in ordinary space. ([1932] 1955, 223f.).

That the Heisenberg cut could be shifted arbitrarily between I and III was interpreted as suggesting a psycho-physical principle. The "as if" in the above quotation has sparked debates as to whether von Neumann took the collapse of the wave packet to be a physical process (Barrett 1999) or not (Becker 2004), and what the philosophical content of the principle of psycho-physical parallelism was. To some extent, such an alternative ascribes too realist an aspiration to the early von Neumann. As strange as it seems in retrospect, he advocated both a descriptivist approach in the style of logical empiricism ([1932] 1955, Chs. 1–4) and a metaphysical subject/object distinction (ibid, Chs. 5–6) that blatantly contradicted the empiricist criterion of meaning (See Quantum Measurement Problem; Vienna Circle).

Motivated by problems with a frequentist interpretation of quantum probabilities, shortly after 1932, von Neumann became dissatisfied with the Hilbert-space framework and investigated what are today called "type II^1 von Neumann algebras" (cf. Rédei 1997). Physically, this amounted to considering the quantum theory of systems with infinitely many particles as more fundamental than QM. Von Neumann also developed—though this was initially hardly noticed by physicists—the mathematical means for a more general algebraic approach to quantum physics: the infinite-dimensional tensor product, operator algebras or rings of operators, nondistributive lattices or quantum logic, and continuous geometry. The Stone–von Neumann uniqueness theorem rigorously established that in QM all representations of the canonical commutation relations for a finite number of degrees of freedom are equivalent up to isomorphism. This also gave a rigorous justification to the equivalence of the Heisenberg and Schrödinger version of the theory. Von Neumann (1931a) worked with the Weyl form of the position and momentum operators

$$\left(U(s) = \exp(-\frac{i}{\hbar}sx), U(r) = \exp(-\frac{i}{\hbar}rp); s, r \in \Re\right)$$

because the unbounded operators themselves give rise to a plethora of domain problems, which might even yield inequivalent representations that are not physically pathological (see Summers 2001; Thirring 1981). It took some time until physicists realized that the existence of inequivalent representations is quite the standard case in quantum statistical mechanics, which involves infinitely many degrees of freedom (e.g., the theory of ferromagnetism), and quantum field theory, where the Fock representation in which the theory is built up by creating and annihilating particles in the vacuum is not equivalent to most interacting interpretations (see Quantum Field Theory).

The great value of the operator algebras developed by Murray and von Neumann (1936) became clear only during the renaissance of mathematical physics in the 1960s. They not only exhibit a rich variety of algebraical and topological features but also permit a unified approach to problems of quantum mechanics, quantum statistical mechanics, and quantum field theory. As the Hepp-Bell debate showed (Hepp 1972; Bell 1975), this approach could also venture a stand on the measurement problem. Over the years the C*-algebraic quantum field theory developed by Haag and Kastler has produced many rigorous results about the conceptual structure of quantum field theory, among them the issues of locality, spontaneous symmetry breaking, and gauge invariance. An increasing number of philosophers of science avail themselves of this approach in analyzing the structure of quantum field theory (e.g., Clifton and Halvarson 2001) (see Quantum Field Theory).

In the same year, Birkhoff and von Neumann (1936) published their seminal paper on quantum logic. In contrast to von Neumann algebras, quantum logic, or the study of nondistributive orthomodular lattices, took off much quicker and has since become a research field in its own right (see Quantum Logic). While the subsequent developments would emphasize the logical aspects, von Neumann's own conception of quantum logic remained intimately related to his research program in axiomatic quantum physics. Already in the *Mathematical Foundations*, he held that "that the concept of 'simultaneous decidability' represents a refinement of the concept of 'simultaneous measurability'" (von Neumann [1932] 1955, 134). With von Neumann algebras in place and the frequency interpretation of probability abandoned at the end of the 1930s, von Neumann kept searching for a way to "interpret the algebraic structure representing quantum logic as the algebra of random events in the sense of a non-commutative probability theory" (Rédei and Stöltzner 2001, 154).

Ever since Boltzmann's statistical derivation of the second law of thermodynamics, the problem of

ergodicity has enjoyed philosophical significance. Historically, the ergodic hypothesis was the indispensable link between the deterministic kinetic theory of gases and the indeterministic behavior macroscopically observed in phenomena, such as Brownian motion, that were governed by the second law of thermodynamics. When the precise nature of the problem became clearer through the work of the Ehrenfests, it quickly turned out that Boltzmann's original version was too strong for realistic systems. Boltzmann demanded that the orbit of a mass point densely cover the energy shell, so that the mean value of a physical quantity on this shell (mathematically speaking, any real-valued function on phase space) was equal to the time average. G. D. Birkhoff (1931) and von Neumann (1932) found a more appropriate definition of ergodicity based on the partition of states following which a dynamically invariant state was ergodic if it could not be decomposed further into invariant states, and proved the pointwise and mean ergodic theorems, respectively. Also, the stronger condition of mixing, when the time average is replaced by the limit, goes back to von Neumann. Subsequently, other notions of ergodic behavior were introduced, and ergodic theory has become an important measure-theoretic tool for analyzing all sorts of dynamical systems (Mackey 1990). Von Neumann (1927b; [1932] 1955) also gave a definition for the entropy of a quantum mechanical system that showed the difference between the classical and quantum concepts. The field has since developed in various directions involving the relationship between entropy and information, the characterization of chaotic behavior, and a rigorous analysis of large quantum systems. Von Neumann's operator-theoretic methods, for instance, permitted an extension of the concept of equilibrium to infinite-dimensional systems (see Thirring 1983).

Game Theory and the Expanding Economy Model

"Among the many areas of mathematics shaped by this genius, none shows more clearly the influence of John von Neumann than the Theory of Games" (Kuhn and Tucker 1958, 100). When von Neumann ([1928] 1959) published his first paper on game theory, there existed, in contrast to quantum mechanics, neither well-entrenched scientific concepts nor a ready-to-use mathematical theory such as Hilbert's theory of integral equations. The introduction to *Theory of Games and Economic Behavior,* coauthored with the economist Morgenstern (von Neumann and Morgenstern 1944), was quite explicit that "mathematical discoveries of a stature comparable to that of calculus will be needed in order to produce decisive success in this field" (6). Rather than importing an unsatisfactory theory formulated in terms of mathematical concepts useful in physics, economists should strive for a mathematically precise formulation of elementary facts about simple games and, constantly comparing them with empirical evidence, approach realistic situations.

Von Neumann's most important achievement in game theory was the *minimax theorem.* It originally stated that every two-person, zero-sum game with finitely many pure strategies has a determined solution. Although in virtue of further developments its reputation changed from being "considered the elegant centerpiece of game theory" to an overly special case, it is beyond doubt that "the most fundamental concepts of the general theory—extensive form, pure strategies, strategic form, randomization, utility theory—were spawned in connection with the minimax theorem" (Aumann 1987, 6f). The *Theory of Games* focused on games of 3, 4, and ultimately n players, of both zero-sum and non-constant sum varieties. It took cooperation as a given and developed a solution concept, the stable set, which showed how any game could give rise to various stable coalition formations, depending on the payoffs available and assuming that a coalition played a 2-person, zero-sum, and thus minimax, game against its nonmembers (see Game Theory).

Through the work of von Neumann and John Nash, game theory became a general methodology that in principle applied to all kinds of interactive situations, from the formation of an industrial oligopoly to the emergence of the social contract, and had consequences for philosophical ideas about rationality (especially decision making) and ethics. More than his contributions discussed so far, von Neumann's works on game theory were embedded into the sociopolitical context of the day. His development of game theory in the late 1930s was sparked by sociopolitical developments in his native Hungary, and parts of the theory soon found application to operations research problems during World War II (see Leonard 2005).

Von Neumann also strongly furthered the development of mathematical economics by his expanding economy model. It is a closed pure production model with a profitless economy in which overproduced goods are free, and inefficient processes are not used. Assuming that every good appears either as output or input and that the total value of all goods is positive, von Neumann could prove the existence of a constantly expanding economy.

Mathematically, the problem corresponded to a system of inequalities and required a generalization of Brouwer's fixed point theorem. By interpreting the quantities and prices as vectors of a mixed strategy in a zero-sum game, von Neumann's model can be related to the minimax theorem. There is some disagreement in the literature as to whether von Neumann's expanding economy was "unlike any other economic model that preceded it" (Thompson 1987, 248) or whether "his contribution is fundamentally a technical one" (Dore, Chakravarty, and Goodwin 1989, 6) because essential features had been discovered before. Scholars also disagree whether it extends the tradition of classical political economy or represents a special case of the Arrow-Debreu-McKenzie model of pure exchange.

Computers, Automata, and the Brain

There are disagreements about the relative credits for the development of the first modern electronic computer. Goldstine (1983) puts von Neumann on top because he not only made substantial contributions, among them the stored-program concept, but also integrated all of them into a coherent whole. Although the computer at the Institute of Advanced Study (IAS) was never the most powerful machine, its logical design and the IAS reports deeply influenced a rapid and decentralized development around the world (cf. Aspray 1990; Heims 1980).

"Von Neumann is the father of modern scientific computing. His work in the major areas of this field—numerical analysis, numerical algorithms, computations, mathematical modeling, and asymptotic analysis—stands today as vital and seminal" (Glimm, Impagliazzo, and Singer 1990, 185). This gave applied mathematicians important tools to study realistic nonlinear problems instead of simplified toy models, and led to a substantial reconfiguration of the terrain between fundamental theory and actual experiment. New topics of interest to philosophers of science thus emerged; they include chaos theory, design and evaluation of large experiments on the computer, and the questions of what a simulation actually shows.

Von Neumann also analyzed the abstract foundations of computing. In this he could build on ideas that had emerged in the foundational debates, such as Gödel numbering or the universal Turing machine (see Turing, Alan). A von Neumann machine, as it was later called, consists of five components: the finite uniform memory in which instructions are stored, a central control unit that interprets instructions, a central arithmetic unit that executes operations on the data contained in memory, and the input and output organs. Memory contents can be either instructions, if executed, or data, if processed. As the machine can thus modify its own program during execution, von Neumann (1993) thought it to be brain-like. During the last years of his life, von Neumann attempted to develop a general theory of information processing automata that embraced both the technological and the biological realm and could thus serve as a rigorous and highly abstract basis to study the similarities and dissimilarities between computers and the brain. In this project he also employed the neural networks of McCulloch and Pitts (see Artificial Intelligence).

An important part of von Neumann's work was the theory of reliable computation with unreliable components, which he modeled by adjoining a probability space to a network model. In this way the failure of the components was determined in the mean. Although this thermodynamic approach did not quite succeed, it provided important insights into how complex structures could still function reliably even if their components are as unreliable as nerve cells.

Complexity studies also triggered von Neumann's (1966) theory of self-reproducing automata. Its aim was not just to produce identical copies of an automaton but to find conditions under which machines were capable of evolution, that is, of interacting with the environment and producing machines of increasing complexity. "A real difficulty here is that of striking the proper balance between formal simplicity and ease of manipulation, on the one hand, and approximation of the model to real physical machines, on the other hand" (Shannon 1958, 126). Artificial life, as this subject is called nowadays, could be trivial or intractable. Von Neumann investigated both the idea of a universal machine capable of constructing any automaton with finite means and a more specific model based on reproducing cells that had 29 possible states and interacted with their nearest neighbors. Today there exists a variety of self-reproducing automata, most famous among them the Game of Life (see McMullin 2000).

Already suffering from his fatal illness, von Neumann (1958) completed a small booklet in which he compares a serial digital computer and the neural machinery in the brain from the standpoint of information theory. Although neurons appear to operate digitally, their rather complex structure and their dependence on certain global potentials make them take on features of an analog machine as well. By a series of comparative numerical estimates, he concluded that the neural

machinery compensates missing logical depth, and poor reliability of its components by logical breadth, that is by a highly parallel architecture.

Assuming that the brain contains both a language proper based on logic and a mathematical language based on numbers, von Neumann (1958) advanced a provocative thesis on the foundations of mathematics. Since the arithmetical part of neuronal activity was of an essentially statistical character and was short of arithmetical depth, "the nervous system appears to be using a radically different system of notation from the ones we are familiar with in ordinary arithmetics and mathematics" (79). Distinguishing the complete code (machine language) and the short code (high-level programming language), he adopted the idea that a Turing machine can imitate the behavior of any other machine. Mathematics thus may well be just a short code, "a secondary language, built on the primary language truly used by the central nervous system" (82). "Just as languages like Greek or Sanskrit . . . it is only reasonable to assume that logics and mathematics are similarly historical, accidental forms of expression" (81).

To be sure, von Neumann advocated neither the contingency of mathematical truth nor a radically empiricist stand in the foundations of mathematics. One must rather view his "systematized set of speculations" (von Neumann 1958, 1) as a continuation of the pragmatist or opportunist conception of the axiomatic method outlined in *The Mathematician* (von Neumann 1947).

OTTO NEURATH

(10 December 1882–22 December 1945)

Otto Neurath was born in Vienna, the son of Wilhelm Neurath, the political economist and social reformer. After initially studying mathematics and physics, and then history, philosophy, and economics, he followed Ferdinand Toennies' advice to move to Berlin, where he received a doctoral degree in the history of economics in 1906. He studied under Eduard Meyer and Gustav Schmoller, and he was awarded the degree for two studies of economic history of antiquity, one on Cicero's *De Officiis* and the other with an emphasis on the nonmonetary economy of Egypt. With a grant from the Carnegie Endowment for International Peace, a subsequent study of the Balkan wars before World War I led to his theory of war economy as a natural (nonmonetary) economy. In 1919, the short-lived Bavarian socialist government appointed him head of the Central Planning Office. His program for full socialization was based on his theory of natural economy and a holistic requirement to bring different institutions and kinds of knowledge together in order to understand, predict, and

control the complex phenomena of the social world: unity of science at the point of action.

From 1920 to 1934, Neurath participated actively in the development of Vienna's socialist politics, especially in housing and adult education. He founded the Social and Economic Museum of Vienna, where he developed and applied the "Vienna method" of picture statistics and the ISOTYPE language (International System of Typographic Picture Education). Like the thought of other Viennese philosophers such as Wittgenstein and Popper, Neurath's philosophy was inextricably linked to pedagogical theory, and also, as in Popper's case, political thought (see Popper, Karl Raimund). In 1928, he helped found the *Verein Ernest Mach*, which, with the publication in 1929 of an intellectual manifesto, became the public face of the Vienna Circle (see Vienna Circle). Subsequently he created the International Foundation for Visual Education in The Hague and spearheaded the International Unity of Science Movement. The latter, inspired by a tradition culminating in the French Encyclopedists of the Enlightenment, launched the project of an Encyclopedia of Unified Science (see Unity of Science Movement). As with the pictorial languages, the scientific encyclopedia was supposed to promote scientific and social cooperation and progress at an international level. Neurath fled from the Nazis, first to The Hague, and then, in 1940, to England, where after nine months in an internment camp, he resumed activities related to the ISOTYPE language and the unity of science. He died in Oxford, England (see Cartwright, Cat, Fleck, and Uebel 1996 for more detail).

Science and Society: Empiricism in the Social Sciences (1910–1931)

Neurath championed the "scientific attitude." He denied any value to philosophy over and above the pursuit of work on science, within science, and for science. From this naturalistic viewpoint, philosophy investigates the conditions of the possibility of science as they appear within science itself, namely, in terms of physical, biological, social, psychological, linguistic, logical, mathematical, and other conditions. His views on the language, method, and unity of science were motivated throughout by his interest in the social life of individuals and their well-being. To theorize about society is inseparable from theorizing for and within society. Science is in every sense a social and historical enterprise. It is as much about social objectives as it is about physical objects, and about social realizations as much as about empirical reality.

Neurath drew from the spirit, if not the letter, of two major turn-of-the-century thinkers: Ernest Mach and Karl Marx. Mach introduced a radical antimetaphysical approach to the analysis of science, which Neurath embraced in part because he believed that metaphysical obscurantism, whether in German philosophy or theology, underwrote social institutions that attacked Enlightenment values such as equality, freedom, and progress (see Mach, Ernest). Neurath's aim was to apply an empirical attitude in the social sciences. He attacked the distinction drawn by Dilthey, Rickert, and Weber between the natural and the cultural (or social) sciences, which he thought rested on metaphysical concepts and nonempirical methods (the "empathic method" of understanding). A purely empiricist language would represent a big step toward unified science. Methodologically, the job of the social sciences, like the natural sciences, would be to establish empirical correlations, statistical when possible, about the behavior of social wholes or complexes or, failing that, partial correlations between aspects or parts thereof, to determine the limits of their validity, and to infer predictions about the future (including, as a distinctive feature, the possibility of self-fulfilling or self-refuting prophecies).

Neurath saw in Marxism a model of empirical social science without metaphysics, of a tool for social reform and also for the unification of sociology, political theory, and economics. He never considered himself an orthodox Marxist. However, Marx inspired in him a belief in historical holism, that there is an ineliminable social and historical context of language, concepts, and beliefs. He also inspired a belief in pragmatic holism, the Enlightenment idea that the scientific attitude and the compilation of knowledge possess a practical and socially redemptive (revolutionary) value—the social scientist is also a social engineer. This influence is reflected in Neurath's work in natural economy and his activities as a social planner. During the 1910s, he articulated an ecological program based on central planning and a nonmonetary economy. It was directed not toward the increase of monetary wealth, but toward replacing the anarchy of wasteful capitalistic production with the nonwasteful allocation of exhaustible resources and goods in a way that increased the standard of living of society as a whole ("Epicurean socialism").

Such views led to the so-called calculation debates about rational choice. In 1920, in the earliest one, Ludwig von Mises objected to socialism on the grounds that it precluded the possibility of rational economic action in the absence of a single unit of comparison and the commensurability of

different values in terms of that unit. Neurath dismissed as "pseudorational" the view that all decisions are or even can be the outcome of algorithmic, unambiguous procedures of technical calculations in an ideal language. Instead, his method acknowledged the limits of rules of reasoning and required an empirical judgment of needs and goals; it suggested, for instance, "qualitative exactness" as exhibited by the logic of relations. His method was supposed to be based on rationality in place of pseudorationality. Comparison between wholes (plans) could not always rest on a commensurability of their parts:

> The question might arise, should one protect coal mines or put greater strain on men? The answer depends for example on whether one thinks that hydraulic power may be sufficiently developed or that solar heat might come to be better used, etc. If one believes the latter, one may "spend" coal more freely and will hardly waste human effort where coal can be used. If however one is afraid that when one generation uses too much coal thousands will freeze to death in the future, one might use more human power and save coal. Such and many other non-technical matters determine the choice of a technically calculable plan. . . . [W]e can see no possibility of reducing the production plan to some kind of unit and then to compare the various plans in terms of such units. (Neurath 1973, 263)

In general, because reasons underdetermine actions, these could not always be technical decisions, the outcome of a calculus of reasons without attention to local contexts and to ethical and political judgments. In a later debate on calculation, Neurath argued that a centralized program required the coordination of available knowledge, in his case in the form of a plan for a practical, cooperative unification of the sciences.

Neurath's ideas also reflect the influence of the French conventionalist thinkers Poincaré (on underdetermination in geometry) and Duhem (on holism in physics) (see Conventionalism; Duhem Thesis; Poincaré, Henri). Their work was a recurrent topic of discussion among Neurath, Hans Hahn, and Philip Frank in the 1910s, in the so-called First Vienna Circle. Neurath's theoretical holism for the natural and social sciences is the view that a multiplicity of theories are equally supported by the same data (underdetermination) and individual hypotheses cannot be tested in isolation but only accompanied by auxiliary ones (holism). From a purely logical point of view, scientific methodology is open-ended. Just as Neurath rejected idealized languages and procedures in the practice of science, he also rejected overidealistic aims. For Neurath the objective was not to determine which theory was true, but which theory, or combination of theories, should be used in a given context for a given purpose. This may involve a decision that is ethical or political: The social scientist should examine all possible theories, scenarios, and predictions that fit the available data, in order (like an engineer) to design social machines that had never been built. In the 1910s, Neurath conceived of both economic and historical theorizing in a combinatorial fashion, *viz.*, as exploring all possible combinations of given elements.

Neurath rejected all pictures of "ideal" science as gross metaphysics. His attention to the inextricable link between science and society had several implications:

1. The amount of knowledge available can never be exhaustive.
2. The uncertainty involved in justifying decision making "scientifically" can be honestly and rationally eliminated only through the introduction of nonempirical "auxiliary motives" (to deny this limitation on the power of scientific logical justification amounts to pseudorationalism).
3. The empirical language of coordinated scientific practice cannot be precise and atomic, since the introduction of vague terms is as inevitable as it can be useful.
4. Nor can such an empirical language be private, since language is essentially social.
5. Abstract analysis of complex phenomena prompts the adoption of a multiplicity of idealized concepts such as social factors or indicators, which are value laden and historically contingent.

Scientific Language and Scientific Method: The Vienna Circle and Neurath's Logical Empiricism (1931–1935)

Neurath's later views on the language and method of science expressed his simultaneous response to problems in the social sciences and to philosophical issues addressed by the Vienna Circle between 1928 and 1934 and by Karl Popper (see Popper, Karl Raimund; Vienna Circle). A primary aim of the Vienna Circle was to account for the objectivity and intelligibility of scientific method and concepts. Their philosophical approach was to take the so-called *linguistic turn,* that is, to investigate the formal framework of scientific knowledge (the emphasis on language was familiar to Neurath from Toennies' formal approach to sociology and social signs). The dominant, and later popularized,

position was that revisable theoretical scientific statements should stand in appropriate logical relations to unrevisable statements about elementary observations (data), called "control sentences" or "protocol sentences" (see Protocol Sentences). Such relations would provide theoretical terms with cognitive meaning or sense, and theoretical statements with verification.

Neurath took the objectivity of scientific knowledge to be provided by the public and social nature of its representations and rules for acceptance. By 1931, his proposal for unifying scientific language was "radical physicalism": Scientific statements must speak of material events and things in space and time (not necessarily in the language of physics) (Neurath 1983, 52–90) (see Physicalism). Physicalism was stimulated by Marx's materialism and also by Neurath's links to the *Neue Sachlichkeit* (New Objectivity or New Factuality), the movement around the Bauhaus School in Dessau (where he and Carnap lectured). Objectivity and the avoidance of metaphysical nonsense require that statements be compared with statements, not with "reality." Protocol statements preserve linguistic empiricism by replacing talk of reality (*contra* Popper and Schlick) and of subjective sense experience (*contra* Schlick and early Carnap). With regard to the latter, he anticipated Wittgenstein's private language argument as central to the controlling function of protocol statements. Neurath motivated the social dimension of language by considering the case of the isolated Robinson Crusoe, whose own successful use of control statements requires intersubjective features of language. The correspondence between Neurath's epistemology and social thought is no surprise. Connections between private experience and private property had been drawn by Berkeley and others. More directly, Marx himself had argued that language was essentially social, and had used the Crusoe example to conclude that Crusoe's planning is a model of control in a moneyless socialized economy.

Neurath's protocol sentences are not atomistic reports of private experiences—Machian "red here now" (Neurath 1983, 91–99). They are syntactically complex; the complexity being in part the result of the physicalist or public status of the information, including the physicalist description of the fact, the spatiotemporal coordinates of the recorded event, a public reference to the observer, and, possibly, the physiological characterization of the experience. Likewise, they are also "rich in theory" and include vague unanalyzable "cluster concepts" (*Ballungen*) from ordinary languages. Lacking the ideal precision of some theoretical terms, scientific language becomes a historically shaped "jargon."

Neurath rejected both Carnap's method of verification and Popper's method, and logic, of falsification. He also rejected the foundationalist tradition of seeking a secure basis for knowledge, whether in a priori principles or in sense data. His Duhemian and historical holism extended to all sciences as well as to logic and mathematics. More importantly, it also extended to the empirical data, that is, to the protocol sentences. Even though protocol sentences provided the necessary stability to scientific inquiry that theoretical hypotheses lacked, their scientific status, insofar as they had any, was underwritten by their testability and revisability when confronted with other protocol sentences. The structure of the protocols captures the possibility of testing. This leads to the Neurath Principle: In case of conflict between a theoretical prediction and a protocol sentence, either could in principle be rejected. The adequacy of this rule is borne out by actual scientific practice. Neurath's naturalism, holism and antifoundationalism are best illustrated by his image of a boat: "We are like sailors who have to rebuild their boat on the open sea, without ever being able to dismantle it in dry-dock and reconstruct it from its best components" (Neurath 1983, 92).

Unity of Science and the Encyclopedia Model (1931–1945)

The boat image also illustrates Neurath's conception of the unification of the sciences as a historical, nonfoundational, and communal enterprise. Despite popular approaches suggesting a hierarchical/pyramidal structure, due to, among others, Comte and Ostwald (and, later, Carnap), from 1910, Neurath's approach to unification was thoroughly antireductionist: cognitively, logically, and pragmatically. Electron talk is irrelevant to understanding and predicting the complex behavior of social groups. He also dismissed the idea of *one* method and *one* ideal language—for instance, of mathematics or physics, to be followed by all the other sciences. In other words, he opposed the ideal of a "system model": an axiomatic, deductively closed, and complete hierarchy. Instead he proposed the "encyclopedia model": a more or less coherent totality of scientific statements at a given time, in flux, incomplete, and with linguistic imprecisions and logical gaps, unified linguistically by the jargon of physicalism, the cooperative and empiricist spirit, and the acceptance of a number of methods or techniques

(Neurath 1983, 145–158, 213–229). Neurath spoke of a "mosaic," an "aggregation," and an interdisciplinary "orchestration" of the sciences (Neurath 1983, 230–242). Correspondingly, his later political writings emphasized internationalism, democracy, and plurality of institutional loyalties.

NEUROBIOLOGY

Most of the issues found in traditional philosophy of science are recapitulated in the philosophy of neuroscience. In particular, philosophers of neuroscience worry about what counts as appropriate empirical justification for a theoretical claim, how to determine which level of organization is the correct one for a scientific explanation, what explanations should look like, whether all explanations will or should reduce to some primitives, and how what is learned about the mind/brain should affect larger social, economic, and political decisions (Bechtel et al. 2001; Schaffner 1993) (see Explanation; Reductionism). In addition, philosophers of neuroscience concern themselves with some traditional aspects of philosophy of mind, including how it is a brain can represent, if it does, and how and whether this representation ties to other notions of representation in cognitive science and beyond (Bechtel et al. 2001) (see Cognitive Science). It is difficult to focus on only one of these concerns to the exclusion of the rest. Most likely, as some particular aspect of the practice of neuroscience becomes understood, others will be as well. What follows discusses these areas of concern as they *differ* from traditional arguments. This discussion therefore should be seen as a complement to the very rich literature in traditional philosophy of science and of mind.

Theory-Laden Observations and Single-Cell Recordings

It is almost a truism in philosophy of science that there is no real distinction between observation and theory. That is, all scientific observations are filtered through and by a prior theoretical framework. Raw data become observations as they are interpreted regarding how they either fit or belie hypotheses (Woodward 1989). In short: what counts as an observation and how that observation functions in the business of science is heavily mediated by theory. In neuroscience in particular, it is easy to change the fundamental nature of observations

using accepted methodological techniques for manipulating raw data. The line between good data tinkering and fudging the data is quite thin.

Good data allow scientists to discriminate among competing claims about phenomena (Suppe 1989). The particular practices of the scientific subfield define how to judge whether data are good. Sometimes these practices involve explicit calculations and formal derivations; sometimes they involve matters of personal judgment and skill. The cases in neuroscience involve both. In particular, it is a matter of personal judgment in single-cell recording when to employ certain computational procedures. Different sorting techniques give rise to different data, so which techniques to employ is an important question. But it is not a question for which any good algorithm exists to answer it.

In 1791, Luigi Galvani was the first person who demonstrated the link between neural communication and electrical impulses when he stimulated frogs' legs with electricity and made them twitch. But not too much could be made of this discovery until the 1920s, when scientists developed the technology that allowed them to measure nerve impulses directly using amplified signals sent via electrodes. Not surprisingly, single-cell recording devices have improved much since then. Most importantly, perhaps, E. V. Evarts (1968) developed techniques for recording from single nervous cells in alert moving animals. But it has been only during the last decade or so that neuroscientists have been able to record from the extracellular space of a large number of neurons from awake and behaving animals.

When scientists record with an electrode near a single cell, they do pick up the cell's action potentials, which is what most people think of when they think of neuronal communication. But they also record things that look like action potentials but are actually voltages generated by axonal bundles, or the field potentials from parallel sets of dendrites. Moreover—and especially if the microelectrode has a relatively low impedance—extracellular electrodes pick up signals from several neurons at the same time, recording from all the cells in a nearby area.

The problem is how to differentiate the contributions of the different cells and cell parts with single lump recording. In many cases scientists care only about one particular action potential; the rest, from their perspective, is background noise. The challenge is how to separate what they want from all the electrical signals they do not want. The challenge is how to move from the recordings of the electrode's output to genuine, reliable, and informative data.

This challenge is compounded by the noisy nature of the recordings themselves. Some of the noise is mechanical and comes from the amplifiers, but some is biological and comes from the neurons. Brain cells jitter around constantly (cf. Connors and Gutnick 1990). Neurons are not quiet until they fire off a spike, as some might think. Instead, they are always producing some activity or other. All in all, scientists have to cull their data from quite a din.

Finally, because scientists cannot assume that anything in a recording remains constant, it is difficult to get a theoretical hook into the waveform. Spike shapes can change over time, electrodes can drift during recording sessions, changing position relative to the cells, which would also alter the spike amplitudes, and the electrical properties of electrodes vary with changes in tip condition or background impedance. Gathering data from single-unit activity presents neuroscientists with a serious technical challenge.

In order to get usable data (to get genuine observations) out of what the electrode transmits, scientists must isolate each neuron's contributions to the recorded waveform. They first need to ascertain exactly how many neurons the recorded waveform reflects. How can they do this if they have a mess of overlapping action potentials and field potentials from a variety of cells at different and unknown distances from the electrode? This question becomes particularly vexing if other neurons in the same area have spikes of the same or similar shape and amplitude.

There are several decomposition algorithms, albeit imperfect ones (Lewicki 1998). Each represents a different way to move from raw output to interpreted and interpretable data, giving scientists different ways of refining the waveforms they have recorded so that they can later interpret them. Each is what philosophers are thinking about when they talk about the theory-ladenness of data. Scientists have to choose what to do with their measurements in order to get something that can be scientifically useful. And how they choose is determined by previously accepted theories.

But even with all these advanced sorting techniques, it is still hard to predict the number of neurons eliciting the data. Ideally, scientists would like to claim that one neuron generates each cluster of spikes they have identified, but if the cells are firing in complex bursts, or if there is nonstationary noise, or if the spike trains overlap one another, they cannot get accurate classifications at all. It is simply an unsolved problem how to decompose coincident action potentials with variable spike

shapes. The best scientists can do at this point is guess. Their guesses are informed by their years of experience, but they are guesses nonetheless.

Guessing is not quite what philosophers of science have in mind when they talk about the theory-ladenness of observation. Their vision of creating data is one of a more "scientific method." That is, to pull data out of the dial movements or changes in color or squiggles on the page, philosophers generally hold that there is some explicit background theory, devised in some other scientific inquiry, that scientists learn and then use to interpret what they are seeing or measuring as something useful for their studies. But there is a theoretical gap in the move from raw recordings to genuine data, which cannot be filled with any sort of decision-making algorithm. The best scientists can do at this point is simply leap across the gap, on blind faith, with an eye to where they want to go.

Neurophysiology travels in a cognitive circle; scientists use what they know to cull data that support what they believe to be the case. Nevertheless, progress is not stymied. Knowledge accrues in small increments, with each set of single-cell recordings altering the face of what is known a wee bit at a time. Because neurophysiological sorting techniques rely so heavily on previously accepted neurophysiological hypotheses, there will likely never be an abrupt or dramatic conceptual revolution. But what is known can evolve slowly but surely until the final resting position is quite far removed from where it started.

Localization and Reduction

When scientists do single-unit recordings from a set of neurons, they assume that they are busy examining a discrete system. They have been wildly successful using this strategy, identifying at least 36 different topographical visual processing areas in cortex (De Gelder 2000), differentiating the "what" from the "where" object processing streams (DeYoe and Van Essen 1988; Mishkin, Ungerleider, and Macko 1983) and distinguishing motion detection from contour calculations (Barinaga 1995), to name but a few examples. Maps of brain function are getting more and more complicated as more and more is learned about the processing capacities of individual cells. And all these projects are founded on the belief that brains have discrete processing streams that feed into one another.

Yet, the most neurons scientists have ever been able to record from simultaneously are around 150; the most cells they can ever see summed local field potential activity over are a few thousand. But brain areas have hundreds of thousands of neurons, several orders of magnitude more than they can access at any given time. And these neurons are of different types, with different response properties and different interconnections with other cells, including other similar neurons, neurons with significantly different response properties, and cells of other types completely. Any conclusions scientists draw about the behavior of whatever cells they are recording from are going to be limited to very basic stimulus-response and correlation analyses of whatever neuronal subtype they are currently examining. Hence, the functionality they ascribe based on these relatively meager sorts of experiments might be much more restricted than what the cells are actually doing.

They insert an electrode in or near a cell and then record what it does as they stimulate the animal in some fashion. They record from a cell in a vestibular nucleus and then move the animal's head about to see if that changes the activity of the neuron. If it does, then they move it some more or they move it differently and see how that changes the neuronal output. If it does not, then they try either another nearby cell or some other stimulus. But what they cannot do is record from all the neurons in some isolated area, even if the area is very small. And what they cannot do is test any given cell for all the known functional contributions of brain cells in general. So, what they conclude about any cell will reflect only the cells they or others have actually recorded from using stimuli they or others have actually used. This research strategy systematically underestimates when neurons actually respond and under what conditions.

This sort of unit study attempts to combine scores, hundreds, or even thousands of single-unit recordings together to try to analyze the population. Theoretically, perhaps a nervous system region could be stereotaxically delineated if it had reproducible correlations between afferent and efferent connections such that researchers could ultimately articulate the neurophysiological function of the defined region. However, the likelihood of success for this type of study decreases as the complexity of the organism increases. Scientists can draw functional conclusions regarding the activities of neurons in the abdominal ganglia of *Aplysia* or the segmental ganglia of the leech. But the architecture of these organisms' central nervous system is so different from mammals' that the probability of successfully using similar techniques for understanding humans is very low.

In addition, the actual processing of information that goes on in those cells involves lots of different

kinds of excitatory and inhibitory inputs from other areas in the brain stem, cerebellum, and cerebral cortex. The dorsal horn is supposed to integrate afferent nociceptive information from the periphery and pass it on to the motor system, but it does not do that segregated from the rest of the brain's activities and ongoing processes. It is integrating and passing on any number and variety of data as the animal is trying to pursue prey or flee from an enemy. Moreover, the brain regions that perform these tasks are often connected to the very area scientists are recording from. The motor system feeds back down into the dorsal horn, as does the thalamus and significant parts of the cortex.

The impact on cognitive processing of such rampant feedback connections in the brain is only now starting to be explored in neuroscientific research, though exactly how to do this remains a difficult question. Neurophysiologists design their experiments keeping in mind the known anatomic connections between and among the relevant structures. At the same time, any actual experimental observations of all the remote influences on the dorsal horn, for example, are impossible, no matter how many individual neurons scientists record from. They simply do not have any way of conducting such extensive, invasive tests on live animals. At best, the particular influences assumed in any particular recording series are a matter of previously accepted gospel, dogma, and faith.

Ideally, neuroscientists try to conjoin their single-cell studies with some sort of lesion experiment. Once scientists construct a general flowchart of the relevant structures based on anatomy experiments and have estimated normal unit behavior from a series of single-cell studies, they then try to knock out the hypothesized functions by placing lesions in otherwise normal animals. They run these experiments based on the assumption that these lesions, placed in regions known to be important, will change the unit behavior of cells they are studying in a consistent fashion. If they witness such a change, they use that information to explain the relative functional contributions of the lesioned region to the cells under scrutiny. In other words, they are using lesion studies to try to derive a functional boxology for the brain, just as cognitive psychologists use reaction time distributions and error measurements to find one for the mind.

But there is a larger theoretical concern. What neuroscientists know, but generally ignore, is that any functional change in the central nervous system will lead to compensatory changes elsewhere. Because it is highly plastic, the brain will compensate elsewhere for a lesion made in one of its sections (e.g., Merzenich et al. 1983). Usually these compensatory sites are not components in the system or region being studied. But even if they are, neuroscientists ignore plasticity of the brain in favor of assuming a consistent functional alteration as caused by the lesion and nothing more. How are investigators supposed to evaluate some observed functional change when the difference they see might have been evoked by the brain's attempt to compensate for its loss and not by any specific deficit induced by the lesion?

The short answer is that they cannot if they are restricted to single-cell recordings and lesion studies. To answer this question, scientists need to be able to see the activity of the entire brain at once and over time. The excitement over functional magnetic resonance imaging and other imaging techniques concerns exactly this point: Researchers do have a way of looking at the activity of the whole brain at one time as tied to some cognitive activity or other. But magnetic resonance imagining, the best noninvasive recording device currently available, has a spatial resolution of only about 0.1 millimeter, and each scan samples about a half second of activity. This imprecision forecloses the possibility of directly connecting single-cell activity—which operates three to four orders of magnitude smaller and faster—with larger brain activation patterns.

Here is how most functional imaging studies work. Experimenters pick two experimental conditions that they believe differ with respect to the cognitive or perceptual process under investigation. They then compare brain activity recorded under one condition with what happens in the second condition, looking for regions whose activity levels differ significantly across the two. These areas, they believe, comprise the neural substrates of the task under scrutiny.

This so-called subtraction method has no way of determining whether the differences found are actually tied to the cognitive process or to something else occurring concurrently but coincidentally. Methodological difficulties with current imaging techniques are now well known and shall not be rehearsed here due to space limitations (see Bechtel 2000; Cabeza and Nyberg 1997 and 2000). Notice that how well the subtraction method will work depends upon the sensitivity of the measuring devices—the worse the instrument is, the better the method seems to be for localization studies. A low signal-to-noise ratio (SNR) means that neuroscientists will find only a few statistically significant differences across conditions, which is just the sort of result they need in order to bolster any claims

identifying particular cognitive processes with discrete brain regions.

But as the imaging technology improves and the SNR increases, more and more sites will differ across trials. The more sites that differ, the more it looks as though essentially the entire brain is involved in each cognitive computation. Thus, any assumption of functional specificity in the brain can be justified.

Neuroscience is a victim of imprecise instrumentation. If scientists extrapolate from what they might learn with more sensitive measures, it can easily be seen that there will come a time when this whole approach just will not work anymore. Put in the harshest terms, brain imaging seems to support reductionism because it is not very good yet.

For example, Brodman area 6 appears significantly active after subtraction in studies of phonetic speech processing, voluntary hand and arm movements, sight-reading of music, spatial working memory, recognizing facial emotions, binocular disparity, sequence learning, idiopathic dystonia, pain, itch, delayed response alternation, and category-specific knowledge, to list only a subset of activities in which it is significantly and differentially active. It could be the case that if neuroscientists keep on doing the sort of subtraction studies they are doing currently, then eventually they will find a unifying and pithy way to describe what premotor cortex is doing. In this instance, neuroscience would be on the right track to determining brain function, but scientists still have a long way to go yet. It could also be true that how a region functions depends heavily on the "neural context." Its functional role in a cognitive economy depends on how it is connected to other areas and how those other areas are responding. (The function of these areas would also be dependent on their particular connectivity and the current patterns of activation.) If this is correct, then searching for *the* function of particular areas is misguided, for different brain regions play different roles depending upon the cognitive tasks at hand.

Neuroscientific Theories

Brains are complicated and messy affairs; theories about brains share these same traits. The difficulty is that in order to make a simple generalization about how some aspect of the brain functions, scientists have to retreat to such a broad level of abstraction that their assertions become almost empirically meaningless. In order to make their claims testable in a laboratory, neuroscientists have to confine their ideas to particular animals, to particular experimental tasks, or to both. As a result, they end up with neuroscientific "theories" that contain two distinct parts: a broad statement of a theoretical principle and a set of detailed descriptions of how that principle plays out across different animal models and experimental tasks. Though the detailed descriptions fall under the general principle, they are not immediately derivable from it. Moreover, as described below, the detailed descriptions can be incompatible with one another, though each will maintain a family resemblance with the others.

At a gross level, mammalian brains are remarkably similar to one another. Indeed, the central nervous system (CNS) in invertebrates is not all that different from the mammalian CNS either. There are innumerable homologous areas, cell types, neurotransmitters, peptides, chemical interactions, and so forth. However, there are important differences beyond these surface resemblances.

For example, consider the semicircular canal of the ear. All mammals have roughly the same five end organs in their ears to support their auditory and vestibular systems, which all work to keep the lateral semicircular canals parallel to the horizontal plane relative to the Earth; keeping it in that position allows mammals to get the best possible information about head position in space. (The lateral canal is maximally excitatory to a yaw [left to right] head motion; keeping the canal in line with the horizontal plane allows the organ to detect this motion with the greatest accuracy.) But rodents ambulate with their necks extended, which keeps their heads in an extreme dorsal position, while humans incline their heads about twenty degrees when walking naturally. In general, the differences in the shape of the semicircular canals in the ear with skull shape are correlated with the position that an animal's head is normally in.

For another example, consider the retina. There are striking differences between herbivores and predators in brain structure, for creatures who munch on grasses and trees require much less precise environmental information than those who hunt moving targets in order to survive. As a result, rodents have no foveae. To maintain visual fixation on a point, they move their necks, using what is known as the vestibular-colic response. The vestibular system in their ears tells them how their head is oriented and they use that information to reorient their heads in order to keep whatever object currently fascinates them in their line of sight.

In contrast, primates have foveae and move their eyeballs to keep their target within the foveal area,

using the vestibular-ocular response. This is a much more precise orienting mechanism, which allows them to move their eyes to compensate for changes in head position such that they can keep objects foveated for as long as they wish. For some indication of how important computing horizontal eye motion is to primate brains, consider that the abducens (or sixth) nerve in humans, which controls horizontal eye abduction, feeds into one of the biggest motor nuclei in the brain stem. This ocular nucleus, which controls only one very tiny muscle, is only slightly smaller than the nucleus that controls all of the twenty or so facial muscles.

In more striking contrast still, bats do not maintain ocular position in the same fashion as the rest of the mammals. Because they fly and so have greater freedom to move in three-dimensional space, maintaining body position relative to the horizontal is not an easy option. As a result, they use other sense organs, primarily hearing (the other half of the eighth nerve), to determine how their eyes should be oriented. Consequently, they need not rely on vestibular-ocular responses, as primates do, even though their bodies are equipped with such reflex machinery.

All of these anatomical and physiological differences are important when neuroscientists want to investigate something, like how the brain learns to compensate for damage to the vestibular pathways. What may seem as small and insignificant differences from a broad mammalian perspective becomes hugely important as scientists seek to understand the particular mechanisms of brain plasticity. Can they use animals with no foveae and a vestibular-colic response to learn about how foveated mammals recover their vestibular-ocular response? More generally, how well do particular animal models translate across the animal kingdom? Should scientists be allowed to generalize from experiments on a single species (or set of species) to how nature functions?

In all vertebrates, a unilateral labyrinthectomy (UL), or a lesion of the labyrinthine structure in one ear, gives rise to two types of ocular motor disorders. There are static deficits, such as a bias toward looking toward the lesioned side when the head is not moving, and dynamic deficits, such as abnormal vestibular-ocular reflexes, which occur in response to head movements. In only two or three days following the UL procedure, the brain starts to compensate for its loss and the static deficits disappear. Since labyrinthine structures do not regenerate, and peripheral neurons continue to fire abnormally, whatever the brain is doing to recover has to be a central effect. Single-neuron recordings from a variety of animals indicate that the vestibular nuclei on the same side of the brain as the lesion start to show normal resting rate activity as the brain learns to compensate for its injury. Scientists do believe that whatever the mechanism is, it is also likely to be a general procedure the brain uses for recovery, for there are similar resting rate recoveries of the sort seen with the ipsilateral vestibular nuclei following denervation in the lateral cuneate nucleus, the trigeminal nucleus, and the dorsal horn, among other areas. Exactly how an argument to defend these convictions is supposed to run, though, is unclear, since it is fairly easy to find significant differences in how organisms recover and compensate for vestibular damage across the animal kingdom.

Frogs, for example, appear to rely on input from the intact labyrinth to regulate the resting activity of the vestibular nuclei. Mammals, however, do not. The recovery of their vestibular nuclei occurs independent of transcommissural inputs. In addition, static symptoms follow different time courses in different animals. In rats, spontaneous nystagmus disappears within hours after UL, while in the rabbit and guinea pig, it persists for several weeks. In humans, it may continue in one form or another for several years. There is a fundamental tension in neuroscience between the big picture and what is found in particular instances. All sciences strip away features of the real world when they devise their generalizations. Physicists neglect friction; economists neglect altruism; chemists neglect impurities, and so on. However, what neuroscientists are doing is not analogous to what the physicists, economists, and chemists are doing. In each of the other cases, the scientists are simplifying the number of parameters they must consider in order to make useful and usable generalizations. In contrast, if neuroscientists were to ignore the differences they find across species, then they would have no data left to build a theory with. There is nothing left over, as it were, once neuroscientists neglect the anatomical and physiological differences found in the brain across the animal kingdom. There is much left over when physicists neglect friction—most of classical mechanics is left, in fact. In contradistinction to the other sciences, there is a tension in neuroscience between the general rules one hopes to find that describe all brains and the particular cases neuroscientists happen to study.

What should the scope and degree of generalization for neuroscientific theories be? It is an unpleasant choice. Either scientists settle for large-scale abstract generalizations, which gloss over what may be important differences, or they focus on

the differences themselves, at the expense of what may be useful generalizations. However, despite appearances, it is not an either–or proposition that has to be resolved before scientists can move ahead, for a proper neuroscientific theory contains both general (and fairly vague) abstractions, as well as detailed comments on specific anatomies and physiologies. The paradigmatic theories of physics are simple elegant equations with universal scope. Theories in neuroscience read more like a list of general principles plus detailed commentaries. One feels the tug of the dilemma posed above only if one is operating with a restricted notion of what a scientific theory is. Some theories are pithy and succinct; some are not. Neuroscientific theories are not.

In neuroscience, what scientists start with is a theoretical description at the most general level; it might be called the ''theoretical framework''—the most general component in a neuroscientific theory. Once they adopt the framework, they can make more precise hypotheses as a way of filling out their theoretical proposal. These claims can be local to particular phyla or species; hence, they are not intended as a more detailed specification of the general framework. Instead, they can be thought of as instances or examples of how the framework might be cashed out in particular cases.

However, it is not the case that all ''fillings out'' fail to generalize. For example, the dynamic symptoms of unilateral labyrinthectomy recover using a different mechanism (probably). One hypothesis is that brains use a form of sensory substitution to compensate for the vestibular-ocular reflex. In this case, the brain uses internally generated signals from the visual or somatosensory systems to compensate for the vestibular loss. It may substitute computations from the saccadic or a visual pursuit system, both of which (probably) reconstruct head velocity internally, for vestibular throughputs. Data drawn from experiments on frogs, cats, and humans indicate that they all apparently use the same mechanism, though it remains to be seen whether this proposal will be applicable to all creatures and can be generalized much beyond vestibular reflexes.

There are different degrees of abstraction one might use once some theoretical framework is adopted. Some discussions are going to be restricted to a single species, or maybe even one developmental stage within a species; others will include several unrelated species or phyla. Both are legitimate ways of cashing out the framework in particular instances, and neither is to be preferred over the other. The data will dictate the scope of subhypotheses, and scope can vary dramatically.

And this is how theories in neuroscience are built and structured. Detailed conclusions regarding a single animal model give rise to general theoretical principles. These principles inspire new experiments done with other animal models, which in turn provide new (and probably incompatible) details but also new general principles. These new principles then connect to other detailed studies using different protocols on still other animals, and so on it goes.

At the end of the day, there is a set of related theoretical principles that jointly compose a general theoretical framework. These principles are held together by the detailed data coming out of a wide variety of animal studies. Neuroscience continually moves between two different ways of understanding the nervous system, first in broad and sweeping strokes and second by being submerged in the minutiae. General theoretical principles arise out of and then feed back into particular animal experiments done on different animal models. Because physiology differs across species, specific experimental protocols are appropriate only for specific models. Sometimes the data arising out of the different animal models or different experimental procedures overlap, but largely they do not. Hence, sometimes the detailed conclusions are consistent, but sometimes (a lot of times) they are not. Neuroscientists weave a story through their animal models and experimental protocols united by a common guiding theoretical thread. They both find commonalties and define differences. This entire exercise, taken together, fashions the theoretical structure of neuroscience.

Representation in the Brain

Important to keep in mind is that brains are evolved products, formed to help animals feed, flee, fight, and reproduce. This contrasts with digital computers, say, which are designed to compute. Early cognitive science generally took minds to be importantly analogous to computers and so tried to build theories of representation that spanned what both computers and humans did (see Cognitive Science). Contemporary neuroscientists think of representation in terms of brains only.

Most operate implicitly under the assumption that individual neurons are the representational engine that drives brains. This assumption is not universally accepted in neuroscience, but it does provide a good starting point nonetheless. As indicated above, the difficulty with looking at the behavior of individual neurons is that it rapidly becomes extremely complicated.

Hence, many working in the area of brain representation carry out their research looking at artificial neural nets, which have the advantage of being much simpler and easier to control than what nature has provided, so it is much easier to design and carry out experiments on them. But this very usefulness becomes a disadvantage because scientists cannot be sure that the behaviors they get out of them are relevantly similar to what is seen in the brain. What representations look like in them are multidimensional phase spaces, which is quite different from what traditional philosophers envision when they speak about representations. Whether a phase-space approach will replace traditional approaches to representation in philosophy remains to be seen.

Part and parcel of the problem of understanding representations is understanding learning, or how creatures get representations in the first place. Brain organization is remarkably constant across structures. Cortex is cortex is cortex. Therefore, most specialized areas have to be carved out via experience. The postulated mechanism for producing such changes is nothing more than Hebbian learning, a mechanism first articulated in the 1940s: Repeated activation will cause future activation to be easy; decreased activation will make future responses more difficult (Hebb 1949).

But to get directed learning, one must combine a learning mechanism with some sort of reward system. Animals need a reason to repeat an event in order to learn about it. Things that feel good they repeat. Things that do not they avoid. Much is now known about reward networks, especially those involving fear conditioning in rats. These give scientists some clues about how all sorts of reward-based learning might be going on in brains, though whatever the final story is, it will be unquestionably more complicated than what is known now.

Neuroethics

As progress is made into understanding how the brain works and how to influence brain functioning, serious ethical questions arise concerning how leaders in such fields as medicine, government, and insurance should react to new information and possibilities (Marcus 2004). This is a newly burgeoning area of research, with national attention only now being focused on the issues. Particular questions that philosophers of neuroscience will have to answer concern how and whether scientists should alter normal functioning brains, how and whether scientists should use brain technology to track individuals' social behavior, and how and whether what is learned about the brain changes how philosophers think of being human.

Scientists know a lot about how memory works and, more importantly, how it fails. Ways in which memory can be imperfect include:

1. Decreased accessibility to memories over time,
2. Lapses in attention,
3. Temporary inability to access stored information,
4. False recognition of things,
5. False remembrance of things,
6. Contamination of stored information by current beliefs, and
7. Recollection of items at inappropriate times.

All of these processes are perfectly normal and occur in everyone at some time or another. Suppose there is some way of correcting some or all of these deficits? Should doctors do it? Or should they accept less-than-perfect memories as the way humans are?

Neuroscientists are already tracking where and how moral decisions are made in the brain; they are also looking at brain differences between normal and sociopathic, psychopathic, and violently impulsive individuals, who respond to violent or otherwise disturbing situations with increased activity in the amygdala and decreased activity in the frontal lobes relative to normal. Scientists can now identify such trends in individuals before they actually commit any crime. Should they? And what should they do with such information once they have it?

If it is concluded that violence is biologically based, as are all other behavioral decisions, then what does this say about notions of self or free will? How might this alter the court systems, since they operate under the assumption that one is guilty if one could have done otherwise in a situation but chose not to? Similar questions arise regarding gender differences in the brains. Female brains differ from males'. What effect, if any, should this fact have on educational systems, social expectations of gendered behavior, or men's and women's professional lives?

Philosophers and neuroscientists are only beginning to confront these sorts of questions, and technology is only beginning to allow scientists to understand and change the brain to any significant degree. The questions philosophers need to confront in the next decade will differ greatly from these, as knowledge of the mind/brain continues to increase exponentially.

OBSERVATION

Empiricism is the doctrine that all our ideas are based on observation. In his classic statement of the doctrine, Hume (1967) maintained that ideas are built from sense impressions by habits of association based on constant spatiotemporal conjunctions. Twentieth-century logical empiricists criticized Hume as having focused too narrowly on psychological association as the way ideas "come from" experience. For them, the problem was to provide a logical rather than a psychological construction of ideas. Their interest in science led them to emphasize this concern by speaking of "observation" rather than "impressions." Their approach through language led them to speak of "observation terms" rather than "observation." These terms were to be distinguished from the terms based on them, which came to be called "theoretical."

A major attempt to carry out this modern version of the empiricist program is well illustrated in the career of Rudolf Carnap, arguably the most influential proponent of what came to be called logical empiricism. In his first major work, *Der logische Aufbau der Welt*, written in 1922–1925, Carnap (1967) attempted to develop a "constructional system" that would be a step-by-step derivation, or construction, of all concepts from "a few fundamental concepts" (1). Such a construction could, he argued, be achieved by building on either a physical or a psychological basis. The advantage of a physical approach would be that "from the standpoint of empirical science the constructional system with a physical basis constitutes a more appropriate arrangement of concepts than any other" (95). But Carnap chose a psychological approach because of his intention "to have the constructional system reflect not only the logical-constructional order of the objects, but also their epistemic order" (101). He called this basis "auto-psychological" or "solipsistic," declaring that it "could also be described as *the given*" (102). In later discussions, the basis on which meaningful concepts could be built (from which they could be derived by logical construction) was widely spoken of as "the given."

It is important to note that the basic elements on which the rest of our concepts are built—what later would be called "observation"—were taken implicitly as synonymous with the deliverances of the senses or some subset thereof. Thus Carnap says, "The basic elements, that is, the experiences of the self as units . . . we call *elementary experiences*" (108). Hempel, writing later, implicitly made the same point: In regard to an observational term, it is possible, under suitable circumstances, to decide

by means of direct observation whether the term does or does not apply to a given situation.

Observation may here be construed so broadly as to include not only perception, but also sensation and introspection; or it may be limited to the perception of what in principle is publicly ascertainable, that is, perceivable also by others (Hempel 1958, 42). Hempel's broadest conception of observation was still limited to "perception" and "sensation and introspection."

Defense of this empiricist doctrine required dealing with three major tasks.

1. *Arriving at an appropriate interpretation of what is to be considered a sense perception*. That is, classical empiricism had to make clear exactly how what is purely given in sense perception, free of interpretation, is to be distinguished from other ideas that are supposed to be based thereon. These other ideas include all concepts and beliefs that go beyond the purely given in sense perception, *viz*., the theoretical ones.
2. *Showing in what sense, and precisely how, those other ideas are based on sense perceptions*. Here we must distinguish between two kinds of ideas: concepts (terms) and propositions (statements having truth values). The focus of this article is on concepts, particularly that of observation; propositions and their testing are relevant only insofar as beliefs established as putative knowledge will be found to shape the formulation of the concept of observation. As to the testing and establishment of propositions, there were two distinct schools of empiricism. The first, often taken to be represented by Bacon, Hume, and Mill, held that our propositional beliefs are based on sense perception by being derived from (or constructed out of or otherwise induced from) sense perceptions. (In the case of Hume, this is a logical reconstruction of his psychologistic view.) The second view of propositions was the hypothetico-deductive (H-D) view, taken by most logical empiricists, according to which our propositional beliefs are based on sense perception in that they must be tested in terms of their implications regarding sense perceptions. Thus, each school had its task laid out. Traditional empiricists would have to show the exact way or ways in which the derivation or induction is made in accordance with specifiable rules whose origin and justification can be understood. Adherents of the H-D view would have to say something about how hypotheses are obtained and show precisely how those hypotheses are to be tested.
3. *Clarifying whether or not ideas are to be counted as knowledge, and why*. That is, the task was to show, first, whether some beliefs legitimately count as knowledge, as opposed to others that do not; and second, if so, why they count as knowledge. The latter task is generally taken to entail showing whether putative knowledge is about a world existing independently of sense perception or is only a coherent or usable way, perhaps one of many, of organizing or relating items of sense perception.

Failures of the Empiricist Program

It is widely admitted today that empiricism, logical or traditional, failed to deal successfully with its three basic tasks.

As to the first task, no clear specification was ever provided of what is to count as a sense perception (or linguistic observation term, as logical empiricists preferred to say), as distinguished from what is based thereon. To guarantee objectivity, the basis would have to be completely free from all interpretation and presupposition whatever: Interpretations should be constructions, conclusions from our perceptions, not assumptions buried within and potentially biasing them. But such a pristine, raw, brute "given" was never found, and the search for it is now generally recognized to have been an utter failure.

This failure carried over to afflict treatments of the second issue: If it remained unclear what was supposed to be the basis of all our other ideas, it also remained unclear whether all our beliefs might be infected by presupposed interpretations that would destroy any claims we might make to having knowledge. But even when a particular vocabulary was taken for granted as the basis (for example, as consisting of unanalyzable sense data, or as a language of objects), it was not clear how the nonbasic terms—the theoretical ones—were supposed to be based on the given. Even in *Der logische Aufbau*, Carnap realized the impossibility of giving all theoretical terms explicit definitions formulated by means of the basis; some terms could be understood only by "definitions in use" (65–67). In *Testability and Meaning*, first published in 1936–1937, Carnap (1954) developed this idea in terms of "reduction sentences," which were implicit rather than explicit definitions of theoretical terms. In *The Methodological Character of Theoretical Terms* (Carnap 1956), he introduced yet another view of

the meanings of theoretical terms, as partially dependent on the meanings of other theoretical terms within a theory.

Responses to the third issue were equally inadequate. For example, the acceptability or rejectability of beliefs appeared not to be understandable in terms of pure, given sense perceptions. That issue also faced further objections, independent of the failures with the first two. Usually on technical grounds, no attempt to develop an inductive logic achieved consensus among philosophers, whether it attempted to show how beliefs could be obtained directly from such sense perceptions or how they could be tested (confirmed or disconfirmed) by sense perceptions.

The development of Carnap's thinking, as outlined above, encapsulates the broader development of empiricism during the twentieth century, and of the concept of observation in particular. Four decades of intense critical analysis showed that, at least in any sense compatible with the programs of traditional and logical empiricism, the attempt to clarify the "logical structure of the world" had failed.

This summary provides a general characterization of attempts to deal with these issues; however, it will not discuss further attempts, or the criticisms they provoked. Discussion of them is omitted here not simply because these arguments and criticisms are by now familiar, or because it is so widely accepted that they show the indefensibility of empiricism, in either of its two versions, but because they do not confront the really fundamental difficulties of the empiricist program. They show only that all efforts to provide an adequate version of the doctrine have failed *so far*, but they offer no indication whether that quest might still succeed, or whether it is wrong in principle. Though they show *where* classical empiricism went wrong, they fail to show *why* it did so—why, for example, its apparently genuine motivation, to avoid any subtle infusion of bias into inquiry, to let nature speak for itself, was misguided (if indeed it was), or why the effort to show how knowledge is based on sense perception failed. Further, the criticisms offer no guidance as to whether or how classical empiricism might be defended, or, if it could be, then in what directions it requires alteration. For such reasons, putting those criticisms at the center of the diagnosis of what was wrong has meant that in recent times, inquiry into the basis and implications of science has wandered without clear direction.

We need to gain more positive insight into two aspects of the failures: first, the fundamental reasons for them, thus answering the question of whether the program was rightly conceived but difficult, or wrong in principle; and second, the positive directions in which a more adequate view of science might be sought. A first step toward such positive insight can be taken by examining the following question: Even if the program of classical empiricism could be successfully fulfilled, what would have been omitted from our understanding of science? This question can be answered through close examination of a case of scientific research that exposes central aspects of the nature and role of observation in sophisticated modern science. Those aspects lead us to a view of observation, and of science generally and how to understand it, that is very different from that of traditional and logical empiricism and reveal far more fundamental reasons for the failures of those views than have been discussed above.

An Alternative View of Observation: Example and Formulation

The question of the source of energy that makes the stars shine arose in the nineteenth century from thermodynamics. The sun was known to be a typical star; its total energy output could be calculated from the amount received on Earth. None of the proposed sources of this energy (e.g., gravitational contraction, chemical burning, meteoritic impact, radioactive decay of heavy elements) were adequate to produce that amount. It was not until the advent of nuclear physics in the early 1930s that a promising theory of stellar energy production could be advanced. Hans Bethe and Carl von Weizsäcker proposed a detailed series of nuclear reactions taking place in the center of the sun at the high temperatures and pressures expected to exist there; the series begins with hydrogen and ends with the production of helium with the release of energy. Once produced, the energy would work its way to the solar surface and from there be emitted, some of it arriving on Earth.

By the time the energy reaches the surface of the sun, it has been degraded and transformed by interactions along the way and is released as electromagnetic energy, through electromagnetic interactions that are very different from the postulated nuclear processes in the deep interior. Thus neither the information obtainable through observing the solar surface nor the inferences made on the basis of them could give direct information about what went on in the central core. How then could the theory be tested in a more direct way?

The possibility of such a direct test lay in another major area of physics in the twentieth century,

which developed the theory of weak interactions. A by-product of the Bethe–von Weizsäcker nuclear processes would be the production of neutrinos, or weakly interacting particles. Unlike the electromagnetic photons degraded by interactions while passing through the sun, these weakly interacting neutrinos would travel through it with extremely low probability of interacting with a single particle of the sun's bulk. They would pass directly to Earth (in the clear sense of not being interfered with and altered on the way) exactly as they were when created in the solar core. Of the enormous number of neutrinos that reach the Earth, most would pass right through it, just as they passed through the sun; but a very tiny number would interact with an appropriate target substance (chlorine in a container the size of a railroad car filled with ordinary cleaning fluid) to produce radioactive argon, with a half-life of roughly 35 days. Despite the infinitesimal number of argon atoms produced, it was shown that these atoms could be extracted from the tank before decaying. Their decays could be monitored and counted, to reveal the number of occurrences of neutrino captures, that is, if account was taken of other possible processes mimicking the production of radioactive argon. The total number of neutrinos produced in the center of the sun by the Bethe–von Weizsäcker processes could then be calculated. That number would constitute *unaltered* information about the nuclear reactions in the solar core and therefore would provide a direct test of the nuclear theory of solar (and stellar) energy production.

Though much of the reasoning involved must be omitted here, a few of the complexities of this test are evident even from this brief summary:

- the body of failed theories of stellar energy production;
- the new theories entering into the conception of the experiment (and their variety, including not only the electromagnetic, weak, and nuclear forces and their modern quantum-theoretic background but also the knowledge that the sun is a star);
- the feasibility of the experiment (e.g., What would be a good target substance, with a product having a convenient half-life? Could the "neutrino telescope" be constructed? Could the product, argon, be removed efficiently from the enormous volume of liquid? How could mimicking processes be guarded against?); and
- the interpretation of the results (What would be the implications of the numbers of neutrinos found?).

But there are dozens of other pieces of what can be called "background information" for the conception, execution, and interpretation of the experiment: Where should it be built? How can one clean the tank so as not to contaminate it? and so on. (See Shapere 1982 for further details about the experiment and its historical roots, and also the theory of observation discussed below.) Without a great deal of background information, not all of it plausibly classified as theoretical, the experiment would have been, in the most literal sense, inconceivable; without a great deal of background information (often different from that involved in conceiving the experiment), it would not have been executable; and without still other background information, its results would not be interpretable.

With only minor qualifications (Shapere 1982), scientists refer to this experiment as an observation (or an experiment set up to make an observation) of what goes on in the center of the sun, made in order to test the theory of stellar energy production in a direct way, which according to physics, cannot be done by relying on electromagnetic information received from the sun's surface. Calling this an observation is fundamentally at odds with the concept of observation in traditional and logical empiricism. But the usage has justification, partly as follows.

Empiricism identified two distinguishable aspects of observation: evidential and perceptual. It thus maintained that the problem of *what counts as evidence* is identical with the problem of *what is given in sense perception*. Further, it held that this given was free of any interpretation whatever (including background information), so that to explain observation was to explain what is given in experience, and simultaneously to explain what counts as evidence in testing a hypothesis or theory. The attempt to fill this out failed; but the point is that, for understanding science, *the attempt was misguided from the start*. In sophisticated cases of observation in modern science, the evidential and perceptual functions are separated, and the focus is on the former. There are good reasons for this. In its concern with testing, the focus of modern science is on observation as evidence, not on observation as perception. Correspondingly, sense perception is limited and unreliable in important ways; the perceptual aspect appears as an interference with the evidential. Therefore, for the purposes of scientific observation, the human eye, which is subject to error, is replaced by detectors that are not. True, to be useful for scientific purposes, the data must be finally put into a form accessible to human senses, but that is only because we are the ones who use the evidence. The real work of collecting evidence, the

scientifically relevant aspects of observation, has already been done independently of the senses. The role left to sense perception is minimal; what is crucial is possession of the background information required to interpret the results.

The analysis of this experiment suggests a new view of observation in science, summarized as follows.

Statement *O*: An entity *X* is said to be *observable* if (1) information can be received by an appropriate receptor and (2) that information can be transmitted directly, that is, without interference, to the receptor from the entity *X* (which is the source of the information). Correlatively, something can be said to be *observed* if it meets these two conditions, with "is" substituted for "can be." This account of observation is heavily dependent on the accepted content of the science (the background information) of a particular era, particularly regarding what is counted as an appropriate receptor, as information, as the types of information there are, and as interference. (Indeed, although this cannot be shown here, Statement *O* in its entirety depends on the way things are.) Each of these is specified in light of the background information that makes possible the conception, execution, and interpretation of the experiment.

This dependence on background information might suggest that the present view resembles the views of such writers as Norwood Russell Hanson, Paul Feyerabend, and Thomas Kuhn. In contrast to the empiricist tradition, those authors argued that observation is "theory-laden" (Hanson 1958), or that "the meaning of observation sentences is determined by the theories with which they are connected" (Feyerabend 1965, 213) or that "no experiment can be conceived without some sort of theory" (Kuhn 1970, 87). However, the view outlined in the present article differs from those in a number of fundamental ways.

For one thing, in contrast to Kuhn, the view of this article is that there is not simply one basic idea (paradigm) or small set of ideas (elements of a disciplinary matrix) operating in all scientific problem situations. As science develops, a pool of background information also develops, and some items from that pool may be used in one problem stuation (such as an experiment) and different ones used in another.

Second, whereas Feyerabend frequently claimed (e.g., 1978) that in science "anything goes," this article holds that the items used in specific research must be specifically relevant to the situation at hand.

Third, unlike both Feyerabend and Kuhn, this article maintains that the background information used in an observation or experiment (as well as in other aspects of scientific research) is not always a theory (much less a paradigm or a disciplinary matrix). Many separate items of background information are brought to bear in particular problem situations; some of those items are naturally called theories, but others, such as how to clean the tank in the solar neutrino experiment, are not. Furthermore, many different theories enter in as background information (nuclear physics, electromagnetic theory, weak interaction theory, etc.), and so do many nontheoretical items.

Finally, as regards Hanson: Dealing with particular problems of observation, experiment, and theoretical research does require background information; but being "laden" with the sorts of background information described in this article does not violate objectivity. (Hanson himself did not say that it does, but his view has often been taken to imply this). Only beliefs that have been established are eligible to serve as background information. (This point holds against Feyerabend also: It is not the case that anything goes.) How this establishment comes about, however, cannot be discussed in the brief space available here.

Fundamental Weaknesses of the Classical Empiricist Program

We now return to the question of whether the empiricist program failed merely because of its difficulty or because it was fundamentally misguided. The points to be made are these:

1. Even if all our knowledge were shown to be ultimately based (in whatever sense) on sense perception, the nature of knowledge and of knowledge seeking would still not be understood by focusing only on that ultimate. That is, even if it were really the ultimate, much more would still need to be understood.
2. Furthermore, not only is the classical empiricist approach insufficient to understand science; its methods and problems are largely irrelevant and are even a hindrance.

In the sixteenth through eighteenth centuries, when classical empiricism was first presented systematically, it was reasonable to try to consider scientific concepts as being exhaustively interpretable in terms of sense perception, at least under some views of that term. Even though it was initially plausible, however, such a program has become more and more difficult to maintain as science has developed. If one were not too strict about adherence to the directness of sense perception, some problematic cases (e.g., the concepts of force, inertia, and space; forms of electromagnetic

radiation beyond the visible) might still be assimilated within the program. But in an increasing proportion of cases in the nineteenth century and (especially) the twentieth, the selection of what was to be observed, how it was to be observed, its description, and the interpretation of the significance of the observation all grew increasingly distant from what was perceptible by the senses.

Again, the solar neutrino experiment provides an example of this departure. It purports to give direct observational evidence of processes occurring in the center of the sun, which is certainly not accessible to sense perception. Or if we say that it is neutrinos we observe, they are not accessible to sense perception either. The role of concepts such as these (e.g., force, neutrino) in science would still remain to be analyzed even if they were, as classical empiricists maintained, based on sense perceptions.

But those roles, and the reasoning involved in them, are crucial to science. The assumption of classical empiricism was that reflection on what could be constructed on the basis of sense perception was both necessary and sufficient for understanding what happens in scientific investigation. It is neither.

First, it is not sufficient, since no matter how sense perception is interpreted, its analysis (even as conceived in mature logical empiricism, with a theory of definition or logical construction) would still not make possible an understanding of the process of seeking and attaining knowledge, or the nature of knowledge, or the implications of the existence of knowledge, by considering solely the ultimate perceptual basis of knowledge or of claims to knowledge.

Second, in modern science, sense perception is only barely necessary, relegated to the periphery of inquiry as it is, and indeed as it must be, in some of the more sophisticated areas of modern science. As noted above, the role of sense perception was reduced dramatically during the nineteenth and twentieth centuries. Sense perception has been found to be too unreliable, in understandable ways, to depend on for the precision and the sophistication required in modern science. New instrumentation has been required to gather information that we have reasons to believe is available but is beyond the grasp of human sense perception. Sense perception still has a role to play in such investigations, but at least in the most sophisticated areas of science, that role now lies in the last stage of the inquiry, when the information received by the instruments (the receptors that replace our senses) is transformed into humanly accessible form. Otherwise, sense perception is relied on as little as possible in carrying out the important stages of obtaining the information and of interpreting it as information. Surely there is something paradoxical in saying that sense perception is fundamental to the scientific enterprise while at the same time it has come to be regarded as so peripheral to that enterprise.

Conclusions and Implications

Two conclusions must be drawn. First, *even if* we assume that a clear understanding of the idea of interpretation-free sense perception could be obtained, and *even if* it could be shown that all scientific concepts and propositions (and particularly those that we are justified in calling knowledge) are ultimately based on such sense perception, the most important reasoning in science will still have been neglected. For example, the central body of reasoning by which scientific ideas have been arrived at, especially in the twentieth century, would have been completely ignored.

Second, even assuming that classical empiricism were to obtain a clear interpretation of what is to count as pure sense perception, we would still be forced to recognize that this is only peripheral, not central, to understanding science and its processes. It is basically unsuitable for the investigations that modern science undertakes, and it appears only when the data achieved in an experiment have to be translated into humanly accessible form.

From the perspective of an attempt to understand modern science, the almost exclusive focus of empiricism on the role of sense perception in constructing or testing scientific ideas was a red herring. It called attention away from the centrally important aspects of scientific reasoning, which has led us to our present views of the universe and our place in it. It deflected attention away from the role of background information in scientific reasoning and activity and from the sources of the background ideas that are used, both specific ones and the general fact that their use almost defines what it is to be "sophisticated" modern science. Since that focus was a red herring, distracting attention from the truly important problems, criticism of classical empiricism on the ground that it never succeeded in specifying what counts as a sense perception, free of all interpretation or assumptions whatever, is largely beside the point. Such criticism is certainly correct, and its correctness certainly undermines the assumption, made above for the sake of argument, that the objection might have been surmountable. But the arguments just made show that even if it had been surmounted, classical empiricism would have given only the most peripheral and superficial insight into the workings of science. Thus not only is the objection profoundly unilluminating,

its negative quality giving no direction to better understanding; it also distracts us from seeking the fuller and better understanding that is needed. Finally, and worse still, focus on this feature of the failure of classical empiricism has opened the way to abandoning any version of the project of empiricism—traditional, classical, or other—and, with that abandonment, giving up the claim that science can achieve, and indeed in many cases has achieved, knowledge.

The standard criticisms of classical empiricism are only symptoms of deeper problems. The classical empiricist program was misguided from the start by fundamental misunderstandings of what is involved in the process of seeking knowledge and in the nature of the knowledge sought. Its fundamental motivations were thus misguided in principle. In particular, the classical empiricist tradition took a wrong turn in insisting that background beliefs ought not to be appealed to in scientific inquiry—that the hazards of bias and error, so dreaded by classical empiricists, would result from the use of any sort of background beliefs in inquiry, whatever those background beliefs might be. All these ideas and worries were phantoms, products of basic misconceptions about the nature of inquiry and knowledge.

The worst part of the story is that even while logical empiricism is widely admitted to be defunct, its more potent phantoms persist. Its anthropomorphic concepts of observation and theory, together with its denial and consequent neglect of the centrally important roles of background information, have continued to haunt, dominate, and confuse discussion in the philosophy of science.

Some writers still defend a ''constructive empiricism,'' which ''requires theories only to give a true account of *what is observable*'' (van Fraassen 1980, 3). Constructive empiricism does not require belief in the existence of unobservables; science requires only minimal empirical adequacy. The thrust of van Fraassen's arguments is directed against realistic treatments of theoretical purported entities. Limitations of space prevent full discussion of the implications of the present view for that topic here; however, one aspect is indicated by van Fraassen's (1980) remark that ''[s]cience presents a picture of the world which is much richer in content than what the unaided eye discerns. But science itself teaches us also that it is richer than the unaided eye *can* discern'' (59).

He distinguishes our being able to observe Jupiter through a telescope from our ability to observe particles moving in a cloud chamber (16–17); in the former case, astronauts will someday be able to get close to Jupiter and perceive it, whereas in the latter case, the inference from track to particle is based only on an analogy with seeing a jet trail in the sky and inferring the existence of a plane up there. As van Fraassen notes, this clearly distinguishes the perceptible from the nonperceptible. But is this relevant to the issue of realism regarding the particle? This entry has contended that the evidential, not the perceptual, is scientifically relevant. Scientists do talk—and for good reason, as was argued earlier—of observing particles in a cloud chamber just as they do of being able to observe the core of the sun by means of neutrinos. Thus if the question of observation is relevant to the question of realism, the latter must be resolved not by considering what is perceptible to the senses but by examining the evidential aspects of observation.

Despite all its criticisms of classical empiricism, the present view does not depart, at least in spirit, from that doctrine. It agrees with classical empiricism that *all our knowledge of the world (universe) is based on interactions with that world and its contents*. As the case of the solar neutrinos brings out, what counts as an interaction is determined by our knowledge and can differ in different fields, though there is always, at least in sophisticated science, a relationship of ancestry and descent (or cousinhood) between the different usages in different fields. We must learn, through investigation, what to count as an interaction. We also learn what to count as information, and as appropriate receptors, which may make use of more types of interaction than sense perception and may even exclude or severely limit appeal thereto. And we apply what we learn, as background information, in our subsequent inquiries.

In short, the view presented here is a *rational* descendant of classical empiricism. While still maintaining (on the basis of reasoned arguments) that we must interact with the world around us if we are to learn about it, this view nevertheless departs from classical empiricism in maintaining that we learn how to investigate nature by learning what it is to be an interaction, a piece of information, an appropriate detector, and much else. By building on what we have learned (i.e., by using background information) we learn how to learn, to think, and to talk about nature and how to assess what we have achieved when we have learned these things. This doctrine therefore emerges as a corrective to classical empiricism, a transition brought about in the development of science from an initially necessary reliance on sense perception, and the equating of sense perception with observation, to a distinction between the two and a focus on observation in

the sense of evidence as the basis of inquiry and knowledge.

If we must have a name for the view, it can be called *interactional empiricism*, to distinguish it from the perceptual focus of classical, logical, and constructive empiricism, which together could equally well be called perceptual empiricism. Kosso (1989) calls his very similar view the "interaction-information account" of observation. This is fine, since information is an essential part of the account presented here.

But the important contrast with classical empiricism, captured in the name "interactional empiricism," lies in the idea of our interaction with nature. The present view is both a generalization of and a departure from classical empiricism. It is a generalization of that view in the sense that it involves considering sense perception as having to do with only one minor region of the electromagnetic spectrum, a manifestation of one of four fundamental forces (types of interaction) with nature. But it departs from classical empiricism in holding that we learn to go beyond the dictates of sense perception. In this double sense, of generalization and departure *on the basis of reasons*, the view presented here is a rational descendant of classical empiricism, just as the concept of Statement *O* is a rational descendant of sense perception.

PARSIMONY

The principle of parsimony—or simplicity (treated here as an equivalent concept)—is also known as Occam's (or Ockham's) razor, after William of Occam, the medieval philosopher who said that plurality is not to be assumed without necessity and that what can be done with fewer assumptions is done in vain with more (Wood 1996, 20–22).

Scientists and philosophers often claim that the *parsimony* of a theory is relevant to deciding whether the theory is true or approximately true or would make accurate predictions. How this can be so is a central puzzle in the epistemology of science. It is not puzzling that people find parsimonious theories aesthetically attractive and easy to understand and manipulate. What requires elucidation is not the pragmatic value but the *epistemic* value of parsimony.

Just as people are said to be parsimonious when they are abstemious in how they spend money, a theory is parsimonious when it is tightfisted with respect to the entities, processes, or events it postulates. There is no cutoff separating theories that are parsimonious from theories that are not; rather, the difference is a matter of degree. The fundamental idea is comparative: One theory is more parsimonious than another. For example, if one theory postulates causes A and B to explain an observed effect E, while a second theory postulates only cause A and does not mention B, the latter theory is more parsimonious.

One epistemically significant feature of this difference is that if A and B are mutually independent, then according to probability theory the conjunction $(A \wedge B)$ will be less probable than A. Does this mean that parsimony and probability always coincide? In what follows, it will be seen that a number of philosophers have strenuously denied this. And even in the case at hand, there is reason to be careful about the suggestion. The second theory is "agnostic" about the relevance of B. But now consider a third theory, which asserts that A is a cause of E and denies that B is a cause. This third theory is "atheistic" about B and is more parsimonious than the first theory. However, probability theory does not say that $(A \wedge \neg B)$—that is, $(A \wedge \neg B)$—is more probable than $(A \wedge B)$. The hypothesis that there is at least one cause of E is more probable than the hypothesis that there are at least two causes, but there is no a priori reason to think that exactly one cause is more probable than exactly two. Parsimony has an obvious link with probability when a logically stronger hypothesis is compared with a hypothesis that is simpler and logically weaker; however, when two theories are mutually incompatible, the connection is anything but obvious.

The giants of the Scientific Revolution frequently referred to the importance of parsimony and its cognates. In *De revolutionibus orbium caelestium*, Copernicus emphasizes that his heliocentric theory differs from Ptolemy's geocentric theory in that the Ptolemaic system requires an independent model for the motion of each planet, whereas the Copernican system unifies the models for the different planets by including a common Earth/sun component in each. Copernicus remarks that his approach "follow[s] Nature, who producing nothing vain or superfluous often prefers to endow one cause with many effects" (Kuhn 1957, 176–179). Newton ([1686] 1953), in *Principia mathematica*, states as his first rule of reasoning in philosophy that

> we are to admit no more causes of natural things than such as are both true and sufficient to explain their appearances. To this purpose the philosophers say that Nature does nothing in vain, and more is in vain when less will serve; for Nature is pleased with simplicity and affects not the pomp of superfluous causes. (3)

Leibniz ([1686] 1973, 11) defended parsimony as a criterion in scientific reasoning by appeal to his doctrine that God created the best of all possible worlds; our world is perfect because it is "at the same time the simplest in hypotheses and the richest in phenomena." For all these thinkers, the methodological principle rests on an ontological foundation. The principle of parsimony should be used in reasoning because nature is simple, and nature is simple because God made it so.

With the falling away of divine design as an acceptable justification of methodological principles, a fissure appeared in the foundation of scientific inference. If the principle of parsimony cannot be justified by tracing it back to a parsimonious creator, what could its justification be? Does the justification of the principle require any substantive assumptions about the natural world? Or is the principle just part and parcel of what it means to be "rational," which we are required to be no matter what the world is like? If the theological account is the thesis, its antithesis is the idea that the principle of parsimony is purely methodological. In between these two extremes, there is much room for accounts that reject both.

Local Versus Global Accounts

Most attempts to explain the epistemic relevance of parsimony treat the problem globally. They assume that if parsimony is epistemically relevant across a range of problems involving inference, the reason for its relevance must always be the same. However, it is worth pondering the possibility that the justification for using a principle of parsimony may vary from problem to problem. Perhaps parsimony needs to be understood not globally but locally (Sober 1990).

As an example, consider the long-standing use of parsimony as a criterion for inferring phylogenetic relationships in evolutionary biology (Sober 1988). Given a set of observed similarities and differences that characterize a set of species, how are these data to be used to figure out which species are closely related and which are related more distantly? A standard procedure is to find the phylogenetic tree that requires the smallest number of changes in "character state" to explain the data. This methodology assumes that the species are genealogically related and proceeds to identify the most parsimonious hypothesis concerning what the pattern of relatedness is. However, there is a prior question about phylogeny: Why think that the observed species have any common ancestors? Perhaps each species can be traced back to a separate origin.

The role of parsimony in answering this question can be understood by examining Crick's (1968) argument that the near universality of a single genetic code among the organisms now on Earth is evidence that they are all genealogically related. Crick says that the shared genetic code is arbitrary—one

among a large number of viable mappings of nucleotide triplets onto amino acids. However, once an organism uses a given code, its fitness is likely to be compromised if it or its descendants modify the code already in place. Stabilizing selection then makes it highly probable that descendants will use the same genetic code as their ancestors. These biological assumptions (which Crick summarizes in the phrase "frozen accident") entail that the universality of the code would be very surprising if the organisms now on Earth were not genealogically related (e.g., were products of 27 separate startups) but is precisely what one should expect if all life can be traced back to a single progenitor. Because of this difference, Crick concludes that the observed universality strongly favors one hypothesis over the other. Notice that Crick's argument compares the likelihood of two hypotheses:

> P (the code is now universal | all current life traces back to a single progenitor) $>$ P (the code is now universal | current life traces back to 27 original progenitors and no fewer).

Here 'likelihood' is used in the technical sense introduced by R. A. Fisher (1925): The likelihood of a hypothesis is the probability it confers on observations, not the probability of the hypothesis, given the observations. The likelihood of H is $P(O|H)$; its posterior probability is $P(H|O)$. According to the law of likelihood, the observations differentially support the hypothesis of higher likelihood (Edwards 1972; Hacking 1965; Royall 1997).

The hypothesis that life can be traced back to a single progenitor is simpler than the hypothesis that it has 27 separate startups (since $1 < 27$). Crick's argument thus provides an example in which the principle of parsimony has a justification in terms of likelihood. However, the connection of likelihood and parsimony in this instance depends on specifically biological assumptions about the genetic code—that it is arbitrary and that it is subject to stabilizing selection. If parsimony has a rationale based on likelihood in inferential problems that arise in other sciences, different empirical assumptions will be required to show that this is so. But more important, there seem to be problems in which parsimony cannot be justified in terms of likelihood; in these problems, likelihood and parsimony are actually at odds.

The inferential task of curve fitting provides an example. Consider the following experiment. A sealed pot is put on a stove. Attached to the pot are a thermometer and a device that measures how much pressure the gas inside exerts on the walls of the pot. The pot is heated to various temperatures, and the resulting pressures are observed. Each temperature reading with its associated pressure reading can be represented as a point in a coordinate system (see Figure 1). The problem is to use these observations to determine the general relationship between temperature and pressure for this system. Each hypothesis about this general relationship takes the form of a curve. Which curve is most plausible, given the observations?

One factor that scientists take into account is goodness of fit. A curve that comes close to the data fits them better than a curve that is more distant. If goodness of fit were the only relevant consideration, scientists would always choose curves that pass exactly through the data points. But they do not do this—and even if they did, the question would remain how to choose among the infinity of curves that fit the data perfectly. Another consideration apparently influences their decisions, and this is simplicity. Often, extremely bumpy curves are thought to be complex, whereas smoother curves are thought to be simpler. Scientists sometimes reject an extremely bumpy curve that fits the data perfectly in favor of a smoother curve that fits the data slightly less well. Scientists care about both goodness of fit and simplicity, which influence how they choose curves in the light of data. However, these two desiderata conflict: Increasing simplicity typically involves reducing goodness of fit.

A curve represents a deterministic relationship between temperature and pressure; it maps x-values onto unique y-values. However, a curve plus an error distribution represents a probabilistic relationship: Any x-value is associated with a distribution of possible y-values, each with its own probability

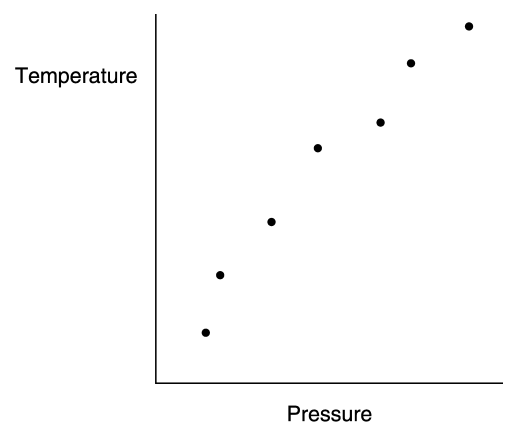

Fig. 1. Data gathered from an experiment in which a pot on a stove is raised to different temperatures and the pressure is recorded.

(density). In the example at hand (Figure 1), the concept of curve plus error distribution is more plausible, since the data are the joint product of the true underlying relationship of temperature and pressure and the measurement errors introduced by the imperfections of the thermometer and the pressure gauge. A standard model of error effects a connection between goodness of fit and likelihood: If one curve fits the data better than another, then the former confers a higher probability on the data. Given the data set depicted in Figure 1, a straight line will have a lower likelihood than a sufficiently complex curve that passes exactly through each data point. Thus, even if simplicity has a rationale based on likelihood in Crick's argument, simplicity and likelihood apparently conflict in the context of curve fitting.

Simplicity and Parsimony

It seems natural to say that curves differ in their simplicity. But what would it mean to say that they differ in parsimony? Parsimony involves paucity of postulation, but how does the idea of abstemiousness apply to curve fitting? Curves are visual representations of equations. For example, a straight line is a representation of a linear equation, which has the form

$$(\text{LIN}) y = a + bx$$

and a parabola is a representation of a quadratic equation, which has the form

$$(\text{PAR}) y = a + bx + cx^2$$

where x and y are the independent and dependent variables, respectively, and a, b, and c are adjustable parameters. In such equations, the adjustable parameters represent existential quantifiers—for example, (LIN) says that there exist values for a and b such that $y = a + bx$. Therefore, (LIN), which makes two "existence claims," may seem more parsimonious than (PAR), which makes three. This point pertains to equations of the form (LIN) and (PAR), not to a specific straight line and a specific parabola (an important distinction, which will come up again). It is worth asking whether simplicity and parsimony in their vernacular meanings always come to the same thing. However, as noted at the outset, the present discussion follows the conventional practice of treating them as equivalent.

Bayesianism

Bayesianism is not the same as Bayes's theorem. The theorem says that the conditional probability $P(H|O)$—the probability of H, given O—is a function of three other quantities:

$$P(H \mid O) = P(O \mid H)P(H)/P(O).$$

This theorem is a consequence of the standard definition of conditional probability: $P(H \mid O) = P(H \wedge O)/P(O)$. Bayesianism is a philosophical position, not a mathematical truth; in its strongest form it asserts that the epistemic notion of plausibility can be understood in terms of the mathematical concept of probability and, furthermore, that all the epistemic concepts bearing on empirical inquiry can be understood in terms of the probabilistic relationships described by Bayes's theorem. A double application of this theorem yields the following comparative principle:

$$P(H_1 \mid O) > P(H_2 \mid O) \text{ if and only if } P(O \mid H_1)P(H_1) > P(O \mid H_2)P(H_2).$$

This biconditional makes it clear that Bayesianism can use exactly two ingredients in explaining how parsimony is able to render one hypothesis more plausible than another in light of a set of observations. If parsimony influences plausibility, it must do so through prior probabilities, likelihoods, or both. If the relevance of simplicity cannot be accommodated in one of these two ways, then either simplicity is epistemically irrelevant or (strong) Bayesianism is mistaken. As noted previously in connection with curve fitting, likelihood can be maximized by making one's hypothesis sufficiently complex; this seems to leave Bayesianism only one alternative: If simplicity in such cases influences the plausibility of a hypothesis, it must do so because simpler theories have higher prior probabilities. This led Jeffreys (1957) to introduce a "simplicity postulate," according to which the complexity of an equation is measured by summing its variables, exponents, and parameters. This simplicity ordering is then said to provide an ordering of the prior probabilities of the hypotheses.

Popper (1959) argued that this postulate is incompatible with the axioms of probability. It assigns (LIN) a higher prior probability than (PAR), but this is impossible, since (LIN) entails (PAR). Howson (1988) replied that the problem can be evaded by stipulating that the parameters in a model have nonzero values. Instead of comparing (LIN) and (PAR), we should compare (LIN*) and (PAR*), which stipulate that $a, b, c \neq 0$. These models are disjoint, not nested, so assigning (LIN*) a higher prior probability is consistent with the axioms.

This suggestion raises two new questions. First, why should the original problem—comparing (LIN)

and (PAR)—be ignored? Should it be said that these two models are not in competition, because they are compatible? If so, scientific practice needs to change, since scientists often compare nested models.

Second, why should (LIN*) be assigned a higher prior probability than (PAR*)? Why think that $c = 0$ is more probable than $c \neq 0$? If probabilities are merely degrees of subjective belief, it is undeniable that someone might have greater confidence in the hypothesis that $c = 0$. However, it is puzzling why, in the absence of evidence, one should feel this way. If a sharp pin is dropped on a line a mile long, would you bet that the pin will land exactly at the beginning of the line or that it will land somewhere else? In the absence of information concerning how the pin is dropped, it is hard to see why you should bet on the first probability—yet this is precisely what Jeffreys's simplicity postulate recommends.

Another problem with this postulate has to do not with its correctness but with its completeness: It imposes an ordering of prior probabilities without providing specific values. This is important in inferential problems when the more complex hypothesis has a higher likelihood. If H_1 has the higher likelihood and H_2 has the higher prior probability, which has the higher posterior probability? Determining how simplicity trades off against likelihood requires more than a simplicity ordering.

Although Jeffreys held out no hope of getting likelihood and parsimony to coincide, later Bayesians saw a way to reopen the question. To grasp their idea, it is important to understand the difference between a model (which contains at least one adjustable parameter) and a specific hypothesis (which contains none). In this regard (LIN) is a model, but $y = 2 + 3x$ is not; it is a specific linear hypothesis. In effect, a model is a disjunction of specific hypotheses. When it was noted earlier that a sufficiently complex equation will fit the data better than a simpler equation, the point pertained to specific hypotheses. However, what would it mean to talk about the likelihood of a model? It is clear how $y = 2 + 3x$ "probabilifies" the data (once an error distribution is specified). But what probability does (LIN) confer on them? The answer is that the likelihood of (LIN) is the average likelihood of the set of straight lines ($i = 1, 2, \ldots$):

$$P(\text{data} \mid \text{LIN}) = \Sigma_i P(\text{data} \mid \text{straight line } i)\, P(\text{straight line } i \mid \text{LIN}).$$

The first term in this summation makes sense, but what should we make of the second? If the relation between temperature and pressure in the example of a pot on a stove is linear, what probabilities do the different specific linear hypotheses have? Schwarz (1978) approached this problem by thinking about the ratio of the average likelihoods of two models, assuming that there is a flat, uniform distribution over parameter values in each model. He derived the following result, which came to be known as the Bayesian information criterion (BIC):

$$\log[P(\text{data} \mid \text{model } M)] = \log\{P[\text{data} \mid L(M)]\} - (k/2)\log(N),$$

where $L(M)$ is the likeliest member of model M, N is the number of data, and k is the number of parameters in M. Notice that BIC includes a penalty term for complexity. If the best-fitting straight line and the best-fitting parabola fit the data in our example about equally well, (PAR) will have the lower estimated average likelihood because it is more complex. Complexity is relevant to estimating the average likelihoods of models, so Jeffreys's recourse to "priors" in his simplicity postulate is not, as it turns out, the only Bayesian approach to the problem.

One virtue of Schwarz's analysis is its avoidance of the criticism already noted—that it seems arbitrary and implausible, if not contradictory, to assign simpler models higher prior probabilities. (Nonetheless, questions can be raised about the assumed flat prior distribution of the values a parameter might have in a model.) Another virtue is that BIC specifies an exact quantitative rule for trading off simplicity and the likelihood of $L(M)$; it describes how much of a gain in one is required for a given loss in the other, if there is to be a net improvement in the estimated average likelihood of the model. However, there is a fly in the ointment. Schwarz's derivation uses improper priors (i.e., priors that do not sum to unity) in such a way that his derivation is not invariant under reparameterization (Forster and Sober 1994). Subsequent Bayesian work derives BIC so as to avoid this defect: The strategy is to use some of the data to transform the initial, improper priors into proper "posteriors"; thereafter, the rest of the data are taken into account to compute the final, average likelihood. (For further discussion, see Wasserman 2000.)

Popper and Falsifiability

Popper (1959) proposed a demarcation criterion that separates scientific from nonscientific statements:

The former are falsifiable. A falsifiable statement is one that is incompatible with a finite conjunction of observation statements. Falsifiable statements do not have to be false; rather, they have the nice property that observation can disprove them if, in fact, they are untrue.

Just as falsifiability separates science from nonscience, so degree of falsifiability distinguishes some scientific statements from others. The (LIN) model can be falsified by three data points, but not by any smaller number. A single data point, or any pair of data points, can be supplied with a straight line that passes through them exactly. On the other hand, (PAR) requires at least four data points to be falsified. This means that (LIN) is more falsifiable than (PAR).

Popper saw this as the key to understanding simplicity in science. Simpler theories are easier to falsify: If they are false, fewer data are required to show this. Popper turns Jeffreys's simplicity postulate on its head; whereas Jeffreys thinks that simpler theories are more probable, Popper thinks that simplicity goes with greater content: Simpler theories say more and hence are less probable.

It is clear that more falsifiable hypotheses have a pragmatic virtue: It is easier for us to prove them false, if they are false. The principal reservation philosophers have had regarding Popper's analysis is that it fails to account for the epistemic significance of parsimony. Why should predictions be based on simpler models rather than on more complicated models that fit the data equally well? It is here that Popper aligns himself with the skeptic and in opposition to the Bayesian. There is no assurance that our best hypotheses are true or even probably true. All that can be said is that they so far have evaded our best attempts to disprove them. Simplicity can provide no guarantee of truth or of probable truth, for the simple reason that nothing can.

There are further problems with Popper's account of simplicity. First, although it entails that (LIN) is simpler than (PAR), it does not have this consequence when a specific straight line and a specific parabola are compared. Each can be falsified by a single data point, so the two are equally falsifiable; this means that Popper must say they are equally simple. In addition, Popper's notion of degrees of falsifiability is restricted to hypotheses that have deductive consequences (perhaps in conjunction with auxiliary assumptions) about observations. If the hypotheses in question confer only probabilities on the data, they are not falsifiable. Since observation is virtually always subject to error, this is a large gap in Popper's theory.

Akaike and Selecting Models

The Bayesian approach to selecting models is not the only game in town. Before Schwarz (1978) proved his result, Akaike (1973) provided an alternative treatment (see also Sakamoto, Ishiguro, and Kitagawa 1986; Burnham and Anderson 1998). In fact, Akaike's contribution was twofold: He described a goal for selecting models—predictive accuracy—and he proved a theorem concerning how the predictive accuracy of a model can be estimated (Forster and Sober 1994).

How might a model like (LIN) be used to make a prediction about the pressure in our pot if the pot is brought to a certain temperature? A specific linear hypothesis, such as $y = 2 + 3x$, makes a prediction about the y-values that will be associated with newly observed x-values, but what does (LIN) tell us to expect? The answer is that (LIN) makes predictions by a two-step process. First, one uses old data to estimate the maximum likelihood values of the parameters in (LIN); then one uses this fitted model to predict new data. Thus, from the old data and (LIN) one obtains L(LIN), the likeliest member of (LIN); it is L(LIN) that makes a definite prediction about new data.

How well will L(LIN) predict new data? That depends, of course, on the true underlying relationship between temperature and pressure. In addition, since different data sets drawn from the same underlying distribution may differ, L(LIN) may make fairly accurate predictions about some data sets and rather inaccurate predictions about others. Because data sets may vary, it makes sense to define the predictive accuracy of a model as its average performance across multiple data sets.

If maximizing predictive accuracy is the goal, how is this goal to be achieved? How can we tell whether a model will make accurate predictions about new data, given just the single data set that we have at hand? If we opt for the model that best fits the data, we will usually select a fairly complex model. Working scientists know from practical experience that a complex model fitted to old data is often a poor predictor of new data; in such cases, the model is said to "overfit" the data. Sometimes a simpler model, although it does not fit the old data as well, will be a better predictor of new data. A mathematical explanation of this familiar fact is provided by Akaike's (1973) theorem:

$$\text{An unbiased estimate of the predictive accuracy of model } M \;=\; \log P\,[\text{data} \mid L(M)] - k,$$

where k is the number of adjustable parameters in the model. We obtain the log-likelihood of the

best-fitting member of the model and then subtract k, which is a penalty for complexity. This estimate is called the Akaike information criterion (AIC) score of the model. Forster and Sober (1994) recommend representing the estimate per datum—that is, multiplying the right-hand side by $1/N$, where N is the number of data; this helps defuse the criticism that AIC is statistically inconsistent (Forster 2002). Although it is intuitive to think about Akaike's framework in the context of curve fitting, it and other criteria for selecting models apply to a far larger range of inference problems, including those that arise in causal modeling (Forster and Sober 1994).

Akaike's theorem, as such, must be considered for the assumptions that go into its proof. First, there is an assumption about the uniformity of nature, which has two parts: (1) It says that the old and new data sets described in the definition of predictive accuracy are drawn from the same underlying distribution, and (2) it assumes that the x-values sampled in different data sets are drawn from a single distribution. For this reason, Forster (2000) describes AIC as addressing the problem of interpolation; the model-selection criterion that would be appropriate for extrapolation is not described by Akaike's theorem, whose proof also requires an assumption about normality; roughly, this says that repeated estimates of a parameter in a model form a normal distribution.

What does it mean to say that AIC is unbiased? If your bathroom scale is unbiased, it may give different readings of what you weigh, but the average of these must be your true weight. If the scale is unbiased, so is the procedure of adding or subtracting 50 percent of what it says, depending on the result of tossing a fair coin. This second estimation procedure also is centered on the true value, but it has higher variance than the procedure that just takes the scale's reading at face value. Similarly, the fact that AIC provides an unbiased estimate of a model's predictive accuracy leaves open whether its estimates have minimum variance. Furthermore, it is not clear that lack of bias should be regarded as a necessary condition for an acceptable estimator. Suppose that a scale has very low variance but is slightly biased; on average, it reads a little too high or a little too low (it is not clear which). Would one decline to use this scale if the alternative is to use a scale that is unbiased but has enormous variance?

In the literature on selecting models, AIC and BIC are often treated as competitors. This is odd, since the two criteria were derived as solutions for different problems. BIC estimates average likelihood; AIC estimates predictive accuracy. This does not mean that they cannot be considered as possible solutions to the same problem; however, to do so involves wrenching one of them from its natural conceptual home. Forster (2002) describes a set of simulations in which AIC is better at estimating predictive accuracy in some circumstances, while BIC is better in others. If we knew in advance where the problem we want to solve is located in parameter space, such simulations might indicate which model-selection criterion to use. However, the sad fact of the matter is that we often do not know enough about the factual setting of a problem for this to be possible.

Akaike's framework and criterion have important implications for the debate concerning realism, empiricism, and instrumentalism. It often turns out that a model known to be false has a higher AIC score than a model known to be true. This means that the goal of finding predictively accurate models differs from the goal of finding true models. If realists maintain that the goal of science is to find true theories, and empiricists maintain that the goal of science is to find empirically adequate theories (van Fraassen 1980), then Akaike's framework and theorem open the door to a third possibility. Instrumentalism, shorn of the faulty philosophy of language, which led it to deny that theories have truth values, becomes an option worth exploring (Sober 2002).

PARTICLE PHYSICS

Because its subject matter is the structure and behavior of the fundamental constituents of the physical world, particle physics involves a unique blend of experimental, theoretical, and philosophical issues. In the 1930s, early particle physics looked at cosmic ray traces in Wilson cloud chambers and results from particle accelerators probing distances of the order of the size of an atomic nucleus (energies of about 100 million electron-volts [MeV]) (Brown and Hoddeson 1983). Particle physics made use of a patchwork of models that included quantum electrodynamics, Enrico Fermi's theory of radioactive β-decay, and Hideki Yukawa's meson theory. Today, the Tevatron at Fermilab collides protons and antiprotons accelerated to 980,000 MeV to create charged jets of strongly interacting particles that have probably not existed in the universe since the big bang. The standard model in particle physics, with its unified theory of three of the four fundamental forces in nature, is the current dominant paradigm. A central conceptual problem of particle physics since its inception has been to define and establish an appropriately tight connection between an account of the basic building blocks of matter (fundamental theory) and experimental predictions (phenomenological models).

Early Particle Physics

Particle physics emerged in the 1930s as a confluence of three distinct fields of physics: nuclear physics, cosmic ray physics, and quantum field theory (QFT). The consensus at the time was that matter was composed entirely of two fundamental particles—negatively charged electrons and positively charged protons—and that there were two fundamental forces of nature: electromagnetism, mediated by the photon, and gravitation. Atoms were thought to be composed of electrons orbiting a nucleus composed of protons and electrons bound tightly together. Early observations of fair-weather ''atmospheric electricity'' at the turn of the twentieth century had expanded by late 1920s into a well-developed program of research studying cosmic rays, that is, ionizing radiation from outer space. This radiation was thought to consist of high-energy photons.

On the theoretical side, physics by the mid-1920s appeared equally successful and complete. Einstein's

theories of special and general relativity gave a framework for understanding gravitation and the macroscopic structure of the universe (see Space-Time). The theory of quantum mechanics, established in 1925 and 1926, offered a successful account of the dynamics of atomic particles (see Quantum Mechanics). Modulo a smattering of puzzles and anomalies, relativity and quantum mechanics appeared to cover all the fundamental laws of nature. Early particle physics (1930–1947) is largely the story of how this picture broke down.

The main theoretical challenges were to develop a relativistic account of the electron and a quantum theory of fields (see Quantum Field Theory). Paul Dirac's 1927 theory of quantum electrodynamics (QED), an early QFT, allowed one to calculate the probability distributions for various observable properties of an electron in the relativistic, high-energy domain. As Werner Heisenberg pointed out, however, Dirac's theory had a troubling consequence. In classical relativistic mechanics, particle transitions from positive to negative energy states are impossible. Dirac's theory, by contrast, predicted that positive-energy, negatively charged electrons should fall into negative-energy, positively charged states, rendering all matter highly unstable (Brown and Hoddeson 1983). In early 1930, Robert Oppenheimer suggested a possible solution to this problem: the transitions to negative-energy states do not occur because all these states are already filled. The only positively charged particle known at that time was the proton, but its mass (4,000 times that of the electron) made it difficult to fit into Dirac's theory. It took a year for Dirac publicly to speculate that his theory predicted the existence of a new particle, with the same mass but opposite charge of the electron. It took another year for Carl Anderson to publish cosmic ray experiments showing cloud chamber tracks of a new particle, dubbed the positron, fitting Dirac's description.

Anderson's discovery of the positron had a large impact on early particle physics, making it possible for experimentalists and theortists to extend their ontology beyond the two-particle (electron and proton), two-force (electromagnetism and gravity) picture. Two new nuclear forces were introduced, along with an array of new particles. The subsequent discovery of the neutron solved fundamental problems of nuclear physics. The weak nuclear force was introduced to explain the radioactive decay of nuclei and, in particular, the decay of the neutron into a proton, electron, and anti-neutrino. Finally, Hideki Yukawa developed a revolutionary model introducing the strong nuclear force. Yukawa knew that the force binding protons and neutrons in the atomic nucleus was much stronger than the electromagnetic force. He visualized this strong nuclear force as due to an exchange of some particle. However, no known particle fit the bill: The particle had to have a mass somewhere between 200 times more than the electron and 10 times less than the proton. This speculation, published in November of 1934 (Yukawa 1934; Brown 1981), was extravagant: there must exist a new quantum field requiring a novel kind of particle called a meson, a particle as massive as the electron yet behaving statistically like the photon. A series of cosmic ray experiments in 1937 revealed this new meson, and by the end of the 1930s Yukawa's meson field theory had become universally accepted. (The first nuclear bombs were constructed using Yukawa's meson field theory.) Meson theory became (and remains today) a paradigm for particle physics, in which the fundamental structure of matter involves the creation and annihilation of esoteric and ephemeral particles that have no analog or basis in classical physics and in which abstract, highly mathematical theories are necessary for an acceptable interpretation.

By the early 1940s, particle physics had become an established field of physics, the primary goal of which was the search for fundamental particles and fields. Particle physics could account for three of the four forces of nature (gravity is too weak to be effective in the subatomic domain) and offered a satisfying classification of matter at a fundamental level reminiscent of Mendeleev's periodic table. Particles that underwent strong interactions, such as the proton, neutron, and Yukawa's meson, were classified as hadrons. Particles that underwent only weak or electromagnetic interactions were classified as leptons, and these included the electron, photon, and neutrino. But perhaps the most important result from this period is the classification of particles based on their spin properties, and the profound (and to this day mysterious) connection between spin and the statistical behavior of particles first investigated by Pauli (1940).

Elementary particles, such as electrons, are identical. This means that given a system of n electrons, if one state of that system is allowed by the dynamical laws of nature, so will any other state that can be obtained by permuting (switching) the particles. How does nature know which of these states is the correct one? Or are they all correct? Nature, it turns out, divides particles into two exhaustive and mutually exclusive groups with distinct symmetry (permutation) properties: particles of integer

spin (0, 1, 2, ...), called bosons, and particles of half-integer spin ($\frac{1}{2}, \frac{3}{2}, \frac{5}{2}$, ...), called fermions. These symmetry properties have profound consequences for the structure of the universe: they enable fermions (e.g., electrons, protons, neutrons) to form substantial matter, and bosons (e.g., photons, mesons) to provide the glue that holds this matter together at the atomic and subatomic levels. This connection between spin and statistical properties of particles was established by Pauli based on very general principles such as Lorentz invariance, microscopic causality, and the conservation of probability (unitarity) (see Quantum Field Theory).

A Proliferation of Symmetries and Particles

From the end of World War II until the mid-1960s, particle physics was driven by a flood of experimental results that completely swamped efforts to develop a unified understanding of the subatomic domain. Particle physics no longer had to rely on cosmic ray observations, as a new generation of powerful particle accelerators was able to produce and detect high-energy particles in a more systematic and efficient way. This resulted in the creation and detection of dozens of new particles, from the *k*-mesons (kaons) of the early 1950s to the ultra-heavy omega-minus (Ω^-) hadron in 1964. It also resulted in astonishing discoveries, such as that of parity violation, which upset deeply held beliefs about the fundamental structure of matter. One common intuition about space, famously articulated by Kant, is that there can be pairs of objects, such as a left hand and a right hand, such that one object is the mirror image of the other, but no rigid motion (translation or rotation) can transform the one into the other. While familiar objects in the world commonly exhibit this kind of handedness, Kant assumed (as have all philosophers and physicists since) that the fundamental structure of nature does not.

Parity is the idea that for any physically possible state, the mirror image state (obtained by inverting one spatial coordinate) is also physically possible, and this obvious and basic spatial symmetry was implicitly assumed in theories in particle physics. Testing for parity is difficult, however, since expectation values of most quantum observables are equal for physical processes and their mirror images. Important exceptions are pseudoscalar processes, those that are the scalar product of vector quantities (which transform $\mathbf{v} \rightarrow -\mathbf{v}$ under reflection) and axial-vector quantities (which transform $\mathbf{a} \rightarrow +\mathbf{a}$ under reflection). Nonzero pseudoscalar processes were observed in an experiment by Wu on the β-decay of cobalt 60 in 1957 (Wu et al. 1957). This violation of parity at a fundamental level came as a severe shock to the particle physics community, and the question posed by Pauli still has not been answered: what physical reason is there for parity to be violated in weak interactions but conserved in strong and electromagnetic ones?

Other symmetries, such as *strangeness*, were invented to try to make sense of particular experimental results. Certain kinds of particle interactions that should be physically possible were not observed, or observed only rarely. The negatively charged sigma particle ($\sum^-$), for instance, was readily produced by the strong interaction $\pi^- p \rightarrow K^+ \sum^-$ (where the pion [π^-], proton [p], and kaon [K^+] are all particles), but it had an anomalously long lifetime and was observed to decay only weakly via $\sum^- \rightarrow n\pi^-$ (where n is the neutron). An economical and powerful way of accounting for these facts is to posit a new symmetry (an additive quantum number), that strangeness, and to stipulate that in strong and electromagnetic interactions strangeness is conserved (these interactions are symmetrical with respect to strangeness), while strangeness is violated in weak interactions. The absence of the strong decay $\sum^- \rightarrow n\pi^-$ is explained by the fact that this decay fails to conserve strangeness. In this way, strangeness is used to explain why certain particles undergo strong or electromagnetic interactions in some situations but not in others. The strangeness symmetry scheme, and many others like it, were clearly stopgap measures in the face of huge amounts of new data and the general failure of quantum field theoretic approaches to predict, retrodict, or explain these results.

Quantum field theoretic approaches also faced a serious problem having to do with the presence of infinities in the theory. For any QFT describing interactions, predictions cannot be derived analytically, but only by means of perturbation techniques. In a perturbation expansion, these QFTs give rise to divergent integrals that yield values that differ, infinitely, from experimental results. Renormalization techniques eliminate these divergent integrals and render the corresponding phenomenological models predictively accurate (see Quantum Field Theory). A guiding principle in particle physics almost since its inception has been that only renormalizable QFTs are even candidates for true fundamental theories, because only renormalizable quantum field theories exhibit the

appropriately tight connection between an account of the basic building blocks of matter and experimental predictions. For QED the problem turned out to be soluble by means of renormalization techniques developed by Richard Feynman and others in the late 1940s (Schweber 1994). QFTs of the strong and weak nuclear forces, by contrast, were not renormalizable and did not work very well computationally.

By the early 1950s, the ability of a theory to produce the right numbers was taken to be its primary, if not exclusive, virtue. A new generation of experiments in particle physics was producing unprecedented amounts of data, enabling a great increase in the accuracy of experimental measurements. There was a widespread conviction among physicists that it would be many years before field-theoretic approaches would yield a theory of the strong or weak interactions that gave the right numbers. This feeling persisted right to the end of the 1960s, and the developments described below—the rapid rise of QFT in the early 1970s—thus came as a surprise.

But which elements of the field-theoretic approach should be abstracted and incorporated into the new, more successful theories? Work in theoretical high-energy physics in the 1950s and 1960s was guided by two main answers to this question. One approach attempted to salvage much of the QFT model, but without the notion of a physical field or the claim to be describing nature at a fundamental level. What replaced field theories were what physicists called *phenomenological theories:* computational schemes of limited scope and accuracy based closely on experimental results and heuristic considerations. The two most well known examples of this kind of approach are the vector/axial-vector (V-A) model of weak interactions and the current-algebra approach to strong interactions (which involves abstracting an interaction current from a hypothetical field and exploring its algebraic properties) (Brown, Dresden, and Hoddeson 1989). Both of these approaches use a field-theoretic apparatus but without any notion of a physical field or particle mediating the interactions. Murray Gell-Mann's oft-quoted culinary metaphor is apt to describe how field-theoretic approaches were used:

> In order to obtain such relations that we conjecture to be true, we use the method of abstraction from a Lagrangian field theory model. In other words, we construct a mathematical [model] . . . , which may or may not have anything to do with reality, find suitable algebraic relations that hold in the model, postulate their validity, and then throw away the [field-theoretic] model. We may compare this process to a method sometimes employed in French cuisine: a piece of pheasant meat is cooked between two slices of veal, which are then discarded. (Gell-Mann 1964, 73)

The S-Matrix Program and Particle Democracy

A more radical approach eschewed the field-theoretic paradigm completely. In the mid-1950s, it was suggested that several constraints of a general sort (such as Lorentz invariance, analyticity, unitarity, and simple boundary conditions) might be enough to specify both strong-interaction dispersion relations and the scattering matrix (S-matrix), two important calculational results that had traditionally been derived using field-theoretic methods (Chew 1962; Cushing 1990). These results describe virtually all experimentally observed quantities and enable one to make empirical predictions. By 1961, an S-matrix research program was well established, which would dominate strong-interaction physics for the next decade. As the leading proponent of the S-matrix research program, Geoffrey Chew (1961), put it:

> So that there can be no misunderstanding of the position I am espousing, let me say at once that I believe the conventional association of fields with strongly interacting particles to be empty. . . . I am convinced that future development of an understanding of strong interactions will be expedited if we eliminate from our thinking such field-theoretical notions as Lagrangians, ''bare'' masses, ''bare'' coupling constants, and even the notion of ''elementary particles.'' (3–4)

The most radical philosophical aspect of the S-matrix program is its proposal of ''particle democracy,'' the idea that the concept of an elementary particle, as it is commonly used in field-theoretic approaches, is incoherent. QFTs proceed by writing down a Lagrangian (field equation) based on information about elementary particles and their corresponding fields, from which eventually an S-matrix is derived. This entails a distinction between elementary particles—those that correspond to quantum fields—and composite particles such as bound states; this distinction is important, since by definition elementary particles and their corresponding fields are those that are sufficient to determine the S-matrix. But this definition begs the question. Only once a complete dynamical theory has been developed can one say which particles are elementary and which particles are not—but in order to solve the dynamical problem, according to QFT, one

must know which particles are elementary. Thus, the notion of an elementary particle is not well defined in QFT.

The S-matrix program avoids this problem by offering a dynamical theory that does not require the notion of an elementary particle: all particles, bound states, and resonances are ontologically equal. Of course, the S-matrix program offers a different sort of conception of dynamics than that offered by field theory, and in two major ways. First, S-matrix theory does not offer a picture of the unobservable elements of strong interaction dynamics, that is, what happens between the measured initial and final states. QFT, on the other hand, appears to offer a picture of particles constrained by potential fields. According to its proponents, S-matrix theory was superior to field theory in this regard, because the picture of the unobservable dynamics offered by QFT is at best unnecessary and at worst extremely problematic (given the above-mentioned problem with the notions of elementary particle and field). Second, field theory is foundational in the sense that it contains a small set of fundamental elements from which all the dynamics can be calculated. S-matrix theory, by contrast, is anti-foundational. Without the elementary-particle concept to focus attention on particular elements of the S-matrix, the question immediately arises: Where does one begin a dynamical calculation? The answer is that it does not matter; one may begin anywhere, taking an arbitrary "particle" (bound state, resonance, etc.) as a starting point and attempting to reach as much of the S-matrix from this point as computational ability allows.

Quantum Field Theory Redux: The Standard Model

The establishment of the standard model in the early 1970s brought with it a renaissance of QFT as the central theoretical tool in particle physics (Hoddeson et al. 1997). In fact the standard model may be described somewhat loosely as two applications of QFT to the real subatomic world, namely quantum electroweak dynamics (QEWD), which covers electromagnetic and weak interactions, and quantum chromodynamics (QCD), which covers strong interactions.

QEWD, first proposed in 1967, extends QED to cover weak interactions by means of a mathematical technique called *spontaneous symmetry breaking* (Weinberg 1967; Salam 1968). This technique allows QEWD to have symmetries that are broken, or not present, in nature. An example of spontaneously broken symmetry in nature is a metal rod, balanced vertically on a flat surface, where a downward force is applied to the top end. The complete theoretical description of the vertical rod and the vertical downward force is rotationally symmetrical around the vertical axis. But if the force is large enough, the rod will buckle, breaking the rotational symmetry of the system. Spontaneous symmetry breaking was the key to a unified theoretical description of electromagnetic and weak forces, and it also provided a theoretical mechanism for giving rise to masses of the leptons and quarks that make up matter and some of the interacting bosons. QEWD was extended to cover electromagnetic and weak interactions of hadrons in 1970 (Glashow, Iliopoulos, and Maiani 1970), was shown to be renormalizable in 1972 (t'Hooft and Veltman 1972), and received a key experimental confirmation with the detection of weak neutral currents in 1974 (Galison 1987 and 1997).

QCD faced an additional conceptual hurdle. In the 1960s, several physicists proposed that hadrons, such as protons and neutrons, were not fundamental entities but were composed of point particles with fractional electric charges, called quarks. Experiments seemed to show that these quarks floated freely inside hadrons. So, why did the hadrons not just fly apart? And why had no single quarks (easily identifiable by their fractional charge) ever been observed? David Gross, the founder of QCD, reasoned that the strong interaction had to be strong at large distances, to keep the quarks together inside hadrons as well as to account for observed strong-interaction phenomena, but very weak at short distances, to account for their behavior as free particles inside hadrons and thus for the experimental results (precisely the opposite of the gravity, electromagnetism, and the weak force!) (Gross and Wilczek 1973). Unlike electrical charge, which is bivalent (positive and negative), the strong charge in QCD is trivalent. Its three values are conventionally called 'colors'—red, green, and blue—and there are eight bosons, called gluons, mediating the strong color force. There remains, however, the problem of confinement: No free quarks have ever been observed, no free gluons have ever been observed, and no color charge has ever been observed (all observed particles are color neutral). On a theoretical level, QCD does not provide a dynamical mechanism that explains confinement. On a conceptual level, the question remains whether and in what sense one can have a fundamental QFT in which the

elementary entities literally do not exist in free space.

QEWD and QCD, which collectively make up the standard model, are characterized by a Lagrangian whose form is determined in part by the constraints of gauge invariance and renormalizability (see Quantum Field Theory). Connection with experimental results is achieved through phenomenological models. In contrast to S-matrix, V-A, and current-algebra theories, the standard model was taken to offer a *fundamental* theory of the subatomic domain, and this was understood as the source of many of its theoretical virtues. The standard model admits a realistic interpretation, in the sense that the matter and interaction fields occurring in the basic Lagrangians can be taken to describe physical quantum fields that produce and explain observed scattering cross-sections and other experimental results. The realist interpretation, moreover, presents a tidy ontological picture in which there are only a small number of fundamental entities: 24 or so basic fields and their associated particles. This realistic picture can be well confirmed by experimental results, in a way that purely phenomenological theories cannot, because confirmation of each phenomenological model accrues also to the fundamental theory from which the model is derived. The point most emphasized by physicists, however, is the unity of the standard model at a fundamental level and the understanding of nature that follows: the whole subatomic realm is composed of a small number of elementary particles and fields, and all dynamics follow from a single equation of motion (Weinberg 1980; Wayne 1996).

The standard model's status as a fundamental theory, and the theoretical virtues that follow, depend on an appropriate connection between QFTs and phenomenological models. Roughly, what is required is that a phenomenological model *is* what the fundamental theory says in the particular circumstances covered by the model. In a semantic approach to scientific theories, this is usually taken to mean that the phenomenological model is a submodel of the fundamental theory (see Theories). In a syntactic approach, the relation is typically taken to be one of deductive entailment, where the phenomenological theory is deduced from the fundamental theory plus a description of the specific conditions in which the phenomenological theory applies. In the standard model, as in earlier QED, the connection is secured by renormalization. Standard-model physics, like early particle physics, has as its central task the search for a fundamental theory. Thus the requirement that standard-model QFTs be renormalizable has functioned as a regulative principle in theory construction and is supposed to yield QFTs that are candidates for true descriptions of the world at all scales, from the ultra-high-energy Planck length to the macroscopic world. (The Planck length, about 10^{-35} meters, is the distance at which gravitational effects become as strong as those due to the other forces of nature.)

Since the standard model was established in the mid-1970s there have been a variety of challenges to its status *qua* fundamental theory, and for the most part, these challenges hinge on the issue of renormalization. A philosophical challenge stems from the fact that renormalization techniques involve steps in which additional information is introduced. This happens first when the QFT is regularized: divergent integrals are replaced with finite ones, via the introduction of momentum cutoffs, dimensional regularization, or some other regularization procedure. Thus, phenomenological theories are not submodels of, or deductive consequences of, the fundamental QFTs (Huggett 2002). There are also a number of technical worries about the mathematical stability, coherence, and domain of applicability of perturbative renormalization techniques (Cao and Schweber 1993). Finally, attempts to extend the standard model to cover the fourth force of nature, gravity, have been unsuccessful. These attempts introduced a new quantum field and associated particle, the graviton, with mass zero and spin 2, which propagates in a flat Minkowskian space-time. It was found, however, that perturbative quantum gravity was not renormalizable and hence not a candidate for fundamental theory (Isham, Penrose, and Sciama 1981). The development of particle physics since the 1970s has been framed by the resulting dilemma: One can retain standard-model QFTs yet abandon the claim that they represent fundamental theory, or one can abandon standard-model QFTs and focus on alternative routes to fundamental theory.

The effective field theory (EFT) program, first developed by Weinberg (1979) in the late 1970s, takes the first horn. The EFT program begins with the assumptions that QFTs at different energy scales take different forms and that no one QFT is applicable across all energy scales. Fermi's nonrenormalizable β-decay model of the weak nuclear force is a prime example of an EFT, valid at an energy scale (up to 300 GeV) set by the masses of the heavy W and Z bosons mediating weak interactions. In this case, there is a renormalizable QFT—electro-weak theory—of which

Fermi's model is a low-energy approximation. In general, however, EFTs are constructed without knowledge of whether there exists any renormalizable theory at a higher energy scale. In the EFT approach, the regulative principle of renormalizability is replaced with a principle that nonrenormalizable EFTs are to be pursued subject to a constraint, which can be formulated precisely, concerning the partial decoupling of the physics in the domain of the EFT from the physics in higher-energy domains. In short, the EFT approach consists of phenomenological models all the way down.

The superstring research program, which began in the mid-1980s, grasps the second horn of the dilemma (Callender and Huggett 2001). The superstring program retains renormalizability as a guiding principle in theory construction and aims at a unified description of the fundamental forces of nature. Superstrings are one-dimensional closed strings that propagate in a space-time of dimension greater than 4, and quantization results in a theory that is perturbatively renormalizable. Superstring theory fits squarely within the fundamentalist tradition in particle physics, in which a Lagrangian field theory is combined with perturbative techniques and renormalization to yield phenomenological models. Work since the 1990s on the foundations of superstring theory is beginning to suggest ultimate limits on the applicability of this sort of approach, stemming in part from the result that the very concept of a space-time manifold is not applicable at the Planck length. Whatever theoretical form it takes next, the desire within particle physics for an account of the fundamental structure of the physical world remains strong.

PERCEPTION

Perception is a traditional focus of philosophical investigation. It has frequently been an area of collaboration between science and philosophy. Plato, Aristotle, Alkindi, Alhazen, Descartes, and Berkeley are philosophers who count as pivotal figures in the history of perceptual science (Lindberg 1976). The study of perception is an area in which sharp lines between science and philosophy get erased. This is one reason why the theory of perception is of particular interest to the philosophy of science. Another reason is that the theory of perception is one of the best-developed areas of scientific study of the mental. Empirical theories of perception stand as object lessons in what a science of the mind might hope to accomplish.

This article reviews some important themes in the theory of perception, with an eye to the dialogue between science and philosophy. It begins, however, with some general comments on the philosophy of perception.

The Philosophy of Perception: An Overview

Philosophical puzzlement about perception stems from two basic facts:

1. Perceptual states (experiences, percepts) are subjective states of consciousness. It is natural to think that perceptual states happen in the perceiver (in the mind, say, or in the nervous system). Perceivers know such states from the inside. Perceptual experiences have a definite felt character. Visual experiences are different from auditory ones, and smelling is different from touching. Whatever else they are, these are differences in their felt character.
2. Perceptual experiences are world referring. They always present things as being some way or other. One might feel that the temperature has gone down in the room, and then look up to see that the fire is out. In this way, perceptual experience raises the question, at least implicitly, of whether things are as they are experienced as being. Perceptual experiences are always either veridical or nonveridical. Many philosophers assume that perceptual experiences are world referring because they are *intentional*, in the philosopher's technical sense: Like thoughts or sentences, perceptual experiences are *about* the world (see Intentionality).

The central challenge faced by any theory of perception is to explain each of these features and how they can both be true.

Many writers have assumed that insofar as perceptual states are subjective, they are a special kind of bodily sensation. For example, there is the sensation of a pin prick, and there is the sensation of red. Bodily sensations, however, are not world referring. They do not present the world as being a certain way. A headache, for example, may hurt (and perhaps suggest overindulgence), and the experience of the headache may likewise inform one of an event taking place in a particular part of one's body (e.g., the left temple), but the headache itself, a mere sensation, does not refer beyond itself; it is not intrinsically *as of* a state of affairs. What is it, then, about *perceptual* sensations that differentiates them from mere bodily sensations and allows them to present the world? One influential strategy for addressing this issue has been to view sensations as, as it were, "natural signs" of that which causes them. This is the guiding metaphor of much empiricist work on perception (in the tradition of Locke, Berkeley, Hume, and Reid). Sensations (or ideas or impressions) are *effects* in one produced by things in the world. Knowledge of what is going on in the world—the very ability of one's perceptions to present states of affairs in the world—derives from one's experience of such patterns as similarity, proximity, and conjunction in simple sensory effects.

This approach has two clear virtues: (a) It is naturalistic, conforming to a plausible model of perceivers as animals on whom the environment impinges through different patterns of physical stimulation, and (b) it nicely addresses the first fact mentioned above, that perceptual states are states of consciousness. In the empiricist view, perceptual states are sensations (see Empiricism). A basic problem with the empiricist strategy, however, is that it falls short of providing an adequate

account of the world-referring character of perceptual experience. As a result, it actually fails to do justice to the character of perceptual consciousness.

Consider the visual experience of deer grazing in a meadow. This is an experience of deer, or at least of what visually appear to be deer. It is not an experience of sensations on the basis of which one infers or concludes that it is the experience of deer. The empiricist confuses the question of veridicality and that of intentionality. It is surely true that there is nothing in the visual experience of deer in the meadow that, as it were, self-certifies the experience as veridical. In that sense, perceptual *judgment* goes beyond what is given in experience. The mere fact that it looks to one as if there are deer is not enough to settle the question of whether there are. However, from this it does not follow that there is also an open question about *how* the experience presents things as being. One may be mistaken that there are deer; but one is not likely to be mistaken about the fact that it looks as if there are. The intentional content of an experience—how it presents things as being—is given *immediately* with the experience. The empiricist fails to account for the intrinsic intentionality of perceptual states and, because of this, misdescribes what sort of conscious states perceptual experiences are. The upshot of these considerations is that perceptual states are not composed of bodily sensations. One needs to look elsewhere for an account of their qualitative character.

Intentionality may provide part of the solution. After all, surely a good deal of what determines the qualitative character of a given perceptual experience is the fact that it is, say, the visual experience *of deer grazing in a meadow.* Some philosophers believe, however, that this cannot be the whole story (e.g., Peacocke 1983). There are aspects of what it is like to have a perceptual experience that are not fixed by the intentional content as features of the way the experience presents the world as being. Philosophers refer to these additional features as qualia (singular: quale), or phenomenal or sensational properties of experience.

In addition, many theorists now believe that not all perceptual states with intentional content are phenomenally conscious. As an example of this, consider "blindsight." Perceivers with damage in the visual cortex have scotomas, or blind fields, where they cannot see. If asked to identify objects presented in the blind field, such patients respond that they cannot see them. If asked to guess as to the identity of presented objects, however, such patients may answer correctly significantly higher than would be expected from chance alone. In cases such as this, it is tempting to say that there is an absence of phenomenal consciousnesss but the presence of intentional content.

Phenomena such as blindsight, if taken at face value, would seem to show that perceptual phenomenology cannot be just a matter of perceptual intentionality. Further support for this conclusion is provided by a consideration of *visual agnosia*, which may exemplify perceptual awareness without intentionality. Some perceivers with ventral stream damage are unable, on the basis of vision, to form a clear judgment of the properties of the scene before them, although they are able to use what they see to guide action. For example, they might be unable to judge whether a slot is vertical or horizontal, but they would be able to orient an envelope appropriately so as to guide it through the slot. Such perceivers see, but it is unclear to what extent their perceptual states are intentional. (It is also unclear to what extent their action-guiding perceptual states are consciousness.)

Perceptual consciousness and the intentionality of perceptual states are central areas of research in contemporary perceptual theory, whether in science or in philosophy.

Two Traditional Puzzles about Perception

Science Versus Common Sense

The world perceptually seems to be noisy, colorful, and full of odor and flavor. Science would seem to teach, however, that color, sound, odor, and flavor, like the sensations of touch, are sensory effects in perceivers brought about by their contact with the world. From this standpoint, one is no more entitled to believe that redness inheres in the tomato than that *paininess* inheres in the pin that pricks us. This is what Galileo, Boyle, Locke, and Newton believed.

If perception informs one not of how things are in themselves, but merely of one's subjective alterations in the face of things, then how can perception ever be a source of knowledge? Some philosophers, such as Descartes, bite the bullet and seem willing to deny that perception can on its own be a source of knowledge. Science proceeds *despite* the misleading influence of perceptual experience. Other philosophers have accepted the scientific starting point but have sought to unsettle the apparent consequence that perceptual knowledge is impossible. Locke seems to have thought that there is enough similarity between interior representations of things and the way they really are to allow perceptual states to be a source of knowledge. It is

difficult to see how such a position could be coherent, however. After all, one is never in a position to test whether things are the way they are represented in experience. To do that, one would need, impossibly, to compare experience and reality from a neutral perspective.

Phenomenalism is another strategy. Hume, for example, granted that what one knows are the subjective contents of the mind, but he asserted that that is all one needs to know, for objects and states of affairs are themselves just patterns of organization in subjective states of consciousness. One problem with this view is that it seems phenomenologically far-fetched. Perceivers take themselves in experience to be aware of things whose nature is independent of their sensory effects, such as shoes, sunsets, and the like (see Phenomenalism).

Kant argued, against Hume and Locke, that if the character of experience were determined, exhaustively, by sensory effects set up in perceivers by their interaction with the world, then experience could not even *seem* to present the world as being this way or that. In order for mere sensory effects to rise to the level of glimpses of a mind-independent world, one must already take oneself to have access to that world, and one must already have concepts of objects and other phenomena to apply to mere sensory stimulation. Only then can one have experience with genuine, world-presenting content. The debate between Kant and empiricism still shapes thinking in the philosophy of perception (see e.g., McDowell 1994).

Sense Data and the Argument from Illusion

Many philosophers have thought that one does not perceive what one thinks one perceives; what one is really aware of in perception are mental intermediaries, or sense data. To establish this, it is not necessary to refer to the discrepancy between how things perceptually seem and what science demonstrates to be the case. Rather, it suffices merely to consider that one can be in the subjective state of seeming to see a tomato, for instance, even though there is no tomato in front of one. Perhaps one is dreaming or is the subject of a drug-induced hallucination. If it is possible for one to have non-veridical perceptual experiences that are qualitatively identical to veridical experiences, then the objects that one sees when the experiences are veridical cannot themselves be constitutive of the experience. If they did play such a constitutive role—if one were aware of them—then surely their absence would alter the experience.

This is known as the argument from illusion, which has been used by philosophers to defend the thesis that the real objects of perception (what one *really* perceives) are mental items (or sense data). This view is closely allied to the so-called *causal theory of perception*, acccording to which when one sees a tomato, one has an experience of a certain class of tomato-like sense data that depends causally in the right sort of way on the presence of an actual tomato.

The problem with the argument from illusion is that it takes the fact that one might be unable to tell whether one is hallucinating to be grounds for believing that hallucinatory and veridical perceptual experiences must be qualitatively identical. One may not realize, when one is in a dream, that one is in a dream. This does not entail, however, that there is not in fact a significant qualitative difference between a dream perceptual experience and the corresponding perceptual experience. Without this entailment, the argument from illusion fails.

David Marr and the Computer Model of Mind

A landmark in the recent scientific study of vision is the work of Marr (1982). Vision, according to Marr, is a process of producing a description of the environment on the basis of information contained in the retinal image. The importance of the retinal image is not that it is a *picture,* that is, an object to be contemplated in the mind's eye. Rather, its importance is that it contains information about the environment. The retinal image can be thought of as an array of points, each of which represents the intensity of light at a point in the scene. From information about the distributions of light intensities, together with a cast of assumptions—for example, that sharp discontinuities in the intensity of light are likely to be edges or object boundaries—it is possible to compute a description of the scene before the eyes.

This analysis has important consequences. First, according to it, vision is a computational rather than a biological process; it can be realized, in principle, in a variety of systems, both biological and artificial (see Cognitive Science). Second, once the computational problem of vision has been spelled out, the central business of the theory of vision is the investigation of algorithms (mechanical procedures) for generating the sought-after descriptions on the basis of the available information about point-light intensity arrays. Crucially, this task is autonomous with respect to implementation-level details. Implementation may

be important when one turns to the question of whether a theory is psychologically or biologically real, or whether, biologically speaking, vision could have evolved in such a way. Attention to the level of implementation provides, at most, a constraint on the study of vision (at the proper algorithmic level).

The power of this approach is evident: (1) It provides a clear program for research; (2) it ensures a domain of investigation that does not reduce to neuroscience (vision science, like cognitive psychology more generally, is an autonomous special science; see Cognitive Science); (3) it addresses the worry (first articulated by Descartes) that explanation of mental powers by appeal to the mental powers of agencies within the animal is circular—the theory of computation (and the existence of the digital computer) demonstrates that it is possible for a system to perform computations without appeal to an internal homunculus.

Marr's theory directly applies the computational model of mind (or functionalism) to the domain of vision. According to functionalism, *mind* stands to *brain* as a *program* stands to the *hardware* on which it is implemented. Mental states are not identical to the physical states in which they are realized; rather, they are functional or computational roles those states perform.

The general approach to vision pioneered by Marr remains influential. Nevertheless, it has been criticized in philosophically interesting ways.

Criticism from Perceptual Psychology

Marr's theory assumes that vision is the process whereby a detailed internal representation of the environment is produced on the basis of information made available to the system. The content of what one sees is given by these representations. What makes the phenomenon of vision difficult to understand is the fact that the information in the retinal image does not uniquely determine a description of the environment. Consider, for example, that a small object nearby and a large object farther away might project the same pattern of stimulation to the eye. Moreover, the retinal image is highly defective: The eyes are in nearly constant motion, the resolving power of the retina is nonuniform, and there is a gap in retinal photoreceptors (the so-called blind spot). Vision, therefore, must be a process whereby the system compensates for these supposed defects. However, a great deal of work in psychology (especially recent work on change and inattentional blindness) suggests that the content of perceptions may be far less rich than has been supposed. If so, then there is much less computational work for the system to perform.

Given this, it may be that the sense of the presence of a richly detailed scene is an illusion; alternatively, it may be that it is not the case that perceivers really take themselves to have all of the detailed scene in visual consciousness at once. On either possibility, visual theory need not concern itself with the processes whereby a detailed internal representation of the scene is produced, because no such model is produced. Two theoretical commitments have tended to occlude this possibility. First, many scientists have just assumed that perceivers take themselves, when they see, to enjoy a richly detailed, picture-like consciousness of the scene. On the assumption that this perceptual consciousness is not a confabulation, the theory of vision must explain how the experience is generated on the basis of the impoverished stimulus. Second, it is widely believed that vision must give rise to detailed models in the head, for how else can vision play the role it does in guiding action?

Several lines of thought have conspired to shake confidence in each of these propositions. First, as already mentioned, work on change and inattentional blindness calls into question whether vision is really like a snapshot (putting to one side the question of whether ordinary, theoretically innocent perceivers *think* their experiences are snapshot-like) (e.g., Rensink, O'Regan, and Clark 1997). Second, in the last few years a number of authors have suggested that given the sparseness of actual visual content, there is no need to produce a detailed model; it suffices if the perceiver has quick and effective access to environmental information when it is needed (e.g., O'Regan 1992). This strategy has been proposed by philosophers, psychologists, and researchers in artificial intelligence and robotics. Third, some perceptual neuroscientists now believe that there are two functionally and anatomically distinct visual systems (Milner and Goodale 1995). One is responsible for experiences of seeing, whereas the other is responsible for visually guided action. A good deal of visually guided action, according to this line of thought, is independent of perceptual consciousness.

The Criticism from Neuroscience

In the last few years there has been an increase in knowledge of the brain and nervous system. Until recently, the study of the behavior of neurons was

confined to invasive single-cell research in animals. Large-scale information about brain structure depended on postmortem examination. In the last few years new technologies have become available that allow for the imaging of neural activity in healthy and intact animals (including humans). New possibilities for learning about the neural basis of cognition and perception have been opened up by positron-emission tomography, functional magnetic resonance imaging, magnetoencephalography, computerized axial tomography, and electroencephalography.

From the standpoint of the neuroscience of perception and cognition, functionalism is viewed with suspicion. Two lines of argument by philosophers have been particularly influential in this area. First, Churchland (1986) has argued, convincingly, that there is no biological reality to the distinction between software and hardware. The brain is a complicated system, to be sure, but *it* is the proper object of investigation for a theory of mind. Second, Searle (1980) has mounted an attack on the idea that minds are or could be suitably programmed computers. Computers perform *syntactic* operations. But mind is an intrinsically *semantic* phenomenon.

Churchland's and Searle's criticisms are important, but they by no means settle the issues. Churchland may be right that the distinction between software and hardware does not correspond to any distinction found in biology. It remains true, nevertheless, that most work in contemporary cognitive and perceptual neuroscience investigates neural processes insofar as they can be understood to realize cognitive function. Actual scientific practice remains very close to what Marr advocated. As for Searle, he is certainly correct that computers are, at best, syntactic machines. It is doubtful, however, that functionalists would be willing to accept that it ought to be possible to derive semantics from syntax. There is no reason for a functionalist to assume that the semantic significance of a computer's (or a brain's) states are determined *only* by internal states of the computer. Semantic content probably depends, as well, on causal history and ongoing interactions with the environment.

The Problem of Consciousness

A more general worry about functionalism is that, like behaviorism, it is unable to account for the subjective, qualitative character of experience (see Behaviorism), which, it is argued, is intrinsic to the experience; but functionalism identifies perceptual quality with extrinsic, functional relations. One of the best-known lines of argument in this area is the so-called inverted spectrum hypothesis. In this view, there is nothing incoherent in the supposition that functionally identical individuals might nevertheless differ in the qualitative character of their color experiences. Perhaps the quality they both call 'red' is experienced by *A* the way the quality they both call 'green' is experienced by *B*. This is a fascinating possibility, which has attracted a great deal of attention. It goes beyond the space allowed here to discuss it fully. If there could be creatures whose color experiences were inverted in this way, then, it would seem, the relevant differences in their color experience would not be accounted for by differences in their functional states. In recent years, not only philosophers, but scientists have explored this question.

Importantly, this criticism of functionalism is frequently advanced by physicalists, who identify qualitative states with brain states or processes. According to physicalism, the qualitative character of experience tracks neural processes, not functional roles. Physicalism has drawbacks, however. First, as of now, no one has even the roughest idea how neural states determine qualitative states. As Crick and Koch (2003) have stated, as of now no one has any idea how the redness of red is produced by action in the brain. This gap in understanding is sometimes called the explanatory gap, in light of which it is hard to see whether functionalism is any worse off than any other approach. Second, the empirical literature may not support physicalism. There is a significant literature on neural plasticity in which neural activity in a given region *changes* its qualitative character, apparently in order to subserve the demands of the larger functional role that neural activity is playing.

Gibson's Attack on Computationalis

Gibson (1979) has criticized Marr's approach on the grounds that it mischaracterizes vision at what Marr calls the computational level. It is just not the case that vision is a process of computing a representation of the scene on the basis of an array of point intensities of light. Neither the retina nor the brain, argues Gibson, is the subject in perception. The subject is the active animal. Moreover, the active animal has access to a *lot* more information than is available on the retina. Gibson suggests that it is a mistake to think of vision as

something that unfolds inside the animal. Rather, vision is a kind of activity that the animal engages in. Gibson's "ecological" approach has been very influential, although it is certainly a minority point of view.

Gibson's view has been characterized as a theory of perception at the *personal* (or *animal*) level, whereas Marr's approach is pitched at the *subpersonal* level. Indeed, some writers have suggested that insofar as the views operate at different explanatory levels, they may be compatible. However, this is unlikely. If Gibson is right, then Marr's analysis of vision as the process whereby a description of the environment is produced on the basis of retinal inputs cannot be right.

Gibson's fundamental point—that perception is not a neural phenomenon—has led a number of writers to investigate the significance of a more embodied, dynamic approach to perception and perceptual consciousness.

Some Outstanding Problems

The theory of perception is a fertile area of scientific and philosophical research. Among areas where further work is needed, five are mentioned briefly here.

1. *What are sensory modalities?* There is no accepted account of the individuation of modalities. Are there really only five senses? Could there be others (e.g., artificial systems)? Are perceptual experiences genuinely unimodal, or are they intrinsically multimodal?
2. *Sound and speech.* For those with sight, vision is the dominant sense. Vision shapes perception in other modalities. For example, when one watches television, one *hears* the voice coming from the lips whose movements one sees, even though it does not really. Speech, and the perception of sound more generally, raises a host of important questions, the central of which is, *what does one hear?* The phenomenology and philosophy in this domain is underdeveloped.
3. *Neural correlates of consciousness.* Are neural systems alone sufficient for experience? Most philosophers and scientists are inclined to think so. This assumption has led to a great increase in knowledge of the neural substrates of experience, but to negligible progress on the explanatory gap. Perhaps neural systems are *not* sufficient for experience. Perhaps neural systems are sufficient for experience only insofar as they are properly embodied in the properly situated, active animal. This is an important area for philosophical and empirical collaboration.
4. *Comparative perception.* How does perceptual consciousness vary from species to species? This is an important topic, but one that too many philosophers have tended to neglect.
5. *Is perceptual experience conceptual?* Most philosophers grant that one needs certain concepts to have some experiences. For example, something could not look like a television to an observer unless the observer knew what televisions were. Many philosophers also believe that the content of experience cannot be entirely conceptual. After all, nonhuman animals and infants have perceptual experience but do not have concepts (or so it is supposed). Many cognitive psychologists believe that perception is cognitively impenetrable. For a broad range of cases, how things look is unaffected by belief and desire. To get clear about these matters is a central problem for contemporary work.

PHENOMENALISM

In certain disputes that have persisted since Descartes, various philosophers have taken the objects, properties, relations, and facts that are experienced directly, and hence know by acquaintance, to be phenomenal entities (Broad 1951; Russell 1956, 7–26). The sense data of Moore, Russell, and Broad, as well as the mental acts (of perception, thought, etc.) of Brentano, Moore, and Husserl (Broad's modes of cognition and states of mind), were taken to exist. Some philosophers, recognizing phenomena as objects of direct experience, and influenced by Kant's distinction between noumena and phenomena and his notion of a "thing in itself" behind phenomena, thought of physical objects as theoretical entities that were postulated to explain the occurrence as well as the order and coherence of phenomena. Others took physical objects as complexes of phenomena.

Thus, "phenomenalism 1," the view that phenomenal entities, not physical objects, are directly experienced in perceptual situations, led some thinkers to "phenomenalism 2," a form of idealism that construed physical objects as logical constructions of mental entities. Phenomenalism 1 also influenced the development by Ernest Mach (1914) of an antimetaphysical empiricism that was a form of "neutral monism" construing the physical and the psychical as constructions out of simpler neutral sense data, and thus emphasizing the "unity" of science. Carnap (1967) is often read as adopting a linguistic variant of either phenomenalism 1 or phenomenalism 2, since he held that a linguistic schema with an "autopsychological" basis, in which statements about physical objects are transcribed into a language of sense data, was "epistemologically primary" (94). This reflected links among logical empiricism, classical empiricism, and Mach's empiricism.

In the vein of Mach's empiricism, Moore and Russell introduced "unsensed sensa" as (some) sense data held to be objects of direct acquaintance that existed whether or not they were apprehended and hence were neither mental nor dependent on the mind. At times, this led Russell to "phenomenalism 3," a form of physicalistic phenomalism with sense data independent of the mind, in physical space, constituting ordinary physical objects.

The introduction of unsensed sensa was implicit in one early argument by Moore (1903) against phenomenalistic idealism. Hume distinguished such processes as perceiving, remembering, and imagining in terms of characteristics of the experienced datum—force and vivacity—thereby not separating mental acts from objects of such acts. This led the idealists, or phenomenalists 2, to exploit a fourfold ambiguity in terms like 'perception' and 'sensation.' Moore distinguished the following:

- A *mental act* of a certain kind (sensing, imagining, etc.)
- An *object* of such an act, such as the color (shade of) blue or a blue patch
- The generic relation, *consciousness of*, between acts and such objects
- The *fact* that an act stands in this relation to an object

Phrases like 'sensation of blue' tend to confuse these distinctions and lead to the idealist formula *esse est percipi* ("to be is to be perceived"). Preserving the distinctions, however, implies that an object of an act can, logically, exist without being so related to a mental act, and thus rebuts idealism. But this analysis of the perceptual situation led Moore to unsensed sensa, which later troubled him, given sense data such as pain.

Phenomenalism and phenomenal entities have been consistently attacked by contemporary materialists, who reject both the phenomenal objects of direct apprehension and the mental acts of apprehension, and by others who simply reject the notion of direct acquaintance. Sellars (1963) attacked the "myth of the given" and, along with Chisholm (1966), set forth an "adverbial" account of perception, involving states of the perceiving subject ("sensing bluely"), in order to dismiss phenomenal objects. Quine (1953a) argued that sensa are not data of experience but hypothetical entities—"myths, like the gods of Homer"—as are ordinary physical objects and the theoretical objects of physics (44). Such myths are justified not by direct access to them (which subjects do not have) but by the success of theories that invoke them. Yet Quine (1953b) speaks problematically of the "linguistic material" being "tied here and there to

experience'' (198; Hochberg 1959, 198). Moore claimed that such direct access was unproblematic, since there are mental acts of direct apprehension, as did Brentano, Husserl, Broad, and Sartre, in one form or another (Brentano 1981, 4). Others have defended the recognition of phenomena and mental acts by arguing that they are required to fit the fact that the knowledge of one's own mental states and experiences is quite different from knowledge of the mental states and experiences of others. The materialists' attempts at physicalistic analyses of mental states thus fail in principle. By contrast, Quine's rejection of purported translations of statements about physical objects into a language of sense data—as too complex to be realistic—does not point to a failure in principle and ignores the similar problem faced by his own physicalistic elimination of phenomena (Quine 1953b; Hochberg 1959).

Although Russell sometimes construed physical objects as logical constructions out of phenomena independent of mind, at other times he took the radically different view that macrophysical objects were like the theoretical entities of physics: unknown hypothetical entities providing a causal explanation of known phenomenal data. His hypothetical realism embraced phenomenalism 1 while rejecting phenomenalistic constructions of physical objects. He took physical objects, properties, and relations to be hypothetical causal correlates of directly experienced phenomenal particulars, qualities, and relations, comparing his view to Kant's distinction between noumena and phenomena. According to Russell (1956, 30–34, 47, 86), a physical object was what Kant called a thing in itself, as the cause of sensations, which could be known only by descriptions such as ''the physical object which *causes* such-and-such sense-data.''

Whitehead's influential technique of ''extensive abstraction'' led Russell (1914) to shift to construing physical objects as logical constructions—and therefore logical fictions—in *Our Knowledge of the External World,* which, along with Russell and Whitehead's *Principia Mathematica*, greatly influenced Carnap's (1967) constructivism espoused in *Der logische Aufbau der Welt* of 1922–1928. But Russell (1919) returned to speaking of physical objects as the unknown inferred causes of directly experienced sense data, standing in hypothetical relations with the same logical ''structure'' as the experienced relations of sense data (61). Such hypothetical entities provided a basis for inferences about the structure but not the content (objects, properties, and relations) of the physical world. Thus, given phenomenal entities instantiating phenomenally given spatial relations (e.g., in a visual field), one could hypothesize that there were unknown physical particulars, properties, and relations among them causally correlated with the phenomenal particulars, properties, and relations, such that the physical relations shared logical properties of their phenomenal counterparts: The correlates of ''red'' and ''yellow'' stood in a relation that was the correlate of ''darker than'' and, like the correlate of the phenomenal ''left of,'' shared logical properties (transitivity, asymmetry, etc.) with their correlates—hence the emphasis on structure and the notion of structural realism. Russell (1927) later argued in greater detail for such a view.

Moore's (1953) commonsense realism, as set out in lectures in 1910–1911, contrasted sharply with Russell's concept and with Broad's variant of phenomenalism 1. From the time when Moore (1903) rebutted idealism, he had consistently rejected phenomenalistic reconstructions of physical objects; but in 1910–1911 he accepted a theme of phenomenalism 1: that subjects do not directly apprehend physical objects and therefore cannot directly refer to them. Phenomenal entities are what one directly experiences and directly refers to when one makes assertions like ''This is a hand.'' Moore sought to analyze such a claim so as to acknowledge that subjects do not directly apprehend the hand, while nevertheless preserving certain commonsense truths: that in speaking about a physical object one knows that it exists.

Idealism and Realism

Russell's theory of descriptions provided the key for Moore's analysis. One indirectly refers to a physical object as the x, such that x is a physical object, and sCx, where x is, say, a hand; s is a directly apprehended datum; and the relation C is sometimes taken as ''is a manifestation of.'' One also indirectly apprehends x by directly apprehending s and immediately knowing that there is a physical object.

Broad, soon afterward, in rejecting phenomenalism, took a similar view of direct and indirect apprehension and a relation like C, ''is an appearance of,'' but without claiming to know immediately that the physical object existed. Moore's claiming to know the existence of the indirectly apprehended physical object immediately was crucial to his undercutting of the basic and familiar arguments of the empiricist tradition (from illusion, perspective, conditions of sense organs, etc.) leading to diverse forms of phenomenalism. The theory of

descriptions provided a way of denoting objects that were not of direct acquaintance for Moore and Russell; and in Moore's case it also provided a way of claiming that subjects have immediate, not inferential, knowledge of the existence of physical objects. For although a physical object is "indirectly apprehended," one (1) "directly apprehends" the proposition that the physical object standing in *C* to the datum *s* exists and (2) "immediately knows" it to be true. The fact that the physical object is only indirectly apprehended (and thus known by description) does not mean that its existence must be inferred from that of the sense datum. However, as the relation *C* was not directly apprehended, Moore was ultimately forced to denote it also by a definite description, as the relation (satisfying certain conditions) obtaining between *s* and the indirectly apprehended physical object.

The obvious vicious circle may, in part, have led Russell to his hypothetical realism. But Moore, perhaps aware of the problem, sought to buttress his view with two additional, remarkably simple arguments for rejecting phenomenalist-inspired reconstructions of physical objects. These would set the pattern for his defense of commonsense realism.

First, all forms of phenomenalism, as well as Russell's hypothetical realism (inspired by Kant), entailed that Moore did not know that his hand was a physical object. Thus either the arguments for such views were mistaken or Moore's belief about his hand was. But to him it was obviously more likely that the arguments were mistaken than that he did not know his belief to be true. In fact he knew it was a hand, and hence a physical object. Second, to take a physical object to be a bundle of sense data was absurd. No one could seriously believe that his hand was a bundle of sense data.

Analyzing causation, Hume (1967) held that one cannot meaningfully speak of unexperienced material objects causing the occurrence of perceptual objects (104–105; Price 1948). This line of thought also applies to the concept of existence itself. Supposedly, one cannot meaningfully claim that material objects exist because one can make meaningful existential claims only about objects, qualities, and relations that are or can be experienced or can be described in terms of experienced qualities and relations. Moore also attacked this central theme of phenomenalism. He argued that the concept of existence can be sensibly asserted of nonexperienced and even nonexperienceable objects. The concept of being experienced is not and cannot be involved in the analysis of existence, since existence is a simple unanalyzable concept. Thus one may make existential claims about objects that are neither experienced nor experienceable.

In the version of phenomenalism 2 that Moore is attacking here, the realist about physical objects is assumed to make a meaningless or self-contradictory claim. It is assumed that the concept of a material object can be sensibly explicated only in terms of phenomenal concepts, by taking a material object as a coherent bundle of phenomenal entities. Such a phenomenalist thus takes this view to be logically true, in that the claim that there are material objects related to, but not composed of, phenomena is either inconsistent or incoherent, since it either involves a meaningless concept or is self-contradictory. To Moore, such a phenomenalist offers no argument but merely mistakenly assumes that one's having obtained concepts from experience implies that one's application of them is limited to objects that are possible from direct experience. But it was obvious to Moore that existence, spatial relations, and causal connections can be sensibly and truly ascribed to what is not and cannot possibly be directly experienced. Thus one can speak meaningfully of the existence of physical objects, their properties, and their relations without taking such objects, properties, and relations to be analyzable in terms of, or reducible to, phenomenal objects, properties, and relations. There is no reason to deny that one can project concepts originating in direct experience onto objects that one does not and cannot directly experience. Moore proceeded to use some such concepts, along with logical concepts, to explain what he meant by a "material object," which he characterized, in part, as something that was neither an object of direct acquaintance nor a mental act but was extended in a space that (unlike the visual field) was not that of direct experience.

Their divergent forms of realism led Russell and Moore to interpret phenomena and knowledge of physical objects in different ways. Russell was motivated by a desire to make as few hypotheses as possible, in order to lessen the probability of being wrong, and so his realism involved hypotheses about, or logical constructions of, physical objects but not claims of immediate knowledge of their existence. Unlike Moore, Russell did not believe he could refute a Humean solipsist, a phenomenalist in yet another, and extreme, sense. However, Russell (1956, 22) held that there was no reason to believe Humean solipsism and, like Hume himself (1967, 110), that no person could seriously adopt it.

PHILOSOPHY OF PHYSICAL SCIENCES

The physical sciences abound with provocations to philosophy. Here are just a few:

- Einstein's general theory of relativity admits solutions in which observers can, traveling steadily into their own futures, reach their own pasts (see Malament 1984).
- If measurement processes obey the laws of quantum dynamics, the superposition rampant in the micro realm infects the measuring apparatus: Schrödinger's "diabolical device" leaves his cat superposed between life and death. On the textbook understanding of superposition, this creature is neither alive nor dead. Measurements involving more humane apparatus also lack outcomes (see Quantum Mechanics).
- Quantum theories countenance states in which spatially separated systems are correlated in a way that no model of causes acting locally can explain (see van Fraassen 1980). Disturbingly, the larger the domain of the quantum theory in question, the more "typical" such entangled states—which are central to protocols for quantum cryptography and quantum computation become (see Causality; Locality).
- The second law of classical thermodynamics, dictating that entropy always increases, reflects the immediate datum of consciousness, that time is directed. And yet classical thermodynamics is supposed to reduce to statistical mechanics, whose fundamental dynamical laws are time-symmetric (see Irreversibility; Kinetic Theory).

Many entries in this volume (given in the "See Also" list at the end of this essay) chronicle philosophical work on specific physical sciences. This article will offer a necessarily incomplete sketch of the forms of, and reasons for, philosophical engagement with the physical sciences.

The Foundations and Interpretation of Physical Theories

Physicists and mathematicians, as well as philosophers, engage in research on the foundations of physical theories. Foundations research aims to

unmask puzzling or noteworthy features of theories (e.g., the failure of certain joint probabilities to be well defined in standard quantum mechanics [Fine 1982]), to identify and to analyze concepts and structures basic to these theories (e.g., the notion of equilibrium in statistical mechanics [Sklar 1993]) and to articulate relations between theories (for example, the ostensive reduction of chemistry to quantum mechanics). Perspicuous formulations of the theories in question aid foundational investigations; disambiguations of vague notions of philosophical currency, which enable the application of these notions to particular physical theories, abet them. The collaboration of philosophical and technical acumen in foundations research can bear fruit: The hierarchy of causal structures in general relativistic space-times (Wald 1984, Ch. 8), once characterized, becomes a powerful tool for advancing questions about determinism and prediction in those settings, once those questions are formulated (see, e.g., Geroch 1977). And relationalism, having been framed as a thesis about particular dynamical theories to the effect that those theories can be fully formulated in phase spaces of specifiable sorts, becomes a target for creative physics (see Belot 2000).

A related aim of foundations research is to develop, catalog, and evaluate interpretations of physical theories. To interpret a physical theory is to characterize the set of worlds possible according to it, to identify and describe the physical systems of which that theory is true. Thus an interpreter of general relativity must decide whether solutions of Einstein's field equations that are identical up to diffeormorphism correspond to one possible world or many (the second option sets the stage for a general relativistic reprisal of the Liebniz shift argument against substantival space). And an interpreter of quantum mechanics must decide whether or not to take that theory to encapsulate statistical generalizations about ensembles of worlds individually and precisely described by the hidden variables of Bohmian mechanics (an interpretive option made available by an effort of creative physics).

Foundational work galvanizes interpretive attention: An interpreter, piqued by foundational investigations, can ask, Of what manner of world is a theory with singularities (without joint probabilities/with dynamical symmetries/with entanglement/with closed timelike loops/with *both* time symmetric fundamental laws *and* steady entropic increase) true? Interpretations of physical theories can reflect epistemological and metaphysical prejudices. But it is unjust to conceive the project of interpretation as one of plastering such prejudices on a solid frame of self-sufficient science, for the impetus to interpret a theory often lies within that theory, in the form of an unresolved problem, an incomplete concept, or an apparent incompatibility with other well-established theories or with common sense.

Although an interpretation of a theory is what a realist believes about it, interpretation holds interest for those who are not confirmed realists. An interpretation enables the constructive empiricist to see the position from which he is virtuously withholding belief (see Empiricism; Scientific Realism). Interpretation helps those contemplating realism about several theories at once to assess whether and on what terms those theories can be true together. Constituting the scientific image, interpretation forms part of the principal task of philosophy, according to Sellars (1963): to combine that image "stereoscopically" with the "manifest image" presented to us by educated ordinary experience. Even working physicists can have a stake in interpretive questions, insofar as their answers suggest directions in which to develop new theories: Some forms of the project of quantizing gravity presuppose a decision about which observables of the classical theory are genuine (see Belot and Earman 1999). Interpretation serves a variety of purposes; the grounds and significance of commitment to particular interpretations vary concordantly and are themselves worthy topics of philosophical investigation.

General Philosophy of Science

Philosophers of science have traditionally sought general accounts of the structure of scientific theories and the nature of scientific explanation, confirmation, intertheoretic reduction, and the like. For such accounts, the history and present practice of the physical sciences form a wide and varied proving ground. In some cases, examples from the physical sciences serve to enliven points discernible in abstraction—the problem of old evidence for Bayesian confirmation theory (see Confirmation Theory) is latent in the statement of Bayes' theorem; it becomes violent when the old evidence in question is the anomalous precession of the perihelion of Mercury. In other cases, bringing general accounts to bear on particular physical theories is revelatory. Consider Reichenbach's principle of the common cause (Reichenbach 1971) as it might be incorporated into a causal-mechanical account

of explanation. On the Reichenbachian account, correlated events require explanation in terms of a cause acting in their common past (see Causality). Made precise to apply to certain quantum correlations, the account implies that those correlations have no explanation, because any theory fostering a common-causal explanation of those correlations makes predictions different from the empirically validated predictions of quantum theory (see van Fraassen 1980, 25–31). By contrast, the correlations in question have an explanation in the deductive-nomological sense (see Scientific Explanation): They are a direct consequence of applying the Born rule to an entangled quantum state. Close attention to quantum theory reveals not only (what was evident at the outset) that Hempel's account of explanation and this Reichenbachian one are rivals, but also that the choice between them involves at least taking a stand on whether quantum correlations are explicable. (This same attention exposes as untenable any interpretation of quantum mechanics that asserts the theory to hold of a world of causes acting locally, if these causes adhere to Reichenbach's model.) Thus the philosopher of quantum mechanics performs for the philosopher of scientific explanation what Reichenbach (1938) identifies as the "advisory" task the competent epistemologist performs for the positive scientist (8–16). This is the task of explicating the decisions (not obviously) entailed by the different options.

In connection with philosophy's advisory role, it is interesting to observe that practicing physicists often take stands, implicit or explicit, on issues in the general philosophy of science. Consider the "horizon problem" (Earman 1995, Ch. 5) of contemporary cosmology: In standard Big Bang models, regions of the universe between which correlations (e.g., in their blackbody spectra) are observed that have no common past, so that no causal mechanism, acting locally, could have established those correlations. Whether these correlations therefore lack explanation depends on one's account of explanation. In the Reichenbachian account of the last paragraph, the correlations cannot be explained, and the horizon problem is genuine; in other accounts, the correlations are explained, and the horizon problem is illusory. By and large, practicing cosmologists have stalwartly Reichenbachian intuitions: They hail inflationary cosmologies for solving the horizon problem, and devote ongoing work to constructing explanations for features—for example, fine tuning (see Anthropic Principle)—that do not (according to many philosophically respectable views of explanation) require explanation. The lesson from this is that philosophers should refrain from evangelism: Many a fruitful scientific research program grows from seeds of suspect philosophic pedigree.

The scientific-realism debate furnishes another illustration of mutual constraint exerted between theses in the general philosophy of science and interpretations of particular theories. One question is: Do grounds, adduced in lofty abstraction, for realism about successful scientific theories support realism about particular successful physical theories? Here quantum mechanics provides a cautionary tale. Fantastically successful, it appears the archetype of a theory for which might be run an "explanationist" defense of scientific realism—an abductive inference that the theory is true because its truth is the best explanation of its empirical success. Suppose someone were convinced by such an argument to be a realist about quantum mechanics. What would that person believe? One needs an interpretation of quantum mechanics to give content to one's realism, but none are unexceptional, and some undermine one's grounds for realism. For instance, the standard collapse interpretation solves the measurement problem by suspending quantum dynamics for the duration of measurement (see Quantum Measurement Problem). On this view, the truth of quantum mechanics hardly explains its empirical adequacy, because the theory must break down for measurements to occur at all.

Physics Centrism

It is sometimes complained, usually against caricatured "positivists," that enthroning physics as the paradigm of science has led to a partial and antiseptic dominant philosophy of science (Harding 1991). One form of the complaint is: If a general philosophy of science takes as its criterion of adequacy only the capacity to deal successfully with physical sciences, then that philosophy exaggerates the role of theoretical structure, particularly mathematical structure (and the variety of precision accompanying it), in sciences. Whatever other justice this complaint might have, it underestimates the extent to which physical theories themselves fail to conform to "positivist" models of physics. For example, the question of the circumstances under which the behavior of some particle physics apparatus counts as evidence, or constitutes a phenomenon to be saved by physical theory, is a highly nontrivial one. Its resolution draws upon interactions

between models and simulations of many sorts, as well as vast collaborations of theorists, experimentalists, technicians, and their machinery (Galison 1987) (see Particle Physics). This might be taken to suggest, *pace* the "positivist," that epistemology should extend its scope beyond the "context of justification" to include, at least, the context of evidence generation as well. It might also be taken to suggest that there are epistemological questions to which theory is not central, a suggestion reinforced by consideration of chemistry and astronomy (see Chemistry, Philosophy of; Astronomy, Philosophy of), where skill and observation call for epistemological analyses not directly supplied by traditional epistemologies of science.

Metaphysics

Metaphysics aims to characterize the possible. Physical sciences can be interpreted to characterize possibilities within their domains of applicability. Physical sciences can thereby serve both to stimulate and to check metaphysics. Interpreted physical sciences supplement the reservoir of possibilities (traditionally constituted by the metaphysician's meager imagination) worth taking seriously. The possibilities evinced by interpreted physical theories include challenges to metaphysical principles: Einstein's field equations can be interpreted to describe consistent time travel scenarios, and quantum mechanics can be interpreted to hold of nexus of events temporally but not causally ordered. What is more, the situations described by interpreted physical sciences have real complexity and antecedent interest. They are thus splendid occasions to flex metaphysical muscle, as a mereologist might in attempting to account for how the properties of a compound relate to the properties of the elements it comprises (see Chemistry, Philosophy of; Emergence). This is not to suggest that interpreted physical sciences serve as neutral data grounding conclusive tests of metaphysical principles. Interpretations can reflect metaphysical as well as epistemological predilections. Thus the clash of an interpreted physical theory with a favored metaphysical principle can be cited as reason for rejecting that interpretation, that theory, or both. Just as with theses in the general philosophy of science, the point of bringing metaphysics into contact with the philosophy of the physical sciences is not to settle disputes in either discipline, but to transform them, by unraveling (and yanking on) the conceptual ties that bind one sort of inquiry to another.

PHYSICAL NECESSITY

See **Laws of Nature**

PHYSICALISM

If any grand metaphysical thesis can lay claim to the title of a received view in contemporary philosophy, it is physicalism—roughly stated, the claim that everything is ultimately physical. The view is most familiar from the philosophy of mind, where the position frequently known as *materialism* is set out as one option available on the mind–body problem. The view is not confined to the philosophy of mind, however; its influence is quite widespread. One can find projects motivated by physicalism in the metaphysics of color, the philosophy of biology, meta-ethics, and so on. While the terms 'materialism' and 'physicalism' are often used interchangeably, the latter term is more likely to be used in referring to the more general thesis that has this widespread influence. The term in fact has a curious history, as it was introduced into the analytic tradition by the later work of the logical positivists. They were, of course, concerned to eliminate anything recognizable as metaphysics, while the term "physicalism" now denotes an unmistakably metaphysical view.

As used by the positivists, physicalism was a position regarding the sorts of sentences that should be used as the touchstone of the process of verification. If, as the positivists thought, the cognitive significance of a sentence is determined by the ways in which it may be empirically verified, it is important to determine what sort of "observation sentence" may aptly describe those events of verification. While earlier positivists tended to think that the relevant observation sentences were reports solely of one's own immediate experience, this approach eventually came to seem untenable. Led by Otto Neurath, the later positivists proposed physicalism as the view that the key verifying sentences are those describing events that are intersubjectively verifiable. The contrast between physical and mental or "phenomenal" was here understood primarily in epistemic terms: The mental is that which is essentially private, verifiable only by one person, and the physical is that which is locatable in the broader spatiotemporal framework, available for inspection by more than one observer. Unlike contemporary physicalism, which is usually put forward as a metaphysical view motivated in some way by the empirical success of physical science, the positivists' physicalism had nothing especially to do with *physics,* but was motivated, rather, by more general considerations about the nature of verification and the communicability of meaning (Uebel 1992).

The shift in the usage of 'physicalism' from the logical empiricists' sense to that found in contemporary philosophy is nicely illustrated in Herbert Feigl's (1968) long essay *The "Mental" and the "Physical,"* first published in 1958, which introduces two senses of physicality. By 'physical$_1$' Feigl means that which is needed to account for the spatiotemporal order and is intended to capture what is intersubjectively available. By 'physical$_2$' he means that which is needed to explain inorganic processes. This latter sense comes closest to what has been operative in the discussions of physicalism as a metaphysical thesis. The claim made by the contemporary physicalist is not a semantic claim about the role of reports of what is intersubjectively

available; it is a claim about the sorts of entities discerned in the study of "mere matter," *viz.,* that those entities provide the ultimate building blocks of everything there is. The unqualified term 'physicalism' will hereafter in this essay denote the contemporary metaphysical view (not that of the positivists) summed up in the slogan "Everything is ultimately physical."

Two Questions About Physicalism

Two main questions about physicalism may be spotlighted. How exactly is the thesis to be *formulated?* And how might it be *justified?*

Consider first the slogan "Everything is ultimately physical." It contains a deliberate hedge. A simpler statement would be "Everything is physical," and the claim would then be that every entity in the appropriate domain is a physical entity. The hedge is needed, however, to accommodate the fact that there are recognizably physicalist positions that allow for entities that are, strictly speaking, not physical but that bear some appropriate relationship to the physical. More precisely, such positions allow for entities the existence and character of which are determined and explainable by the physical in such a way that it is appropriate to say that the nonphysical entities are not entirely distinct from physical ones, or that they are nothing over and above the physical entities involved in that determination.

To clarify the slogan "Everything is ultimately physical," one should answer three sets of questions:

1. What does 'everything' range over? What sorts of entities are supposed to be ultimately physical?
2. What does it mean to classify one of those entities as physical in the first place? In that domain of entities, how is the special class of physical entities to be picked out?
3. What exactly does the physicalist want to say about the relation of the entirety of that domain to that special class of physical entities? Is the claim simply that everything in the intended domain is itself a member of that special class? If not, how are the nonphysical entities related to the physical ones?

The first set of questions has occasioned the least controversy. Most physicalists agree that the doctrine must be at least strong enough to imply that *the way the world is generally* is determined by *the way the world is physically*. Hence, the thesis must be strong enough to make a claim about properties (and relations) and their distribution in the world. It is for this reason that the idea that the doctrine might be formulated as the claim that all events are physical events, which enjoyed a run of popularity in the wake of Davidson (1970), has lost its appeal. Unless events are understood as themselves nothing more than property exemplifications, that claim seems not to imply anything significant about the distribution of physical and other properties. In light of this, the focus in this article will be just on claims about properties. The next section will concern the controversies attending the second set of questions about the meaning of the physical, followed by a discussion of the third set of questions about the relation that *all* properties might be said to bear to physical properties.

While the question of formulation has received the most attention in the literature, the question of justification is no less important. One may distinguish two justification projects here. There is, first, the project of defending physicalism against apparent counterevidence. Consciousness, intentionality, ethical properties, biological functions—these are all phenomena that have been thought incompatible with physicalism. There is no question that philosophers have devoted considerable energy to this defensive project. Discussion of these defenses of physicalism is beyond the scope of this article (see Consciousness; Function; Intentionality). The other project is to provide some positive reason to adopt physicalism in the first place. The most important arguments of this sort range from the (alleged) history of successful physicalist theorizing to various causal and counterfactual arguments. The last three sections of this article will provide a survey of these arguments and the challenges they face.

Specifying the Physical

What is meant by classifying a property as physical? One may be tempted to appeal in some way to the traditional definition of matter as that which is extended in space, perhaps by defining a physical property as one the instantiation of which confers spatial extension on its bearer. But this approach will not engage with contemporary physicalism, which gives pride of place to the science of physics, not spatial extension. (This point is reflected in the shift, earlier noted, from Feigl's physical$_1$ to physical$_2$.) It is worth bearing in mind, too, that it is not at all clear that such a criterion will coincide with one that appeals to physical theory. The entities to which physical theory is committed cannot be counted as straightforward material in the sense

of having spatial extension; forces and fields, for instance, do not seem to have spatial extension. If one takes into account, further, the picture of space found in quantum mechanics, it becomes even less clear how to think about any spatial extension criterion. For these reasons, most physicalists are inclined to appeal in some way to physical theory without invoking spatial extension at all.

Physics and the Physical

How exactly should the physicalist appeal to the entities at issue in physical theory? One approach is simply to consult the details of the actual theory and define the physical in those terms—perhaps by a simple list. Of course, there is a question about which physical theory exactly is at issue here. Is physical science to include not only microphysics but all disciplines that might be thought of as physical, such as chemistry, astronomy, geology, and so forth? Though not all physicalists have been explicit about this, most seem to opt for the more restricted theory. There are two good reasons to take this option. First, the properties at issue in the other physical sciences seem likely to be appropriately nothing over and above the more basic properties delineated by microphysical theory, so including them in the domain of the properly physical is unnecessary (see Chemistry, Philosophy of; Emergence; Reductionism). Second, and more important, the justification of physicalism that appeals to causal considerations makes the most sense when the causal considerations make reference specifically to the causal completeness of physics, which implies that the physicalist should focus solely on microphysics (Sturgeon 1998).

If it is agreed that the physical properties should be limited in this way to the microphysical, one must bear in mind the fact that much discussion of physicalism has been conducted as if physicality included a broader range of properties. For instance, Smart's (1959) celebrated defense of the identity theory focused on the identity of mental properties with *neurophysiological* properties, which would not count as properly physical on the present suggestion. Nor is it plausible to suppose that neurophysiological properties can be identified with strictly physical properties. What might be plausible, instead, is the thesis that such physical properties can be defined in terms of aggregations of basic individuals having certain physical properties and standing in certain physical relations to each other (see Kim 1998 for a discussion of such "micro-based" properties). In light of this, certain philosophical discussions about physical properties might best be interpreted as being about properties that are either physical or defined in this way in terms of the physical.

Skeptical Worries

The idea that the physical should be defined by reference to physics has prompted a number of philosophers to argue that no adequate account of the physical can be given (Crane and Mellor 1990). The core argument can be given as a dilemma. The theory by reference to which the physical is to be defined is either the physical theory that actually exists in the present or some envisaged future or ideal theory. In light of the history of science, it is likely that present theories are false, even if they are in some sense closer to the truth than past theories. As a result, the physicalist who takes the former option will be defining physicalism by reference to a false theory, which seems an unhappy result. On the other hand, if the physicalist chooses the latter option, the doctrine will be defined by reference to an unformulated theory, which seems again to be undesirable. In that case, it is said, the relevant notion of the physical becomes objectionably obscure, or perhaps is such as to render the thesis of physicalism trivially true.

Neither horn of the dilemma is quite as sharp as it may first appear. Consider the first option. Even if a physical property is defined by reference to current physical theory, physicalism is not committed to the *truth* of that physical theory. That theory is being exploited only for its ontology, not for its doctrine. So long as it has the right inventory of properties, regardless of the claims it makes about them, this actual theory will not be problematic. Still, if actual theory is in error in including nonexistent properties, or in failing to include certain properties, those errors seem to count against this option.

Consider the second option, whereby a physical property is defined by reference to an ideal physical theory. Two objections should be distinguished here: the triviality objection and the obscurity objection. The triviality objection may be understood as follows. In what sense is the ideal physical theory "ideal"? One may suspect that its being ideal implies that it is successful as a theory about all those phenomena that the physicalist believes to be ultimately physical. In that case, however, all those phenomena are trivially counted as physical simply by virtue of being the subject matter of the ideal physical theory. The point can be made dramatic

by considering some properties that are intuitively not physical at all, such as mental properties. If the ideal physical theory is defined as one that includes an account of everything of interest, including the mental, then such mental properties trivially count as physical—an intolerable result.

But this result is hardly inevitable. The physicalist who opts to define physicality by reference to an ideal physical theory need not understand the theory as ideal in the sense that it is successful about all phenomena of interest to the physicalist. Rather, the ideal physical theory may be better understood as ideal in the more limited sense of succeeding as a theory about all phenomena of interest to *physicists.* Of course, there remains work to do by way of clarifying just what this more limited domain is to include, but the present point is simply that the physicalist is not required to define the relevant theory in a way that trivializes physicalism.

The other objection from the obscurity point of view is more serious. An appeal to some ideal physical theory is an appeal to a theory not actually formulated. But if the details of this theory are in fact unavailable, how can anyone even begin to evaluate claims like "Everything is ultimately physical"? If philosophers do not have the ideal physical theory in hand, do they have any grasp of physicalism itself? If philosophers are profitably to discuss the doctrine, they need to have at least some grasp of what counts as prima facie physicality and what does not; the objection is that an appeal to an ideal physical theory does not allow philosophers to have any such grasp.

Responses to Skepticism

Responses to these skeptical worries can be divided into three categories: those that embrace the first option of appealing to present physical theory, those that embrace the second option of appealing to some ideal physical theory, and those that attempt to avoid the choice altogether.

The first response has been defended by Melnyk (2003), who argues that physicalism is itself a scientific hypothesis and, hence, that the attitude the physicalist takes toward it should be comparable to that which scientific realists take toward what they consider to be the best of current scientific theories (see Scientific Realism). As scientific realists usually recognize that current theories are likely to be false, the attitude in question need not be one that is rendered irrational by that recognition. In Melnyk's account of the appropriate attitude, one assigns the endorsed theory a higher probability than any of its *relevant rivals*, where the class of relevant rivals is limited in various ways—for instance, only actually formulated theories are included. As a result, the physicalist can take this attitude toward current physical theory without being committed to its truth or even likely truth.

The second response is perhaps the most popular (Papineau 1993; Poland 1994). The complaint that the resulting notion of physicality is too obscure can be blunted if there is good reason to suppose that certain concepts will not be needed to understand the ideal physical theory. If, for instance, no concepts of the mental are needed for this purpose, then the mental is not trivially included as part of the physical, and it is a good and substantive question whether the mental can be located in a fundamentally physical world. (This strategy may be generalized, of course, for other phenomena typically seen as needing special accommodation: One may suppose explicitly that no biological concepts, for instance, will be needed to understand the ideal physical theory, and so on.)

One important question for this strategy concerns the nature of this confidence that certain entities will not appear as such in the ideal physical theory: Is this exclusion to be imposed by definitional fiat, or is it to be understood as an empirically grounded prediction about the likely character of the ideal physical theory? Even if the former were chosen, a commitment would presumably be required to an empirical claim about some sort of continuity between actual physical theory and the envisaged ideal, for a lack of such continuity would make unclear how the success of actual physical theory plays a role in motivating the physicalism thus defined.

Finally, a different response that has recently been aired is to *replace* talk of the physical with that of the "nonmental" or other negatively defined notions. It can be seen as a natural descendant of one version of the previous strategy, whereby one defines the ideal physical theory so as to guarantee that certain phenomena are excluded. The suggestion is to drop the term 'physical' altogether and formulate a thesis negatively—as, say, the claim that everything is ultimately *nonmental.* Physicalism itself, on this suggestion, would presumably splinter into a variety of theses of this sort: In addition to the nonmental thesis, there would be the claims that everything is ultimately nonbiological, nonaesthetic, and so on.

In evaluating these responses to skeptical worries, one should bear in mind that an appropriate response should maintain contact with the motivation for physicalism. If physicalism is supposed to be

motivated by something about the actual success of physical theory, that motivation should continue to make sense given the chosen interpretation of (or, as in the third option, replacement for) the physical. In light of this, it is worth noting that it is not entirely clear that even present physical theory avoids incorporating the mental as an essential part of its machinery. If, as some speculate, the best way to make sense of quantum mechanics requires the essential involvement of a mental event of observation, then actual, non-ideal physical theory itself includes the mental as such, and an attempt to define the physical by reference to that theory will run the risk of counting the mental as such as already physical.

The following sections explore the relation of all else to the physical.

Identity Theses

The most straightforward way of formulating physicalism is a property identity claim:

(PI) Every property is a physical propery.

To many, PI has seemed too strong to be a fair expression of physicalism. If physical properties are understood as limited to those that are *microphysical*, this thesis will be simply incredible. This consideration is not, however, responsible for convincing many to reject PI as too strong, as much discussion of PI and its problems has taken place without having that specific method of defining the physical in the background.

The more famous consideration regarding PI is that it seems to be inconsistent with the claim that some properties are *multiply realizable,* which does not seem to be inconsistent with physicalism itself. The multiple realizability claim may be set out thus:

(MR) There is at least one property F such that it is possible for F to be instantiated on different occasions by virtue of being realized by different physical properties.

Exactly how the relation of realization is to be understood is a good question (addressed below under ''Realizationism''). It may be enough for the moment to point out that realization is meant by physicalists to be a sort of determination relation that licenses the claim that the realized property is not entirely distinct from its realizers, so that one could accept MR while remaining a physicalist.

MR seems to imply the following corollary, which one may call the *lack of coextension thesis:*

(LC) There is at least one property F such that there is no physical property with which F is necessarily coextensive.

Given MR, it seems that several different physical properties are all sufficient for the instantiation of the multiply realizable property; as a result, no single physical property is necessary for it. LC, of course, is inconsistent with PI; so if MR implies LC, it is inconsistent with PI.

The option of formulating physicalism in terms of identity is not thereby rendered hopeless, however. There are three positions worth considering that may be appealing to those originally tempted to PI. The first (the disjunction option) retains MR but maintains that MR does not imply LC; the second (the quasi-eliminativist option) rejects MR but retains a thesis similar to it; the third (the trope identity option) retains MR and LC but rejects PI in favor of a similar thesis.

The Disjunction Option

The disjunction option rejects the claim that MR implies LC; it aims to ensure that a physical property necessarily coextensive with the multiply realizable property can be found by constructing one from the various possible physical realizers of it. Suppose that pain is multiply realizable and that R_1, R_2, ... R_n are all the possible physical realizers of pain. Now consider the open sentence 'x has R_1 or x has R_2 or ... x has R_n' and call this the *disjunctive predicate.* The disjunction option identifies pain with the property allegedly expressed by the disjunctive predicate. There are three key questions about this option.

The first question is: Does the maneuver succeed in specifying a property that is necessarily coextensive with pain? The disjunctive predicate is constructed out of names of the physical realizers of pain, but if there are possible *nonphysical* realizers of pain, then the disjunctive predicate is not in fact necessarily coextensive with pain. However, if the nonphysical realizers are never instantiated in the actual world, it is not clear that physicalism runs counter to such possible nonphysical realization.

The second question is more fundamental: Does the disjunctive predicate succeed even in expressing a genuine property? If, as some argue, there is nothing genuinely in common among the various individuals that form the extension of the disjunctive predicate, then one might conclude that there is no property corresponding to the predicate. It is not obvious that one should suppose there is nothing in common, however, in light of the fact that each individual in the extension has in fact been grouped

together (at least by humans) as an exemplifier of pain.

Finally, the third question concerns the classification of the alleged property. Supposing that the disjunctive predicate indeed expresses a genuine property, it is not obvious that this property will count as a *physical* property. If the disjunction option is to save PI, the property with which it identifies pain has to be, of course, a physical property. The fact that the disjunctive predicate is constructed out of the names of physical properties is no guarantee that the resulting construction captures a physical property. The predicate '*x* does not have mass' is constructed from the name of a physical property, but it is doubtful that the property it captures should count as physical.

The Quasi-Eliminativist Option

The quasi-eliminativist option rejects MR but replaces it with a similar-looking thesis about predicates:

(MR*) There is at least one predicate *F* such that it is possible for *F* to be satisfied on different occasions by virtue of different physical properties being instantiated.

Suppose again that pain is one of the allegedly multiply realizable properties. The quasi-eliminativist does not insist that pain is realized in only one way; he allows that different things can be in pain by virtue of exemplifying distinct physical properties, but he rejects the claim that there is a genuine property of being in pain. There is a generally applicable predicate 'is in pain,' but there is no single property shared by all the individuals in the extension of that predicate. In effect, the quasi-eliminativist takes up the skepticism earlier expressed toward the alleged property expressed by the disjunctive predicate and applies it to the multiply realized property itself. The multiply realizable property is eliminated while the realizing properties are retained.

In fairness, the position is not described *simply* as eliminativist, since it allows that statements using the 'is in pain' predicate can be true. Indeed, one might adopt a version of this position according to which the various physical realizers of pain are themselves described as *kinds* of pain, thus allowing one to say that certain kinds of pain are genuine properties.

The quasi-eliminativist option has the undoubted attraction of providing a simple formulation of physicalism while not denying what seems to be the real substance of multiple realizability. It is hardly without cost, however, since the claim that there is no genuine property of being in pain is not very plausible at the outset. Perhaps, however, the advocate of this option could argue that insofar as one finds it plausible to think of a given alleged property as multiply realizable, one will also find it plausible to think that the property is merely alleged. In other words, if it is not plausible to think that there is no genuine property of being in pain, this may be because it is not plausible to think that pain is multiply realized.

The Trope Identity Option

The trope identity option abandons PI in favor of the thesis that every *trope* is a physical trope. This thesis is distinct from PI only if it is coherent to suppose that an individual exemplifies two distinct properties—the instantiations of which are nonetheless identical. If one understands tropes as being derivative on the more fundamental existence of properties as universals, so that they inherit their individuation conditions from the properties of which they are instances, it is not clear that this supposition is coherent. If, however, properties as universals are themselves constructed out of tropes understood as more fundamental entities, the supposition may be coherent. So long as there are at least two distinct equivalence relations by which tropes might be grouped into properties, the same trope could belong to two different groups and therefore be counted as an instantiation of two distinct properties.

The trope identity thesis can accommodate multiple realizability in a straightforward fashion. If a property *F* is multiply realized, no physical property is necessarily coextensive with *F;* nonetheless, each instance of *F* might be identical with an instance of some physical property—perhaps the physical property that realizes *F* on that occasion.

Supervenience Theses

While there are various ways to maintain an identity thesis in the face of MR, it may seem simpler to abandon identity for a rather different approach. The notion of supervenience has seemed to many to be a promising alternative. Supervenience is a relation that holds between families of properties: The *A*-properties supervene on the *B*-properties just in case there can be no difference in *A*-properties without some difference in *B*-properties (see Supervenience).

A good way to understand the attraction of supervenience is to think of it as an appropriately minimal way of talking about sufficiency. If *A*-properties supervene on *B*-properties, then there is a total state of each individual with regard to its *B*-properties that suffices for its total state with regard to its *A*-properties. Such sufficiency is just what one would expect if the *A*-properties were to be explained as being nothing over and above the *B*-properties. By appealing to supervenience, however, one avoids having to say just *which* of the explanatory properties do the explaining. Further, one allows that different physical properties do the explaining in different circumstances, thus accommodating multiple realizability.

The claim that the nonphysical properties supervene on the physical properties admits of more than one interpretation, however, and much of the literature on supervenience can be seen as devoted to distinguishing those interpretations and assessing them as expressions of physicalism. When it is said that there can be no difference in *A*-properties without a difference in *B*-properties, there are three key parameters to be specified. First, of course, one must specify the families *A* and *B*. Second, one must specify the modal status of the claim. Third, one must specify how the relevant comparisons are to be made. When it is said that a difference in *A*-properties requires a difference in *B*-properties, what sorts of objects are to be compared for sameness and difference, and how exactly are the relevant pairs to be selected? Permutations of these parameters can result in a wide variety of distinct supervenience claims. (See Supervenience for an overview of the varieties and their significance.)

The sort of supervenience thesis that has gained widespread popularity is global in form, comparing entire possible worlds for sameness or difference in the relevant families of properties. A *global supervenience* thesis seems well placed to capture the idea:

(GS) For any two possible worlds W_1 and W_2, if W_1 and W_2 are physically exactly alike, then W_1 and W_2 are exactly alike in all respects.

This is in accord with the notion mentioned earlier as central to physicalism, that *the way the world is generally* is determined by *the way the world is physically*. Nonetheless, GS is rejected by most physicalists as too strong. Most think of the doctrine as a contingent truth, so that there are possible worlds in which it is false. Given this, it seems that GS is false. Consider a possible world in which traditional Cartesian dualism is true and in which a particular body *B* is associated with a Cartesian soul. Now consider another possible world in which dualism is true just as in the first, with the sole exception that body *B* is, in this world, unconnected to any mental substance. This pair of worlds is a counterexample to GS, yet the physicalist may want to allow them as possible.

In order to focus on the character of the actual world, the physicalist is better off with a global supervenience thesis that compares other possible worlds with this actual world. If any world is just like this one in its physical character, then it must be just like this one generally. The desired thesis can be made more precise with the notion of a "minimal physical duplicate" (Jackson 1998). A minimal physical duplicate of a world *W* is, intuitively, what one would get if one were to take the physical description of *W* as a recipe, building a new world out of nothing but the ingredients spelled out in it, with no additional individuals or properties. Now consider the following supervenience thesis:

(MPD) Any minimal physical duplicate of the actual world is indiscernible from the actual world generally.

MPD appears to specify a supervenience thesis that is at least necessary for physicalism to be true. Whether it is *sufficient* is another question. A consensus appears to be emerging that *no* supervenience thesis is sufficient for physicalism. Supervenience is in itself simply a sufficiency claim. But physicalism is committed to an explanatory claim: If there are any nonphysical properties, their instantiation is to be explained by reference to the distribution of physical properties. Since it is a familiar idea from philosophy of science that sufficiency is not itself sufficient for explanation, supervenience does not seem capable of guaranteeing the explanatory import of physicalism.

This point has been emphasized by several philosophers in recent years (Horgan 1993; McLaughlin 1995). One way of making the point vivid is to demonstrate that there may be explanations of the truth of supervenience theses that are inconsistent with the sort of explanation desired by physicalists. Consider, for instance, how a traditional property dualist might explain the fact that any two physically indiscernible individuals are indiscernible with respect to their mental properties; the dualist might say that there are natural laws governing mental properties that dictate that they appear and evolve according to the physical states of individuals. Thus, a position plainly incompatible with physicalism seems compatible with supervenience.

But matters are not quite that simple, as much depends on the modal strength of the supervenience claim. The dualist explanation just considered depends on the natural laws thought to link the mental and the physical. In the two formulations given above (GS and MPD), there was no restriction on the domain of possible worlds. If there are possible worlds in which the actual laws of nature are not laws, then the dualist explanation just given will not carry over to those worlds. Of course, one might maintain that the actual laws of nature are necessary in the strongest sense, so that there are no possible worlds in which they fail to be laws. Barring that, it is not obvious how an unrestricted supervenience thesis like MPD might be explained in a way not consistent with physicalism. In any case, the point to be appreciated is that the relevance of supervenience theses depends both on one's general views about modality and the stipulated modal strength of the supervenience thesis.

Realizationism

An increasingly popular rival to the identity and supervenience approaches to formulating physicalism is *realizationism* (Melnyk 2003). This is the thesis that every property either is physical or, on every occasion of instantiation, is realized by a physical property. Because the claim that one property realizes another seems to carry explanatory force, realizationism seems to avoid the weakness of supervenience approaches while not being as strong as the property identity thesis.

The notion of realization is not grounded in ordinary talk but has flourished in the context of philosophical discussion of functionalism. As such, realization talk should be understood by reference to the notion of a second-order property. Suppose F is a second-order property defined in the following way:

x has F = there is some property P such that
(i) x has P and
(ii) x's having P meets condition C.

If the definitive condition C is that of playing a certain causal or functional role, then F may be said to be a functional property. Advocates of realizationism are likely to be functionalists as well as physicalists, taking advantage of the fact that functional properties are second order.

In one standard way of talking about realization, one can say that F is realized by a property P on the occasion of being instantiated by an individual x just in case x has P and x's having P meets condition C. If 'realizer' is used in this way, however, one should bear in mind that even if F is realized by P on a given occasion, the property P is not thereby sufficient for the instantiation of F. It is the combination of P and the fact that the individual's having P meets condition C that is sufficient for F.

The point is highlighted by some terminology introduced by Shoemaker (1981). Shoemaker distinguishes between "core" and "total" realizers. In the example given above, P is the core realizer of F on that occasion of instantiation. The total realizer can be specified as the property of having P *and being such that one's having P meets condition C.* Given the definition of F, it is trivially necessary that any individual that exemplifies a total realizer of F will also exemplify F. Further, it seems plausible to say that when F is instantiated in this fashion, that instance of F is nothing over and above the instantiation of that total realizer. By contrast, it does not seem appropriate to say that the instance of F is nothing over and above the instantiation of the core realizer P. In light of the core/total distinction, it seems that the realizationist thesis should be understood as the claim that every nonphysical property has, on every actual occasion of instantiation, a physical total realizer.

Realizationism thus understood is not as distant from the identity approach as one may have expected. If the total realizers of F are themselves physical, then the definitive condition C is itself physical. In that case, one may well want to say that F is physically definable. After all, F would then be definable using nothing but logical connectives, quantification over properties, and terms for physical properties. One may say that the identity thesis has been vindicated, for the multiply realizable properties are all identical with second-order properties, which can be seen to be themselves physical (Field 1992).

The Question of Justification

The History of Successful Physicalist Theorizing

One route to justifying physicalism is quite straightforward: Argue that since a wide variety of phenomena have already been shown to be ultimately physical in nature, the physicalist is justified in making the inductive leap to conclude that all phenomena are ultimately physical.

One way of thinking about this is in terms of the history of reductive success. That is certainly the justification imagined by those philosophers writing in the middle of the twentieth century who were concerned to defend a physicalist theory of the mind. They took it more or less for granted that

scientific results had already demonstrated that sciences other than psychology reduced to "lower-level" sciences, and ultimately to physics. In effect, in this view, physicalism as a view about everything else (other than the mental and those things dependent on the mental) had already been demonstrated by a string of successful reductions. All that remained was to justify the extension of physicalism to the realm of the mental and the like.

This way of justifying physicalism is, however, hampered by controversies over the notion of reduction. The claim that biology has been shown to be completely reducible to chemistry, for instance, will not command immediate assent (see Reductionism). No one doubts that all sorts of interesting links have been found and developed, but the controversy is over the proper interpretation of those achievements.

Nonetheless, the general drift of the argument is clear: There is a history of what might be called successful physicalist theorizing—a history of success in showing that various properties are indeed to be counted as ultimately physical, as well as an invitation to generalize to all properties. Whether the argument is a good one depends on how exactly the relation of being "ultimately physical" is understood and whether, in light of that understanding, it is the sort of feature one can find in the actual results of science and should confidently project to other cases.

A somewhat different way to use the history of science to argue for physicalism is via what one can call the *argument from proven methodological utility.* Instead of claiming that what history displays is a string of successful theories showing that various properties are ultimately physical, this argument strategy turns on the claim that scientific practice has often *presupposed* that physicalism is true, and this presupposition is at least partly responsible for its success. The history of science shows that it pays to presume physicalism; the best explanation of this proven utility is that physicalism is true.

One advantage of this argument is that it does not require its advocate to find in the history of science any explicit theories setting out how apparently nonphysical properties are to be explained as ultimately physical. All that is needed is evidence that confidence in the existence of such an explanation played a key role in advancing scientific inquiry. The disadvantage is that it is not easy to adjudicate claims about the role of presuppositions. Even if it is plausible to say that actual scientists have presumed physicalism, more work is needed to show that this presumption (and not perhaps some less weighty or less significant one) played a role in dictating the theories constructed, experiments designed, or the like.

The Causal Impact Argument

The causal impact argument for physicalism is easy to state in a rough form. There are three premises. The first is the causal impact thesis: Every event is a cause of some physical event or other. The second is the causal completeness of physics: Every physical effect that has a sufficient cause has a sufficient *physical* cause. (Physical events that are not causally determined may be said to have their objective chances of occurrence determined by physical causes.) The third is the claim that causal overdetermination is not rampant.

Together, these three premises seem to imply that any apparently nonphysical property must be ultimately physical; any such property is involved in some event and thereby has a causal impact on the physical. Given the causal completeness of physics, however, anything that has a causal impact on the physical must be itself physical—unless, of course, the physical event is causally overdetermined, which option is ruled out by the third premise.

While the first and third premises seem to be plausible on casual examination, the second—the causal completeness of physics—needs special comment. It should be stressed that the thesis does not imply that the only legitimate causal explanations of physical events are ones that appeal exclusively to physical conditions and laws; it implies only that for every physical event that can be causally explained at all, there exists a *sufficient* causal explanation of it that appeals only to physical conditions and laws. The thesis can therefore be supported by considerations internal to physical theory, by judging the success of physical theory in producing such explanations, without having to rely on any claims about the relation of physical theory to anything else. This is a considerable advantage, as any such claims are likely to be philosophically contentious.

The causal impact argument should be sharply distinguished from the traditional attack on Cartesian dualism that questions the intelligibility of causation spanning the mental and physical divide. The argument does not concern the mental/physical divide in particular, nor does it turn on claims about intelligibility at all. It should also be distinguished from Davidson's (1970) famous argument for the thesis that every event is a physical event. While there are a few (indirect) relations between this argument and Davidson's, the latter turns fundamentally on considerations about the availability of strict causal laws to subsume cause/effect pairs,

whereas the causal impact argument in no way relies on such considerations.

The causal impact argument has gained ground as the most popular route for justifying physicalism. There is one very important way in which the argument needs further careful development, however. How exactly should its conclusion be understood? If causation relates events, then one may take the argument as concluding that every event is a physical event. But that conclusion seems insufficient for physicalism, as discussed earlier. If the argument is to give us a conclusion that is recognizably physicalist, its premises must be, so to speak, appropriately calibrated, so that they concern properties and their role in causation. For example, if physicalism is understood as realizationism, the advocate of the argument must find a way both to refer to the role of properties in causation *and* to show that the only alternative to genuine overdetermination is for the causally relevant property to be either itself physical or, on that occasion, physically realized.

The Manifestability Argument

The manifestability argument is akin to the causal impact argument in that it, too, makes use of the causal completeness of physics. It does not, however, rely on the assignment of causes; it turns solely on counterfactual claims. The key premise is that the nonphysical is physically *manifestable* in the sense that if two individuals differ in some nonphysical respect, this difference is capable of showing up in a difference of physical conditions. More precisely, if x and y are discernible in some nonphysical respect, then there is some physical context C and some physical event type E such that if x were in C, an E-type event would occur, while if y were in C, no E-type event would occur.

The premise has considerable intuitive plausibility. Consider the infamous case of the mental. It seems that differences in mental states, even if they do not actually manifest themselves physically, are capable of doing so. (If, for instance, two people differ in their beliefs as to whether there are ducks present, the physical condition that amounts to asking "Are there ducks about?" would elicit different behaviors.) If the manifestability premise is granted, any nonphysical difference is reflected in a difference in potential physical consequences. But given the causal completeness of physics, any difference in potential physical consequences is grounded in actual physical differences. Hence, any nonphysical difference is reflected in some actual physical difference. In other words, the nonphysical supervenes on the physical (Papineau 1993; Loewer 1995).

Although the manifestability argument has not received the same attention given the causal impact argument, it is accused of being incapable of supporting an appropriately strong supervenience thesis (Witmer 1998). Even if the argument is not successful on its own, however, those physicalists inclined to rest their convictions on the causal impact argument should keep it in mind. Since counterfactuals are intimately related to causal claims, the manifestability argument may contain resources relevant to the proper development of the causal impact argument.

JULES HENRI POINCARÉ

(29 April 1854–17 July 1912)

Jules Henri Poincaré was a prolific mathematician, mathematical physicist, and philosopher. Often compared to Gauss, he made significant contributions to many areas of mathematics, including topology, non-Euclidean geometry, Lie groups, and differential equations. He also published four volumes of philosophical and popular writings on science and mathematics.

As a philosopher of science, Poincaré is sometimes thought of as a conventionalist (see Giedymin 1982). Poincaré did argue that certain central decisions in science have a strongly conventional element. But as a general label, "conventionalism" does not accurately account for the variety and complexity of views that make up his philosophy of science. His clearest and most convincing arguments for conventionalism are found in his philosophy of geometry. Poincaré argued that the choice between Euclidean and non-Euclidean geometry is radically underdetermined. Either can be chosen, for either hypothesis can be made to fit any data. The result is thus a convention, for only convenience can determine the choice. But even here, at his most conventional, Poincaré (1982) believed that the candidates for a geometric choice are a priori constrained by the nature of human minds; furthermore, which choice appears to be the most convenient is influenced by the nature of the empirical world (276). In this way, all reference to "convention" in Poincaré must be balanced by his semi-Kantianism on the one side and his empiricism/realism on the other. Conventions in science were not in general "mere" for Poincaré.

Geometric Conventionalism

Poincaré argued that geometry is not synthetic a priori as Kant thought because it is not possible to have intuitions of points, lines, or spatial distances. Nor is geometry in any straightforward sense analytic a priori, for its truths are not determined by the nature of the fundamental geometric concepts alone. In the absence of axioms, the concepts of point, line, and plane do not distinguish one geometrical system from another. On the contrary, the fundamental geometric concepts become

"implicitly defined" only after the geometric axioms are chosen.

Geometry is not empirical either. In order to test whether space is Euclidean or non-Euclidean, some measurements would have to be made. But such measurements would have to be based on assumptions in physics—for example, that light travels in straight lines. So they would have to depend on a prior understanding of 'straight line' and its physical realizations. This point was brought out very clearly by the parallax result, which showed that a fixed star observed during a solar eclipse appears in a different location than its ordinary location observed at night. The intuitive response is that the light from the star bends as it travels past the sun, owing to the sun's gravitational field. Poincaré famously pointed out that this means that geometry cannot be empirically tested in any straightforward manner. In the light of the parallax result, a choice had to be made whether to revise the physical hypothesis that light travels in straight lines or the Euclidean hypothesis that space is flat. In such a case, which choice is "correct" is undetermined by the evidence, for it depends only on what is most convenient given the global background theory. That Euclidean geometry can be chosen no matter what the data say means that geometry is more like language than an empirical claim. It is in this sense that it is conventional. The argument relies on the thesis that it is possible to test only the conjunction of physics plus geometry. Generalized by Duhem into the view that it is possible to test only a cluster of hypotheses rather than a single one, and further generalized by Quine, one can see that Poincaré's "conventionalism" was in some ways a foundation for contemporary holism (see Duheim Thesis).

An important limitation on Poincaré's candidates for geometry was that they had to be of constant curvature. This was of course rejected by the theory of general relativity, according to which the curvature of space depends on the distribution of its matter. However, Poincaré regarded the very idea of spatial measurement as requiring rigid body motion, where rigid bodies are simply idealizations of physical bodies. People know that ordinary bodies, including their own, move. Indeed it is precisely the possibilities underlying this sort of motion by which the difference between change of state and change of place is understood. And understanding the idea of motion—change of place—is central to geometrical thinking.

Also central to geometric thinking is the idea of a group, which Poincaré regarded as a form of understanding, given a priori. When conjoined with the presupposition that rigid body motion is possible, the group concept yields the Lie groups, which entail that there are three basic geometries of constant curvature: Euclidean, Riemannian, and Lobachevskian. According to Poincaré, experience helps us to pick out which group is merely the most convenient among the three possible. The indefinite iterability of the geometric operations means that geometry also presupposes arithmetic and its a priori intuitive basis (Poincaré 1982, 276) (see Conventionalism).

Intuition in Pure Mathematics

In his philosophy of pure mathematics, and especially of arithmetic, Poincaré was a self-declared defender of Kant against both logicism and Hilbert's program. The extent to which he was truly Kantian is a tricky question. Like Kant, Poincaré appealed to intuition as a necessary—yet nonlogical and nonconceptual—source of knowledge. Unlike Kant, the a priori intuition he focused on is indefinite iteration rather than space or time, where 'indefinite iteration' means the capacity of the mind to conceive the unlimited repetition of certain acts. There was an important connection between intuition and sense experience for Poincaré as for Kant, in that indefinite repeatability was presupposed in his displacement account of motion in, and experience of, space. But iterability seems a little less immediate than Kant's spatiotemporality. (The spatiotemporality of the world of experience seems obvious; the indefinite iterability of certain features of experience may seem downright false.) Poincaré (1913, 44) later also endorsed the intuitive nature of the continuum, claiming that experience would be impossible without it. Why this is so is left mostly unexplained and remains somewhat obscure.

Though the intuitive nature of the continuum is not clearly defended, Poincaré did argue vehemently for the intuitive basis of arithmetic. The nature and role of intuition in Poincaré's philosophy of mathematics is relevant to his philosophy of the natural sciences, and in particular to understanding what sort of a so-called conventionalist he was for the following reason. He believed that there is a hierarchy of sciences with arithmetic at the most fundamental level. Analysis builds on arithmetic, geometry builds on analysis, and physics builds on geometry. The epistemology of arithmetic thus provides a foundation for the epistemology of the rest of science in Poincaré's hierarchy (Poincaré 1902; Folina 1992 and 1995).

The main opposition to the Kantian paradigm for arithmetic was logicism, represented to Poincaré by

people such as Russell and Couturat. In contrast to the logicists, Poincaré regarded mathematics as irreducibly mathematical, and intuition was his answer to the question of what the essence of mathematics is. Poincaré's strongest arguments against logicism and for intuition were circularity objections against any formal attempts to symbolically reconstruct arithmetic. His claim was that all such formal systems, if they are adequate for deriving the theory of the natural numbers, presuppose the intuition they are trying to avoid. This is a strong claim and one that is hard to defend in general.

His defense of intuition came in two stages. Prior to 1906, his most potent argument was that symbolic logic after Frege, Boole, etc., is itself inherently combinatorial, and so inherently mathematical in that it presupposes iteration in the form of recursive procedures. Thus, any derivation of arithmetic from logic has already presupposed something inherently mathematical. So it is circular.

By 1906, his circularity objection was modified in light of the set-theoretic paradoxes. Hereafter, he was no longer so concerned with mere circularity; his objections instead focused on the vicious circularity of certain definitions available in naive set theory and elsewhere in classical mathematics. The problematic definitions typically involve a property the scope of whose quantifier includes the object being defined. These definitions, via writings by both Poincaré and Russell, became known as "impredicative."

As it turned out, impredicative definitions are very common in mathematics. So the class of definitions affected by the critique was surprisingly broad. The problem in accepting Poincaré's point of view is that not many mathematicians would be willing to sacrifice mathematical methods for a philosophically based restriction—especially not when there are other available ways to avoid paradox, such as axiomatic set theory. Poincaré himself did not restrict his work to predicative mathematics. With his other circularity arguments he sometimes argued that the ineliminability of impredicativity simply showed the need for intuition in certain domains (see Heinzmann 1985).

The main point for this entry is that Poincaré persisted in defending the intuitive basis of mathematics, in his efforts to defend Kant's basic picture of mathematics from the attacks of logicism. In this account, at least part of the nature of mathematics is determined by the kinds of minds that human beings have: finite, yet capable of infinite combinatorial thinking. Since the rest of science appeals to mathematics and rests on it, science is not governed *simply* by conventions. The existence of certain conventional choices in science does not, therefore, mean that science as a whole is "merely" conventional.

Scientific Realism

If Poincaré's modified Kantianism balances his conventionalism from the a priori side, his empiricist-based realism balances it from the other. Whereas a priori intuition can be thought of as dictated by the a priori nature of the mind, empirical facts are dictated by the *a posteriori* nature of the physical world. It should be noted that by 'fact' in science Poincaré meant an intersubjectively verifiable state of affairs. The empirical world is in this account relevant to the "conventional" choice between Euclidean and non-Euclidean geometry. Which geometry is most convenient will depend on the use to which it needs to be put. Physics uses geometry, so the best current theories in physics will contribute to determining what counts as the simplest, most convenient geometry. And the best current theories in physics are at least in part determined by the way the world is.

Of course, one must not overemphasize the sense in which Poincaré was a realist. His conventionalism was not strictly limited to his philosophy of applied geometry. Poincaré used the term 'convention' outside of geometry as well, to include certain principles that originated as part of experimental science. His view was that when a bit of science is particularly well confirmed and particularly fundamental, it can end up being called a "principle" and treated as a convention. There is obviously some affinity here with Quine's "web of belief" metaphor. Though Poincaré would not have carried the view so far as to eliminate distinctions such as analytic/synthetic, or to eliminate all hierarchy in science, he did regard the boundary between the conventional and the experimental parts of science as both elastic and a little bit fuzzy. Not only can an experimentally based principle become a convention; a convention rooted in a principle can still be undermined by experiment—even if not directly falsified (Poincaré 1982, 318–319). Nevertheless, at any one time, there is a difference between the conventional and the empirical parts of science; and, in emphasizing this distinction, Poincaré resembles the logical positivists whom he influenced.

Despite the appeal to convention further up in Poincaré's hierarchy from geometry, the real world is "out there" and cannot be changed at will. That is, despite Poincaré's anti-realist sympathies, he

argued (against the more radical, exaggerated conventionalism of Le Roy) that science is neither whimsical nor wholly conventional (Poincaré 1982, 335). Its theories are not mere creations. Scientific facts are "crude facts" translated into scientific language; but scientific facts are not *created* by scientists (208). The existence of conventions in a scientific theory does not, therefore, mean that the theory as a whole is a mere convention, nor does it mean that any part of it is trivial. Furthermore, change in science is governed and limited by the facts. Progress in science can involve a kind of revolution, where a whole paradigm is overturned for another. But Poincaré argued that even in this sort of case, the success of the new theory usually depends on some kernels of truth in the old. He thus emphasized continuities in science underlying the changes and even the revolutions. Objective truth in science and in everyday life consists of the enduring relations between things. Even an overturned theory can contain many truths about the relations between things—especially when what is overturned is the conception of the "things" themselves rather than the relations, and especially when these relations can be expressed mathematically (Poincaré 1982, 350–351). Poincaré's realism is thus expressed in his beliefs in genuine progress in science and that science discovers objective truths, even if these truths are largely structural, or relational, in nature.

Conclusion

Poincaré's philosophy of science is both complicated and interesting (see Stump 1989). He appears in different guises as a conventionalist, empiricist, Kantian, constructivist, logical positivist, anti-realist, and even a realist with a robust concept of truth and an interesting conception of objectivity. Though his popular writings often appear glib and polemical, they contain much wisdom, and remain influential, for philosophers of science today.

KARL RAIMUND POPPER

(28 July 1902–17 September 1994)

Karl Popper (Sir Karl Raimund) is widely considered to have been one of the greatest philosophers of science of the twentieth century. He was also an eminent social and political philosopher, a metaphysical indeterminist, and a relentless critic of authoritarianism. Popper's famously trenchant

defense of the "open society" has been widely influential, not least for the highly original manner in which he traced the roots of totalitarian ideologies to historicist presuppositions. However, his most original and lasting contributions to the philosophy of science were his rejection of the Baconian observationalist-inductivist view of scientific methodology, his emphasis on the centrality of problem solving to the scientific enterprise, and his advocacy of the view that only a system of theories that is falsifiable by experience should be accorded genuine scientific status.

Life

Karl Raimund Popper was born in Vienna, the youngest child of middle-class parents of Jewish origin. His father, a barrister, communicated to him an interest in social and political issues that he was never to lose, while his mother cultivated in him a deep and abiding passion for music. He was educated at the University of Vienna, where he studied mathematics, physics, psychology, music, and philosophy. He obtained a Ph.D. in philosophy in 1928 and taught in secondary schools from 1930 to 1936. Although he was friendly with some members of the Vienna circle of logical positivists, whose concern with science he shared, he was sharply critical of many of their central principles, particularly what he took to be their misplaced concern with the theory of meaning. In 1937, concerns about the growth of Nazism led him to emigrate to New Zealand, where he became a lecturer in philosophy at Canterbury University College, Christchurch. In 1946, he moved to England to become a reader in logic and scientific method at the London School of Economics; he became a professor there in 1949. As his reputation and influence grew, Popper received many honors. He was knighted in 1965 and elected a Fellow of the Royal Society in 1976. He retired from academic life in 1969, though he remained intellectually active until his death.

Works

Popper's philosophy of science was first articulated in *Logik der Forschung* (Popper 1935), which was published in the Vienna Circle's series *Schriften zur wissenschaftlichen Weltauffassung*. This circumstance contributed to the initial misconception in the anglophone world that Popper was a positivist. Popper (1945 and [1957] 1961) widened his focus to cover historical, social, and political issues, and advanced a powerful critique of historical determinism as the theoretical assumption underpinning totalitarian ideologies. He published two collections of thematically linked papers (Popper [1963, 1965] 1969 and [1972] 1979), a reply to his critics in the volume on his work in the Schilpp (1974) Library of Living Philosophers, an intellectual autobiography (Popper 1976), and an examination of the mind–body problem with John Eccles (Popper and Eccles 1977). Most of these works have gone through several editions, in some cases incurring significant modification in the process. In the 1990s, Routledge published a number of posthumous editions of Popper's work and thought. These include collections of his lectures and essays (Popper 1992 and 1994 [including a critique of contemporary irrationalism]), an interview (Popper 1997), a series of essays on early Greek philosophy (Popper 1998), and the translation *All Life Is Problem Solving* (Popper 1999). Popper's manuscripts and correspondence are collected in the archives of the Hoover Institution, Stanford University, where he was a senior research fellow.

Science and Metaphysics: The Problem of Demarcation

Popper's main enterprise was to construct a model of scientific rationality that embodied an account of the logical relationships between theoretical and observation statements in science, and, associated with this, a prescriptive methodology. He was an epistemological fallibilist who recognized that the "central problem of epistemology has always been and still is the growth of knowledge" but who held that the growth of knowledge "can be studied best by studying the growth of scientific knowledge" (Popper [1935] 1959, 15). Consequently, his concern with the problem of demarcation in philosophy of science was intended to be seen as having the widest-ranging philosophical implications, since he proposed that epistemology "should be identified with the theory of scientific method" (49). He described how the issue of demarcation relates to his own general objectives as follows:

> [My] business, as I see it, is not to bring about the overthrow of metaphysics. It is, rather, to formulate a suitable characterization of empirical science, or to define the concepts "empirical science" and "metaphysics" in such a way that we shall be able to say of a given system of statements whether or not its closer study is the concern of empirical science. ([1935] 1959, 37)

Demarcation, then, is the problem of distinguishing the empirical sciences from nonempirical areas such as logic, pure mathematics, and metaphysics,

as well as pseudosciences such as astrology and phrenology. However, Popper dissented from the approach of the logical positivists, who had addressed this problem by effectively identifying it with that of meaning, thus making the verifiability of a proposition a criterion of both its meaningfulness and its scientific status. This, in Popper's eyes, reduces a real philosophical issue to a trivial verbal issue. It is also a naturalistic error, because it treats demarcation as a problem amenable to the method of discovery and presupposes the existence of a clear-cut, impenetrable line between science and metaphysics. Thus it ignores the fact that metaphysical theories can generate, or even develop into, scientific theories, as, for example, with the classical theory of atoms. By contrast, Popper's approach to formulating a criterion of demarcation was nonnaturalistic or prescriptive; it involved offering a "proposal for an agreement or convention" ([1935] 1959, 37). For him, the line between science and metaphysics was to be drawn by agreement and decision, not by discovery. Such an agreement, however, must be informed by both logical and methodological considerations, and while he acknowledged that "a reasonable discussion of these questions is only possible between parties having some purpose in common" (ibid), he was optimistic about the possibility of rational assent on the part of those who shared his goal of adequately characterizing empirical science.

Popper's rejection of the naturalistic approach to the problem of demarcation taken by the logical positivists has a counterpoint in his repudiation of their view that science is characterized by its inductive methods, in which universal laws are supposedly inferred from a set of singular statements such as experimental observation reports. This is the traditional observationalist-inductivist paradigm of scientific investigation; the repudiation of this paradigm links the problems of induction and demarcation in Popper's philosophy. His case against it rests on three central contentions. First, there are no "pure" or theory-free observations. "Observation is always selective. It needs a chosen object, a definite task, an interest, a point of view, a problem" (Popper [1963, 1965] 1969, 46). Therefore, observation is theory laden and involves applying theoretical terms, a descriptive language, and a conceptual scheme to particular experiential situations. Second, scientific laws are strictly unverifiable. All such theories are universal in nature, and no finite collection of observation statements, however great, is logically equivalent to, or can justify, an unrestricted universal proposition. Third, induction, conceived of as a system of logical inferences that generates scientific law from the particularity of experimental results, is a "myth" (53). Such inferences, Popper held, play no role in scientific investigation or in human life generally.

At one level, then, Popper concurred with Hume's critique of induction. However, a crucial counterpart, which he believed Hume himself had missed, is that while no number of positive outcomes at the level of experimental testing can demonstrate the truth of a scientific theory, a single genuine counterinstance is logically decisive. "Hume showed that it is not possible to infer a theory from observation statements; but this does not affect the possibility of refuting a theory by observation statements" (Popper [1963, 1965] 1969, 55). By the canonical *modus tollens* rule of classical logic, it is possible to deductively infer the falsity of a universal proposition once the truth-value of an appropriately related singular proposition is established. For Popper, this means that the central kind of inferences involved in science are deductive ones from observation reports of the form "This A is not X" to the *falsity* of the corresponding universal hypotheses, and such inferences occur in the critical testing of such hypotheses rather than in their generation.

Accordingly, Popper's view of the relationship between scientific theory and experience was both anti-inductivist and anti-Humean: Theory is not logically derived from, nor can it be confirmed by, experience, though experience can and does delimit it. He argued that human knowledge generally, including scientific theory as one of its most refined forms, is both fallible and wholly hypothetical, and it is produced not by logical inference but by the creative imagination. The central rational activity in science is problem solving, whereby new hypotheses are imaginatively projected to solve problems that have arisen with respect to a preexisting theoretical framework. This process may be retrospectively retraced though "more and more primitive theories and myths ... [to] unconscious, inborn expectations" (Popper [1963, 1965] 1969, 47). The critical role of experience in science is to show us not which theories are true but which theories are false. However, a theory that has successfully withstood critical testing is thereby "corroborated" and may be regarded as preferable to falsified rivals. In the case of rival nonfalsified theories, for Popper, the higher the informative content of a theory, the better it is scientifically, because every gain in content brings with it a commensurate gain in predictive scope and testability. For that reason, he held that a good scientific theory will be more *improbable* than its rivals, because the probability

and informative content of a theory vary inversely: "If our aim is the advancement or growth of knowledge, then a high probability (in the sense of calculus of probability) cannot possibly be our aim as well: *these two aims are incompatible*" (218).

It is thus not too much to say that Popper's perception of the asymmetrical logical relation between verification and falsification lies at the heart of his philosophy of science: A universal scientific theory cannot, in principle, be verified, but a single counterinstance can and does decisively falsify it. Accordingly, he held that from a logical perspective, a system of theories is scientific only if it is refutable or falsifiable:

> I shall not require of a scientific system that it shall be capable of being singled out, once and for all, in a positive sense; but I shall require that its logical form shall be such that can be singled out, by means of empirical tests, in a negative sense: *it must be possible for an empirical scientific system to be refuted by experience*. ([1935] 1959, 40–41)

Popper defined this demarcation criterion most clearly in terms of the relation between a scientific theory and "basic statements," which are to be understood as singular existential statements of the form "There is an *X* at *Y*." In this definition, where a theory is scientific, it must exhaustively divide basic statements into two nonempty classes:

1. the class of basic statements that are consistent with the theory, or that the theory "permits" (class 1); and
2. the class of basic statements that the theory rules out, or "prohibits" (class 2).

The latter class is, in Popper's account, by far the more important, as it constitutes the theory's potential falsifiers; that is, the truth of any statement in class 2 implies the falsity of the theory. In short, for Popper ([1935] 1959), "[A] theory is falsifiable if the class of its potential falsifiers is not empty" (86).

One of the most controversial implications of this criterion, which Popper strongly affirmed, is that psychoanalytic theory and the contemporary Marxist theory of history cannot be deemed scientific. Ironically, the all-inclusive nature of psychoanalytic explanation, which Freud and his followers saw as the principal basis for the scientific status of psychoanalysis, turns out on this account to be a critical weakness, for it entails that psychoanalysis is not genuinely predictive. Psychoanalytic theories, Popper argued, are insufficiently precise to be "prohibitive," that is, to have negative implications in the form of a class of potential falsifiers, and so are not subject to experimental falsification. Popper denied the claim to scientific standing of the Marxist theory of history on the grounds that while it was prohibitive and therefore testable in its original form, many of its implications turned out to be false. However, Marxists responded by reformulating the theory ad hoc to make it consistent with the falsifying evidence. They thus "gave a 'conventionalist twist' to the theory; and by this stratagem they destroyed its much advertised claim to scientific status" (Popper [1963, 1965] 1969, 37).

Falsificationism and Methodological Rules

Popper was aware that there is a significant disparity between the precision of the logical analysis of statements contained in his demarcation criterion and the complex, heterogeneous nature of actual scientific practice. Since observation is, as he insisted, itself fallible, an experimental result can always be questioned. His account of the logic of falsifiability was thus tempered by an explicit recognition that scientific theories are often retained in the face of conflicting or anomalous empirical evidence and that, in actual scientific practice, a single conflicting instance or counterinstance is never sufficient to force the repudiation of an established theory. He was also cognizant of the fact that against dogmatic or uncritical advocacy, "no conclusive disproof of a theory can ever be produced" ([1935] 1959, 50). In short, he recognized that a logical analysis of statements alone is not sufficient to recapitulate the unique character of empirical science.

To achieve that objective, Popper concluded, it is necessary to embed falsifiability in a normative methodology, which in this connection relates to decisions that must be made as to how to deal with scientific statements—decisions which, in turn, are determined by one's aims. For Popper ([1935] 1959), the aims of elucidating empirical science and constructing a model of scientific rationality bring with them a need to adopt a set of rules that will "ensure the testability of scientific statements; which is to say, their falsifiability" (49). Accordingly, the "supreme rule" associated with the falsifiability criterion, which functions as a norm with which all other methodological rules must accord, is "the rule which says that the other rules of scientific procedure must be designed in such a way that they do not protect any statement in science against falsification" (54). This rule prohibits, as unscientific, any ad hoc reformulation of a theory to meet contradictory evidence. The recognition of the hypothetical and fallible nature of human

knowledge, and with this recognition the willingness to subject even one's most cherished theory to a critical test that could conceivably show it to be false, became, for him, the defining characteristic of the true scientific mentality: "The wrong view of science betrays itself in the craving to be right; for it is not his *possession* of knowledge, of irrefutable truth, that makes the man of science, but his persistent and recklessly critical *quest* for truth" (281).

Science, History, and Society

Popper's emphasis on the epistemological and methodological importance of conditions that foster the critical evaluation of deeply held beliefs is an important link between his philosophy of science and his social and political philosophy. In *The Open Society and Its Enemies* and *The Poverty of Historicism* he launched a powerful attack on historicism (Popper 1945 and [1957] 1961). Historicism encompasses the views that historical processes and events are governed by immutable deterministic laws and that history itself evolves inexorably toward a teleological goal, a conception that is fundamental to most "dialectical" theories of history. Popper saw it as the principal theoretical assumption underlying political authoritarianism, and he considered the theories of Plato and Marx particularly illustrative in this regard. Associated with historicism is the "historicist doctrine of the social sciences," the view that the main task of the social sciences is "to make historical predictions, such as the predictions of social revolutions" (Popper [1963, 1965] 1969, 338). For the historicist, just as the natural sciences allow the prediction of eclipses, appropriate knowledge of the "laws of history" would allow the social sciences to predict social processes such as revolutions. Popper argued that this presupposes an incorrect view of the nature of scientific law and scientific prediction—a view in which the unconditional prediction of eclipses is wrongly taken as typical, whereas it actually applies only to systems, such as our solar system, that are "well-isolated, stationary, and recurrent" (339). Because of the universality of scientific theory, prediction in natural science is typically conditional and limited in scope to a particular aspect of the system under investigation. In general, Popper further argued, a predictive science of human history is impossible, because the "course of human history is strongly influenced by the growth of human knowledge ... [and] we cannot predict, by rational or scientific methods, the future growth of our scientific knowledge" ([1957] 1961, v–vi).

Popper saw "large-scale social planning"—for instance, revolutionary attempts to restructure the social order—as an inevitable consequence of historicism, and he accordingly rejected it, advocating instead "piecemeal social engineering" as the central mechanism for social reform. In this latter mode, he argued, intentional actions should be directed toward a limited number of objectives, facilitating the observation of any adverse unintended effects. Here Popper's conservatism contrasts strongly with his advocacy of bold scientific conjectures, but the strategy outlined does parallel the critical testing of theories in scientific investigation. It is also linked with Popper's commitment to negative utilitarianism, the moral principle that one should seek to reduce suffering to a minimum. In his view, the function of the state is not to impose a preconceived ideal of the good but rather to ameliorate generally acknowledged social ills. Popper held that an open society, providing as it does for peaceful changes of government and a milieu in which the critical appraisal of policy is fostered and encouraged, is an essential prerequisite for critical thought and the emancipatory goals flowing from such thought. It thus happens that problem solving is as characteristic and reflective of common humanity at the social and political levels as at the level of scientific investigation—an insight that is one of the integrating forces in Popper's thought.

Later Developments: Objective Knowledge, the Third World, and Verisimilitude

In his later works Popper looked to biology rather than physics, seeing the growth of human knowledge through the critical appraisal of competing theories in terms that are strongly Darwinian:

> The growth of our knowledge is the result of a process closely resembling what Darwin called "natural selection"; that is, *the natural selection of hypotheses*: our knowledge consists, at every moment, of those hypotheses which have shown their (comparative) fitness by surviving so far in their struggle for existence; a competitive struggle which eliminates those hypotheses which are unfit. (Popper [1972] 1979, 261)

This led him to advance an evolutionary epistemology, in which he attempted to account for the very existence of the philosophical and scientific quest for truth in terms of natural selection. In this he represented biological adaptations as forms of problem solving and, ultimately, of knowledge. This epistemology related in turn to a new, radically pluralist metaphysics, in which Popper

construed objective knowledge as residing in neither the world of physical objects and states (the "first world") nor in the world of minds and mental processes (the "second world"), but in an autonomous objective world containing products of the human mind such as theories, possible objects of thought, arguments, and values, which he called a "third world" or "World 3" (Popper [1972] 1979, 154–160). These products of the human mind are encoded in such material first-world objects as books, journals, and mathematical tables but are as autonomous relative to them as they are relative to minds: Their logical interrelations and properties have no direct counterparts in the first or second worlds, and their development transcends the minds in which they originate and the media in which they are instantiated. Knowledge thus stored is objective, he argued (controversially), in the sense that although it is a product of the human mind, its continued existence is nonetheless independent of its being accessed by any mind: It is knowledge without a knowing subject (109). He contended that scientific knowledge, properly understood, is objective in this sense, and that much of traditional epistemology is misguided in its focus on knowledge in the subjective sense of the mental states of the second world.

One of the more important later developments of Popper's thought was an explicit engagement with the notion that theoretic progress in science is explicable in terms of ever-closer approximations to the truth. A lifelong realist, Popper was nevertheless initially relatively silent regarding the truth of scientific theories, largely because he was aware of the contemporary metaphysical difficulties associated with that concept. However, under the influence of Alfred Tarski, Popper came to endorse the correspondence theory of truth as the fundamental idea underpinning rational criticism (Popper [1972] 1979, 263–264). This in turn precipitated a move on his part toward formalizing the intuitive notion of "truthlikeness" or "verisimilitude," on the grounds that "we simply cannot do without something like ... [the] idea of a better or a worse approximation to truth" (Popper [1963, 1965] 1969, 232). Accordingly, Popper formulated the metalogical concept of verisimilitude by linking the ideas of truth and content. The content of any statement is the class of all statements that follow from it, which is zero only in the case of tautologies. Hence, the class of true logical consequences of a theory is its "truth content," while its "falsity content" is the class of its false consequences. Given two rival theories t_1 and t_2, and assuming that their truth content and falsity content are comparable, then, Popper ([1963, 1965] 1969) asserted:

> We can say that t_2 is more closely similar to the truth, or corresponds better to the facts, than t_1, if and only if either: (a) the truth-content but not the falsity-content of t_2 exceeds that of t_1, or (b) the falsity-content of t_1, but not its truth-content, exceeds that of t_2. (233)

Popper's purpose here was to address, positively, the problem of scientific progress within a falsificationist frame of reference. This is a crucial issue, not least because the working scientist frequently has to operate with theories that are approximations and, as such, are known to be, strictly speaking, false. Given this, and his insistence that empirical testing can demonstrate the falsity but not the truth of a theory, and that it is consequently impossible to know whether any theory is in fact true, Popper needed to show that there are rational grounds for preferring some false theories over others. With the theory of verisimilitude he sought to provide just such an account. In this theory, it is legitimate to regard a falsified scientific theory t_2 that has a higher truth content than a rival falsified theory t_1 as a better theory than t_1, provided the falsity content of t_2 is not also greater than that of t_1. Moreover, "better" in this context is now understood to mean not merely that theory t_2 is more testable or has greater explanatory force than theory t_1, but that it has a higher level of verisimilitude or is closer to the truth than t_1. The growth of scientific knowledge, in other words, is here represented as progress toward the truth, even where such progress takes place through falsification of theories.

However, the work of Miller (1974a, b), Harris (1974), and Tichý (1974) demonstrated that Popper's two conditions for comparing the truth and falsity contents of theories are both satisfiable only when the theories concerned are true. In the crucially important cases of false theories, Popper's account is formally defective, in that where any false theory t_2 has excess content over a rival false theory t_1, the truth content and falsity content of t_2 will both exceed those of t_1. Fatally, in the case of false theories, the conditions outlined by Popper can never be satisfied.

Popper ([1972] 1979) subsequently acknowledged this deficiency in his definition of verisimilitude, but he argued that it had never been his intention to imply "that degrees of verisimilitude ... can ever be numerically determined, except in certain limiting cases" (59). The central merit of the concept is heuristic and intuitive, he maintained, and the failure of his formal definition of

verisimilitude should not preclude its utilization in evaluating theories whose content is relativized to problems considered relevant by the practicing scientist (368, 371–372).

Whereas some commentators have found that this response acceptably reflects the position of verisimilitude in Popper's philosophy, many others remain critical, seeing the failure of Popper's definition as indicating a more general fragility in his philosophy of science. It is clear, however, that the deficiencies in this account of verisimilitude leave unresolved the important problem of defining scientific progress through falsification in a formally satisfactory way.

Quine and Lakatos, following an argument first suggested by Poincaré (1902 and 1905) and Duhem ([1906] 1914), have both also attacked the key notion in Popper that the falsification of scientific theories can be yielded by discrete critical tests. Quine (1963), who called into question the assumption of a clear-cut distinction between analytic and synthetic statements as one of the two "dogmas of empiricism," also vigorously advocated a holistic view of empirical tests, contending that "our statements about the external world face the tribunal of experience not individually but only as a corporate body" (41). In this view, the entire system of human knowledge impinges on experience "only along the edges" (42); hence, contradictory empirical evidence has no necessary connection with any given theory and may in fact force a reassessment of a range of elements within the system.

In a similar vein, Lakatos (1970) argued that many of the most respected scientific theories cannot be refuted by individual critical tests, as they are not in themselves prohibitive; rather, they "forbid an event occurring in some specified finite spatio-temporal region ... only on the condition that no other factor ... has any influence on it" (101). Such theories, in other words, require the addition of an implicit *ceteris paribus* clause if they are to have prohibitive implications at all, and the *ceteris paribus* clause can always be replaced by another to make the theory consistent with apparently falsifying evidence. Hence, Lakatos contended, theories are falsified not in isolation but as integral elements of a "degenerating" research program that is supplanted by a rival program with equal predictive success and additional "heuristic power" (155).

Popper's response to these and related criticisms was to emphasize the significance of assumed background knowledge in the encounter between theory and experimental results, acknowledging that such assumed knowledge is fully as open to challenge and revision as the theory that its tentative acceptance permits us to test. He argued, however, that such considerations do not entail holistic conclusions, because in many cases it is quite possible to determine which hypothesis or group of hypotheses "is responsible for the refutation" ([1963, 1965] 1969, 239). This reply indicates Popper's awareness, in his later works, that his falsifiability criterion requires supplementation by extraneous pragmatic considerations—an awareness that extended to his recognition of ad hoc modification of theory as a recurrent, albeit undesirable, feature of general scientific practice. Consequently, while maintaining his advocacy of proposals that enshrine the critical spirit in scientific investigation, he went so far as to state that "the methodology of science (and the history of science also) becomes understandable in its details if we assume that the aim of science is to get explanatory theories which are as little ad hoc as possible: a 'good' theory is not ad hoc, while a 'bad' theory is" ([1963, 1965] 1969, 61).

This contention is not at all implausible, and, like many of Popper's other methodological precepts for science, it has been influential. However, "bad" theories here are to be taken as including bad scientific theories, and this is a significant move away from Popper's earlier view that the incorporation of ad hoc elements, as in the Marxist theory of history, suffices to make a theory unscientific. It also remains questionable whether the concept of the ad hoc can be made sufficiently determinate to do the work required of it in Popper's later work, in which there is thus an evident weakening of his formal demarcation criterion in the direction of pragmatic interpretation (Stokes 1998, 21).

POPULATION GENETICS

Evolutionary population genetics is the study of the dynamics of change in the genetic constitution of populations. The discipline grew out of the need to establish the Darwinian theory of evolution by natural selection on Mendelian hereditary principles. Prior to 1900, the view that the diversity of life arose from common ancestry was widely accepted in the scientific community, but Darwin's hypothesis that natural selection was the main mechanism of descent with modification was controversial (see Bowler 1983). This was due in part to Darwin's confused views about heredity. If, as Darwin thought, any character in the offspring was a blend of the corresponding characters in the parents, then in every generation, the character would regress toward the mean. This would make natural selection ineffective at generating change beyond the "sphere of variation" of the species (Jenkin 1867). So, for Darwin's hypothesis to be vindicated, it was necessary to establish a theory of heredity according to which variation was not lost in every generation. Mendelism, rediscovered in 1900, met this need. Unfortunately, Mendelism was not immediately accepted. There was a disagreement between two competing schools of thought in the early 1900s on the nature of heredity and of evolutionary change. Two critics in particular, the biometricians Pearson and Weldon, accepted Darwin's claim that changes due to selection were gradual and that selection acted on variations in quantitative characters, or characters like height or weight (Provine 2001). In contrast, Mendelians by and large rejected

Darwin's claim of gradual change. Their theory of heredity focused primarily on qualitatively varying characters, or characters like color or shape. On the whole, Mendelians held that evolution was the result of selection acting on major mutations, and not gradual selection on slightly varying traits. Gradually, however, biologists came to accept that Darwinian gradual selection was compatible with a Mendelian theory of inheritance. The development of a quantitative theory of evolution relying upon Mendelian principles of inheritance (population genetics) was crucial to the acceptance of Darwin's hypothesis that natural selection played a significant role in evolution and thus in generating the diversity of life.

The early population geneticists, R. A. Fisher, J. B. S. Haldane, and Sewall Wright, used primarily single-locus algebraic models to describe changes at the population level (see Evolution for an example). These were *prospective* models—given a set of values for selective parameters, migration rates and mutation rates, equations could be solved indicating, for instance, the rate at which evolutionary change would occur, or predicting genotype frequencies from one generation to the next. The above parameters describe deterministic factors effecting change in allelic frequencies. However, allelic frequencies change because of purely random factors as well. Fisher (1918) was the first to use diffusion methods to consider the stochastic changes in gene frequencies arising in finite populations, and Wright (1931) made "drift" a factor in his overall evolutionary theory. *Drift* refers to the random changes in gene frequency brought about by the random sampling of genes from one generation to the next, that is, the chance survivorship and reproduction of individuals irrespective of their fitness relative to their cohort. Any population that is sampled from one generation to the next will show some shift in distribution of characters due to chance alone. The effects of drift are accelerated in smaller populations; that is, the smaller the population, the more quickly will random sampling tend to make a population homogeneous, or uniformly of one or another genotype. In sum, prospective models describe how allele frequencies may change as a result of five different factors: mutation, migration, assortative mating, drift, and selection (cf. Haldane 1924). (Genotypic frequencies can change with or without changes in allelic frequency; for instance, as a result of assortative mating, inbreeding, and [in multilocus systems] recombination between gene loci.) Since the 1950s, multilocus models have been developed, which represent the change from one generation to the next at two or more loci. For the most part, however, many evolutionary questions can be answered using simple one-locus models. In the past twenty-five years, *retrospective* or "coalescent" models have been developed to assist in drawing inferences about the history of some lineage. Given some DNA sequence data, one can use retrospective models to answer questions like: "Given this information, when did the most recent common female ancestor of all humans alive today live?"

Evolutionary population genetics is but one part of population genetics generally. The mathematical component of population genetics is used not only in the evolutionary context but also in plant and animal breeding theory and in theoretical aspects of human genetics, especially in the search for the chromosomal location of disease genes. This article will focus on evolutionary questions and their mathematical analysis. First, there will be a summary of several of the major results of early population genetics theory and some of its more controversial aspects. Second, there will be an overview of some recent developments in population genetics—in particular, the influence of developments in molecular biology on theoretical population genetics. In conclusion, there will be a brief discussion of the scope and limitations of modeling in evolutionary genetics more generally.

The History of Population Genetics

The Hardy-Weinberg Law and the Maintenance of Variation

As mentioned above, the Darwinian theory of evolution by natural selection requires genetic variation. Variation is ultimately caused by mutation and subsequently also by chromosomal rearrangements, but it must be preserved for long periods for natural selection to act. The hereditary theory assumed by Darwin, that the characteristic of any child is in some sense a blend of that characteristic in the two parents, leads to rapid dissipation of variation. Thus, the very variation needed by the Darwinian theory is not supplied by the hereditary mechanism that he assumed. The Mendelian hereditary mechanism was rediscovered some forty years after the publication of *On the Origin of Species* and seventeen years after Darwin's death. Not only did this prove to be the correct hereditary model: It was one of the early triumphs of the mathematical theory to show that the Mendelian hereditary system is a variation-preserving one. Indeed, Mendelism supplies possibly the only hereditary mechanism maintaining the variation that is necessary for the Darwinian theory to work.

Weinberg and Hardy independently established the "law of panmictic equilibrium," today known as the Hardy-Weinberg law or principle. The law might be better described as a neutral or equilibrium model—a mathematical derivation starting from assumptions (some known to be false) for the purposes of evaluating the baseline state of a Mendelian system absent perturbing forces. Interestingly, the consequences of the segregation law were issues that Mendel himself explored but did not follow through to the case of random mixing—he was working with self-pollinating plants, and his "law of disjunction" treated only the case of reversion to type. In 1902, and later in 1903, Yule and Pearson independently examined the consequences of Mendel's law of segregation for a randomly mating population. However, their examinations of the question were yet again specific to a case in which the two factors were at the same initial frequency.

In 1908, Punnett, then a geneticist at Cambridge, asked Hardy, a mathematician, to derive the consequences of Mendel's laws for a randomly breeding population. Hardy demonstrated that *whatever the genotype frequencies* might be in a population, stable frequencies will result after one generation of random mating. The significance of this result is that given a particulate, or Mendelian, system of heredity, variation will be maintained in a population. The initial genotype frequencies in a population will remain unchanged from one generation to the next. This simple consequence of Mendel's law had been discovered a few months earlier by Weinberg. The derivation is as follows.

First, assume a diploid organism, sexual (or hermaphrodite) reproduction, nonoverlapping generations, perfectly random mating (no assortative mating), infinite population, and no migration, mutation, or selection. Let the two alleles at a locus be A and a. Suppose that in any generation the proportions of the three genotypes AA, Aa, and aa are P, Q, and R, where $P + Q + R = 1$. Correspondingly, let the frequencies of the A allele equal p, where $p = (2P + Q)/2 = P + Q/2$, and, for the a allele, the frequency $q = (2R + Q)/2 = R + Q/2$. The frequency of matings of $AA \times AA$, given random pairing of individuals, will be P^2. Likewise, the probability of an $AA \times Aa$ mating is $2PQ$, and the probability of an $Aa \times Aa$ mating is Q^2. Only these three matings can produce AA offspring, and they do so with respective probabilities 1, $\frac{1}{2}$, and $\frac{1}{4}$. Table 1 lists the genotypic frequencies resulting from each mating.

Table 1. Frequencies of offspring genotypes in a randomly mating population

Mating	Frequencies of mating	Offspring genotype frequencies		
		AA	Aa	aa
$AA \times AA$	P^2	1	0	0
$AA \times Aa$	$2PQ$	$\frac{1}{2}$	$\frac{1}{2}$	0
$AA \times aa$	$2PR$	0	1	0
$Aa \times Aa$	Q^2	$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{4}$
$Aa \times aa$	$2QR$	0	$\frac{1}{2}$	$\frac{1}{2}$
$aa \times aa$	R^2	0	0	1

It follows that the frequency of AA offspring after one generation will be:

$$P' = P^2 + \frac{1}{2}(2PQ) + \frac{1}{4}(Q^2)$$
$$= (P + Q/2)^2 = p^2.$$

Similarly, the frequency of Aa and aa after one generation will be:

$$Q' = \frac{1}{2}(2PQ) + 2PR + Q^2/2 + 2QR/2$$
$$= 2(P + Q/2)(R + Q/2) = 2pq$$
$$R' = Q/4 + 2QR/2 + R^2 = (R + Q/2)^2 = q^2.$$

Thus, the frequency of each genotype after one generation of random mating will be p^2, $2pq$, and q^2. Replacing the values P', Q', and R', in the above equations, in order to determine the values for P'', Q'', and R'' in the subsequent generation, the same frequencies result. In other words, the genotype frequencies obtained after one generation of random mating are maintained in all subsequent generations. Thus, Hardy and Weinberg demonstrated that given the assumptions above, after one generation of random mating, stable genotype frequencies will result and be maintained. The key point here is that if there is no action by external forces (selection, mutation, migration, or random drift), then variation will be preserved in a population. This simple mathematical demonstration of the consequences of Mendel's law on the assumption of random mating thus answers one of the longstanding objections to Darwinism, *viz.,* that given a blending theory of inheritance, the variation needed for evolution through natural selection would rapidly be dissipated (Jenkin 1867). In contrast, under a Mendelian or particulate scheme of inheritance, variation will be preserved, *ceteris paribus.*

The Correlation Between Relatives

The Mendelian theory did not win immediate acceptance upon its rediscovery in 1900. One reason why it was not accepted quickly was that it was

widely felt that biometrical data, including in particular the correlation between parent and offspring for characters such as height and weight, could not be explained on Mendelian grounds. Fisher (1918) showed not only that the broad pattern of these correlations could be explained assuming a Mendelian hereditary system, but that the numerical values for the correlations could also be explained. A Mendelian system of inheritance had to account for the observations of the normal distribution of most quantitative characters (e.g., height, weight) and the measurements of correlations between relatives with respect to these same characters. Fisher's (1918) paper showed that Mendelism did just that. First, by assuming that the character value for the heterozygote could be halfway between those of the two homozygotes, that the relevant Mendelian factors were entirely independent in their effects, and that the number and effects of such factors affecting any particular trait were quite large, Fisher showed how a normal distribution of measurements of some trait followed from a particulate scheme of inheritance. Second, and more significantly, Fisher demonstrated the consistency of the biometricians' observation of correlations between continuously varying traits and the Mendelian theory. There is no doubt that Fisher's specific genetical models were simplified. However, by showing that a reasonable fit to the observed correlations could be obtained under the Mendelian scheme, Fisher's work was a major force in leading to the acceptance of that hereditary scheme. A model does not have to be too precise to be useful.

The Fundamental Theorem

Having fused the biometrical and Mendelian viewpoints, Fisher then tried to establish general principles of evolution as a Mendelian process. Perhaps the best-known of these is his *fundamental theorem of natural selection:*

> The rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time. (Fisher 1930, 37)

Careful attention to Fisher's intended meaning shows that although this is a true theorem, its significance is perhaps more circumscribed than Fisher claims. With the fundamental theorem, Fisher believed that he had discovered a universal generalization akin to the second law of thermodynamics. He believed the theorem to be a law of nature. Fisher (1930) describes his object in the opening pages of his chapter on the fundamental theorem:

> [t]o combine certain ideas derivable from a consideration of the rates of death and reproduction in a population of organisms with the concepts of a factorial scheme of inheritance, so as to state the principle of natural selection in the form of a rigorous mathematical theorem, by which the rate of improvement of any species of organisms in relation to its environment is determined by its present condition. (22)

Despite the appearance of progressivist language here, the fundamental theorem is not a statement about the unending or necessary adaptation of the species to its environment, but an expression of a fundamental relationship between the reservoir of genetic variation available and accessible to selection and the rate of increase in fitness in a population. Fisher was well aware that genetic interactions, rapid changes in or deterioration of the environment, overpopulation, and many other factors could affect whether or not a population of organisms would increase in numbers or continue to adapt over time. The fundamental theorem is thus a statement not of the necessary improvement of the species, but about the relation between genetic variance in some trait and increase in numbers of individuals possessing such a trait.

What Fisher's demonstration actually shows is simply that the additive variance in fitness (or that portion of the genetic variance that contributed to the correlation of relatives) is equal to that component of the increase in mean fitness in the population brought about by changes in gene frequencies only. This change was called the "partial change" by Ewens (1989), following a clarification of the meaning of the theorem by Price (1972). However, almost all commentators, starting with Wright (1930), have misunderstood the meaning of the theorem. Wright, for example, "corrected" the theorem as follows: "The total variance in fitness of a population is ascribable to the variance in fitness due to natural selection, which excludes the effects of dominance, epistasis, mutation, migration, change in environment, and drift." Subsequent commentators, and indeed the majority of textbooks in population genetics through the 1970s (Li 1955; Moran 1962; Crow and Kimura 1970; Jacquard 1974), misinterpreted Fisher's theorem along the same lines. The "received" interpretation thus came to be that "the increase in mean fitness of a population is approximately the current additive genetic variance in fitness, and this is non-negative"(Edwards 1994). This takes the theorem to refer to the mean fitness of the population and to be an approximate result. However, Price (1972), Ewens (1989), and Lessard (1997) have shown that the theorem, as correctly interpreted, is exact, not approximate.

Wright Versus Fisher

A continuing point of controversy in population genetics theory is the relative significance of two different models of the evolution of adaptation: Wright's and Fisher's. According to Fisher, evolution takes place for the most part in large, panmictic populations, and the factor of greatest significance in shaping adaptation is selection acting on alleles, even those with small selective effects. According to Wright, the landscape of gene combination consists of multiple adaptive peaks, separated by maladaptive valleys, or gene combinations that are less fit. The most effective means of traversing such peaks is via a three-phase process of isolation of small subpopulations and intrademic and interdemic selection. Wright called this process the "shifting balance model" of evolution.

The diagnosis and resolution of this controversy is contentious. Some argue that at the core are differing views about the nature and extent of genetic interaction, tied to the presuppositions behind Wright's model of the adaptive landscape (Whitlock et al. 1995). If indeed genetic variation is held tightly in "balance," or if there are many epistatic interactions for fitness, then it would seem that a mechanism like shifting balance is necessary for populations to move from suboptimal, or lower, to higher peaks in the adaptive landscape. On the other hand, it may be the case that whatever the extent of epistatic interactions for fitness, populations may always find "ridges" to traverse adaptive valleys via selection. For instance, assortative mating may permit the traversion of valleys (Williams and Sarkar 1994).

Others argue that the core of the divide between Wright and Fisher has to do with the rather delicately timed balance of isolation, selection, and migration Wright requires for shifting balance to go forward. In particular, it seems unduly restrictive to expect no migration between demes for the time necessary for them to diverge significantly for there to be a difference in fitness between them, followed suddenly by migration. The controversy over the shifting balance model continues today. Coyne, Barton, and Turelli (1997), neo-Fisherians, and Wade and Goodnight (1998), neo-Wrightians, continue to debate the extent of empirical support and the interpretation of mathematical and metaphorical models such as Wright's adaptive landscape.

The Introduction of Molecular Biology and the Neutral Theory

In the mid-1960s, molecular methods were introduced into the study of evolution. Protein sequencing revealed that the number of amino acid substitutions among species increases approximately linearly with time since divergence (Zuckerkandl and Pauling, 1962). Electrophoretic studies by Lewontin and Hubby (1966) demonstrated that there was a great deal of genetic variation at the protein level within natural populations. These observations eventually led to Kimura's (1968) proposal of the neutral theory of molecular evolution, which says that most changes detected at the molecular level were not acted upon by natural selection, but were neutral with respect to selection (that is, did not affect fitness). Kimura's reasoning was as follows. First, he examined molecular data on the variation among hemoglobins and cytochromes *c* in a wide range of species. Second, he calculated the rates of change of these proteins. Third, he extrapolated these rates to the entire genome. When he saw the rapidity of change that this implied, Kimura concluded that there simply could not be strong enough selection pressures to drive such rapid evolution. He therefore hypothesized that most evolution at the molecular level was the result of random processes like mutation and drift. Kimura called this hypothesis the *neutral theory of molecular evolution.*

Kimura's theory met with a great deal of controversy, as many interpreted it to run counter to the neo-Darwinian view that selection was the main agent of evolutionary change. This false impression was exacerbated by a paper published immediately after Kimura's by King and Jukes (1969), defending roughly the same thesis. Many were led to the mistaken view that the neutral theory denies the fact of adaptive evolution. However, it simply states that a large quantity of the turnover of molecular variation within populations has nothing to do with adaptation—it is simply neutral with respect to selection; that is, it has no effect on an organism's survival.

Today, most biologists accept that there is a great deal of molecular variation that is neutral with respect to selection. However, the rate of sequence change in evolution varies considerably with the DNA region examined. The more important the function of the region, the lower the rate of sequence change, as would be expected (Nei 1987). Much of systematics today uses the rapid turnover of some relatively neutral regions, such as the region that controls cytochrome *c*, to reconstruct phylogenetic relationships.

Kimura was in part inspired by the work of Sewall Wright, and in particular by Wright's emphasis on drift as a significant factor in evolutionary change. It should be noted, however, that it is a confusion to equate the neutral theory with Sewall

Wright's view on adaptive evolution in populations, the shifting balance theory. In other words, there may well be a great deal of turnover in a population at the molecular level, whether or not selection or drift is the main force changing the genotypic constitution of such a population over the long term. "Random drift" in the classical sense refers to chance fluctuations in the genetic constitution of a population, or sampling error. By chance alone, some individuals, irrespective of their selective advantages, may not survive to reproduction. In this way, one or another allele may become fixed in a population, irrespective of its selective advantage (or disadvantage). Reduction in population size accelerates the effects of drift in the sense that the average time to fixation of an allele is shorter, the smaller the population. So, over the short term, and in smaller populations, drift will be of greater significance in any population relative to selection. The neutral theory simply describes the turnover of sequence at the molecular level. Changes in some loci are effectively neutral with respect to selection, so there is significant turnover at the molecular level in such loci. This does not preclude that over the longer term, the effect of selection may significantly change the constitution of populations.

Retrospective Models, Molecular Genetics, and Coalescence Theory

Much of the early modeling in population genetics theory was prospective: Given certain fitness values, mutation rates, etc., equations could be solved indicating the rate at which evolution could occur. In the early years of this century such an analysis was needed, largely to support the Darwinian theory. But the Darwinian theory is now in effect accepted, and with the information provided by DNA sequence data, theory and modeling have branched into a retrospective analysis, as noted above.

Coalescent theory uses mathematical models and molecular data to determine times since most recent common ancestor of different lineages, or time to *coalescence*. While the mathematical demonstration of coalescence theory is beyond the scope of this article, the following are some basic premises of coalescence theory. All genes in a population ultimately trace their way back to a single ancestor gene, so that their ancestry coalesces at that gene. However, the allelic types of the genes in the population might differ from that of this common ancestor, because of mutation. These mutational differences help answer questions about the size, structure, and history of populations.

Coalescence theory assumes, in part for reasons of simplifying the mathematics, that most changes in the genome are neutral, so that most of the changes seen are a result of drift. This is in fact a very reasonable assumption when the scope of investigation is shorter time frames, or changes in populations over thousands, as opposed to tens of thousands, of years. For shorter time frames, the effects of drift will predominate. With the development of molecular methods, and of coalescence theory, there has thus been a shift in focus of the models of evolutionary genetics from longer to shorter time frames, and in these models, the significance of selection relative to drift will be negligible. For longer-term evolutionary questions of the sort that interested Wright and Fisher, selection will, relatively speaking, be a more significant factor, changing the genetic constitution of populations.

Conclusion

Theoretical population geneticists use mathematical models to investigate the dynamics of evolutionary change in populations. Essentially, they describe and explain the conditions on the possibility of evolution. Thus, population genetics constitutes that theoretical core of evolutionary biology. While the mathematical models of theoretical population genetics are necessarily idealized, they nonetheless constitute a useful tool for describing the main mechanisms of evolutionary change and answering questions about the relative significance of this or that factor in evolution, under some description of initial conditions. Rather than attempt to capture all the subtleties of inheritance (cytoplasmic as well as nuclear), development, and gene expression, classical population genetics treats evolution as simply change in allele frequency. In the context of investigating loci that contribute to disease, classical Mendelian models represent the disease of interest as a product of a single allele that is either dominant or recessive. Of course, many loci contribute in the expression of most diseases (and most traits), and the same allele may be expressed differently in different genetic contexts. Given what is known now about the nature and extent of genetic interaction, one may think that Mendelian "beanbag" genetics is obsolete (Provine 2001).

To the contrary, simplified treatment is necessary—first, because the complexity of the genetics of evolving populations ensures that a completely accurate description of reality is impossible; and second, were such descriptions possible, they would be mathematically intractable (see Crow 2001 for further discussion). Theoretical population

genetics gives mathematically tractable ways to begin to describe the evolutionary process. Such models are in some sense idealizations, but they are useful tools to answer many simple questions, providing a framework for looking at phenomena that often take place over the lifetimes of many individual scientists.

As Wimsatt (1987) has pointed out, null (or false) models can be enormously useful tools for arriving at true theories. For instance, oversimplified models may serve as the starting point in a series of models of greater complexity and realism and may provide a simpler arena for answering questions that would be impossible to answer in more complex models. Or false models may describe extremes of a continuum in which the real case is presumed to lie (Wimsatt 1987, 30–31). For example, the neutral theory claims that all change at the molecular level is neutral, but using the neutral theory as a null model, biologists have now found that different regions of the genome turn over at different rates, indicating that the truth lies somewhere in between the continuum of complete neutrality and selection at every locus. Coalescent theory assumes that all change is neutral, but this strictly false assumption allows biologists to determine times since divergence of modern taxa.

Population genetics models, despite their many simplifications of genetic systems, provide real insight not otherwise obtainable into the evolutionary process. Such models may enable one to describe the common features of many systems that all differ in detail, determine how varying outcomes depend on the relative magnitude of one or another parameter, and decide which factors may legitimately be ignored, given the question or time frame under consideration. For example, population genetics theory shows that selection is more effective than drift in populations of large size (where $4Ns \gg 1$), whereas the effects of drift will overpower those of selection when the opposite is the case.

One may use such models to conclude which outcomes are very unlikely or impossible given some initial conditions. And mathematical analysis may serve to generate conclusions that could not be arrived at by empirical research at a given stage of inquiry. Lewontin (2000) describes the role of modeling in population genetics as delimiting what is possible and what is prohibited in microevolutionary change. And some biologists have extended the use of these models to answer questions about change above the species level, such as in speciation (e.g., Barton and Charlesworth 1984).

Exact prediction in population genetics is a near impossibility. While the models of Newtonian mechancs may be used to predict the motions of the planets or the trajectory of a projectile here on Earth with a high degree of accuracy, one ought not to expect this sort of predictive power from population genetics models. While one might hope that models of biological evolution will help with short-term predictions, one cannot hope that they will lead to explicit long-term predictions. In effect, the allele passed on by a parent to a child at any locus results from a random choice of one of the two alleles that the parent has at that locus, and one can never know which one this will be for each gene in each individual. At best, one may predict trends, given initial population sizes and rates of mutation and migration. Thus, theoretical population genetics is an irreducibly probabilistic theory. However, population genetics theory provides a rigorous way to determine the relative significance of different factors over long time frames in the changes of the genetic constitution of populations.

Which simplifications to employ in modeling a biological system will depend upon the context and the question at issue. For example, when considering the effects of geographical dispersal, it might be reasonable to assume only one sex; and when addressing questions asking why sexual dimorphism exists, it might be reasonable to ignore geographical distribution. In general, the problem of finding a balance between a model's being sufficiently complex to describe reality adequately and at the same time being sufficiently simple to allow a mathematical analysis is not only a question of philosophical interest, but also a serious one faced in the everyday practice of theoretical biology.

PREDICTION

Whether one predicts rainfall, recessions, or racetrack winners, predicting an event or state of affairs often, perhaps even typically, involves saying that it will happen before it occurs, and this common association is presumably responsible for the idea that predictions must be about the future. But in scientific contexts one often characterizes a theory's predictions as its implications or entailments without regard for temporal constraints, as when one says a successful theory of cosmology predicts the existence of cosmic background radiation at all times. The language of prediction is also used to describe declarative assertions about past and present events made in light of a theory, as when

evolutionary theory was used to predict that marsupial mammals must once have lived in what is now Antarctica and left fossilized remains there. A temporal element might be preserved by insisting that these are really cases of postdiction, retrodiction, or even shorthand predictions about future evidential findings. But perhaps these comfortable extensions of predictive language more naturally suggest that the central element in prediction is not temporal but epistemic. To predict is to make a claim about matters that are not already known, not necessarily about events that have not yet transpired.

Of course, prediction cannot be as simple as that, because one way to know something is to predict it correctly on the basis of a well-confirmed theory. Predictive language seems most appropriate when one makes claims about unknown matters using tools (like inductive generalization, scientific theorizing, or sheer guesswork) that can be contrasted with more direct methods of ascertaining the same information (like simply observing in the right place and/or at the right time and/or under the right conditions, or looking for physical traces of some past state of affairs). Although specific philosophical and scientific conceptions of what is immediately given in experience or known directly have shifted over time, predictive language has continuously respected the fundamental idea that a prediction is a claim about unknown matters of fact whose truth or falsity has not already been independently ascertained by some more direct method than that used to make the prediction itself (see Phenomenalism; Physicalism).

As this account suggests, successful prediction is valuable because it goes beyond what is already known most directly, but this same feature renders prediction inherently risky. The most interesting and useful predictions typically concern matters to which more direct intersubjective access is ultimately expected, so prediction is characteristically something that one can be caught out on given the shared standards of the community of inquirers.

This idea that scientific prediction involves risk led Karl Popper (1963) to single out the willingness to make risky predictions as what distinguishes genuine science from pseudoscience (see Popper, Karl Raimund). Pseudoscientific theories, he suggested, typically include the resources to explain any outcome in their intended domain of application after it is known. Marxist history, Freudian psychoanalysis, and Adlerian "individual" psychology were among Popper's favorite examples. He urged that such theories not be regarded as genuinely confirmed by passing tests that they could not possibly have failed. Confirmation, or for Popper "corroboration," requires that a theory succeed where it might have failed (see Confirmation Theory; Corroboration). Thus, Popper argued, genuine science requires theories that rule out some states of affairs and make risky predictions about unknown cases, exposing themselves to the serious possibility of refutation.

In empirical science, the requirement of shared epistemic access to the success or failure of a prediction means that the fate of a prediction is typically decided in the court of experiment and observation.

The Problems of Induction

The Scottish empiricist David Hume may have posed the problem of the rational justification for prediction in its starkest form. Hume's empiricism led him to regard the most general problem about knowledge to be how one comes to know anything whatsoever "beyond the present testimony of our senses, or the records of our memory" (Hume [1748] 1977, 16). Hume pointed out that the mere occurrence of one event or sense impression never deductively implies that another will occur. From this he concluded that it must be on the basis of experience that one learns which particular events reliably cause, precede, or are otherwise associated with others. One is thereby able to make predictions about events or states of affairs beyond those immediately perceived (see Empiricism).

But how can one possibly justify assuming that the regular associations or even causal relationships that have been noted between past events will persist into the future? Again there is no logical contradiction in supposing that things will change. That the sun will not rise tomorrow, Hume notes (15), is no less intelligible a proposition than that it will rise—indeed, the future will almost certainly be quite unlike the past in innumerable particular respects. And any attempt to justify this assumption by appeal to past experience of uniformity in nature, Hume claims, will be "going in a circle, and taking that for granted, which is the very point in question" (23). That the future has been like the past *in the past* constitutes evidence only about what one's own future will be like if one already assumes that how things have been in the past is a good guide to what they will be like in the future, which was the very assumption needed to justify the inferential practice in the first place (see Causality).

Efforts to solve or dissolve Hume's problem of induction are a topic of continuing debate (see Induction, Problem of). For his part, Hume

concluded that there can be no rational justification whatsoever for predictions concerning unexperienced matters of fact, and he took this to illustrate that reason or rational justification does not play anything like the role usually supposed in the cognitive lives of human beings. In his skeptical solution to the problem, Hume argues that what generates expectations about unknown cases is a primitive or instinctive psychological disposition he calls *custom*, which is not itself mediated by any process of reasoning at all. Custom leads one, automatically and without reflection, to expect an event of type *B* on the appearance of an event of type *A* just in case *B*s have followed *A*s reliably in the past. Thus, Hume offers a naturalistic *explanation* of the psychological mechanism by which empirical predictions are made but not any rational *justification* for this practice. But this is not to say that it is a mistake to rely on custom: Not only do we have no choice in the matter, Hume ([1748] 1977) argues, but "[c]ustom . . . is the great guide of human life. It is that principle alone which renders our experience useful to us. . . . Without the influence of custom, we should be entirely ignorant of every matter of fact, beyond what is immediately present to the memory and senses" (29). The fact that there is no rational justification for such an important and useful cognitive function, he suggests, simply illustrates that nature has secured "so necessary an act of the mind, by some instinct or mechanical tendency" rather than leaving it "to the fallacious deductions of our reason" (37). The most central aspects of human cognitive lives, he suggests, are neither products of nor even subject to reason. Instead they are "a species of natural instincts, which no reasoning or process of the thought and understanding is able either to produce or to prevent" (30).

A further problem of inductive justification, arguably anticipated in Hume's treatment, is clearly articulated by Nelson Goodman (1954). Here the problem is not how to justify the belief that unexperienced cases will resemble experienced ones, but how to understand, categorize, or describe experienced cases so as to know just what it would be like for unexperienced cases to resemble them. Present inductive evidence fully supports the claim that all emeralds are green, for example, but it equally well supports the claim that they are all grue, where 'grue' means "green if first observed before 2050 and blue if not observed before 2050." Those who believe that emeralds are grue rather than green, however, will have expectations concerning the appearance of emeralds that diverge significantly from the customary one starting in 2050. Nor can one say that the predicate 'grue' is somehow artificially conjunctive or really disguises a change, Goodman argues, for it is relative only to a set of predicates that regards green and blue as natural categories that it does so. If one takes 'grue' and, say, 'bleen' (understood as "blue if first observed before 2050, and green if not observed before 2050") as natural and primitive predicates of a language it will be "green" that must be defined in an artificially conjunctive way (i.e., "grue if first observed before 2050 and bleen if not"). But, of course, it was the choice of green and not grue as natural, primitive, or singularly appropriate for law-like generalization for which a defense was sought in the first place. Goodman thus argues that any attempt to use inductive evidence to project future or unknown cases relies on a set of entrenched predicates, and it is controversial whether the entrenchment of one set of predicates rather than another can be rationally defended. Like Hume's custom, Goodman's entrenchment may offer a kind of naturalistic explanation of how humans come to make the predictions they do, but not one that seeks or provides any rational justification for the practice.

Models of Empirical Prediction

Hume's empiricist approach to the foundations of knowledge proved attractive to such later theorists of science as the logical empiricists, many of whom held that the aim of empirical science was to determine the dependence of observable phenomena on one another; indeed, some famously insisted that every meaningful statement derived its meaning from its implications regarding observable phenomena (see Cognitive Significance; Verificationism). In this broad view, empirical predictions were required to be statements (i) in a specified observation language, (ii) entailed by one's theory together with one's past observations, and (iii) concerning unobserved but observable phenomena. It is important to recognize, however, that the logical empiricists did not always agree even among themselves about how to characterize the nature of empirical predictions. To take just one example of controversy, in Carnap's (1967) *Logische Aufbau der Welt*, the empirical predictions made by a scientific theory do not concern the "given" of sense experience but rather *structural* features of the intersubjective domain constructed from experience (see Carnap, Rudolf).

Carl Hempel's (1965) model of scientific knowledge was both deeply influenced by the earlier logical empiricist tradition and itself widely influential

in turn. In the simplest, deductive-nomological case, predictions and explanations are logical deductions of the form

$$C_1 \wedge C_2 \wedge \ldots \wedge C_k$$
$$\underline{L_1 \wedge L_2 \wedge \ldots \wedge L_r},$$
$$E$$

where $C_1 \wedge C_2 \wedge \ldots \wedge C_k$ are statements of particular occurrences (e.g., the positions and momenta of certain celestial bodies at a time), $L_1 \wedge L_2 \wedge \ldots \wedge L_r$ are general laws (e.g., of Newtonian mechanics), and E is the sentence stating whatever is being explained, predicted, or postdicted (e.g., the time of the next solar eclipse), in Hempelian terms. Hempel (1965) also allows for what he calls inductive-statistical predictions, where the argument has the same basic form, but the laws invoked are statistical probability statements. Here a specific event is not logically implied by the boundary conditions and laws, but only supported to a certain degree (175–177). For Hempel, the conclusion of any argument of this form qualifies as a prediction if E refers to an occurrence at a time later than that at which the argument is offered. A fascinating and controversial feature of this account is the symmetry it asserts between prediction and explanation: To explain an event by appeal to a set of laws and conditions is simply to show that it could have been predicted using them (see Hempel, Carl Gustav; Explanation).

More recent accounts of empirical prediction have moved progressively away from the logical empiricists' original requirement of a neutral "sense datum" language for reporting observation or representing experience. In van Fraassen's (1980) constructive empiricism, for example, presenting an empirical theory involves specifying a model for the language of the theory: a domain of objects together with a description of the properties they can have and the relations they can bear to one another. In presenting the theory, one also specifies those substructures of the model that are candidates for representing observable phenomena. The theory is empirically adequate just in case the appearances given in phenomenal experience are isomorphic to the observable substructures of the model (64) (see Empiricism; Instrumentalism). As in the empiricist tradition more generally, then, the distinction between observable and unobservable phenomena does significant work here, but this distinction is not drawn in linguistic terms. Rather, for van Fraassen, the distinction is supposed to be grounded in the actual observational capacities of human observers, and it is natural science itself that shows what those observational capacities are (see Phenomenalism; Perception).

The naturalistic suggestion that observability is a question to be settled by natural science is perhaps promising. But how could one's best theories determine what is observable? If they characterize important features of the natural world and one's place in it, then they also might be expected to specify how and the circumstances under which reliable inferences from measurements are possible for human observers. It is presumably in just those circumstances for which one's theories indicate that measurements will provide the resources for reliable inferences about the presence or absence of some entity that one is inclined to characterize the entity as observable. In such a naturalistic view, an empirical prediction might in principle concern any feature of the world that one's best theories indicate can be reliably detected.

But herein also lies a problem for the naturalist. What one judges to be observable will depend on one's current best understanding of the natural world, but this best understanding will itself depend on what one believes one has observed. Since the naturalist's account of what is observable itself depends on the theories the naturalist accepts, observations cannot test the truth or falsity of theories in any direct or simple way. As Quine (1951) and others have noted, one can always respond to a failed test of a theory by blaming background assumptions, presumably including the assumptions used to characterize what empirical observations are and the conditions under which they can be reliably made, rather than admitting that a particular prediction was mistaken. But if empirical predictions need never be given up, then they cannot, strictly speaking, test the theory that makes them (see Quine, Willard Van).

In practice, however, this general epistemic problem is more often a point of logic rather than a real obstacle to naturalistic inquiry, as Quine himself noted in developing his own naturalistic position. Testing a given empirical prediction to the satisfaction of the scientific community requires only that there be a sufficient context of shared background assumptions to provide the understanding of and rules for the empirical test. The understanding and rules might be implicit, change over time, and be subject to challenge, but none of this undermines the possibility of testing predictions in principle and, consequently, the possibility of testing the theories that make them. That empirical predictions are in fact often taken by the scientific community to be thoroughly tested and that theories are in fact accepted or rejected on this basis suggest that

there are often, perhaps typically, unambiguous standards for checking them.

The Epistemic Significance of Prediction

As the preceding discussion of the relationship between theories and their predictions suggests, testing a theory's predictions is often taken to be a crucial aspect of how it is confirmed or disconfirmed. The most persistent question here concerns whether the ability to predict *novel* phenomena is of fundamental significance in the testing and confirmation of specific theories in the special sciences, that is, whether it counts in favor of a theory's confirmation that it has predicted novel phenomena rather than merely accommodating, explaining, or anticipating phenomena already known to occur. In this context the relevant sense of prediction involves not anticipating when and where familiar phenomena will recur but rather discovering the existence of phenomena unlike those that are already familiar.

The roots of this debate reach back at least to the foundations of modern science itself; perhaps its most famous iteration pitted William Whewell against John Stuart Mill, who expressed amazement at Whewell's view that

> an hypothesis . . . is entitled to a more favourable reception, if besides accounting for all the facts previously known, it has led to the anticipation and prediction of others which experience afterwards verified. Such predictions and their fulfillment are, indeed, well calculated to impress the uninformed. . . . But it is strange that any considerable stress should be laid upon such a coincidence by persons of scientific attainments. (*System of Logic*, III, xiv, 6, cited in Musgrave 1974, 2)

Mill's amazement notwithstanding, versions of this Whewellian intuition have been defended by "persons of scientific attainments" as diverse as Clavius, Descartes, Leibniz, Huygens, Peirce, and Duhem. By contrast, Mill defended the view that confirmation depends only on the match between a theory's entailments and the phenomena. While decidedly less popular, this competing view also recruited influential champions, such as John Maynard Keynes (Giere 1983, Sec. 3).

Enthusiasts have sometimes gone so far as to claim that only predictions of novel phenomena are of any confirmational significance at all or that any prediction of a novel phenomenon is of greater confirmational significance than any amount of accommodation of existing evidence. But the claim of a special confirmational significance for prediction does not require such extremes. For prediction as such to enjoy a special confirmational privilege, it seems sufficient that predicting a given phenomenon provides (or would have provided) greater confirmation for a theory that does so than the mere accommodation of *that same phenomenon* does (or would have). A view having this consequence, including the extremes just described, may be described as a form of *predictivism.* Predictivist themes have recently loomed large in debates over the progressiveness of research programs, the adequacy of various approaches to confirmation (especially Bayesianism), and the so-called miracle defense of scientific realism.

Imre Lakatos is widely credited with having reintroduced this concern over the confirmational significance of novel prediction, specifically in connection with his "methodology of research programs" (see Lakatos, Imre). Lakatos's bold claim was that it is *only* the ability of the successive theories in a research program to make successful novel predictions that bears on its progressiveness or acceptability. But even Lakatos's own work includes several competing lines of thought about the nature of novelty (Gardner 1982, 2–3). At times he seems to construe the novelty of a prediction for a theory purely temporally, though his most famous account holds novel prediction to consist in predicting phenomena that are "improbable or even impossible in the light of previous knowledge" (Lakatos 1970, 118), and he later accepted Zahar's (1973) revisionist proposal that the novelty of a fact for a hypothesis requires only that it "not belong to the problem-situation which governed the construction of the hypothesis" (103). Each of these lines of thought has been more fully developed by later thinkers, even as they have lost any immediate connection to concerns about the evaluation of research programs (see Research Programs).

The second issue of recent interest concerns whether standard philosophical approaches to confirmation can recognize a special confirmational significance for novel prediction, and if not, whether this weighs against such approaches to confirmation or against the legitimacy of predictivist intuitions instead. Such approaches are described as taking into account only "logical" and not "historical" relations between theory and evidence, or alternatively, only the content of theories and evidence and not historical facts about them. It has sometimes been claimed that a logical approach to confirmation is strictly inconsistent with predictivism; but this is too strong, for the fact of successful prediction can itself simply be treated as part of the evidence supporting a theory. In Bayesian terms,

one need only treat the fact that a novel result was *predicted* as part of the evidence on which the theory's probability is conditionalized to allow a special confirmational role for novel prediction. This brute-force solution to the problem invites the complaint that a special epistemological significance for novel prediction still finds no expression in the formal *machinery* of either Bayesian or any other extant logical accounts of confirmation. But even this is far from uncontroversial (see Bayesianism; Confirmation Theory).

There has been widespread discussion among Bayesians concerning the nature and plausibility of the further assumptions that must be granted in order to accord novel prediction a special confirmational significance within the Bayesian framework. Central to this discussion has been Glymour's (1980) "problem of old evidence": The Bayesian approach to confirmation suggests that known evidence cannot provide any support for a theory because probability 1 is conferred on that evidence by background knowledge alone (see Bayes's theorem below). To make matters worse, it is difficult to see how one could conditionalize on or even specify what one's background knowledge "would have been" without the evidence in question. Indeed, it has variously been argued that Bayesianism is legitimate because it recognizes a special confirmational significance for novel prediction, that it is legitimate because it does not, that it is illegitimate because it does, and that it is illegitimate because it does not (Brush 1995).

Finally, it has sometimes been argued that the ability of a theory to make successful novel predictions is the one form of scientific success for which only the truth of a theory can provide any explanation. This grounds a specific form of the traditional miracle or explanationist argument for scientific realism on behalf of theories enjoying success in making novel predictions. Leplin's (1997) account of novel prediction, for example, is an explicit effort to pick out just those forms of scientific success that only the truth of the successful theory could explain (see Scientific Realism).

A related point of contention concerns whether predictivist convictions have in fact played any role historically in the confirmational judgments made by actual scientific communities. Theorists have appealed to such famous cases of novel prediction as the Poisson "bright spot" by Fresnel's formulation of the wave theory of light, the gravitational bending of light by the general theory of relativity, and the existence and properties of three new elements by Mendeleev's periodic law to argue that particular novel predictions have or have not been accorded exceptional confirmational weight by actual scientific communities relative to the mere accommodation of existing evidence (see Scerri and Worrall 2001 for references and discussion). Such claims about scientific practices are also invoked to either bolster or defuse the further claim that an adequate account of confirmation will have to respect predictivist intuitions. This historical debate serves to underscore the contentious character of the *explanandum* for which accounts of novel prediction are supposed to provide explanations. For even if it is true that scientific communities have not historically weighted novel predictions over other kinds of evidence, this itself would seem to call for some kind of explanation, in light of the grip that predictivist intuitions seem to hold on ordinary thinking about confirmation.

Indeed, any serious assessment of the epistemic significance of novel prediction seems to invite a stark conflict of powerful normative intuitions. There is something especially impressive about such famous cases of novel prediction as gravitational light bending and the Poisson bright spot, but it seems perfectly fair to ask why the temporal order or other historical circumstances of discovery should have any bearing on the confirmational significance of the evidence for a theory. After all, whether a phenomenon was already known does not have any impact whatsoever on how convincing the theory's account of that phenomenon is. Why should it make any difference whether the data were predicted by a theory or acted as a constraint on the development or selection of that same theory in the first place? Features such as the theory's fit to the data, the auxiliary assumptions required to obtain that fit, and the theory's intrinsic plausibility remain precisely the same whatever the order, manner, or other circumstances of their discovery. It seems perverse to treat such apparent historical accidents as relevant to the degree of confirmation conferred on that theory by the evidence at hand.

Predictivism's defenders have turned, therefore, to specifying criteria for genuinely novel prediction in a way that seeks to avoid dependence on apparently arbitrary or epistemically insignificant features. Meanwhile, their opponents have sought to show that the apparent significance of novel prediction is a product of its confusion, conflation, or frequent association with something else that is of genuine epistemic importance. It is, however, sometimes hard to see more than a rhetorical or terminological difference between the positions of those who seek to creatively refine the conception of novel prediction so as to guarantee its epistemic

significance and those who seek to explain the apparent importance of novel prediction as dependent upon the genuine epistemic significance of something else altogether. Sometimes both camps appeal to the same or similar relationships between theory and evidence, and it is not always clear whether a given author even means to explain the epistemic significance of novel prediction or explain it away. A similar ambiguity infects the discussion of the confirmational role of novelty in actual historical cases.

Complicating this dialectical situation are two competing strands of thinking about the epistemic significance of novel prediction, whether real or apparent. The first, sometimes called ''heuristic,'' holds that the epistemic significance of genuine novelty is a matter of the independence, in some sense, of a given result from the formulation of the theory for which it counts as a novel prediction. Various formulations count a given phenomenon as novel for a given theory if and only if it was not part of the problem situation that led to the theory (Zahar 1973), was not actually used in the formulation of the theory (Worrall 1978 and 1989), was not known to some theorist who formulated the theory (Gardner 1982), or fits the hypothesis despite its not having been designed for that purpose (Campbell and Vinci 1983). These accounts differ most centrally in the precise role that known data must play in the formulation of a hypothesis in order for it to lose the special confirmational significance associated with novel prediction.

The second approach, sometimes unfortunately called ''epistemic,'' proposes instead that novelty be understood as a matter of unexpectedness or low probability in light of what is believed absent the theory. Examples include Lakatos's (1970) construal of novel prediction as the prediction of phenomena that are ''improbable or even impossible in the light of previous knowledge'' (118) and Musgrave's (1974) suggestion that a novel prediction of a theory is one that either conflicts with or is at least not also made by its competitors or predecessors (see also Popper 1963, 36). These accounts differ centrally over what should form the foundation for the expectations that a predicted phenomenon must violate in order for it to enjoy the exceptional confirmational significance associated with novel prediction, and thus recall the problem of old evidence for Bayesianism.

Each approach is sometimes motivated by canvassing weaknesses or challenges to various versions of the other, but it is worth noting that each encapsulates one of two quite different phenomena that might reasonably be called novel prediction. The first is aimed at a theory's entailment of a result not involved in its own development, that is, a result that is novel *for the theory*, while the second concerns a theory's prediction of phenomena unlike those with which an epistemic community is already familiar, that is, a novelty *for an epistemic community*.

Among theorists who seem inclined to argue that the apparent epistemic significance of novel prediction is a product of its confusion with some other condition of genuine epistemic significance, the most influential proposal has been that the evidence must provide a ''severe test'' of the theory, that is, one that the theory is likely to fail if it is in fact false (Popper 1963; Horwich 1982; Giere 1984; Mayo 1991). Other analyses propose alternative sources of confusion, such as the assurance novel prediction typically provides that the hypothesis be well supported by earlier subsets of the data as well as by the whole (Schlesinger 1987), that there be no opportunity for ''fudging'' the hypothesis to fit the data (Lipton 1991), or that the hypothesis itself not be an arbitrary conjunction of facts (Lange 2001).

One natural way to unify these divergent intuitions about the epistemic significance of novelty is to suggest that each is concerned to rule out a different possible explanation of the evidential situation that would undermine the support a given piece of evidence would otherwise provide for a given theory. The idea here is that the various attempts to define novelty and to explain or to explain away its confirmational significance appeal to different ways in which the *prima facie* support that evidence provides for a theory can be undermined by further information, such as finding out that the theory was constructed, manipulated, or chosen so as to yield its supporting data, that there are reasons besides the theory to expect the results reported in the data, that the theory itself is simply an arbitrary conjunction of unrelated facts, and so on. If this view is right, the various competing accounts of novel prediction reflect the variety of possible confirmation-undermining explanations of the evidential situation, and it was a mistake all along to insist on just a single criterion of ''genuine'' novel prediction or even a single analysis of its epistemic significance, real or apparent. This suggests that paradigmatic cases of novel prediction like the Poisson bright spot are particularly impressive precisely because they preclude nearly all of the most likely confirmation-undermining possibilities. In a similar spirit, Leplin's effort to pick out the sort of predictive success that could only be plausibly explained by the truth of a theory that enjoys it

includes criteria of both heuristic and epistemic varieties.

Any such pluralistic proposal regarding the epistemic significance of novelty must face up to an argument given by Horwich (1982), who grants that the confirmation provided for a theory by a given result would be compromised by the existence of plausible competing explanations for that same result, and endorses a Bayesian version of the severe-tests conception of confirmational significance. But he denies that the explanations ruled out by the heuristic novelty of a result (e.g., that the theory was formulated or even manipulated so as to entail the result) are actually competitors to the theory itself as explanations *of the available data.* Instead, he suggests, the explanations ruled out by heuristic novelty are those of *why a given theory fits the data as well as it does*, and thus do not compete with the theory itself to explain the data at hand. For this reason, he suggests, neither heuristic novelty nor the explanations of our evidential situation that it is able to preclude carry any genuine confirmational significance.

But what about the latter explanatory demand alone? Even if the fact that a theory was formulated or manipulated so as to entail the data simply offers an explanation for why the theory fits the data, this would seem to compete with the alternative explanation that the theory fits the data because it is true. Horwich resists this suggestion by way of an intriguing analogy designed to illustrate that even different explanations of the same state of affairs need not always be genuine competitors. He points out that being out of gas and having a broken starter compete to explain why Smith's car will not start: Both could obtain, but the probability reasonably assigned to one will be dramatically lowered upon learning that the other is true, because they answer the same explanatory demand in the same way. But not all explanations of the same state of affairs compete in this way. Consider, he suggests, the following explanations for the fact that his car is green: Is it because he buys only green cars or because the previous owner painted it green? In this case, the candidate explanations do not compete, in the sense that the fact that one obtains does not reduce the probability that the other also obtains. He further suggests that the explanations of fit precluded by heuristic novelty and provided by the truth of a theory are like the second case and not the first: The fact that a theory fits the data because one requires or even manipulates the hypothesis to ensure that this is so simply does not compete with the explanation that the resulting hypothesis fits the data because it is true. If so, there is no prior reason to think that hypotheses that merely accommodate existing data are less likely to be true than those that successfully predicted the same data as novel phenomena.

It is far from clear that this claim must be accepted as it stands. Perhaps there is no competition if data simply constrained the formation of a theory in the first place. But if one manipulated a theory's variable parameters to get it to fit the data, and if one believed that such adjustment could have accommodated most any data of the kind in question, this might indeed seem to compete with the claim that the theory fits the data because it is true. But even if one accepts Horwich's claim, all need not be lost for heuristic novelty. It remains possible that one might find a promising *inductive* justification for the epistemic significance of heuristic novelty. But this would require making the case that theories successfully predicting heuristically novel phenomena go on to enjoy especially impressive track records.

How to Make Predictions

In the spirit of Hume's skeptical solution to the problem of induction, one might wonder whether questions about the rational justification of predictions are not best dealt with by investigating how successful predictions have in fact been made. What inferential techniques and assumptions are actually used to move from known facts to predictions about unknown cases?

It may help to start with simple cases. Hans Reichenbach took the aim of inductive inference to be that of finding series of events whose frequency of occurrence converges toward a limit (see Reichenbach, Hans). If this is all one wants, one might simply keep track of the relative frequencies in any series of data one finds interesting. Suppose, for example, one wants to determine the probability of tossing a coin and having it come up heads. Start tossing it, keeping track of the relative frequency of heads to all tosses. If there is a well-defined relative frequency in the limit as the coin is tossed interminably, then it would be guaranteed that the probability would be found in this way. If the limiting relative frequency is undefined, then, for Reichenbach, it makes no sense to assign probabilities to the possible outcomes of any toss of the coin, and there is no solution to the problem of induction for that particular series of events. That is, the world is predictable insofar as it is sufficiently ordered to enable one to construct limiting relative frequencies from empirical data. While Reichenbach admits that "we do not know whether the world is predictable," keeping track of relative frequencies in a world that is in

fact predictable is guaranteed eventually to deliver the right probabilities, and this sort of inductive inference will work; and if the world is not predictable, then nothing will work. Moreover, if something besides this sort of inductive inference does reliably work to predict future events, then this sort of inductive inference would track the success of the alternative method and warrant its use (Reichenbach 1938, 350).

While raw relative frequencies sometimes are the best estimates of probabilities, several caveats are in order. Although Reichenbach's procedure is guaranteed to deliver the actual relative frequencies in the long run if there are any, one never in fact performs an infinite number of observations calculating relative frequencies at each step, and it is not even clear that this is in principle possible (a real coin would not survive). Furthermore, a series of events might very well have well-defined limiting relative frequencies but be such that one would not find them in the short to medium run.

This last caveat helps to illustrate an important general principle: The kinds of tools that allow one to make predictions based on past evidence require the use of background assumptions about how a given segment of the time series of events one observes relates to the time series more generally. In this case, if the local relative frequencies are approximately equal to the relative frequencies in future segments of the time series, then keeping track of local relative frequencies clearly provides a good way of making future predictions. Of course, as a solution to the general problem of induction, such an assumption simply begs the question. But it would perhaps be surprising to find that accurate predictions could be made without any background assumptions whatsoever. Thus, one might usefully classify methods of prediction by the type of background assumptions that must be satisfied for the method's predictions to be reliable.

One might, for instance, roughly distinguish *basic tools*, which make predictions on the basis of empirical data with only the most basic statistical assumptions, from *model-based tools*, which make predictions by estimating unknown parameters in more complex or intricately structured predictive models (see Hamilton 1994 for a generous sample of both sorts of predictive tools). Reichenbach's suggestion that one take local relative frequencies as probability estimates is an example of a basic predictive tool. Here a prediction is a bet that one's short-to-medium-run evidence faithfully reflects longer-run relative frequencies. While one may never be certain that this is the case, it is easy to imagine evidence for or against the claim that the assumption is reasonable in a given context. If it is, one can confidently use this basic tool for empirical prediction.

Another relatively basic predictive tool is Bayesian updating. This tool requires that one have prior probabilities to be updated on the basis of one's new evidence. This is an advantage in that more than one's relevant prior beliefs can be used in making predictions, and a disadvantage in that one must have an appropriate set of prior probabilities in order to use the predictive tool at all.

There are two steps to Bayesian updating. One first calculates the probability of the hypothesis under consideration H being true given evidence E using Bayes's theorem:

$$P(H \mid E) = \frac{P(H)P(E \mid H)}{P(E)}.$$

For a Bayesian subjectivist, $P(H)$ is one's prior degree of belief in H, $P(E|H)$ is the degree to which H being true would explain evidence E, and $P(E)$ is one's prior degree of belief that E would occur. Bayes's theorem follows from the axioms of probability theory and the definition of conditional probability.

The total probability theorem can be used to expand $P(E)$, yielding Bayes's theorem in a form that is often more useful:

$$P(H \mid E) = \frac{P(H)P(E \mid H)}{\sum_i P(H_i)P(E \mid H_i)},$$

where H_i values form a mutually exclusive and exhaustive set of possible hypotheses (which typically includes H), and $P(E|H_i)$ is a measure of how well each rival hypothesis would explain the occurrence of E.

After calculating the old probability of hypothesis H given evidence E, one updates the probability of H given that E has in fact occurred. In the simplest case, where one's evidence is itself certain, one might use strict conditionalization:

$$P_{new}(H) = P_{old}(H \mid E).$$

For a subjective Bayesian, P_{new} (H) represents the degree of belief one ought to have in H after evaluating evidence E. The justification here is given in a series of Dutch Book arguments, where one shows why an agent would accept irrational wagers guaranteed to lose money if the agent adopts an incompatible strategy for revising degrees of belief (Howson and Urbach 1989) (see Dutch Book Argument).

The use of prior probabilities in Bayesian updating requires stronger initial assumptions than

Reichenbach's method. But in return it allows inferential use of more of one's relevant background beliefs about the nature of the world and the context in which a prediction is made.

Because predictive tools are characterized by the background assumptions needed to apply them, basic prediction and model-based prediction differ only in the number, detail, and complexity of the background assumptions they require. Model-based prediction begins with a model for a selected set of empirical data on which reliable future predictions can be made if its parameters are correctly set. As one might expect, model-based predictive tools are both numerous and diverse. Adopting a predictive model might involve anything from assuming that the data should fit to a straight line (the parameters to be estimated here might be the line's slope and y-intercept) to assuming that the data should fit a broad range of specific parameters in a detailed causal description of the system being observed (the parameters to be estimated here might be the state of a physical system at a time and its Hamiltonian). Stronger background assumptions may permit the use of predictive tools that yield more detailed and/or accurate predictions, but the stronger assumptions are also more likely to be mistaken.

The methods one might use to set the parameters of a predictive model are similarly diverse. Basic predictive tools may be used to estimate the values of the unknown parameters in a more complex predictive model, or another model might very well be used to estimate these parameters. And the accuracy of one's subsequent predictions will depend upon whether the background assumptions required by the models are satisfied, the number of parameters estimated, the accuracy of the estimations, and the sensitivity of the models to specific failures in accuracy. In short, then, the reliability of the predictions of the model will typically depend upon a host of nontrivial background assumptions.

One might take from Hume's problem of induction the general lesson that information about the past cannot guide rational expectations about the future without some additional background assumptions about the system under consideration. It is perhaps not surprising that there are genuine choices to be made concerning what background assumptions and associated predictive tools are applicable in a given context. In real cases of justification of a particular set of background assumptions, the issue is not whether the future will resemble the past in some vague general sense. Rather, one typically finds a variety of concrete argumentative and evidential considerations weighing in favor of competing ways in which it might be expected to do so. And theories in the particular sciences discussed below are typically associated with one or more predictive models requiring various sets of both substantive and controversial background assumptions.

Prediction in the Empirical Sciences

Classical Mechanics and Chaotic Systems

Newton's classical mechanics is perhaps the most influential example of a predictive theory. It is deterministic in that the physical state (i.e., the position and momentum of each particle) of a closed and finite physical system at a time, $S(t_0)$, together with the energy properties of the system uniquely determine the physical state at all other times (see Determinism). Since the position of each particle can be given by 3 coordinates and the momentum can be given by 3 coordinates, the complete state of an N-particle system can be given by $6N$ coordinates or a single point in a $6N$ dimensional phase space. As the system evolves, the point representing its state in phase space moves in a continuous way. The past, present, and future history of a particular closed system is represented by the curve in phase space that represents the state of the system at each time. The dynamics can be represented as a set of differential equations that have as solutions the possible phase-space trajectories of the system. Since the history of the system is fully determined by the initial state $S(t_0)$ and the system's dynamical properties, this information and sufficiently precise calculations would, at least in principle, enable one to predict with perfect accuracy the state of the system at any time (see Classical Mechanics).

This ideal is compromised in application by the fact that observational error is always introduced in measuring continuous quantities like position, momentum, and energy with limited precision. Moreover, computational errors are nearly always introduced by rounding, since analytic solutions to the dynamical laws are rare in general and almost never perfectly applicable. Nonetheless, classical mechanics allows one to make very accurate empirical predictions in a wide variety of contexts, and Newton's *Principia* famously employs his theory of mechanics to explain and predict the future motions of the five primary planets, the moon, the satellites of Jupiter and Saturn, the precession of the equinoxes, tidal phenomena in the Earth's seas, and the motions of comets. And it does all this so successfully that many thought he had determined, as Edmund Halley wrote in his ode honoring Newton's accomplishment, "Jove's calculation and

the laws / That the creator of all things, while he was setting the beginnings of the world, would not violate" (Newton [1713] 1999, 379).

Notwithstanding these and other remarkable successes, there are severe limits to prediction in classical mechanics that are consequences of its theories' nonlinear dynamics. The problem is that phase-space trajectories that are initially close may diverge exponentially with respect to time. Thus, the inevitable small errors in determining the initial state of a system or introduced into computation may generate large predictive errors. And it can happen that the expected error becomes so large over even relatively short times that one can predict almost nothing concerning the future state of the system from its current state. A chaotic system is one that exhibits such exponential sensitivity to initial conditions. More precisely, the chaotic domain of a system is that region of its phase space where the trajectories associated with infinitesimally displaced initial conditions separate from each other exponentially in time.

Chaotic behavior is exhibited by many familiar physical systems (Ott 1993). A dripping water faucet, for example, will often exhibit nearly equal times between drops for low, even inflows, then shift to an unpredictable sequence of times between drops when the inflow is increased. Chaotic behavior is also exhibited by some chemical and biological systems. And curiously, there is reason to expect the motions of the planets in the solar system, the paradigmatic example of clockwork regularity, to exhibit chaotic behavior. Given that the best estimates of the relevant continuous physical parameters are approximate and that numerical methods for performing computations invariably introduce error, there are strict limits on the reliability of the predictions concerning the motions of the planets obtainable from classical mechanics.

The behavior of chaotic systems is not, however, entirely unpredictable. In many cases, a chaotic system can be characterized for the purposes of prediction by its attractors, those sets of points in phase space (whether singular points, limit cycles, or more complex regions) that are attractive to all neighboring trajectories. Knowing the type and location of the attractors can allow one to predict the long-term behavior of even a chaotic system, although the nature and precision of such predictions will depend on the existence and type of attractors exhibited by the system. Some dynamical systems are associated with limit sets that are asymptotically attractive to neighboring trajectories but contain trajectories that are locally divergent within the attractive set. Such a limit set is called a *strange attractor*. If the system begins within the region attracted by the strange attractor, one would be able to predict convergence to the attractor but virtually nothing concerning the behavior within the attractor. Such attractors may even be typical in nonlinear systems of order higher than 2 (Cook 1994).

A rather different predictive problem in classical mechanics concerns the fact that it is deterministic for only finite, closed physical systems. Consider a particle that is moving at 1 m/s at $t = 0$, then is accelerated to 2 m/s at $t = \frac{1}{2}$ s, to 4 m/s at $t = \frac{3}{4}$ s, to 8 m/s at $t = \frac{7}{8}$ s, etc. After $t = 1$ s, the particle will be farther than any finite distance from where it started. Since any possible physical history can in classical mechanics be run backward as well as forward, consider the time-reversed version of this history. Here the particle starts farther than any finite distance from a system—for instance, one whose behavior one wishes to predict—and ends up crashing into it and ruining the prediction. In this case, one would not be able to make any predictions concerning the behavior of the system whatsoever, even after taking into account every particle that has a well-defined position at the beginning of the time-reversed story (Earman 1986).

Quantum Mechanics

Quantum mechanics is the most successful empirical theory ever, but unlike classical mechanics, it typically allows predictions that are only probabilistic (see Quantum Mechanics). In quantum mechanics the state of a physical system, S, is given by a vector, ψ_S, in an appropriate vector space. ψ_S is sometimes called the wave function of S. The state of the system almost always evolves in a linear, deterministic way that depends only on the energy properties of the system. In nonrelativistic quantum mechanics, this deterministic evolution is described by the time-dependent Schrödinger wave equation. Given the standard way of interpreting the quantum mechanical state, a physical system typically fails determinately to have or determinately not to have a given classical physical property at a time. But systems are found to have the determinate property being measured when a measurement is made. In the von Neumann–Dirac *collapse formulation* of quantum mechanics, this is explained by the collapse of the quantum mechanical state on measurement: When a system S, initially in state ψ_S, is measured, S instantaneously and randomly jumps to a state where the property being measured is determinate (see Quantum Measurement Problem). Which state S jumps to is taken

to be an irreducible matter of chance. The probability of ending up in the determinate-property state χ_S is determined by the geometric relationship between the vectors ψ_S and χ_S (the probability is equal to $|\langle\psi|\chi\rangle|^2$). It is because the collapse dynamics is random that one is typically limited to making only probabilistic predictions concerning the results of future observations.

While there is disagreement concerning how one ought to understand quantum mechanics generally, and the collapse dynamics in particular, there is nearly universal agreement that one will never be able to make empirical predictions that do better than the standard quantum probabilities (Albert 1992). In this sense, the quantum probabilities are taken to represent a fundamental limitation to empirical prediction in physics.

Biological and Social Sciences

It is sometimes claimed that biological sciences in general, and evolutionary biology in particular, are not predictive, but this is at worst simply false and at best a simplistic description of a complex situation. There is no question, however, that there are systematic differences between the predictive capabilities characteristic of biological sciences and those familiar from the physical sciences. Some of these are illustrated by an example Mary Williams (1982) borrows of characteristic prediction in evolutionary theory: "Sexual dimorphism in the length and color of the furry body covering of bumblebees should show a latitudinal and altitudinal gradient among species of bumblebees, with tropical and low altitude species having more dimorphism" (293). As the example suggests, biological predictions more typically concern groups, species, populations, or ensembles than individuals, and they more often describe unknown past or present states of affairs than future ones. Moreover, the intended scope of predictive generalizations in biology is typically not spatiotemporally unrestricted: They are at a minimum restricted to circumstances in which particular (often unique and evolutionarily contingent) causal mechanisms operate, and they are typically exception-ridden or asserted *ceteris paribus*, even within the scope of such intended domains. Mendel's law of segregation, for example, can be used to make reliable predictions (of ratios for populations or probabilities for individuals), but even these predictions are both restricted to contexts in which a particular, evolutionarily contingent causal mechanism is operating (i.e., sexual reproduction) and are subject to exceptions (e.g., meiotic drive) even in that domain. Perhaps the most interesting question, then, concerns the source of these characteristic differences in predictive capabilities (see Population Genetics).

The first and most obvious is the relatively greater causal complexity of the natural systems studied by biological sciences as compared with those in the restricted domains in which physical science is able to deliver precise and accurate predictions. As Mitchell (2003, chap. 5) effectively documents, the relevant complexity here is of several kinds, including the compositional complexity of actual biological systems, the number and variety of causal processes operating in them, the sometimes dramatic and sudden shifts in the relationships between key variables across different ranges of their variation, and the characteristic embeddedness of biological entities in levels of organization with multiple weak, nonadditive forces and redundant mechanisms operating both within and between these various levels. The impact of such causal complexity is amplified by the long timescale of evolutionarily significant effects, during which such complexity must be modeled, controlled, or eliminated to allow effective prediction. Also significant is the characteristic contingency of the states of affairs studied by evolutionary biology and other historical sciences on the occurrence of particular (often rare) events, which themselves constrain and shape the course of future evolutionary change. Perhaps the simplest example here is the effect of mutation: At a given time, different mutational substitutions of just a single amino acid can easily lead to extremely different evolutionary outcomes over relatively short timescales, but the process of mutation is treated as a random variable by evolutionary theory, either because it is genuinely indeterministic or because one does not yet know enough about the process or relevant conditions in particular organisms to predict with any precision what, when, and how particular mutations will occur. It is for all these sorts of reasons (although not always in these terms) that philosophers of science have enthusiastically debated whether there are laws of any traditional variety in biological science and the ultimate source of the indeterministic character of evolutionary theory.

Taking these sorts of complexities and contingencies into account suggests that the physical analogue for biological sciences is not predicting the speed and position of a ball rolling down an inclined plane, but something more like predicting the path of a bag of feathers dumped out of an airplane. Physical sciences are able to make some predictions about what will happen in these circumstances, but these predictions will be relatively weak, more likely to concern the feathers as a

group, and will be reliable only *ceteris paribus* or subject to the operation and/or interference of particular causal mechanisms that affect their trajectory (e.g., prevailing weather conditions). Of course, the extent to which these features are characteristic of the predictive application of the physical sciences generally is also controversial (see Cartwright 1983), but biological sciences appear to fare even worse in natural settings and to be even less amenable to the construction of specialized contexts that make precise and powerful prediction possible.

Rosenberg (1983 and 1994) and others have argued for a related but perhaps more fundamental kind of limitation on the predictive capabilities of biological sciences. Rosenberg suggests that such predictive limitations arise because in typical cases (arguably excluding some parts of molecular genetics) biologically significant categories must be characterized functionally or teleologically, and there is a wide diversity (which seems unlikely to admit of finite specification even in a disjunctive list) of possible physical realizations of such functionally characterized entities (see Function).

Put another way, the claims here are that

- there are no type identities between important explanatory biological categories (like fitness, mimicry, temperature-regulating mechanism, balanced polymorphism, regulatory gene) and the mechanistic physical descriptions of the tokens instantiating these functional kinds in particular cases; and
- it is these mechanistic descriptions that offer power and precision in predicting the range of conditions under which a mechanism will operate, what causal factors might interfere with it, its probable evolutionary trajectory, and the like.

Rosenberg thus argues that the goals of prediction and explanation pull in different directions here and that the diversity and potential infinity of the possible realizations of functionally characterized biological kinds conspire to ensure that biological sciences retain their weakly predictive character if they are to remain useful to us.

Perhaps a useful example of how this can be so is provided by Fisher's (1930) famous explanation of why the sex ratio in sexually reproducing diploid species at reproductive age is typically 1:1. Briefly, the explanation is that (assuming equal parental cost to produce offspring of either sex and ignorance of offspring quality, and setting aside complications) no matter what the mating system, a parent will spread more copies of its genes by producing offspring of the less numerous sex: Since every successful mating requires the genetic contribution of exactly one member of each sex, members of the less numerous sex are more easily able to obtain multiple successful matings, be more choosy about mates, or enjoy whatever reproductive advantages members of that sex enjoy in the mating system. Even if a species' mating is structured in such a way that a few successful males do all the mating and most males do not mate at all, when males are less numerous than females, a parent will do better on average by producing sons with a proportional *chance* of being one of the lucky few than daughters who are guaranteed to mate. Therefore, it pays to produce members of whichever sex is more rare, ensuring strong selective pressure against any mechanism that favors producing male offspring over female or vice versa.

Contrast this explanation of the sex ratio with that provided by conjoining the physical histories of each organism in each species. There is certainly a sense in which the sex ratio is thereby explained, for this complex history (including the random segregation of sex-determining chromosomes, the details of development and survivorship for each organism, and even the survival and propagation of the specific genetic, physiological, and ontogenetic mechanisms responsible for sex determination in each species in the first place) deductively imply that sex ratios are what they are (near 1:1 in each case). But this mechanistic explanation, provided in terms that would increase predictive power and precision regarding individual cases, provides nothing like Fisher's insight into the evolutionary reasons for the emergence and persistence of the 1:1 sex ratio. Similarly, a detailed molecular description of the operation of a particular DNA-repair mechanism may permit effective prediction of the conditions under which the mechanism will operate, but it will be unable to explain *why* such a mechanism exists and persists and perhaps even obscure the fact that it is a mechanism for repairing DNA (and thereby minimizing mutational changes). Of course, without this functional characterization, there would seem little sense left to be made of the question of under what conditions such a mechanism will operate (or do so effectively). Such examples illustrate why the relative predictive weakness of biological sciences might not simply be an unfortunate consequence of increased complexity and contingency in their domains of application, but also an aspect of those sciences intimately bound up with what renders them useful.

An interesting further question concerns to what extent any of these predictively limiting aspects of biological science also underlie the relative

predictive weakness of the social sciences. Causal complexity and contingency are often invoked in this connection, perhaps most famously in an influential argument due to Karl Popper (1957) (helpfully discussed by Rosenberg 1993) to the effect that because the growth of scientific knowledge has persistently exerted dramatic effects on the course of history and human affairs, the unpredictable trajectory and directions of such growth preclude even the possibility of a predictively robust social science. However, the failure of type identities between important explanatory categories has also been invoked to explain the relative predictive weakness of the social sciences (see Rosenberg 1994). Here it is the *intentional* explanatory categories of the social sciences that are supposedly both ineliminable and multiply realized by tokens that are heterogeneous in the terms of more predictively precise and powerful sciences, including biology itself (but cf. Nelson 1990) (see Intentionality). These and closely related considerations are invoked to support a variety of predictively relevant conclusions concerning the social sciences, including the claims that the kinds of predictive limitations discussed above will prove to be ineliminable from them; social scientific predictions will remain merely "generic" or qualitative; genuinely scientific and predictive social science will have to eliminate any appeals to intentional notions; the study of social phenomena is autonomous and cannot be understood in terms of aggregate actions and dispositions of individuals; and social inquiry must or should be restricted to the interpretive study of others (see Social Sciences, Philosophy of).

PROBABILITY

There are two central questions concerning probability. First, what are its formal features? That is a *mathematical* question, to which there is a standard, widely, though not universally, agreed upon answer (reviewed in the next section). Second, what sorts of things *are* probabilities—what, that is, is the *subject matter* of probability theory? This is a *philosophical* question, and while the mathematical theory of probability certainly bears on it, the answer must come from elsewhere. To see why, observe that there are many things in the world that have the *mathematical structure* of probabilities (e.g., the set of measurable regions on the surface of a table) but that would never be mistaken for *being* probabilities. So probability is distinguished by more than just its formal characteristics. The bulk of this essay will be taken up with the central question of what this "more" might be.

Kolmogorov's Axiomatization

Probability theory was inspired by games of chance in seventeenth-century France and inaugurated by the Fermat–Pascal correspondence, which culminated in the *Port Royal Logic* (Arnauld [1662] 1964). Its axiomatization had to wait nearly another three centuries. The locus classicus of the mathematical theory of probability is Kolmogorov's ([1933] 1950) *Foundations of Probability*. Inspired by measure theory, Kolmogorov's axiomatization has become orthodoxy. Let Ω be a nonempty set. A *field* (*algebra*) on Ω is a set F of subsets of Ω that has Ω as a member and that is closed under complementation (with respect to Ω) and union. Assume for now that F is finite. Let P be a function from F to the real numbers, obeying the following axioms:

$$P(a) \geq 0 \text{ for all } a \in F, \qquad \text{A1}$$

$$P(\Omega) = 1, \text{and} \qquad \text{A2}$$

$$P(a\ \Omega\ b) = P(a) + P(b) \text{ for all } a, b \in F \text{ such that } a \cap b = \phi. \qquad \text{A3}$$

Call P a probability function, and (Ω, F, P) a probability space.

One could instead attach probabilities to members of a collection of *sentences* of a formal language, closed under truth-functional combinations. Either way, a kind of reflective equilibrium is achieved between these axioms, which are thought to be intuitively plausible, and various important interpretations of probability (to be discussed in the subsequent sections), which obey them and bring them to life in applications.

It is often thought that the only nonconventional part of the axiomatization is A3. That is too quick, for it is substantive that probabilities are

1. Defined by *functions* (rather than by one-many or many-many mappings);
2. Functions of *one variable* (unlike primitive conditional probability functions, which are functions of two variables);
3. Defined on a *field* (rather than a set with weaker closure conditions);
4. Represented *numerically* (rather than qualitatively, as is "possibility"; or comparatively, as is "similarity to a given world" in the Stalnaker/Lewis style of semantics for counterfactuals [Lewis 1986a]);
5. *Real* numbers (rather than those of some other number system);
6. *Bounded* (unlike other quantities that are treated measure-theoretically, such as lengths);
7. Bounded by *Maximal* and *minimal* values (thus prohibiting open or half-open ranges).

For a discussion of rival theories that relax or replace points 2, 3, 4, and 6 above, see Fine 1973. Complex-valued probabilities are proposed by Feynman and Cox (Mückenheim et al. 1986); infinitesimal probabilities (of nonstandard analysis) by Skyrms (1980) and Lewis (1986b), among others; and unbounded probabilities by Renyi (1970). Primitive conditional probability functions will be briefly discussed at the end of this section.

Kolmogorov extends his axiomatization to cover infinite probability spaces. Probabilities are now defined on a *σ-field* (*σ-algebra*)—a field that is further closed under *countable* unions—and A3 is correspondingly strengthened:

A3′ (Countable additivity) If $a_1, a_2, a_3, \ldots$ is a countable sequence of (pairwise) disjoint sets, each belonging to F, then $P(\bigcup_{n=1}^{\infty} a_n) = \sum_{n=1}^{\infty} P(a_n)$.

De Finetti (1990) is a notable opponent of countable additivity.

Kolmogorov then defines the conditional probability of a given b by the ratio of unconditional probabilities:

$$P(a|b) = \frac{P(a \cap b)}{P(b)}, \text{provided } P(b) > 0.$$

Note that this ratio is undefined if either or both of the unconditional probabilities are undefined, or if $P(b) = 0$. Yet in uncountable spaces there can be genuine, nontrivial events whose probabilities are undefined (so-called "nonmeasurable" sets), and others whose probabilities are 0 ("probability 0 does not imply impossible," as textbooks and Kolmogorov himself caution us). So Kolmogorov's definition does not guarantee that certain intuitive constraints on conditional probability are met—for example, that the probability of an event, *given itself*, is 1.

Kolmogorov addresses the probability-0 problem with a more sophisticated account of conditional probability as a random variable conditional on a sigma algebra, appealing to the Radon-Nikodym theorem to guarantee the existence of such a random variable (see, e.g., Billingsley 1995). A rival approach takes conditional probability $P(\_,\_)$ as primitive and defines the unconditional probability of a as $P(a, \mathbf{T})$, where $\mathbf{T}$ is a necessary (e.g., tautological) proposition. Various axiomatizations of primitive conditional probability have been defended in the literature, typically differing only in the handling of conditional probabilities with zero unconditional probability antecedents. In many ways, the most general and elegant of the proposed axiomatizations is Popper's (1959). (See Roeper and Leblanc 1999 for an encyclopedic discussion of competing theories of conditional probability, and Keynes 1921, Carnap 1950, Popper 1959, and Hájek 2003b for arguments that probability is inherently a two-place function.)

Versions of Bayes's theorem can now be proven (see Bayesianism):

$$P(a \mid b) = \frac{P(b \mid a)P(a)}{P(b)} = \frac{P(b \mid a)P(a)}{P(b \mid a)P(a) + P(b \mid \neg a)P(\neg a)}.$$

More generally, suppose there is a partition of hypotheses $\{h_1, h_2, \ldots, h_n\}$ and evidence e. Then for each i,

$$P(h_i \mid e) = \frac{P(e \mid h_i)P(h_i)}{\sum_{j=1}^{n} P(e \mid h_j)P(h_j)}.$$

The $P(e|h_i)$ terms are called likelihoods, and the $P(h_i)$ terms are called priors. Finally, Kolmogorov defines a and b to be *independent* iff (if and only if) $P(a|b) = P(a)$; equivalently, iff $P(b|a) = P(b)$; equivalently, iff $P(a \cap b) = P(a)P(b)$ (for $P(a) \neq 0 \neq P(b)$). The terminology suppresses the fact that such independence is really a *three*-place relation between an event, another event, and a *probability function.* This distinguishes probabilistic independence from such two-place relations as logical, causal, and counterfactual independence.

The next section turns to the so-called *interpretations* of probability—attempts to answer the central philosophical question: What is probability?

Frequentism

Ask a scientist what probability is, and one will typically get a *frequentist* answer: The probability of an event is the relative frequency of trials of a repeatable experiment on which that event occurs; sometimes the words "in the long run" are added. This leaves open important questions: Which are the trials to be counted? How long does the run have to be? One may confine one's attention to *actual* trials, realized in this world, or countenance *hypothetical* trials. And one may have merely finitely many trials to contend with or infinitely many, in which case probability will be identified with the *limit* of the relative frequency in a *sequence* of trials. One may thus immediately distinguish $2 \times 2 = 4$ variants of frequentism. However, the actual world typically delivers only finitely many trials of any given experiment. And it is often thought that if one is going to allow the trials to be hypothetical anyway, there is no obstacle to letting the sequence of trials be infinite, thus *guaranteeing* a "long run." So one may confine one's attention, as frequentists typically do, to just two of the possible positions: finite actual frequentism and infinite hypothetical frequentism.

In his discussion of the proportion of births of males and females, Venn (1866) contends that "probability is nothing but that proportion" (84)—a version of finite actual frequentism. Von Mises (1957), by contrast, insists that probabilities exist only relative to virtual infinite sequences of "attributes" called *collectives*. In a collective, the limiting relative frequency of any attribute exists and is the same on any recursively specified subsequence. (Von Mises' original definition, in terms of "place selections," is finessed by Church.) The probability of a given attribute, relative to a collective, is then identified with its limiting relative frequency in that collective. Von Mises' position is thus a version of infinite hypothetical frequentism, as are those of Reichenbach and van Fraassen.

Any version of frequentism faces the notorious *reference class problem.* Any event, in all its detail, occurs exactly once, so if nontrivial frequencies are to be associated with it, it must be regarded as a token of a more general event type, whose instances constitute its reference class. However, there are indefinitely many ways of typing a given event. This would not be a problem if its relative frequency were the same in each reference class, or if one such class stood out as natural or privileged. The problem gains teeth to the extent that various competing reference classes have equal claim to determining the probability and that they yield different relative frequencies for the event.

In some cases, the reference class problem may be solved for the actual, finite frequentist, but at the price of creating the equally notorious *problem of the single case:* Intuitively, the objective probability of a one-off event may be less than 1, but finite frequentism cannot respect this intuition. Many events occur only once by any reasonable standard of typing: the 2000 presidential election, the invasion of Iraq, the last Lakers–Bulls game, and so on. The only natural reference class for such an event is the singleton set consisting of itself, and thus it has relative frequency 1 (and its nonoccurrence has relative frequency 0). Nonetheless, it seems natural to think of nonextreme probabilities attaching to at least some of these "single-case" events.

The problem of the single case is particularly striking, but there is really a sequence of related "granularity" problems: the problem of the double case, the problem of the triple case, and so on. A finite reference class of size n can produce relative frequencies at only a certain level of "grain," namely $\frac{1}{n}$. Among other things, this rules out irrational probabilities; yet, the best physical theories say otherwise (for example, various decay probabilities delivered by quantum mechanics are irrational). Furthermore, there is a sense in which any of these problems can be transformed into the problem of the single case. Suppose that a coin is tossed a thousand times. This can be regarded as a *single* trial of a thousand-tosses-of-the-coin experiment. Yet one does not want to be committed to saying that *that* experiment yields its actual result with probability 1.

The move to infinite hypothetical frequentism makes the reference class problem only worse, for not only must a set of events be chosen in which to place a given event, but since the set is now infinite, an *ordering* among the events must be chosen. After all, in nontrivial cases a limiting relative frequency can be made whatever value one likes simply by reordering the results of a given sequence. Consider the limiting relative frequency of even numbers among positive integers. In the "natural" ordering $<1, 2, 3, \ldots >$ it is $\frac{1}{2}$; however, one can make it $\frac{1}{4}$ by reordering the integers so that the even numbers occur at every fourth place in the sequence: $<1, 3, 5, 2, 7, 9, 11, 4, 13, \ldots >$; and so on. Thus, limiting relative frequencies are sensitive to apparently arbitrary choices of ordering, while it appears that probabilities need not be. One might call this the *reference sequence problem.*

A sequence of events is said to be *exchangeable* with respect to a given probability function if all the joint probabilities of the events are invariant under finitely many permutations of the sequence: Every event has the same probability, every conjunction of two events has the same probability, every conjunction of three events has the same probability, and so on. A sequence of events is automatically exchangeable with respect to the relative frequency function: The frequency of an event is insensitive to *which* trials the event occurs at. Yet various events intuitively are not exchangeable with respect to the relevant probability function. Consider someone learning to throw a dart at a bull's-eye: The sequence <MISS, MISS, HIT> is presumably more probable than <HIT, MISS, MISS>, because the dart thrower's accuracy improves with practice. Yet the (finite) relative frequency of HIT is $\frac{1}{3}$ either way. Since relative frequencies *force* a kind of symmetry that probabilities need not obey, they cannot be the same thing. (Ironically, it was the failure of a more thoroughgoing "infinite exchangeability" that proved to be the undoing of hypothetical infinite frequentism in the previous paragraph.)

The Classical Interpretation

The brainchild of such founding fathers of probability as Pascal, Fermat, Huygens, and Leibniz, and clearly articulated in Laplace ([1814] 1951), the classical interpretation is the oldest interpretation of probability—indeed, it dates back to a time when the axiomatization and interpretation of probability were not clearly distinguished. It seeks to characterize the probability assignment of a rational agent in a state of epistemic neutrality with respect to a finite set of "equipossibilities": The agent has either *no evidence* or *symmetrically balanced evidence* regarding the possibilities. It appeals to the so-called principle of indifference: Whenever there is no evidence favoring one possibility over another, each should be assigned the same probability as the others. So

$$P(e) = \frac{\text{number of equipossibilities in which } e \text{ occurs}}{\text{total number of equipossibilities.}}$$

But the notion of "equipossibilities" seems to presuppose some prior notion of probability. After all, the most obvious characterization of "symmetrically balanced evidence" is in terms of equality of conditional probabilities: Given evidence e and possible outcomes $o_1, o_2, \ldots, o_n$, the evidence is symmetrically balanced with respect to the outcomes iff $P(o_1|e) = P(o_2|e) = \ldots = P(o_n|e)$. Perhaps, then, one should regard the classical interpretation as an attempt to reduce *quantitative* probability to *comparative* probability: All *numerical* probabilities are ultimately based on facts about *equalities* among probabilities.

Note the structural resemblance of the classical theory to finite frequentism. Both theories see probability as a matter of evenhanded counting and ratio taking:

$$P(e) = \frac{\text{number of cases favorable to } e}{\text{total number of cases}}.$$

It is just that for frequentism, the cases are *actual* outcomes of a *repeated* experiment, whereas for the classical theory they are *possible* outcomes of a *single* experiment. And indeed the classical theory faces many of the same problems as frequentism. There is the granularity problem: Clearly, every classical probability is some fraction of the form $\frac{m}{n}$, where n is the number of possibilities. There is the exchangeability problem: Classical probabilities are invariant under permutation of the labeling of the possibilities (for example, relabeling the faces of a die makes no difference to their probabilities of coming up). Thus, the classical interpretation cannot readily provide *asymmetric* probability distributions (e.g., for biased dice or coins), and it cannot handle distributions that evolve over time (e.g., for the dart thrower's hitting the bull's-eye).

Moreover, the reference class problem reappears. If one is truly ignorant about the results of some experiment, then presumably there is nothing to favor various competing choices of sample space. One should then be indifferent between, for example, {heads, tails} and {heads, tails, edge}. And one should be indifferent between various refinements of the original space: for example, between spaces that refine in different ways the heads outcome according to its final orientation relative to due north. Thus, probabilities will be determined by an apparently arbitrary choice of sample space. To adapt an example from physics: Bose-Einstein statistics, Fermi-Dirac statistics, and Maxwell-Boltzmann statistics each arise by considering the ways in which particles can be assigned to states and then partitioning the set of alternatives in different ways (see, e.g., Fine 1973). Someone ignorant of which statistics apply to a given type of particle can make only an arbitrary choice and hope for the best.

In typical applications of the classical theory (gambling, for example), one is not wholly ignorant, but the evidence that one has is symmetrically balanced regarding the possibilities. There are two problems here: in the evidence and in the symmetry. Classical probabilities are acutely sensitive to the

evidence. If the evidence becomes *unbalanced*, favoring some outcomes over others, then classical probabilities are not merely revised; they are *destroyed.* And there may be competing respects of symmetry, each equally compelling. This problem arises especially when there are infinitely many possible outcomes. Then, the equipossibilities must be a finite partition of the outcomes. But *which* partition?

A tempting answer may be: the most "natural" partition. However, "Bertrand's paradoxes" show that there need not be any. The trick is to give competing parameterizations of a given problem that are nonlinearly related to one another but equally natural. Suppose one is told only that a car traveled 100 miles at an average speed between 50 and 100 mph. What is the probability that its average speed was between 75 and 100 mph? Perhaps 0.5, since (50, 75) and (75, 100) are equipossible intervals for the average speed. But the question could be equivalently formulated: A car took between 1 and 2 hours to travel 100 miles. What is the probability that it took between 1 hour and $1\frac{1}{3}$ hours? Now it seems that there are three equipossible intervals for the time taken: $(1, 1\frac{1}{3})$, $(1\frac{1}{3}, 1\frac{2}{3})$, and $(1\frac{2}{3}, 2)$; whence the answer should be $\frac{1}{3}$.

Logical Probability

Many philosophers—Leibniz, von Kries, Keynes, Wittgenstein, Waismann, Carnap, and others—have tried to explicate the following "logical" concept of conditional probability:

$$P(p \mid q) = \frac{\text{the proportion of logically possible worlds in which both } p \text{ and } q \text{ are true}}{\text{the proportion of logically possible worlds in which } q \text{ is true}}.$$

An obvious problem has been to justify a *measure* of the "proportion of logically possible worlds in which a proposition is true." Early attempts (including those by Carnap that will be the focus here) tried to apply the controversial principle of indifference (see Carnap, Rudolf). Carnap's (1950) early constructions are very similar to systems developed earlier by W. E. Johnson (1921) (see Inductive Logic for further references on Carnapian inductive logic and logical probability).

Begin with a first-order language L containing a finite number of monadic predicates: *F, G, H, ...*, and a finite or denumerable number of individual constants *a, b, c, ...* . Then define an (a priori) unconditional probability function $P(\bullet)$ over the sentences of L, in a way that appeals to only their *syntactic structure* (whence the name "logical" probability). Finally, use the standard ratio definition to construct a conditional probability function $P(\bullet|\bullet)$ over pairs of sentences of L.

The results of this procedure will be *language relative:* If one describes the same phenomena by means of a different language L^*—equipped with a different stock of monadic predicates—one will typically not recover the same probabilities. Consider two languages used to represent the outcomes of random draws from an urn filled with colored balls. Let L contain the color predicates "blue" and "green" and let L^* contain the predicates "grue" and "bleen." The intended interpretation is that a draw is grue just in case it is one of the first million and green or a later one and blue; a draw is bleen just in case it is one of the first million and blue or a later one and green. Starting with L, use whatever is the appropriate procedure to calculate

> P(draw 1,000,001 is green | the first 1,000,000 draws are green).

Starting with L^*, use this procedure to calculate

> P(draw 1,000,001 is grue | the first 1,000,000 draws are grue).

If syntax is all that matters, then these conditional probability values will be identical—and surely greater than $\frac{1}{2}$, at least if logical probability is to have a hope of modeling actual inductive reasoning (see Inductive Logic). The trouble is that the second conditional probability, translated into L, is just

> P(draw 1,000,001 is blue | the first 1,000,000 draws are green).

One can avoid contradiction, but only by explicitly insisting that probability is language-relative. And that raises a serious problem—really, the reference class problem in a new guise: If one wishes to employ logical probability as a foundation for inductive inference, which is the "right" language to use? The remainder of this discussion will presuppose that an answer to this question has been found (for Carnap [1980], this question was "external" to inductive logic anyway, and his later systems did not have this blatant form of language relativity).

Returning now to Carnap's early systems, consider a simple language with only two monadic predicates F and G and only two individual constants a and b. This language yields exactly sixteen maximally specific descriptions of the world—the *state descriptions* of L: $(Fa \wedge Ga \wedge Fb \wedge Gb)$, $(Fa \wedge Ga \wedge Fb \wedge \neg Gb)$, etc. Two state descriptions S_1 and S_2 are *permutations* of each other if S_1 can be obtained from S_2 by some permutation of the individual constants. For example, $Fa \wedge \neg Ga \wedge \neg Fb \wedge Gb$ and $\neg Fa \wedge Ga \wedge Fb \wedge \neg Gb$ are permutations of each

other. A *structure description* in L is a disjunction of state descriptions, closed under permutation. The L language provides these ten structure descriptions:

$Fa \wedge Ga \wedge Fb \wedge Gb$	$(Fa \wedge \neg Ga \wedge \neg Fb \wedge Gb) \vee (\neg Fa \wedge Ga \wedge Fb \wedge \neg Gb)$
$(Fa \wedge Ga \wedge Fb \wedge \neg Gb) \vee (Fa \wedge \neg Ga \wedge Fb \wedge Gb)$	$(Fa \wedge \neg Ga \wedge \neg Fb \wedge \neg Gb) \vee (\neg Fa \wedge \neg Ga \wedge Fb \wedge \neg Gb)$
$(Fa \wedge Ga \wedge \neg Fb \wedge Gb) \vee (\neg Fa \wedge Ga \wedge Fb \wedge Gb)$	$\neg Fa \wedge Ga \wedge \neg Fb \wedge Gb$
$Fa \wedge Ga \wedge \neg Fb \wedge \neg Gb) \vee (\neg Fa \wedge \neg Ga \wedge Fb \wedge Gb)$	$(\neg Fa \wedge Ga \wedge \neg Fb \wedge \neg Gb) \vee (\neg Fa \wedge \neg Ga \wedge \neg Fb \wedge Gb)$
$Fa \wedge \neg Ga \wedge Fb \wedge \neg Gb$	$\neg Fa \wedge \neg Ga \wedge \neg Fb \wedge \neg Gb$

Now, assign nonnegative real numbers to the state descriptions, so that these sixteen numbers sum to 1. Any such assignment will constitute an (a priori) unconditional probability function $P(\bullet)$ over the state descriptions of L. To extend $P(\bullet)$ to the entire language L, note that the probability of a disjunction of mutually exclusive sentences is the sum of the probabilities of its disjuncts. Since every sentence in L is equivalent to some disjunction of state descriptions, and all the state descriptions are mutually exclusive, this gives a complete unconditional probability function $P(\bullet)$ over L—typically called a *measure function.* The standard ratio definition then yields a conditional probability function $P(\bullet|\bullet)$ over pairs of sentences in L. Carnap (1950) discusses two natural measure functions. The first, $m\dagger$, treats each state description as equiprobable a priori: If there are N state descriptions in L, then $m^\dagger$ assigns $\frac{1}{N}$ to each. However natural this measure function may seem, it has the consequence that the resulting probabilities cannot undergird *learning from experience.* To see why, observe that

$$P(Fb \mid Fa) = \frac{m^\dagger(Fb \wedge Fa)}{m^\dagger(Fa)} = \frac{1}{2} = m^\dagger(Fb) = P(Fb).$$

So "learning" that one object has property F cannot affect the probability that any other object will also have property F. Indeed, it can be shown that *no matter how many objects are assumed to be F*, this will (according to probability functions based on $m^\dagger$) *always be irrelevant* to the hypothesis that a distinct object will also be F—a feature widely viewed as a serious shortcoming of $m^\dagger$.

As a result, Carnap formulated an alternative measure function m^*: First, assign equal probabilities to each *structure* description. Then, each state description entailing a given structure description is assigned an equal portion of the probability assigned to that structure description. So, in the present toy language, the state description $Fa \wedge Ga \wedge \neg Fb \wedge Gb$ gets assigned an a priori probability of $\frac{1}{20}$ ($\frac{1}{2}$ of $\frac{1}{10}$), but the state description $Fa \wedge Ga \wedge Fb \wedge Gb$ receives an a priori probability of $\frac{1}{10}$ ($\frac{1}{1}$ of $\frac{1}{10}$). Unlike $m^\dagger$, m^* *does* allow for learning from experience; for example, $P(Fa \mid Fb) = \frac{3}{5} > \frac{1}{2} = P(Fa)$. Still, even m^* can give unintuitive results in more complex languages (see Carnap 1952 for discussion). Also, note that the state descriptions are exchangeable with respect to m^*, an omen that logical probabilities will face some of the problems that plagued the frequentist and the classical probabilist.

Carnap (1952) presents a more complicated "continuum" of conditional probability functions. This continuum depends on a parameter λ intended to reflect the "speed" with which learning from experience is possible. $\lambda = 0$ corresponds to the "straight rule," which says that the probability that the next object observed will be F, conditional upon a sequence of past observations, is simply the frequency of F objects in that sequence; $\lambda = +\infty$ yields a conditional probability function much like that derived from the measure function $m^\dagger$ (i.e., $\lambda = +\infty$ implies that there is no learning from experience); $\lambda = \kappa$ (which is the number of independent families of predicates in Carnap's more elaborate [1952] linguistic framework) yields a conditional probability function equivalent to that generated by the measure function m^*.

Problems remain. None of the Carnapian systems allow universal generalizations to have nonzero probability. Carnap's early systems also failed to allow for *analogical effects*, since in these systems the fact that two objects have several properties in common is (in many cases) *irrelevant* to whether they have any *other* properties in common. Carnap's most recent (and most complex) theories of logical probability (1980) include two additional parameters designed to provide the theory with enough flexibility to overcome these (and other) limitations. Unfortunately, no Carnapian logical theory of probability to date has dealt successfully with the problem of analogical effects (see Maher 2001 for further discussion). The consensus now seems to be that the Carnapian project of constructing an adequate logical theory of probability is all but hopeless: The syntactical constraints implicit in any such theory will inevitably prevent the theory from being able to model certain essential features of statistical inference and/or inductive logic (see Inductive Logic).

Subjectivism

In slogan form, subjectivism regards probabilities as *degrees of belief,* or *credences.* But what are

credences? Subjectivists since Ramsey ([1926] 1980) have insisted that they must be intimately tied to the behavioral dispositions of suitable agents. In one influential account, advocated by de Finetti ([1937] 1980):

> An agent's credence in e is p iff p units of utility is the price at which the agent would buy or sell a bet that pays 1 unit of utility if e, 0 if $\neg e$.

This is at best a first approximation to an analysis of credence. One surely should allow the buying and selling prices of at least some bets to come apart. And even when they agree, there are problems. How does one separate the agent's epistemic attitude to e from his or her attitude (favorable, unfavorable, or neutral) to gambling? Indeed, one may insist on separating epistemic attitudes from desire-based attitudes altogether; one can imagine, for example, a chronic apathetic who has opinions but lacks corresponding desires (for bets or for anything). Moreover, the very placement of the bet may change the world in ways that affect the agent's credences.

Be that as it may, there are famous arguments that credences must conform to the probability calculus, at least if one demands that the agent be in some sense *ideally rational.* For example, if one's credences do *not* so conform, one is susceptible to a **Dutch Book**, a sequence of bets that one regards as acceptable taken individually but that collectively guarantee one's loss, however the world turns out. Conversely, if one's credences *do* so conform, one is immune to a Dutch Book. Rationality, it is concluded, requires obedience to the probability calculus (see Dutch Book Argument).

Utilities (desirabilities) of outcomes, their probabilities, and rational preferences are all intimately linked. The *Port Royal Logic* (Arnauld [1662] 1964) showed how utilities and probabilities together determine rational preferences; de Finetti's betting interpretation derives probabilities from utilities and rational preferences; von Neumann and Morgenstern (1944) derive utilities from probabilities and rational preferences. And most remarkably, Ramsey ([1926] 1980) (and later, Savage 1954 and Jeffrey 1983) derives *both* probabilities *and* utilities from rational preferences alone (see Ramsey, Frank Plumpton).

First, Ramsey defines a proposition to be *ethically neutral*—relative to an agent and an outcome—if the agent is indifferent between having that outcome when the proposition is true and when it is false. Suppose that the agent prefers a to b. Then an ethically neutral proposition n has probability $\frac{1}{2}$ iff the agent is indifferent between the gambles

> a if n, b if not.
> b if n, a if not.

One may assign arbitrarily to a and b any two real numbers $u(a)$ and $u(b)$ such that $u(a) > u(b)$, thought of as their respective desirabilities. Having done this for the one arbitrarily chosen pair a and b, the utilities of all other propositions are determined. Given various assumptions about the richness of the preference space, and certain "consistency assumptions," Ramsey can define a real-valued utility function of the outcomes a, b, etc.—in fact, various such functions will represent the agent's preferences. He is then able to define equality of differences in utility for any outcomes over which the agent has preferences. It turns out that ratios of utility differences are invariant—the same whichever representative utility function one chooses. This fact allows Ramsey to define degrees of belief as ratios of such differences. For example, suppose the agent is indifferent between a and the gamble "b if x, c otherwise." Then his or her degree of belief in x, $P(x)$, is given by:

$$P(x) = \frac{u(a) - u(c)}{u(b) - u(c)}.$$

Ramsey shows that degrees of belief so derived obey the probability calculus (with finite additivity). He calls what results "the logic of partial belief."

Ramsey avoids some of the objections to the betting interpretation, but not all of them. Notably, the essential appeal to gambles again raises the concern that the wrong quantities are being measured. And his account has new difficulties. It is unclear what facts about agents fix their preference rankings. It is also dubious that *consistency* alone requires one to have a set of preferences as rich as Ramsey requires, or that one can find ethically neutral propositions of probability $\frac{1}{2}$ This in turn casts some doubt on Ramsey's claim to assimilate probability theory to logic.

Savage (1954) likewise derives probabilities and utilities from preferences among options that are constrained by certain putative "rationality" principles. For a given set of such preferences, he generates a class of utility functions, each a positive linear transformation of the other (i.e., of the form $u_1 = au_2 + b$, where $a > 0$) and a unique probability function. Together these are said to "represent" the agent's preferences. Jeffrey (1983) refines the method further. The result is theory of decision according to which rational choice maximizes "expected utility," a certain probability-weighted average of utilities.

So far, this is a static picture of a rational agent. How should one update one's degrees of belief in the light of new evidence? The favored rule among subjectivists is *conditionalization:* Where e is the strongest proposition of which one becomes certain, one's new credence function is related to the old by:

$$\text{(Conditionalization)} \quad C_{new}(\bullet) = C_{old}(\bullet \mid e),$$

using $C(\bullet)$ here and in what follows to distinguish credence from other kinds of probability.

So-called *subjective Bayesianism* holds that an agent's epistemic trajectory is rational iff the agent's credences are representable at any moment by a probability function and the agent always updates by conditionalization. This is at once a highly demanding and highly permissive epistemology. It is demanding because conformity to probability theory is demanding. It is permissive because there is no requirement that degrees of belief in any way correspond to the way the world is. So someone who assigns probability 1 to the universe being ruled by a rubber chicken can meet the Bayesian standards for rationality—as long as the agent obeys the probability calculus in all other assignments and always updates by conditionalizing. Bayesians reply that various convergence theorems show roughly that in the long run, agents who do not give probability 0 to genuine possibilities, and whose stream of evidence is sufficiently rich, will eventually be arbitrarily close to being certain regarding the truth about the world in which they live. For skepticism about the value of these theorems, see Earman (1992).

In any case, there are numerous proposals for further constraints on priors. Some (e.g., Jeffreys and Jaynes) appeal to a version of the principle of indifference. Some can be regarded as instances of a certain schema, proposed by Gaifman (1988). He coins the term "expert probability" for a probability assignment that a given agent strives to track, codifying this idea as follows:

$$\text{(Expert)} \quad C(a \mid pr(a) = x) = x, \text{for all } x \text{ such that } C(pr(a) = x) > 0.$$

Here $pr(a)$ is the assignment that the agent regards as expert. For example, if one regards the local weather forecaster as an expert, and he or she assigns probability 0.1 to it raining tomorrow, then one may well follow suit:

$$C(\text{rain} \mid pr(\text{rain}) = 0.1) = 0.1.$$

More generally, one might speak of an entire probability function as being such a guide for an agent, over a specified set of propositions—so that (Expert) holds for any choice of A from that set. A *universal expert function* would guide *all* of the agent's probability assignments in this way. Van Fraassen (1995) argues that an agent's *future* probability functions are universal expert functions for that agent—his *reflection principle* is:

$$C_t(a \mid C_{t'}(a) = x) = x, \text{for all } a \text{ and for all } x \text{ such that } C_t(C_{t'}(a) = x) > 0,$$

where C_t is the agent's probability function at time t, and $C_{t'}$ his or her function at a later time t'. The principle encapsulates a certain demand for "diachronic coherence" imposed by rationality. Van Fraassen defends it with a diachronic Dutch Book argument (one that considers bets placed at different times) and by analogizing violations of it to the sort of pragmatic inconsistency that one finds in Moore's paradox. For example, suppose an agent is certain that he will tomorrow assign probability $\frac{1}{2}$ to it raining the day after but that he nonetheless assigns it probability $\frac{1}{3}$ now. While this is not logically inconsistent, it is surely puzzling.

One may go still further. There may be universal expert functions for all rational agents. The *principle of direct probability* regards the relative frequency function as a universal expert function. Let a be an event type, and let $relfreq(a)$ be the relative frequency of a (in some suitable reference class). Then for any rational agent:

$$C(a \mid relfreq(a) = x) = x, \text{for all } a \text{ and for all } x \text{ such that } C(relfreq(a) = x) > 0.$$

The next section takes up what many consider the most important such universal expert function.

Objective Chance

De Finetti (1990, x), the great probabilist, quipped that "probability does not exist." What he meant was that all probability is subjective. Yet there is a strong *prima facie* case for recognizing the existence of *objective chances:* probabilities that attach to physical systems and their behavior independently of anyone's mental state and that capture *contingent* facts about those systems, not merely quasi-logical relations among propositions concerning them. One wonders, for example, whether a certain coin is biased, and if so, to what degree and in what direction. Translation: One wonders what the *chance of heads* would be were the coin tossed fairly.

This example would not faze a committed subjectivist such as de Finetti or a frequentist like von Mises (1957), who denies that probability ever

applies in the single case. But more serious examples from physics suggest that ultimately, resistance is futile. For starters, *statistical physics* says that the entire universe *could* evolve toward a state of lower entropy but that the chance of its doing so is vanishingly small. Such chances are seemingly compatible with determinism at the level of the fundamental dynamical laws (this is controversial; see Irreversibility; Statistical Mechanics), and following Bernoulli, various authors have for that reason doubted their credentials (however, see Levi 1990 for a valuable discussion of authors since Cournot and Venn who countenance such compatibilist chances). The compatibility is putatively secured by relativizing chances to a kind of trial. For example, a coin may have chance $\frac{1}{2}$ of landing heads relative to the specification of being tossed high above a flat surface, while it has a chance 1 of landing heads relative to a precise specification of the initial conditions of a particular toss in a deterministic world. Levi argues that the applicability of chance hypotheses and statistical techniques does not presuppose an underlying indeterminism, and so a theory of chance should remain neutral vis-à-vis determinism.

In any case, commitment to chances has a second source: collapse theories of quantum mechanics. These theories explicitly introduce indeterministic dynamical laws that not only specify what courses of evolution are possible for a given physical system with a given initial state, but also specify exact *probabilities* for each such trajectory (see Quantum Measurement Problem; Quantum Mechanics). The subjectivist or von Mises–style frequentist seems left only with the option of denying—from the armchair!—that the physical theories that postulate them are true or coherent. It is better simply to acknowledge that objective chances are or at least could be real, and then to go on to consider what sort of account one could give of them.

Reductionist accounts attempt to reduce facts about objective chances to the totality of nonmodal facts about a world. Nonreductionist accounts deny that chance even supervenes on the nonmodal facts. Actual frequentism is clearly a reductionist view. More sophisticated is Lewis's (1994) "best systems" approach, which sees the laws for a world W as, roughly, being theorems of that axiomatic system for describing nonmodal facts about W that achieves an optimal balance of simplicity and informativeness. In the case of probabilistic laws, Lewis invokes a third criterion: A system for W is "better" to the extent that it assigns a higher probability to the total history of W. The simplest form of nonreductionism is *primitivism*, which takes chances to be unanalyzable features of the world. Alternatively, one might try to explain one's nonreductionist chances by appeal to some other bit of metaphysical gadgetry, such as Armstrong's interpretation of chances as consisting in higher-order relations of "probabilification" that obtain between universals.

No mention has been made so far of "propensity" interpretations of probability. Everyone, reductionist and nonreductionist alike, can agree that in a chancy world, some physical systems will have propensities to exhibit certain behaviors under certain conditions, for all one need *mean* by that is that counterfactuals of the following form are true of these systems: "Were the system in conditions C, there would be a chance of x that it would manifest behavior B." So propensities—understood as tendencies, or variable-strength dispositions—can be analyzed straightforwardly in terms of subjunctive conditionals whose consequents make reference to objective chances.

Propensity interpretations of probability aim to reverse this order of analysis, explaining objective chances directly in terms of propensities. For some authors (Popper, Gillies), chances are dispositions for a chance setup to produce long-run relative frequencies; for others (Giere, Fetzer, Miller), they are dispositions for a chance setup to produce outcomes on single trials. Subtle variations can be found in the work of Hacking, Mellor, and Levi (see Gillies 2000 and Hájek 2003a for surveys.)

But there are some general problems that any propensity account faces. Suppose that system S has a certain tendency to manifest behavior B under conditions C. One must be able to attach numbers to such a tendency as a measure of its strength *without* appealing to the concept of chance; it is not clear how this is to be done or why the results should obey the probability calculus. Moreover, how do propensities for distinct systems yield propensities for the composite systems they make up? Here are two coins, each with a propensity of 0.5 of landing heads if tossed. Suppose both are tossed at once. If there is a chance that both will land heads, then there must be a propensity possessed by the *combined* two-coin system. If so, what guarantees that the marginal probabilities (for each coin considered separately) will be recovered correctly from this composite propensity? And one cannot stop here, but had better say that *the world as a whole* exhibits, at each moment, propensities to evolve in various different ways. Having gone thus far, one might as well simply say that instead of exhibiting propensities, the world exhibits *chances,* thus avoiding (by

stipulation) the original problem of their conformity to the probability calculus—and thus arriving at primitivism about chance. If that is right, then it is not clear that propensity accounts offer a genuinely new option for understanding probability.

Although distinct, objective and subjective probability display an extremely important connection. Lewis (1980) formulates it in his principal principle:

$$(\text{PP}) \quad C_0(a \mid e \wedge ch_t(a) = x) = x.$$

Here C_0 is some reasonable "initial" (a priori) credence function; a an arbitrary proposition; $ch_t(a) = x$ the claim that the chance, at time t, of a is x; and e an "admissible" proposition—one that does not contain information relevant to a beyond that given by its chance at t (thus, e.g., a itself is inadmissible).

One can apply (PP) to a non-initial agent by modeling credence C as the result of conditionalizing some reasonable initial credence C_0 on some suitable evidence. Let h describe a complete possible course of history until time t. Let l describe some possible fundamental laws compatible with h, and assume that the way in which chances depend on history is underwritten by these laws. Then the conjunction $h \wedge l$ picks out a unique chance distribution $P(\bullet)$ for time t. Thus, if a proposition of the form $(h \wedge l \wedge ch_t(a) = x)$ is consistent, then the third conjunct is entailed by the first two. Assuming, as seems reasonable, that the conjunction $h \wedge l$ is admissible, it follows that

$$(\text{PP}^*) \quad C_0(a \mid h \wedge l) = P(a).$$

Much of the debate between reductionists and nonreductionists consists in a war of intuitions. For instance, the reductionist claims to find the nonreductionist's extra, irreducibly modal feature of metaphysical reality unintelligible, while the nonreductionist claims to "show" that distinct chances can give rise to exactly the same total histories of nonmodal fact—a draw, perhaps. But (PP) and (PP*) appear to open up new lines of argument.

The nonreductionist alleges that reductionism is *inconsistent* with (PP*). Typical reductionist views will allow that the chance laws can have some nonzero chance of failing to obtain, for the reductionist says that these laws are determined by the total history of nonmodal fact. But these laws issue in chance distributions over possible total histories of nonmodal fact. Thus, it may turn out that positive chances are assigned to total histories that would specify *different* laws—the "undermining" of the chance laws by themselves (see Lewis 1994). Example: A coin is about to be tossed exactly 10^{10} times. As it happens, exactly half the tosses will land heads. A reductionist might say that it *follows* that the chance of heads on each toss is 0.5, adding that the correct chance laws will treat the tosses as independent. So there is now a large chance that the frequency of heads will be *different* from what it actually is—and if so, the *laws* will be different as well.

The inconsistency with (PP*) is now manifest. Consider those consistent history–law conjunctions $h \wedge l$ that entail that $P(l) < 1$. Pick such a conjunction; by (PP*),

$$C_0(l \mid h \wedge l) = P(l) < 1.$$

But by the probability calculus,

$$C_0(l \mid h \wedge l) = 1.$$

Lewis responds by amending (PP*) to what he calls the "new principle":

$$(\text{NP}) \quad C_0(a \mid h \wedge l) = P(a \mid l),$$

thus avoiding the inconsistency. The consensus in the literature seems to be that unlike the original principal principle, (NP) is unintuitive and, in application, unwieldy.

The reductionist (e.g., Lewis 1994) retorts that nonreductionists are hard-pressed to show how chances, understood their way, constrain rational credences according to (PP). But can the *reductionist* meet this challenge? Presumably, in addition to his reductionist analysis of chance, he ought to provide a *derivation* of (PP) from constraints on rational credence to which he is *already* committed. The literature provides no such derivation. And while a nonreductionist may also be unable to supply such a derivation, it is not clear why it would be needed. Arguably, both the reductionist and the nonreductionist are committed to the existence of substantive constraints on rational credence; why can't the nonreductionist simply include (PP) as one of them? (See Hall 2003 for further discussion.) Perhaps, then, the debate between reductionism and nonreductionism remains a stalemate.

Finally, a "deflationary" account of chance, associated with de Finetti and his followers, has proved to be very influential. Consider an infinite exchangeable sequence of events with respect to a probability function P. De Finetti's representation theorem states that the probability according to P of exactly k of the events occurring in n trials is given by

$$\int_0^1 \binom{n}{k} p^k (1-p)^{n-k} f(p)\,dp,$$

for all n and k and for some density function f. The upshot is that any such probability distribution is representable as a "weighted average" of distributions. Each distribution corresponds to a hypothesis about the value of the probability p of an event occurring on a single trial; it gives the probability of k such events occurring in n independent, identically distributed trials, given that fixed value of p. One can then average these distributions using the probabilities of their corresponding hypotheses about the value of p as weights. The result is significant because it enables a subjectivist to "simulate" being an objectivist about chance when the exchangeability assumption holds, and for many situations this seems reasonable. If P is one's subjective probability function, then it is *as if* one spread probability over various hypotheses about the single-case objective chance of the event, which remains fixed across infinitely many independent trials of the experiment in question. (See Skyrms 1994 for an excellent discussion of generalizations of exchangeability and their use in formulating various Goodmanian theses about projectability.) Indeed, common sense often (but not invariably) seems to require that probabilities be exchangeable over "green"-like hypotheses but not "grue"-like hypotheses.

Conclusion

Feller (1957, 19) writes: "All possible definitions of probability fall short of the actual practice." Certainly, a lot is asked of the concept of probability. It is supposed at once to capture a quasi-logical notion, a subjective notion, and an objective notion instantiated in the mind-independent world. Perhaps one would do better to think of these as distinct *concepts* of probability. Each of the leading interpretations, then, attempts to illuminate one of these concepts, while leaving the others in the dark. In that sense, the interpretations might be regarded as complementary, although to be sure each may need some further refinement. Clearly, much work remains to be done on the philosophical foundations of probability. Equally clearly, the field has come a long way since the *Port Royal Logic*.

PROTOCOL SENTENCES

Protocol sentences are reports of an individual's experiences. The simplest and paradigmatic example is a report of "red here now." The term 'protocol sentence' was introduced by Rudolf Carnap (1932a, b) (and the example here is his). It reflects two chief aspects of logical empiricism (or positivism): (i) the importance of linguistic form and (ii) the role of experience as the source of acceptability and cognitive significance of scientific beliefs (see Logical Empiricism). The form, role, and status of protocol sentences became the topic of an important philosophical debate in the early 1930s involving logical empiricists such as Carnap, Moritz Schlick, Edgar Zilsel, Otto Neurath, Karl Popper, and a few others.

In *Der logische Aufbau der Welt*, Carnap ([1928] 1967) investigated the logical "construction" of objects of intersubjective knowledge from several possible bases. These included a physicalist basis, but Carnap epistemically privileged a basis consisting of the autopsychological objects of private sense experience, termed "elementary experiences," which were supposed to provide the simplest and natural starting point for epistemological constructions. The main problem then became how objective knowledge is possible. To solve that problem required the existence of connecting statements or rules linking those other statements to these epistemically privileged experiential statements.

The *Aufbau*'s focus on an empiricist or phenomenalist model of knowledge in terms of the immediate experiential basis was interpreted by other members of the Vienna Circle as manifesting three philosophical positions: reductionism, atomism, and foundationalism. Reductionism took one set of terms to be fundamental or primitive; the rest

would be logically derived from them. Atomism, especially in Neurath's reading, was manifest in the elementary structure of protocol sentences each as a single experiential report, such as "red here now." Foundationalism took autopsychological beliefs to be infallible and as epistemic warrant for all other beliefs.

Neurath rejected Carnap's subjectivism on the grounds that if the language and the system of statements that constitute scientific knowledge are intersubjective, then phenomenalist talk of immediate subjective, private experiences should have no place. To replace Carnap's phenomenalist language, Neurath (1932) introduced a physicalist language. Along with it came the thesis of *physicalism:* The unity, intelligibility, and objectivity of science rests on statements in a language of public things, events, and processes in space and time, including behavioral and physiological events. While inspired by materialism, for Neurath this was a methodological and linguistic rule, and not an ontological thesis.

Following Neurath, Carnap also explicitly drew a contrast between the language of experience and an intersubjective physicalist language. After the *Aufbau,* the unity of science rested on the universal possibility of translation of any scientific statement into this physicalist language. The physicalist language was intersubjective because it was also intersensual, that is, translatable into the private protocol language of any type of sensory experience of any subject, such as the atomic elementary statement reporting "red here now." For Carnap, a protocol language was a subjective language for each subject and, by the translation rules, also part of the physicalist language. However, it was still the epistemic point of departure for all scientific theorizing. The protocol language thus provided the tools for empirical verification in any language or knowledge system. It is the language of statements that have the function of control, support, or warrant. Even with its limitations, it is an indispensable source of knowledge:

> [A]n inferential connection between the protocol sentences and the singular physical statements must exist, for if, from the physical statements, nothing can be deduced as to the truth or falsity of the protocol statements there would be no connection between scientific knowledge and experience. Physical statements would float in a void disconnected, in principle, from all experience. (Carnap 1932a, 81)

Neurath (1932) responded to Carnap with a different account of protocol sentences that considered their distinctive linguistic form, contents, and methodological status. This account was supposed to explicate the concept of scientific evidence in an empiricist framework, by specifying the conditions for acceptance of a statement as empirical scientific evidence. The doctrine was meant to circumvent the pitfalls of the alleged subjectivism, atomism, reductionism, and foundationalism attributed to Carnap's earlier discussion in the *Aufbau.*

Unlike Carnap's ideal of a basic statement, whether as a protocol sentence or in the physicalist language, Neurath's protocol sentences were not clean, precise, or pure. For Neurath, the physical language, and hence science in turn, was inseparable from ordinary language of any time and place. In particular, it is muddled with imprecise, unanalyzed, cluster-like terms (*Ballungen*) that appear especially in the protocol sentences. They were often to be further analyzable into more precise terms or mathematical coordinations, but they often could not be eliminated. Even the empirical character of protocol sentences was not pure and primitive, as physicalism allowed the introduction of theoretical terms.

The empirical genealogy expressed by protocol sentences was the linguistic expression of empiricism that identified protocol sentences as epistemologically special units in the system of statements that would constitute objective scientific knowledge. This was both Carnap's and Neurath's attempt to develop a full-fledged empiricist position. Yet another difference from Carnap's account of protocol sentences appears in the second aspect of Neurath's account, in their role in providing empirical tests. Neurath's protocol sentences did not have the atomic structure or the atomic testing role that Carnap's did. Their methodological role reflected Duhem's holism (see Duhem Thesis). Hypotheses are not tested individually; only clusters of statements confront empirical data. Their methodological value in the testing of other statements did not make Neurath's protocol sentences unrevisable. Carnap (1932b and 1934) later adopted a similar conventionalist and pragmatic attitude. Such is the anti-Cartesian nonfoundationalism and fallibilism of Neurath's account. The system of knowledge is constrained by historically and theoretically accepted terms and beliefs and cannot be rebuilt on pure, secure, infallible empirical foundations. This was made only worse by the presence of *Ballung*-type terms. The method of testing could not be carried out in a logically precise, determinate, and conclusive manner. Protocol sentences, by virtue of perception terms, would provide a certain stability in the permanence of information.

But methodologically they could only bolster or shake confidence. Reasons underdetermine actions, and thus pragmatic extralogical factors were required to make decisions about what hypotheses to accept. A loose coherentist view of justification and unification is the only option available. To acknowledge these limitations is a mark of rationality, which Neurath opposed to "pseudorationalism." (see Neurath, Otto).

Carnap came to share Neurath's epistemological attitude (especially in *Logical Syntax*), but found the complexity of Neurath's protocol sentences excessive, raising too many practical difficulties. He also believed that their self-referential character raised logical difficulties. In reaction to Neurath's proposal, Carnap (1932b) adopted a distinct conventionalist and pragmatist attitude toward protocol sentences. He distinguished his early protocol theory from Neurath's (1932) proposal and another, unpublished one from Popper. He believed, under Popper's influence, that any concrete physicalist statement could be used as a protocol or basic sentence. The foundation or stopping-point of reduction or validation was achieved pragmatically. Neurath agreed only in that the equivalence between Carnap's physicalist basic statements and his own protocol sentences was logical or functional because both were revisable and that their acceptance was ultimately pragmatic. He lamented, however, that the conventionalist Carnap–Popper standpoint had cut itself loose from any references to perception, and thus amounted to abandoning empiricism.

In 1936, after adopting the semantic turn—in contrast to the syntactic approach of *Logical Syntax*—Carnap defended the distinctive character of protocol sentences in science provided by observational predicates. While defending a distinction between theoretical and observational language, he acknowledged that the distinction could not be made precise and fixed. The observational character was not a logical or syntactic property, but a psychological and instrumental one decided in the course of actual scientific practice.

By 1934, Popper had adopted an approach to scientific knowledge based on the logic of method, not on meaning. For Popper, any talk of individual experience could have no linguistic expression; a theory of scientific knowledge was to be not a subjective or descriptive account, but a normative logic of justification and demarcation (Popper [1935] 1959). He also criticized Neurath's antifoundationalism about protocol sentences as a form of anti-empiricism that merely opened the door to dogmatism or arbitrariness. Instead of protocol sentences, Popper proposed to speak about "basic statements"—a term more attuned to their logical and functional role. They are basic relative to a theory under test and are singular existential statements reporting observable facts. But acceptance of basic statements, much as in Neurath's account, could in principle be revoked.

Finally, the most radical empiricist attitude toward protocol sentences within the Vienna Circle came from Schlick, who endorsed a formal, structural notion of communicable, objective knowledge and meaning as well as a correspondence theory of truth. His realism opposed Neurath's coherentism, as well as the pragmatism and conventionalism of Carnap. In 1934, Schlick proposed to treat protocol sentences, left by Neurath with the status of little more than mere hypotheses, as key to the foundation of knowledge. They would be physicalist statements that, albeit fallible, could be subjectively linked to statements about immediate private experiences of reality, such as "red here now," which he called *affirmations* (Schlick 1934). Affirmations carried certainty and elucidated what could be shown but not said. They provided the elusive confrontation or correspondence between theoretical propositions and facts of reality. In this sense they afforded the fixed starting points and the foundation of all knowledge. But the foundation raised a psychological and semantic problem about the acceptance of a protocol sentence. Affirmations, as acts of verification or giving meaning, lacked logical inferential force; in Schlick's words, they "do not occur within science itself, and can neither be derived from scientific propositions, nor the latter from them" (Schlick 1934, 95). Schlick's empiricism regarding the role of protocol sentences suggests, but does not logically support, any strong epistemological foundationalism.

Neurath (1934 and 1935) replied to Schlick's and Popper's criticisms, respectively, emphasizing the role of extralogical factors in accepting theories and criticizing metaphysical talk of comparing knowledge and reality and the overidealized notion of a precise and conclusive logic of science. The discussion of the nature and value of protocol sentences was taken up subsequently by Hanson, Kuhn, Feyerabend, and others, all of whom stressed the theory-ladenness of observations (Feyerabend 1958 and 1962; Hanson 1961; Kuhn 1962). They denied that an absolute distinction between observation and theoretical predicates and statements was available and could ground the rationalism of scientific testing. Quine made famous the holistic idea of a *web of beliefs;* he and Davidson examined the role of experience by

looking at the relation between empirical beliefs and reality (Quine 1963; Davidson 1987). The physicalist bridge they see is neural and causal, respectively, but not epistemological in an inferential sense. These bridges nevertheless play a crucial role in our attempts to fix meaning and belief.

PHILOSOPHY OF PSYCHOLOGY

Traditionally, when general philosophy of science dominated the discipline, a simple division was often invoked to talk about philosophical issues specific to particular kinds of science: that between

the natural sciences and the social sciences. Over the last twenty years, philosophical studies shaped around this dichotomy have given way to those organized by more fine-grained categories, corresponding to specific disciplines, as the literatures on the philosophy of physics, biology, economics, and psychology—to take the most prominent four examples—have blossomed. In general terms, work in each of these areas has become increasingly enmeshed with that in the corresponding science itself, and so increasingly naturalistic (in at least one sense of that term).

The philosophy of psychology, like psychology itself, is concerned with mind and cognition. When psychology cut itself loose—institutionally and professionally—from philosophy in the late nineteenth and early twentieth centuries, it was the discipline that predominantly studied mind and cognition. This has changed over the last thirty years. With the development of artificial intelligence, cognitive anthropology, linguistics, and neuroscience—perhaps, together with psychology, best referred to collectively as the "cognitive sciences"—philosophers of psychology have found themselves both drawing on and contributing to scientific work in this more interdisciplinary milieu. There are two consequences of this. The first is that the field has become increasingly entwined with the philosophical aspects of cognitive science. One view is that one does greater justice to the interdisciplinary motivations behind cognitive science by placing an emphasis on the cognitive sciences, rather than on foundational assumptions that constitute a single paradigm of cognitive science (see Cognitive Science). In this view, the philosophical aspects of the cognitive sciences occupy the greater part of the philosophy of psychology (cf. Wilson 1999). The second consequence is that the more lively areas or topics of contemporary discussion in the philosophy of psychology are quite diverse, including (for example) philosophical issues in neuroscience, the nature and physical bases of consciousness, the evolution of mind, and the ontogenetic and phylogenetic development of intentional states in human agents.

Despite the first of these points, and contributing to the second, the material that philosophers of psychology discuss also covers questions about the mind and areas of psychology that even a pluralistic conception of the cognitive sciences excludes. These issues include debates over the scientific status of psychoanalysis, questions about the foundations of the taxonomy of psychopathology, and discussions of the nature of social psychology, all of which concern areas of psychology other than cognitive psychology.

What further complicates any simple characterization of work in the philosophy of psychology, and to some extent what distinguishes it from the other "philosophy of *X*" studies within the philosophy of science, is its close relationship to a traditional area of philosophy—the philosophy of mind—that has not typically viewed itself as a part of the philosophy of science at all. Thus, many of the topics that philosophers of psychology discuss that arise from their reflection on the cognitive sciences have analogues in traditional philosophy of mind. For example, concerns about the causal role of semantic- or representational-level properties in computational theories of cognition echo the more general problem of mental causation; many of the issues about the nature of cognitive architecture that separate, for example, "classic" from connectionist approaches to cognitive architecture are also reflected in the historical debates between rationalists and empiricists. Perhaps because the nature of the mind has been one of the central issues in metaphysics and epistemology throughout the history of philosophy, the connections between the philosophy of psychology and philosophy more generally are more extensive than in any other disciplinarily specialized area of the philosophy of science. What follows will attempt to convey something of the flavor of three topics within the philosophy of psychology that have dominated the field over the last twenty years: intentionality, cognitive architecture, and consciousness. It will also briefly discuss another pair of more specific topic clusters that represent novel and perhaps trend-setting topics for future research.

Intentionality and Mental Representation

The postulation of mental representation has been central to the cognitive sciences throughout their history. Human agents do not simply or reflexively respond to their environments, but are equipped with some internal, mediating mental machinery, which is sensitive to what is in the environment but which has enough complexity to it to thwart any attempt (e.g., made by behaviorists) to exhaustively characterize it in terms of that environment (e.g., in terms of stimulus–response pairs) (see Behaviorism). Mental representations play precisely such a mediating role, both containing information about the world and combining to guide an individual's behavior in that world (see Intentionality).

The form that mental representation takes in commonsense, folk psychology is *propositional:* Agents have beliefs and desires, where each of these mental states can be thought of as an attitude to a proposition. Psychology has built on such folk psychological representations since its inception, from the Freudian extension of folk psychology from conscious to unconscious states, to work on stereotypes and schemata in social psychology, to classic artificial intelligence (AI) models of human problem solving or reasoning. Because of this link between folk and scientific psychology, propositional representation has been a focus of discussion within the philosophy of psychology. In fact, due to its prominence, many general discussions of mental representation have been cast exclusively in terms of propositional representation, or even its folk psychological guise. What follows constitutes three of the central issues in the literature and a sampling of positions that have been adopted with respect to them:

1. *How many kinds of mental representation are there?* Much of the debate over mental imagery (Pylyshyn, in press) has focused on the reality of mental images and their relationship to propositional representations. There has also been more recent discussion of the extent to which mental representations are ''local'' as opposed to ''distributed'' in their nature. The role of language in mental representation, and thus thought, has also structured a range of related debates, such as over the language of thought hypothesis and the question of the form that mental representation takes in nonlinguistic creatures, such as human infants and nonhuman animals.
2. *What determines a representation's content?* Three chief answers to this question have been entertained: conceptual role or procedural semantics, causal or informational theories, and teleological theories (see also Cognitive Science). The first of these is typically internalist in that mental content is determined entirely by intrinsic, physical properties of the agent or system. But the most pervasive views here are externalist; that is, they allow an individual's social or physical environment to be a determinant of the type of mental states the individual has, which reinforces externalist views of psychology and psychological explanation (Wilson 1995 and 2002). Both causal and teleological views allow an individual's historical, social, and physical location to partially determine what content its representations have. An alternative form of externalism that departs from the sort of realism about mental representation that has been taken for granted by the three chief views here is a conventionalism about the nature of representational content (see Horst 1996).
3. *Is mental representation dispensable within the cognitive sciences?* Stich (1983) was an early defender of the view that the cognitive sciences could be (indeed, should be) content free. Patricia S. Churchland (2002) has expressed an alternative, neuroscientifically inspired form of eliminativism about mental representation. Both of these forms of eliminativism about mental representation have pitched their critiques at the sorts of representations posited by folk psychology. Proponents of connectionist architectures and, more recently, of dynamic approaches to cognition have also often introduced their views as avoiding the postulation of mental representation. But as the descriptors 'distributed' and 'dynamic' suggest, such approaches do not necessarily imply the rejection of all forms of mental representation, and the place of mental representation within them remains a topic of continuing interest (Érdi 2000) (see Epistemology).

Cognitive Architecture and Processing

If debates over the nature of mental representation concern *what* it is that cognition ranges over, those over cognitive architecture and processing concern *how* it is that cognition proceeds. Part and parcel of the ''cognitive revolution'' of the late 1950s that formed the basis for the cognitive sciences was the conceptualization of cognitive processing as a form of *computation.* This view, computationalism, has received both general and somewhat vague characterizations (''cognition is computation'') as well as more specific formulations (''cognition is explicit symbol manipulation'') that are tied to particular research programs, the best known of which is the *physical symbol system hypothesis*, associated with Allen Newell and Herb Simon (1981): ''A physical symbol system has the necessary and sufficient means for general intelligent action'' (41). Central to any account of cognitive processing is a commitment to the nature of the basic design of the cognitive system, the *cognitive architecture* of that system, and hypotheses about cognitive architecture have usually been formulated as explicit

computational models that generate behavior that approximates some aspect of (often human) cognitive behavior. In Newell and Simon's own view, production systems, which consist of chains of condition-action rules defined over data structures, form the heart of human cognitive architecture, and the types of behaviors to which their computational models were applied most extensively were problem solving and reasoning. Variations on this general view were predominant in much of AI and psychology until the 1980s, and the philosopher perhaps most firmly associated with this sort of "rules and representations" approach to cognitive architecture is Jerry Fodor (1981).

Over the past twenty years, connectionism has come to represent a general alternative to the rules and representation approach. The basic idea of connectionist architectures and the neural network models that correspond to them is that cognition involves the adjustment of weighted connections between many relatively simple processing units through a process of feedback from environmental inputs (learning). Although these basic units are often compared to neurons, the bulk of the psychological work to which philosophers appeal (e.g., in modeling the acquisition of the past tense in English) involves processing units that are on the wrong scale to be very neuron-like (see Connectionism).

The most fruitful work within the computational paradigm, broadly construed, involves models that appeal to aspects of both rules and representations and connectionist architectures. A common suggestion is that the former handles "higher" cognitive functions, such as problem solving, while the latter are applicable to "lower-level" cognition, such as pattern recognition. But more truly integrative models of cognitive architecture focus on the role that *probability* has within computational models; for example, Boltzmann machines, developed within the neural network paradigm, are essentially identical to Bayesian networks developed within traditional AI (Pearl 2000). The significance of such models is that they straddle the supposed divide between "classic" and "connectionist" architectures. Their rise within work on computational intelligence signals the next stage in cognitive modeling (see Jordan and Russell 1999).

Dynamic approaches to cognition attempt to pose a more radical challenge to these two views of cognitive architecture and their corresponding paradigms for the cognitive sciences. The chief idea of dynamicism is that cognitive systems are a form of dynamic system that exists in real time and whose movement over time is not governed by any special computational principles (Port and van Gelder 1995). On the dynamic conception of cognitive processing, internalized rules and symbols do not play any special role in cognition; rather, cognition proceeds through the settling of the cognitive system into an equilibrium state. The mathematical equations that govern such processes are not internalized within the cognizer any more than Newton's laws of motion are internalized in the objects whose behavior they govern. The dynamic approach has thus challenged both the representational and computational dimensions to standard cognitive science, and it also suggests that cognitive systems are fundamentally *embedded* or *embodied*, a point discussed further later.

The development of connectionist architectures has led many philosophers of psychology to rethink a range of issues concerning the nature of cognitive processing. Many of these concern the nature of mental representation, as noted above, but the rise of connectionism has also generated more general discussions, such as those over the nature of computation (including the relationship between computational models and computation) and the role that cognitive neuroscience has to play in addressing some of these questions about large-scale cognitive organization. Despite the fact that most of the neural network models of influence within the cognitive sciences are not neurally very realistic, connectionist architectures have redirected attention to the brain itself, particularly as noninvasive techniques of imaging, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have allowed researchers to explore the activity of the brain in real time. One pair of related themes concerning cognitive architecture has been the modularity of cognitive design and the localization of mental processes. Fodor (1983), crystallizing and generalizing a view of the mind articulated within linguistics by Chomsky as part of his approach to generative grammar in linguistics, rekindled interest in a modular view of cognitive capacities of the sort introduced originally by Gall almost two hundred years earlier. According to Fodor's view, many such capacities are *domain specific* and *encapsulated:* roughly, cognition is structured so that particular mental organs are sensitive only to specific kinds of inputs and are insulated from the causal influence of the operation of other mental organs. Fodor's own view here was that such a view of the mind held only of input systems—the five senses, plus language, according to Fodor—and he cautioned against the extension of the view to "central systems." This caution has been largely ignored as developmental psychologists have

postulated Fodorean modules for the domains of physics, number, biology, and psychology, and evolutionary psychologists have endorsed what has become known as the *massive modularity* thesis, the claim that the mind is overwhelmingly modular, with the number of modules running into the hundreds if not thousands (see Evolutionary Psychology). Philosophers have had much to say about these topics, particularly about the "theory of mind" within developmental psychology and evolutionary psychology in general.

It has typically been assumed that modules are *physically localized* in the brain, roughly in the way in which other bodily organs, such as the heart or the kidney, are so localized. As Fodor (1983) himself pointed out in his brief discussion of the "fixed neural architecture" (98–99) associated with modules, one might articulate this assumption in terms of broader systems that are somewhat distributed throughout the brain. But the basic idea is that functionally individuated modules have neural hardware specifically dedicated to the function they perform. As PET and fMRI have been increasingly used in experimental investigations of cognition, data on such localization assumptions have accumulated, though it is worth mentioning that these methods themselves have often been used in ways that presuppose a basically localistic view of cognitive function (Uttal 2001). Lloyd (2000) has presented a striking, even if preliminary, meta-analysis of the data across independent studies, arguing that these data support the claim that the brain is a distributed processor and refutes the stronger, "localistic," modularity hypotheses common in the field (see also Neurobiology).

Consciousness

Consciousness has been a buzz topic in the philosophy of psychology for the past ten years, returning to occupy center stage after a long absence, and commanding the attention both of philosophers of science (i.e., of psychology) and of traditional philosophers of mind (see Consciousness). Amongst the latter, there has been an explicit a priori strand, with a focus on the challenge that consciousness, phenomenal states, and qualia pose to views, such as physicalism and functionalism, that continue to operate as working assumptions for many within the cognitive sciences. A work that has galvanized such discussion is Chalmers' *The Conscious Mind* (1996), a book whose central conclusions echo the skepticism about physicalism associated with well-known, earlier papers by Thomas Nagel and Frank Jackson, and whose emphasis on conceivability arguments and what they putatively show about the limits to the scientific study of consciousness has fueled some interesting debate over the role of conceptual analysis within a naturalistic account of the mind. Philosophical work on consciousness has also reacted to attempts to eliminate qualia, developed representationalist views of the nature of phenomenal experience, and debated the idea that consciousness is just awareness, so that a conscious mental state is some sort of second- (or, in general, higher-) order mental state. A succinct overview of this work is provided by Levine (1997).

Within the cognitive sciences themselves during roughly the same period, consciousness also had a renaissance, with much of this literature focused on the phenomena of visual awareness and attention. There has been speculation in this literature about the function(s) and evolutionary origins of consciousness, as well as a variety of neural techniques to try to pinpoint the parts of the brain that are most directly causally responsible for conscious experience. In an influential paper, Crick and Koch (1990) advocated that the time was ripe for neural speculations about consciousness, and proposed (building on the work of von Malsburg and others) that 40-hertz oscillatory cycles in the brain, particularly in the visual cortex, were especially important to consciousness. A detailed, recent empirical account of consciousness has been offered by Rodney Cotterill (1998), which emphasizes the relationship between consciousness and movement and the importance of *timing* to consciousness. Cotterill offers an integrated psychological and neurological view of the bases for consciousness that posits a triangular neural circuit linking the posterior lobes, the premotor area of the frontal lobes, and the nucleus reticularis thalami between the thalamus and the medulla oblongata as the neural basis for conscious experience.

One obvious question concerns the relationship between such work on consciousness and that on the nonconscious, representational mental states that have been central to the cognitive sciences over the last thirty years. *Representationalism* about conscious states constitutes one sort of answer, for it holds that qualitative states just *are* representational states. Indeed, one of the motivations for representationalism is to deflate the commitments that one makes in admitting conscious mental states as well as intentional states to one's ontology. Another type of answer is provided by John Searle (1992), who has defended what he calls *the connection principle*, which says that unconscious mental states must be, in principle, accessible to consciousness (see Searle, John). This principle

has one of two implications for traditional cognitive science: Either the states it posits do not exist or those states are, contrary to what most of those investigating them believe, accessible to consciousness. Given the disparate writings on consciousness, it is no surprise that some of these have become more explicitly self-reflective. Perhaps the best-known is by Block (1995), who introduced the distinction between "phenomenal consciousness," or *p*-consciousness (the what-it's-likeness of mental experience), and "access consciousness," or *a*-consciousness (the feature of mental experience that allows its reportability). One suggestion is that mental states such as pain and sensations are *p*-conscious, while those such as occurrent thoughts are *a*-conscious; another is that the former is really the subject of the literature inspired by Nagel, by Jackson, and by Chalmers, while the latter is what cognitive scientists investigate. Block himself introduced the distinction to critique claims, especially in the psychological literature, that were often made about the function of phenomenal consciousness that relied implicitly only on data about access consciousness. Philosophers remain divided over whether Block's distinction makes sense of much of the consciousness literature or constitutes a confusion about consciousness itself (see Consciousness).

Pain, Psychopathology, and Color

One of the concomitant products of the extended-consciousness fest has been work on topics concerning particular phenomenal states. *Color* is perhaps the most richly mined of these, beginning with C. L. Hardin's *Color for Philosophers* (1988), which significantly raised the bar regarding the level of empirical detail relevant to philosophical discussions of color. From its characterization as a secondary quality in seventeenth-century mechanical philosophy and science, color has constituted both an epistemic and an ontological puzzle: Just what is color, in the world, and does one's epistemic access to it constitute some sort of privileged knowledge? Some of the recent work on color processing in the cognitive sciences suggests that color is at least as much of an enigma in accounts of cognitive processing. For example, it now appears that there is no place or system in the central nervous system that is modularly dedicated to process color, and this has led some philosophers to rethink the evolutionary function of color perception and its role within the perceptual life of the individual (cf. Matthen 1999).

While psychopathology itself is not a new topic for philosophers, work here has taken a novel turn as a by-product of the focus on consciousness. Conscious experience sometimes deviates from its normal course. Philosophical issues abound here, whether it be in cases of blindsight in patients with severed corpus callosa, where subjects are causally influenced by phenomena of which they report no conscious awareness (Weiskrantz 1986), or in clinical breakdowns of the self, such as those involving "injected selves," or dissipated and disjoint mental lives (Graham and Stephens 1994). Clinical, medical, and cognitive psychologies have represented distinct traditions studying mental pathologies, and as they begin to share more common phenomena, data, and theoretical bases, there is an opportunity for philosophers of psychology not only to contribute to discussions of foundational questions about the nature of the self, rationality, and normative mental functioning, but also to bring together these discussions with those on each of the three topics with which this article began: mental representation, cognitive architecture, and consciousness. Pain is the third and newest of these topics within empirically attentive philosophy of psychology. The large community of researchers on pain have their home base in the medical sciences and have focused not so much on the theorization of pain as on its amelioration and treatment. Along with color, pain is the qualitative mental phenomenon most commonly invoked by philosophers discussing consciousness, and like color the empirical work on pain has exploded in recent years. There are sensory and affective dimensions to pain, where the former reflects the role of pain as a detector of bodily damage, and the latter, the phenomenal character of pain. Moreover, there turns out to be considerable interpersonal bodily variability for those experiencing pain. Conceptually, the sensory and affective dimensions of pain are distinct, and early empirical work offered support for the hypothesis that there are two separate pain systems. Dennett ([1978] 1998) used some of the complexities of the folk psychology commonsense conception of pain to argue for an eliminativist view of pain, and more recently philosophers have taken opposing views on whether pain is essentially perceptual or emotional in nature (see Aydede, Güzeldere, and Nakamura, forthcoming).

Embodied, Embedded, and Situated Cognition

A second general area in which there has been a hive of activity is that of *embedded* cognition, also referred to as *situated* or *embodied* cognition. In

part as a reaction to the general character of traditional symbolic AI and connectionism, both of which have abstracted away from the nature of the environment in which cognition actually operates, this cluster of views emphasizes the organism/environment coupling in theorizing about cognition. While the "embeddedness movement" has sometimes represented itself as anticomputational (e.g., Brooks 1997), there has been a concerted effort within an overarching computational framework to capture the spirit of the movement, ranging from Cantwell Smith's (1996) reconceptualization of computation to Dennett's (2000) emphasis on the important role of out-of-the-head scaffolding in higher mental processes. Central to the embedded movement is the idea that cognizers are *agents* who act in the world, gathering information about the world in order to act. This agent-centered conception of cognition has become increasingly a part of mainstream artificial intelligence (e.g., Russell and Norvig 1995). Indeed, as stated at the outset, it is one of the motivating themes of folk psychology. In light of these points, this development within the philosophy of psychology is less a departure from traditional views than a return to one of the themes familiar to those in the field.

There is an obvious affinity between such approaches to cognition and the externalist views that have come to dominate philosophical reflection on intentionality and mental representation. There are a number of attempts (e.g., Clark 1997) to build some firmer bridges between the philosophical and scientific work. But there is much more to be done here.

HILARY PUTNAM

(31 July 1926–)

Hilary Putnam is a philosopher whose unmistakable originality has had a great impact on many areas of contemporary philosophical concern, including, but not restricted to, the philosophy of science, the philosophy of language, and the philosophy of mind. He is also commonly perceived as having changed his mind drastically on a myriad of interrelated issues over the years, notably in areas in which his ideas have been extremely influential, such as functionalism in the philosophy of mind. This perception, which at times Putnam himself appears to share, is, however, very much overstated. The better interpretation of his scholarship and contribution to philosophy emphasizes continuities in his thought. Indeed, careful attention to his writings reveals a remarkable unity of overall concern.

Quine and the later Wittgenstein have been unquestionably important influences on Putnam's thinking over the years. With each he shares, in different ways, a stance that shuns speculative metaphysics as First Philosophy. But Putnam's own position is distinctive. He has always rejected Quine's austere scientism, in particular Quine's tendency to regard philosophy as a branch of natural science—the branch of science that studies how human organisms can have contrived the language of science, the very language within which this investigation is pursued. And in contradistinction to the later Wittgenstein, Putnam has not abstained from offering novel theoretical solutions to philosophical perplexities at the level at which they were traditionally contemplated, concerns as fundamental as how it is possible to think and talk about the world at all. Putnam's lifelong suspicion of speculative metaphysics is evidenced in his earliest writings. In a classic paper on microreduction coauthored with Paul Oppenheim (Openheim and Putnam 1958), Putnam portrays the unity of science—understood as the microreduction of all of science (including social science) to the level of particle physics—as a working hypothesis within science (see Unity and Disunity of Science; Unity of Science Movement; Reductionism). One remarkable aspect of this early paper is its choice of main target: the view that acceptance of the microreducibility of all of science to a single lowest level is a mere act of faith. As against the speculative physicalist metaphysician, who professes belief in all facts being at bottom physical facts, Oppenheim and Putnam defend microreducibility as a hypothesis that is made credible both by empirical evidence and on general methodological grounds. In other words, in Putnam's hands, physicalism, which has become the metaphysics of choice for an entire generation of analytic metaphysicians, becomes a hypothesis on a par with other working hypotheses within science.

Among the main themes running throughout Putnam's corpus are:

- the rejection of an absolute analytic/synthetic distinction and a concomitant rejection of an absolute a priori (for some early statements, see Putnam 1962a, 1962b, and 1968);
- emphasis on the primacy of practice within the philosophical understanding of natural science (for an early statement, see Putnam 1974);
- realism and the attendant accommodation of the possibility of constancy of meaning across radical theory change (see, e.g., Putnam 1975a);
- anti-scientism and the insistence on the indispensability of nonscientific knowledge (see, e.g., Putnam 1978 and 1981);
- anti-Cartesianism in the philosophy of mind and language (see, e.g., Putnam 1988);
- interest-relativity of explanation and what Putnam terms "conceptual relativity" (see, e.g., Putnam 1987); and
- rejection of the fact/value dichotomy (see, e.g., Putnam 1981, Ch. 6; 1990, pt. 2; 2002).

In this article, only some of these themes can be elaborated. The overall aim will be to show that many of them are best viewed as elements in a sustained engagement with, and rejection of, a certain Cartesian outlook on people's cognitive rapport with the world.

It is worth noting in this context that other anti-Cartesian strains abound throughout Putnam's work. A vivid early illustration is provided by his anti-Cartesian rejection of absolute a priori. He argues (Putnam 1968) that even logic itself is empirical. While this may sound familiar to readers of Quine, Putnam's method of argumentation is characteristic of a distinct philosophical style. Unlike Quine (see Quine, Willard Van), whose attack on the analytic/synthetic distinction consists mainly of narrowly circumscribed illustrations of the circularity and futility of various attempts to draw it, Putnam's arguments are rich in historical-scientific precedents. In his view, just as Euclidean geometry is best viewed as falsified by general relativity, classical logic may best be viewed as falsified by quantum mechanics. Specifically, it may be reasonable to conclude that quantum logic, according to which conjunction does not distribute over disjunction, is the "correct" logic on empirical grounds. So much the worse, contends Putnam, for the alleged a priori of logic.

Realism and Reference

A natural point of entry into Putnam's work is through the question of realism (see Realism; Instrumentalism). Putnam has always aligned his position with one form or other of realism, even though some of these versions seem to his critics too remote from what they claim to understand by the term 'realism.' However, one of Putnam's main concerns in this area has been to inquire after what 'realism' might possibly mean. Part of the problem here, of which anyone who has thought about the realism issue is aware, is that it is far from obvious how to formulate realism as a distinctive, and therefore controversial, thesis.

As part of his ongoing engagement with realism, and alongside his insistent realist commitment to the distinction between what is the case and what only seems to be the case (even at the level of the entire species), Putnam has vehemently criticized a version of realism he terms "metaphysical realism." His main efforts in this area have been to find formulations of metaphysical realism that would actually render the position controversial, and then to proceed to controvert it. It is against this backdrop that his most famous argument against metaphysical realism, the model-theoretic argument, should be understood (Putnam 1976 and 1977; see Putnam 1989 for a discussion of the implications of naturalizing semantics). The remainder of this section will be devoted to summarizing the argument, and the next section will examine Putnam's own later reservations about it. This will pave the way for a consideration of Putnam's staunch anti-Cartesianism about content.

The model-theoretic argument is designed to demonstrate the inconsistency of the following set of claims presumed to encapsulate the metaphysical realist position:

The world is a totality of mind-independent objects. (1)

Sentences are true or false by virtue of a correspondence between words and portions of this mind-independent totality. (2)

A theory that is epistemically ideal might be false. (3)

The upshot of this position is that truth might very well outrun what is epistemically best. Theories of the world are true or false by virtue of a correspondence between the terms employed and portions of the world, a correspondence to which agents have no direct cognitive access. Thus, even the very best theory that agents come up with might really be false for all they are able to tell.

Putnam's argument for the inconsistency of the set {(1),(2),(3)} is as follows. Let T be a formalization within first-order logic of an epistemically ideal theory meeting all theoretical and operational constraints. (The former restraints are requirements such as elegance, simplicity, and explanatory power; the latter restraints are requirements roughly of the form "If T implies that agent A sees object O, then it seems to A that A is seeing O.") Now, if T is epistemically ideal, then it is at least consistent. So, given certain minimal requirements on T and on the size of the world, T has a model M of exactly the same size as the world. (Suppose that the world is an infinite totality of things, that the size of L, the language of T, does not exceed that of the world, and that T has infinite models. Then, by one version of the Löwenheim-Skolem theorem, T has a model of exactly the same size as the world. If the world happens to be finite, enrich L to $L \cup \{c_j \mid j \in J\}$, where the index set J is of the same finite size n as the world and for every $j \in J$, $c_j \notin L$. It is then assumed that the extended theory $T \cup \{\forall j, k \in J, c_j \neq c_k\} \cup \{\forall x(x = c_1 \vee \ldots \vee x = c_n)\}$ is consistent, so that T has, once again, a model of the same size as the world. Either way, given minimal requirements on T and on the size of the world, T will have a model M of that size.) But if T has a model of the same size as the world, then T has

a model M^W isomorphic to M that has the world itself as its domain. So, given (1) and (2), T is true of the world, that is, true *simpliciter*. In other words, the sentences of T are made true by a correspondence—the one supplied by M^W —between L and portions of the world. So it turns out that (3) is false: T is bound to be true (under the above minimal conditions). The moral of this argument is not the falsity of (3). After all, (1) and (2) are not supposed to be Putnam's premises but rather the metaphysical realist's. The moral, rather, is the inconsistency of the set {(1),(2),(3)}.

Metaphysical realist replies to the model-theoretic argument usually amplify the original set of theses in some way so as to block the inference from metaphysical realist premises to the negation of (3). For example, David Lewis's (1984) version of this move is to claim that metaphysical realists should insist on supplanting (1) and (2) with something more metaphysically robust along the lines of the following two theses:

> The world is a totality of mind-independent objects *that bear objective similarity relations to one another*. (1′)

> Sentences are true or false by virtue of a correspondence *that respects those objective similarity relations* between words and portions of this mind-independent totality. (2′)

By "objective similarity" in this context is to be understood a similarity among things that is prior to and independent of any explanatory interests investigators might have—a primitive similarity built into the world itself. With this understanding, endorsing (1′) and (2′) indeed allows the metaphysical realist to endorse (3) as well: Given that the world is already carved into objective similarity classes, there is no guarantee that T will have a model isomorphic to this structure. So T might turn out to be false of the world after all. But whether or not metaphysical realism is worth the price of commitment to such objective similarity relations is a question on which Lewis and Putnam strongly disagree.

Reference and Perception

In more recent work (Putnam 1993; 1994a, Lecture I), Putnam identifies the following difficulty in the model-theoretic argument's transition from epistemic ideality, through having a model with the world itself as its domain, to being true *simpliciter*. The transition rests on the tacit assumption that there can be no independent determination of what T's terms refer to other than through the theory's meeting the theoretical and operational constraints. In other words, it is assumed that the correspondence of T's terms to portions of the world is an interpretation in the formal sense, that is, a mapping that figures in a definition of satisfaction, where speakers' perceptions are treated as perceptual conditions ("appearances") to be interpreted as part of the operational constraints. Given the assumption, and given that T has model M^W, T's terms cannot but refer to portions of the world in such a way that T comes out true, as the model-theoretic argument illustrates. And, while the assumption is shared by many of the intended targets of the argument, Putnam himself finds it deeply problematic.

To fully appreciate why requires turning to Putnam's earlier work on the so-called new theory of reference. This will occupy the next section and will reveal an often-neglected continuity in Putnam's thought about meaning and mind—his pronounced anti-Cartesianism. But for now, a preliminary consideration of the implications of the above assumption for the general bearing of speakers' words on their environment is in order. These implications become most vivid by setting aside the subtleties of the model-theoretic argument and focusing on the worn example of the cat on the mat.

Consider a speaker who, in the presence of a certain salient cat on a certain salient mat, reports: "The cat is on the mat." Question: What makes it the case that it is the salient cat being on the salient mat that make the speaker's "The cat is on the mat" come out true? How is it that the speaker's words are about this cat and this mat, rather than about anything else? In a traditional epistemological view famously bolstered by Bertrand Russell (1910; [1912] 1952), the expression 'the cat' contributes a certain perceptual condition ϕ to what is said by 'The cat is on the mat,' the condition of being appeared to as if some specific cat is before one under the relevant conditions. Similarly, the expression 'the mat' contributes a certain perceptual condition ψ to what is said by 'The cat is on the mat,' the condition of being appeared to as if some specific mat is before one under the relevant conditions. So what is said overall by 'The cat is on the mat' is that the ϕ is on the ψ, which Russell analyzes as the following existence claim:

$$\exists x \exists y(\forall z(\phi z \leftrightarrow z = x) \wedge \forall z(\psi z \leftrightarrow z = y) \wedge (\mathrm{ON}xy)).$$

In short, what makes it the case that the speaker's 'the cat' is about the salient cat and the speaker's 'the mat' is about the salient mat is that the cat and mat in question uniquely satisfy conditions ϕ and ψ, respectively.

Suppose all perceptual judgments receive a similar treatment in terms of satisfaction of perceptual conditions. Terms employed for perceived objects are about them by virtue of the objects satisfying associated conditions in the manner illustrated above. Now consider the totality of sentences held true—call it the agent's "overall theory." According to the view of reference espoused by the model-theoretic argument, all terms are about whatever is assigned to them under an interpretation that makes the overall theory come out true. In other words, terms are about whatever satisfies the overall theory, including the perceptual part of the theory. For a term to be about a thing (or things) is for it to pose a certain condition that the thing satisfies (or things satisfy) so as to make the overall theory come out true. This is what reference comes to in this picture—a word-world relation that makes the overall theory come out true.

Even from this rough sketch of the view of reference presupposed by the model-theoretic argument, some lessons can be drawn. For example, if all that is required for a term to refer is that the referent be assigned to the term by an interpretation that makes the overall theory come out true, then reference is bound to be a radically underdetermined affair. Given any interpretation of the language that makes the overall theory come out true, it is a trivial matter to construct a systematic reinterpretation of the language, with compensatory adjustments accommodating all occurrences of the terms in the overall theory, that is truth preserving. To borrow a vivid example from Quine (1992, Ch. 2), any singular term for some spatio-temporally extended item under the old interpretation can be reinterpreted as referring to the item's mereological complement, that is, the whole universe minus the item, with compensatory adjustments to the assignments to all other terms such that truth-values of all whole sentences remain unaltered. One implication of the existence of such possibilities might be that reference is indeed radically underdetermined. This is the conclusion Quine draws (Quine 1969; 1992). For him, there is no fact of the matter as to what a given term refers to independently of some assignment under which the overall theory is true. But Putnam draws a different conclusion. For him, reference is not a matter of interpreting the language of a theory so as to render the theory true. It is not a mapping that figures in the satisfaction of theories. It should be clear that there is a certain traditional view of perception that accompanies the above view of reference-as-mapping (see Putnam 1993). It is the view that the objects of perceptual judgments are specified only through satisfying perceptual conditions that are entertained in the mind, that perceptual judgments are about items in the environment only to the extent that the latter satisfy perceptual conditions with which the agent is "acquainted." (A corollary is that ordinary perceptual beliefs are at bottom general, or *de dicto*, and are never genuinely singular, or *de re*.) This view of perception figures prominently in a general Cartesian picture of the relation between mind and world. A thing is experienced visually, say, to the extent that it "fits" an appearance present before the mind. So the mind comes into contact with the object itself only derivatively, via the mind's immediate contact with an appearance. In this picture, perceivers are confined in their cognitions to how things appear to them and are never in direct contact with the objects about which they cognize. Specifically, their only perceptual contact with the world is through portions of the world satisfying perceptual conditions. Reference and perception are inevitably indirect.

Much of Putnam's work has been devoted to uprooting this picture of the relation between mind and world. But perhaps none has been more influential than his celebrated work on meaning, which is the next topic of discussion.

Meaning and Mind

In considering accounts of meaning, or semantic content, it is useful to draw a distinction between two kinds of theories that are easily conflated (see Kaplan 1989; Stalnaker 2001). The first kind is a semantic theory. Such a theory specifies what the semantic contents of expressions are and their modes of composition. So, for example, the Millian thesis that the semantic content of a name is its bearer is a semantic thesis. The second kind of theory is a *meta-semantic* theory. A meta-semantic theory specifies how the semantic contents of expressions are determined—how, in other words, expressions come to possess the contents they do. So, for example, the historical-chain view of names, according to which the content of a name—its bearer—is determined by an initial act of naming and subsequent inheritance down the generations of users, is a meta-semantic thesis.

From the start, Putnam's work on meaning has been motivated by an effort to explain how meanings can remain fixed despite substantial changes in theory. During the heyday of logical positivism, philosophers of science were attracted to the view that terms gain their meanings from the theories in which they are couched, so that differences in theory implied differences in the meanings of the terms contained therein. This was a certain application of a widely received and traditional view about meaning—that the meaning of terms are general extension-fixing criteria that are shaped by the speakers' body of general beliefs. Thus, for example, it was thought that the meaning of a noun such as 'gold' is given by a set of severally necessary and jointly sufficient general conditions for being gold. And proficiency with the noun was thought to entail an implicit grasp of such an extension-fixing criterion.

Putnam's reaction to this picture, which grounds his overall attack on the positivists' construal of natural science, consists in making two central moves. The first is semantic. As against the tradition that saw meaning as an extension-fixing criterion, Putnam argues that extension is the crucial determinant of the meaning of a typical common noun and that an extension-fixing criterion is no part of the meaning. He concedes that there are some common nouns in the language, such as vixen, mare, and sow, that are associated with extension-fixing criteria in the sense that knowledge of meaning demands grasp of such a criterion. These are the so-called one-criterion nouns, but they are clearly the exception among the nouns. For the vast majority of nouns, no such extension-fixing criterion is forthcoming.

It would surely be an unreasonable cognitive burden on speakers of the language to have to grasp general extension-fixing criteria for nouns such as gold, water, aluminum, and elm, and it seems that no amount of loose talk about implicit grasp of such criteria could loosen this unreasonable requirement on proficiency. The point is vividly illustrated by Putnam in a series of provocative thought experiments involving a distant planet ("Twin Earth") that is indistinguishable from Earth but for a complete absence of H_2O and a complementary abundance of some superficially similar yet alien substance ("XYZ"). Putnam considers a community of English speakers on Earth and its counterpart community of Twin English speakers on Twin Earth before the rise of Daltonian chemistry. The two linguistic communities are stipulated to be exact replicas of one another but for the above difference between Earth and Twin Earth, and it is presumed that the state of knowledge in the two communities is such that it does not support any ability to distinguish H_2O from XYZ. Yet, when English speakers employ 'water,' they refer to portions of H_2O, whereas when Twin English speakers employ 'water,' they refer to portions of XYZ. Whatever general criterion individuals on one planet can be said to associate with 'water,' or to grasp collectively, no such criterion can fix the extension of the term to the exclusion of the substance on the other planet. But there is still a strong inclination to conclude that the extension of 'water' on Earth is H_2O, while the extension of 'water' on Twin Earth is XYZ.

In Putnam's account, the meaning of a typical common noun does not determine the noun's extension. Rather, the meaning of a typical common noun is determined by its extension, whereas an extension-fixing criterion is no part of the overall meaning of the noun. Of course, if the meaning, or semantic content, of the noun is determined by its extension rather than the other way around, and if an extension-fixing criterion is no part of its content, then there is no question of proficiency with the noun being a matter of speakers' grasp of an extension-fixing criterion as its meaning. Semantic content, in this view, turns out not to be in the head.

Putnam's second move against the traditional view of meaning is meta-semantic. If extensions of common nouns are components of their overall contents and are not fixed by grasped criteria, then how are they determined? To make the issue vivid, consider a speaker who has the terms 'elm' and 'beech' in his idiolect and also has some undifferentiating general beliefs about elms and beeches, but who cannot distinguish elms from beeches. (Putnam famously claims himself to be such a speaker.) In the old view, 'elm' and 'beech' for such a speaker would be synonymous and thus coextensive. Yet it seems that by 'elm,' this person can intend to refer to elms, and by 'beech' to refer to beeches. For example, such a person might easily wish to affirm the distinctness of elms from beeches. It would be a distortion of the situation to construe what such a person would be affirming as the contradictory claim that anything is an elm (a beech) just in case it is not an elm (a beech). Perhaps an even more vivid illustration is afforded by the noun 'gold.' Most speakers cannot distinguish gold from iron pyrite, yet, by employing 'gold,' they mean to speak of gold and not of either-gold-or-iron-pyrite. How can such an extension determination be achieved if the meaning of gold does not include an extension-fixing criterion?

Putnam's answer consists of a novel meta-semantic account with two importantly distinct components. The first is the claim that extension determination is achieved indexically. The second is the claim that extension determination is often a social matter. Consider these points in turn. As for the indexical or environmental aspect of extension determination, Putnam's view is that speakers employ a typical common noun N as if they are committed to the following extension-fixing stipulation:

$$N(x) \leftrightarrow \text{same}_{\text{r}}(x, \text{this}),$$

where same_{r} is a relevant similarity relation and the demonstrative 'this' refers to a paradigmatic instance of N. In other words, the stipulation specifies that x is N just in case it is relevantly similar to a paradigmatic instance of N demonstratively referred to. And even though Putnam himself does not fully unpack what it is to speak "as if" one is committed to such an extension-fixing stipulation, his account implies that speakers employ N with the intention to refer to anything bearing same_{r} to paradigm instances.

The second component of Putnam's meta-semantic account is social. For nouns such as 'gold,' 'elm,' and 'beech,' the average speaker cannot determine that something or other is relevantly similar to paradigmatic instances of the relevant kind. Yet 'gold' in the mouth of the average speaker refers determinately to gold. How is this determination achieved? It is achieved through a social cooperation that Putnam dubs 'division of linguistic labor.' In the case of gold, an average speaker intends to refer to anything bearing the relevant similarity relation, $\text{sameness}_{\text{metal}}$, to paradigmatic instances. But whether or not $\text{sameness}_{\text{metal}}$ obtains among samples of substance is not a determination that the average speaker can be presumed capable of making. It is a matter left to metallurgy to decide. Similarly for elm and beech. The extension-fixing stipulations for them would be: $\text{elm}(x) \leftrightarrow \text{same}_{\text{plant}}(x,\text{this})$ and $\text{beech}(x) \leftrightarrow \text{same}_{\text{plant}}(x,\text{this})$. But whether or not $\text{sameness}_{\text{plant}}$ obtains is not something that the average speaker can be presumed capable of deciding. It is a matter left to botany to decide. In other words, for nouns such as 'gold,' 'elm,' and 'beech,' speakers are linguistically deferential to a relevant expertise for fixing their extensions. In this way, there is a special sense in which extension determination for many nouns in language is a social matter. For such nouns, extension, and thus semantic content more generally, is determined both environmentally and socially.

The implications of Putnam's meta-semantic account for the philosophy of science, specifically for the possibility of constancy of meaning across radical theory change, are far-reaching. If extension determines content rather than being determined by it, and is itself fixed in the manner sketched above, then there is little mystery as to how, for example, the ancient Greek term for gold (*chrysos*) and the English term 'gold' can share in meaning. Generally speaking, what is relevant for determinations of sameness of content are the contents themselves and not the ways in which they are determined.

Consider any mass noun N_1 as it is used in linguistic community C_1, and any mass noun N_2 as it is used in a remote linguistic community C_2. Suppose that the two terms are linguistically deferential, that the dominant theory about N_1 in C_1 is T_1 and that the dominant theory about N_2 in C_2 is T_2. Finally, suppose that T_1 informs procedure P_1 for detecting N_1, whereas T_2 informs procedure P_2 for detecting N_2. Then an important consequence of Putnam's meta-semantic account is that N_1 and N_2 can share in meaning as long as P_1 and P_2 overlap sufficiently in their outcomes, that is, as long as there is sufficient overlap in what P_1 identifies as N_1 and what P_2 identifies as N_2.

So regarding *chrysos* and 'gold,' the following explanation emerges. It is highly likely that an average ancient Greek speaker employing *chrysos* back then was linguistically deferential to a certain gold-expertise of that time. And the average English speaker employing 'gold' today is linguistically deferential to a certain contemporary gold-expertise. And it so happens that the two procedures for detecting the presence of the relevant substance are largely (although surely not entirely) consonant. This is the crucial detail in what warrants translating their term *chrysos* into the term 'gold.'

Further Implications

Some broader implications of Putnam's views about meaning are noteworthy. One is a general anti-Cartesian outlook on speakers' cognitive rapport with the environment. If Putnam's semantic and meta-semantic views are on the right track, then portions of the world that speakers think and talk about are not determined via satisfying conditions, perceptual or other, that are entertained in their minds. In Putnam's view, reference, and thus content more generally, is a world-involving affair. It is no longer thought to be a

criterion-involving affair internal to the mental lives of the agents, as the Cartesian tradition would have it.

The importance of this point for general epistemology is difficult to exaggerate. It makes agents' cognitive contact with the environment direct, as it were, rather than mediated by criteria entertained in their minds. If one says "Water is wet" and one's twin on Twin Earth utters the same words, then the content of one's 'water' involves H_2O directly, whereas the content of one's twin's 'water' involves XYZ directly. And this is so even if neither one can distinguish the two contents from one another. Generally speaking, an important implication of Putnam's views is that one cannot identify what one says or thinks in abstraction from the global context in which the saying or thinking is conducted, that is, in abstraction from one's relations to others and to the environment. This immediately raises questions about first-person epistemic access to one's own thoughts. If what one says or thinks is shaped by one's relations to the world, then knowledge of these contents depends on knowledge of the world more generally. (For recent work on this topic, see Wright, Smith, and Macdonald 1998.)

Another interesting implication of Putnam's work on meaning regards the prospects of naturalizing reference within some branch or other of cognitive science. If Putnam's views are correct, then it seems hopeless to look to cognitive science for explaining reference. Consider, for example, the phenomenon of division of linguistic labor. One of the striking features of Putnam's meta-semantic story is the hypothesis that linguistic practices are organized within elaborate authority structures—social networks in which novices are deferential to experts by virtue of the latter's possession of expert doctrines in which the former place their trust. If this is correct, then it is highly implausible that reference can be naturalized within cognitive science to the extent that it is highly implausible that such notions as authority can be captured within cognitive science. (For a different take, see Fodor 1994, especially Ch. 2.) If reference implicates an elaborate social structure in the way emphasized by Putnam, then there is good reason for thinking that reference will resist naturalization in the way that is often envisioned by those who think that cognitive science holds the key to the most philosophically fundamental issues concerning the relation between the mind and the world.

Finally, there is an important implication of Putnam's views on meaning for the question of realism. As mentioned at the outset, Putnam has always aligned his views with one form or other of realism, even though many philosophers (including, at times, himself) have viewed his take on the realism question as having undergone dramatic shifts over the years. But one thing that Putnam's work on meaning illustrates is that a realist commitment to the idea that sentences are made true or false by virtue of something external to speakers is already packed into the very notion of semantic content. Consider, again, the term 'gold' and the meta-semantic question of how it gains its content. Putnam's view is that content determination proceeds by way of extension determination, and that extension determination proceeds via referential intentions to pick out anything relevantly similar to paradigmatic instances of the kind in the speakers' environment, where the relevant similarity in this case is left to metallurgy to decide. One thing that emerges from this account is that in order for the term to gain a determinate extension and thus become semantically significant, there has to be an objective standard of relevant similarity. Otherwise, whatever will *seem* to speakers to be relevantly similar to paradigmatic instances will thereby *be* relevantly similar, in which case no determinate extension will be secured for the term after all, and sentences involving 'gold' will not be truth-evaluable. In short, in order to think of words as significant, the relevant seem/is distinction has to be in place. And the latter can be facilitated only by a standard that is external to speakers in the sense of opening up the possibility that what seems to be the case falls short of what is the case. This is clearly a realist commitment in any reasonable understanding of the term 'realism,' and it is one that Putnam has never abandoned. To be sure, it is a far cry from the metaphysical realist picture according to which a theory that is epistemically ideal may nevertheless be false of the world as it is "in itself" because what the terms of the theory refer to is beyond the cognitive access of the theorist. Indeed, Putnam's emphatic rejection of the latter picture is inseparable from his insistence on a person's cognitive being-in-the-world, an insistence he sometimes refers to as 'direct' or 'natural' realism.

Q

QUANTUM FIELD THEORY

Quantum field theory (QFT) provides the mathematical framework of modern fundamental elementary particle physics. It grew out of relativistic quantum mechanics conjoined with the demand for a variable particle number (which is required because particles may be created or annihilated during interactions) (see Particle Physics).

Although some of QFT's predictions, notably in quantum electrodynamics (QED), show a highly remarkable agreement with experimental results, its mathematical foundations still suffer from consistency problems. From a philosophical point of view, QFT raises such questions as whether a field or particle ontology applies, how to understand the lack of individuality of field quanta, what the meaning of the vacuum state and virtual particles is, whether and how quantized fields will be measurable and observable, and what quantization in general means.

Field Theory and Canonical Quantization

The need for a QFT in the literal sense of a "quantized field" theory can be seen from the fact that a field is a physical system with infinitely many degrees of freedom, which cannot be captured by ordinary quantum mechanics of finite systems (see Quantum Mechanics). A chain of connected simple harmonic oscillators, for instance, will—in the continuum limit of infinitely many oscillators—allow for infinitely many modes of oscillation. Since fields in physics generally refer to quantities with values associated with space-time points, the continuous character of space-time (as usually presumed in classical space-time physics) is the reason why fields represent systems with infinitely many degrees of freedom. A mathematical expression representing this situation is given by the fact that the field value at a point most generally requires a superposition in terms of a continuous Fourier expansion $\psi(x) = \int d^4k/(2\pi)^4 \tilde{\psi}(k) e^{ikx}$ where $\psi(x)$ is the field amplitude and $\tilde{\psi}(k)$ is its Fourier transform in momentum space, with arbitrarily high four-momenta k representing an infinite number of modes.

With the advent of quantum mechanics in the years between 1925 and 1927, the question of the quantization of the electromagnetic field arose. Following previous work by Born, Heisenberg, and Jordan, Paul Dirac (1927) in his seminal paper first arrived at a full-fledged version of a QFT in terms of the canonical quantization of the free electromagnetic field. The general scheme of canonical quantization is to formulate the theory

within the Hamiltonian framework and then to impose commutation relations between the canonical variables. Generally, for a field $\varphi(x)$ with Lagrangian $L(x)$ the canonical variables are $\varphi(x)$ and the canonical momentum $\pi(x) = \partial L(x)/\partial\dot{\varphi}(x)$. These variables are analogous to classical positions and momenta in quantum mechanics, and by making them operator valued, one gets canonical commutation relations (CCRs) analogous to the ordinary Heisenberg relations between $\hat{x}_i$ and $\hat{p}_i$ in quantum mechanics (where the hats ^ denote operators).

In more technical terms (see Ryder 1985) and for the simple case of a scalar field, one starts from the Fourier expansion

$$\hat{\varphi}(\vec{x}, t) = \int \frac{d^3k}{\sqrt{(2\pi)^3 2\omega}} \Big(\hat{a}(\vec{k}) e^{-i(\vec{k}\vec{x} - \omega t)} + \hat{a}^+(\vec{k}) e^{i(\vec{k}\vec{x} - \omega t)} \Big).$$

Here, the Fourier coefficients $\hat{a}^+(\vec{k})$, $\hat{a}(\vec{k})$ can be considered as creation and annihilation operators of momentum states $|\vec{k}\rangle$ (written in abstract Dirac notation) with the CCRs

$$[\hat{a}(\vec{k}), \hat{a}(\vec{k}')] = [\hat{a}^+(\vec{k}), \hat{a}^+(\vec{k}')] = 0,$$
$$[\hat{a}(\vec{k}), \hat{a}^+(\vec{k}')] = \delta(\vec{k} - \vec{k}').$$

The Hamiltonian can be written as $\hat{H} = \int d^3k \omega(\vec{k}) \big(\hat{n}(\vec{k}) + 1/2\big)$, where the number of states $\hat{n}(\vec{k}) = \hat{a}^+(\vec{k})\hat{a}(\vec{k})$ depends on creation and annihilation operations.

The structure of the CCRs determines the structure of the many-particle Hilbert space, the so-called Fock space, which is defined over a vacuum state $|0\rangle$ with the property $\hat{a}(\vec{k})\,|0\rangle = 0$. Applying creation operators to the vacuum produces field quanta states $|\vec{k}\rangle = \hat{a}^+(\vec{k})\,|0\rangle$, which are characterized by the number $\hat{n}(\vec{k})$ only. Therefore, the Fock space allows for an occupation number representation (see below) and can be understood as a direct sum $H = H_1 \oplus H_2 \oplus H_3 \oplus \ldots$ of n-particle Hilbert spaces $H_n = \bigotimes_n H_1$ (where H_1 denotes the one-particle state space).

Two Routes to Quantum Field Theory

The canonical quantization of a classical field theory is not the only route to QFT proper. It can be shown that the quantum mechanics of many particles is indeed mathematically equivalent to the description given above of a QFT in Fock space. Starting from classical particle mechanics *CM*, one may go over to a classical theory with infinitely many particles being equivalent to a classical field theory *CFT*. Applying now the techniques of canonical quantization (basically by imposing CCRs) directly leads to QFT. This route chiefly consists of two procedures: first, the transition from one to (infinitely) many degrees of freedom ($n \to \infty$) and, second, the introduction of commutation relations (CCRs). Reversing the order of these procedures leads in a first step from *CM* to ordinary quantum mechanics *QM* (of a finite number of particles) by canonical quantization. In a second step, the transition to a theory with infinitely many particles yields a theory equivalent to *QFT*. One may therefore draw the following diagram:

$$\begin{array}{ccccc} & & \overset{n\to\infty}{\longrightarrow} & & \\ & QM & & QFT & \\ CCRs & \uparrow & & \uparrow & CCRs \\ & CM & \longrightarrow & CFT & \\ & & \underset{n\to\infty}{\longrightarrow} & & \end{array}$$

Puzzles arise once the quantum mechanical wave function is formally treated as a classical field (e.g., the "Schrödinger" or "Klein-Gordon field"). Since this tacitly assumes the equivalence $QM \Leftrightarrow CFT$, the two routes become confusingly intertwined. In his 1927 paper, Dirac introduced this procedure under the heading "second quantization." The usual stance among physicists on this is best captured in a quote from Ryder (1985, 126):

> What we shall do first is to consider the equation as describing a field $\phi(x)$. Since the equation has no classical analogue, $\phi(x)$ is a strictly quantum field, but nevertheless we shall begin by treating it as a classical field. ... We shall then take seriously the fact that $\phi(x)$ is a quantum field by recognising that it should be treated as an operator, which is subject to various commutation relations analogous to those in ordinary quantum mechanics. This process is often referred to as 'second quantisation', but I prefer not to use this term. There is, after all, only one quantum theory, not two; what we are doing is quantising a field, rather than the motion of a single particle, as we do in quantum mechanics. It turns out that the field quantisation has an obvious interpretation as a many-particle theory, which is just what we want.

But the conceptual and philosophical problems surely lie deeper (see Cao 1997, Sec. 7.3). One must at least carefully distinguish between the quantization of real-valued fields (such as the electromagnetic field, which allows for a classical interpretation of waves in space-time) and complex-valued fields (such as probability wave functions defined on a configuration rather than position space). For the latter the field operators are non-Hermitean operators and, hence, not observable, whereas for the first

the fields—classical and quantized—are observable. In these cases, however, there exist no conserved (particle) currents, and, thus, as Pauli (1933) put it in an early paper, for real fields "the notion of a local particle density [e.g., the photon density] ... does not meaningfully exist."

Particles or Fields?

Roughly stated, the two routes to QFT indicate the two primary ontological aspects of quantum fields—the wave or field aspect on the "right-up-route" $CM \rightarrow CFT \rightarrow QFT$, as opposed to the particle aspect on the "up-left-route" $CM \rightarrow QM \rightarrow QFT$. As philosophical debates have shown, both views do contain certain, seemingly ineliminatable problems. Teller (1995), for instance, has argued that quantum fields may be described by space-time–indexed operators but that those operators do not, as classical fields do, represent *specific values* of physical quantities associated with space-time points, but rather represent the quantities ("determinables") themselves—by possibly taking any of a continuum of values. A simple particle interpretation, on the other hand, is also blocked. As a technical result, Malament (1996) has proved a no-go theorem, which excludes the possibility of localizable particles in relativistic quantum theory (see Locality). The other important attack on the particle view stems from the indistinguishability of field quanta.

Indistinguishability

As already mentioned, Fock space allows for an occupation number representation, more formally $|n_1, n_2, n_3 \ldots\rangle = \frac{1}{\sqrt{n_1! n_2! n_3! \ldots}} (\hat{a}_1^+)^{n_1} (\hat{a}_2^+)^{n_2} (\hat{a}_3^+)^{n_3} \ldots |0\rangle$ with $\hat{a}_i^+ \equiv \hat{a}^+(\vec{k}_i)$, where n_i denotes the number of the i-th state. The combinatorial factor in the state representation, here written for bosonic fields, indicates that quanta are observationally indistinguishable. (For fermionic fields one has to use totally antisymmetrized representations instead due to the spin-statistics theorem (see Particle Physics). This holds true already on the level of quantum mechanics and becomes a generic feature of QFT.

Ontologically speaking, the indistinguishability means that quanta possess all intrinsic properties in common. Nevertheless, quanta do possess a cardinality. In this sense, then, Leibniz's principle of the identity of indiscernibles fails as a principle of individuation. One way of dealing with this is to consider quanta as nonindividuals lacking even such basal substance-ontological categories as "transcendental individuality," "primitive thisness," or "haecceity." Obviously the indistinguishability of quanta poses a serious problem for a straightforward particle ontology of QFT (cf. French and Redhead 1988; Teller 1995).

Alternative Approaches to Quantum Field Theory

The interpretive issues of QFT become even more complicated due to the fact that there is more than one approach to QFT. Over and above the canonical Hilbert space formulation, mention must be made at least of path integrals and algebraic quantum field theory (AQFT).

Path integrals are based on Feynman's representation of transition amplitudes in nonrelativistic quantum mechanics as sums over path histories weighted by the classical action (Feynman 1948). Due to the principle of least action, the classical trajectory of a particle corresponds to an extremal action functional. The quantum-mechanical interpretation consists of allowing all the possible trajectories "at once." This leads to a transition amplitude $K(x_f, t_f; x_i, t_i) = \int_i^f D[x(t)] e^{iS[x(t)]}$ between an initial state $|x_i, t_i\rangle$ and a final state $|x_f, t_f\rangle$, where $S[x(t)]$ is the action functional (with a suitable measure $D[x(t)]$ in the function space of all trajectories $x(t)$). This formalism can straightforwardly be extended to infinite degrees of freedom—and also provides a convenient method of performing perturbation theory visualized in terms of Feynman diagrams and needed for the calculation of interactions (see below). However, a literal interpretation of Feynman diagrams in terms of spatiotemporal particle trajectories is untenable and does not support a particle ontology.

AQFT, the second approach, was invented by Haag and others in the 1960s (see Haag 1992) as an attempt to construct QFT on a more rigorous and solid mathematical basis. The main idea is that the algebra of observables represents the core physical structure of quantum theory. Given such an algebra A, it is possible to identify the physical states with the linear forms ω over A. It can be shown that each ω defines a Hilbert space H_ω and a representation π_ω of A by linear operators acting on H_ω (Gelfand-Naimark-Segal [GNS] construction).

One considers in particular the C^*-algebra $A(O)$ of all bounded operators associated with a space-time region O; thus, AQFT replaces the correspondence $x \rightarrow \psi(x)$ (where x is the position and $\psi(x)$ is a field amplitude) by the more operationally defined correspondence $O \rightarrow A(O)$. In AQFT, the

description of systems with an infinite number of degrees of freedom leads to unitarily inequivalent representations. Different representation classes, so-called *sectors*, must therefore be connected to each other by superselection rules, which include the different, empirically known charges. It is of particular conceptual and philosophical interest to explore the meaning of inequivalent representations.

An important result of AQFT is the Reeh-Schlieder theorem, which, roughly, asserts that any physical state may be created from the vacuum. Due to this theorem and in spite of AQFT's superficial spirit of locality, the notorious quantum nonlocalities (such as EPR-Bell correlations) reappear and can be demonstrated also within the framework of a relativistic QFT (see Redhead 1995) (see Locality).

Interacting Fields

For real applications of QFT, one has to consider interacting fields. Here the field equations become nonlinear (they contain coupling and self-interaction terms with two or more fields) and can be solved only by means of perturbation theory (i.e., as approximations in terms of infinite power series in the coupling constants). Higher-order expansions will then include divergent terms that are due to the integration over internal loops. In order to cope with the infinities, one introduces renormalization procedures, where the various coupling constants and masses are treated first as "bare" infinite parameters that, in a next step, become interaction modified. In QED, for instance, the electric bare charge is screened by vacuum polarization, which means that, for instance, the naked electron charge attracts positrons and repels electrons from the surrounding cloud of virtual electron-positron pairs leading to an effective finite electron charge. It can be shown that the interaction theories in the standard model (see Particle Physics) can be made finite at all orders through the renormalization procedure. From a meta-theoretical point of view, the very idea of renormalization touches the deep question, whether and on what grounds one should expect a unified and rigorous fundamental theory.

Moreover, the fundamental standard model of today distinguishes between quantized matter and interaction fields and describes their interconnection in terms of gauge theories. The latter are characterized by a local symmetry requirement; more precisely, the postulate of local gauge covariance of the free matter field theory leads to the introduction of a covariant derivative where the inhomogeneous connection term can be interpreted as a gauge potential field (cf. Auyang 1995). However, since gauge transformations refer to unphysical degrees of freedom, only gauge invariant quantities can be observable. This raises questions about the status of the seemingly redundant excess or "surplus structure" in gauge theories. Apparently, modern physics QFTs show in many ways the unresolved puzzles of the notorious intertwining between mathematics and physics.

Good starting points for further studies can be found in Huggett (2000) and Redhead (1982), as well as in the collection of papers in Brown and Harré (1988), Cao (1999), Clifton (1996), and Kuhlmann, Lyre, and Wayne (2001).

QUANTUM LOGIC

Much work done under the rubric 'quantum logic' concerns various mathematical structures connected with quantum mechanics (for reviews, see Beltrametti and Casinelli 1981; Pták and Pulmannová 1991). It includes important elucidations of the physical content of the formalism; in particular, "to what extent is the Hilbert space description of quantum systems coded into the order structure of propositions?" (Beltrametti and Casinelli 1981, 89). But this entry is concerned with a different issue: the possibility—or necessity—of using nonstandard logical systems in the interpretation of quantum-mechanical formalism. In keeping with most literature on the topic, discussion is confined, on the physical side, to nonrelativistic quantum mechanics; and, on the logical side, to first-order propositional calculus and first-order logic—also called first-order functional or predicate calculus (see, e.g., Stoll [1963] 1979). Certain needed topics in classic mechanics (see "Classical Ensembles and Probability Densities") and quantum mechanics (see "Probability Amplitudes and Feynman Paths") not treated elsewhere in this volume are also discussed.

In assessing various 'quantum logics,' a distinction is made between "*the* logic *of*" approaches, which claim that some unique nonstandard logic is *necessary* for the correct interpretation of quantum mechanics, and 'logic(s) *for*' approaches, which discuss the possible utility of one or more alternate logic(s) in the interpretation of the formalism (cf. Gibbins [1987, 142] distinction between *activist* and *quietist* interpretations of quantum lattice logic).

History

Von Neumann ([1932] 1955, 247–254) and Birkhoff and von Neumann (1936) claimed that a nonstandard propositional calculus based on the non-Boolean lattice structure of the closed linear subspaces of a quantum-mechanical Hilbert space (see Quantum Mechanics) should replace the classical propositional calculus based on the Boolean lattice of subspaces of a classical-mechanical phase space. Strauss ([1936] 1972) used a propositional calculus based on the partial Boolean algebra of projection operators acting on Hilbert space to formalize Bohr's concept of complementarity (see Complementarity). Both of these approaches preserved the traditional bivalent valuation of propositions as either true or false, but Février (1937) (later Destouches-Février) and Reichenbach (1944) introduced indeterminacy as a third truth value; and von Weiszsäcker (1958) advocated a many-valued "complementarity logic," in which a probability rather than a definite truth value is associated with each proposition. Recent discussions of quantum logic devote little attention to nonbivalent logics (but see Haack 1996 on Reichenbach's three-valued logic); nor has there been extensive discussion of operational or dialogic approaches to quantum logic or of a probabilistic variant of intuitionist logic for the consistent-histories interpretation of quantum mechanics, both of which are briefly discussed at the end of this entry. The rest of this entry is devoted to the discussion of quantum logics based on either non-Boolean lattices or partial Boolean algebras (see Jammer 1974, 340–416, for a history of quantum logic; Hooker 1975 for a selection of the relevant papers).

Classical Mechanics and Classical Logic

Phase space is the space of all possible states of a classical mechanical system. This state is determined by particular values of the system's

generalized position q and momentum p (hereafter, in a system with n degrees of freedom, a single symbol such as q or p will stand for the entire set of n components of the corresponding quantity). Physically, phase space coordinates may represent energies, angles, angular momenta, etc. (see Classical Mechanics). The Boolean lattice of all subsets (or just measurable subsets if desired) of its phase space may be put in correspondence with the standard ("classical") logic of a corresponding set of predicates of, or propositions about, the system, which form an isomorphic Boolean lattice. That is, each such subset can be interpreted semantically as corresponding to either a predicate of the system or a proposition about the system—or even to a "yes-no" question about the system in operationalist interpretations of this logic. For brevity, 'proposition' will be used hereafter to stand for any of these possible interpretations. A singleton set, that is, one containing a single point (q, p) of phase space, corresponds to an "elementary proposition," representing the maximal possible specification of the properties of the system at a given time: "The system has position q and momentum p."

Throughout this entry, all propositions are interpreted extensionally. For example, if a set of canonical variables q and p are related to a new set Q and P by a canonical transformation, then the propositions 'The system has values Q, P' and 'The system has values q, p' are equivalent. With this identification of equivalent propositions, the Boolean algebra associated with the lattice of subspaces discussed above becomes a Lindenbaum algebra (see, e.g., Stoll [1963] 1979, chap. 6).

The point in phase space occupied by the system at any time t is often referred to as 'the state of the system at t.' A classical system that is closed in the interval between the times t_1 and t_2 is assumed to be deterministic during that interval: given its state at some intermediate time t, the equations of motion of the system (usually, but not necessarily, assumed to be derivable from a Hamiltonian) may be used to *predict* its future state up to t_2, or *retrodict* its past state back to t_1. Consequently, each *elementary* proposition, 'The system has position q and momentum p' is either true or false (with exclusive 'or') at any time t; and for each t, the proposition is true for one and only one pair of values, let us say q_0 and p_0.

There is an isomorphism between the Boolean algebra of subspaces of phase space and the Boolean algebra of elementary and compound propositions about the system. Any *compound* proposition about the system is equivalent to one of the form 'The system's position and momentum lie within some subset S of the phase space' and also has a determinate truth value for each t: it is true if the point (q_0, p_0) lies in the subset S at that time, false if it does not. Such compound propositions are generated by logical operations on elementary or other compound propositions. (Note that propositions like 'The system has position p,' which might appear simple, are actually *compound*.) The logical operations correspond to set-theoretical operations on the subsets corresponding to the propositions, the basic correspondences being given in the following table:

Logical operation	Set-theoretical operation
Negation ('not,' '$\neg$')	Complementation
Conjunction ('and,' '$\wedge$')	Intersection ('$\cap$')
Disjunction ('or,' '$\vee$')	Union ('$\cup$')

All other logical operations may be defined in terms of these. In particular, the (material) conditional ('if ... then') '$a \rightarrow b$' is defined as '$\neg a \vee b$'; and the biconditional ('if and only if') '$a \leftrightarrow b$' is defined as '$(a \rightarrow b) \wedge (b \rightarrow a)$.' All of these operations are *truth-functional;* that is, the truth or falsity of any compound proposition is uniquely determined by a valuation, that is, the assignment of bivalent (true or false) truth values to each of the propositions entering into the compound.

Various other logical concepts can be defined in terms of such sets or relations between them. For example:

Logical concept	Set or relation between sets
Tautology ('T')	The universal set ('I')
Contradiction ('F')	The empty set ('$\square$')
Implication $\Rightarrow$	Inclusion ('$\subseteq$')

This means that a proposition corresponding to the universal set—the entire phase space in our case—is a tautology; a proposition corresponding to the empty set is a contradiction; and if the set corresponding to a proposition is included in the set corresponding to a second one, then the first proposition implies the second.

Since the classical propositional calculus is truth-functional, the semantic interpretation of all classical logical operations and concepts may be defined in terms of the above set-theoretical operations and relations (see 'Semantic Problems' below). Nevertheless, it has recently been shown (Pavičić and Megill 1999) that there exist complete, non-Boolean lattice models of the axioms of the classical propositional calculus.

Classical Ensembles and Probability Densities

When introduced into classical mechanics, probabilities are always symptomatic of ignorance, i.e., renunciation of full information about a classical system that, in principle, could be obtained. Classical ensembles in configuration space (Schiller 1962; Berry and Mount 1972) provide an example that is important for comparison with the situation in quantum mechanics (see "Probability Amplitudes and Feynman Paths" below). Consider a complete solution $W(q, \alpha, t)$ to the Hamilton-Jacobi equation for a system with Hamiltonian H. The solution is based on stipulation of "half" the total number of variables needed to specify an individual trajectory in phase space, i.e., each pair (q, α) specifies such a trajectory. The complete solution corresponds to a real or virtual ensemble of such trajectories, one for each value of α. The density $\rho(q, \alpha, t)$ of these trajectories in the extended configuration space with coordinates (q, t) is given by the Van Vleck determinant $|\partial^2 W/\partial q\, \partial\alpha|$; and, hence, if a trajectory is chosen at random, the probability $P(q, \alpha, t)$ of its having the values (q, α) at time t is proportional to $\rho(q, \alpha, t)$.

But, whether one *knows* their values or not, at any time each individual system in a classical ensemble always *possesses* some *definite* position and momentum, and it is only renunciation of a possible measurement of half this information in preparing the ensemble that leads to the probabilities of values for individual systems in the ensemble. In other words, a Hamilton-Jacobi ensemble can always be subdivided into subensembles, for which more narrowly defined probabilities can be calculated; and it is ultimately divisible into individual trajectories, with each of which definite values are associated.

For later comparison with quantum ensembles, consider a complete solution of the form $W(q_i, t_i; q, t)$—a Hamilton's principal function—and let t be later than t_i. It follows from the previous discussion that the conditional probability for a system initially prepared with position q_i at time t_i to be found in an interval dq around q at time t is given by:

$$P(q_i, t_i; q, t)dq,$$

where the probability density $P(q_i, t_i; q, t)$ is proportional to the Van Vleck determinant of Hamilton's principal function. This probability may be given a propensity interpretation for a virtual ensemble associated with a single system, or a frequency interpretation for an ensemble of identically prepared systems (see Probability).

As noted above, the entire ensemble of trajectories associated with a principal function may be decomposed into subensembles of trajectories, with each of which a probability density is associated. A collection of such subensembles is *complete* if

- no trajectory belongs to more than one subensemble; and
- every trajectory belongs to some member of the collection.

It follows that the robability density for the entire ensemble is the sum of the densities for all the members of the complete collection.

It also follows from the properties of the principal function and its Van Vleck determinant that probabilities are cumulative. That is, for $t_i \leq t \leq t_f$:

$$P(q_i, t_i; q_f, t_f) = P(q_i, t_i; q, t)P(q, t; q_f, t_f).$$

The main difference between classical and quantum-mechanical conditional probabilities is that probability densities must be replaced by probability amplitudes in the assertions of the last two paragraphs (see "Probability Amplitudes and Feynman Paths"; but see "Consistent-Histories Approach" below for an attempt to associate probabilities with quantum histories).

First-Order Functional Calculus

Standard first-order functional calculus deals with statements involving one or more propositional or predicate functions and the universal and existential quantifiers. A typical function is symbolized by $F(x)$, where x ranges over some class C of individuals. As x ranges over its values, the truth values of $F(x)$ range over true and false. Propositional functions are compounded in the same ways as propositions. The universal quantifier $(\forall x)[F(x)]$ asserts that $F(x)$ is true for all values of x in C. The existential quantifier $(\exists x)[G(x)]$ asserts that there is at least one value of x in C for which $G(x)$ is true.

In the case of classical mechanics, the class C is the Boolean (or rather Lindenbaum) algebra of subspaces of the phase space of the system being considered. Then the *universal* quantifier is equivalent to the assertion of the *conjunction* of all propositions $F(x)$ as x ranges over the points (or better, the singleton subsets) of phase space; while the *existential* quantifier is equivalent to the assertion of the *disjunction* of all these propositions.

A semantics for the standard propositional and first-order functional calculi is easily developed such that given the antecedent of any conditional propositional tautology, the consequent can be

proven using standard rules of inference (basically *modus ponens*).

What Is a Quantum-Mechanical Proposition?

Much of the debate over quantum logic(s) hinges (implicitly if not explicitly) on the question of the quantum-mechanical analogue of the classical-mechanical propositions discussed above. Classically, propositions refer to only the properties of the system itself, considered as closed (that is, not interacting with anything outside the system). But, as Bohr emphasized, the existence of the quantum of action h prevents such a complete separation between a quantum-mechanical system and its macroscopic surroundings. Two major consequences are:

1. A full description of a quantum-mechanical *phenomenon* (Bohr 1958) or *process* (Feynman 1968; the word "process" will be used hereafter) must include a specification of the result of an initial preparation of the system, an account of the type of interactions it undergoes subsequently, and the result of some act of *registration* ("measurement") to which the system is finally subjected (see Quantum Measurement Problem);
2. A maximal quantum-mechanical preparation or registration specifies only half the data about a system that would be specifiable classically. For example, while one could in principle prepare or register a classical-mechanical system with both a determinate position *and* momentum, one can prepare or register a quantum-mechanical system only with *either* a determinate position *or* momentum. (Such quantum-mechanical quantities are often referred to, in a somewhat misleading fashion, as *observables.*)

As a consequence, a typical proposition about a process involving an electron might read: "At time t_1 the electron was prepared with momentum p_0, subsequently passed through a certain electric field E, and at (a later) time t_2 was registered at position q_0." Quantum mechanics assigns a probability to such a proposition as explained in the next section.

Probability Amplitudes and Feynman Paths

Because of consequence (2) above, rather than being analogous to preparation of an individual classical system, a quantum-mechanical preparation is analogous to the preparation of a classical ensemble (see "Classical Ensembles and Probability Densities" above). Given such an ensemble, only the probability for a definite value of that half of the final data chosen for final registration (measurement) can be calculated. In quantum mechanics too, only the *probability* of a quantum-mechanical process leading from an initial preparation to a final measurement can be defined—in limiting cases, this probability may be 1 (certainty) or 0 (impossibility). The central difference in quantum mechanics is that rather than a probability (or probability density in the continuous case), as in the classical system, one computes a *probability amplitude*—a complex number of amplitude ≤ 1—for each process. This amplitude must then be "squared" to get the corresponding probability. *Partial amplitudes* are calculated for all paths leading from the initial preparation to the final measurement that are indistinguishable within the given process, and (rather than partial probabilities as in the classical case) these partial amplitudes must be summed to get the total amplitude for the process. Again, it is the probability amplitudes that are cumulative, rather than the probabilities.

Using Dirac's bra-ket notation, one may write $<b|a>$ as the total amplitude for some process connecting an initially prepared value a and a finally registered reading b (note that a and b may be the values of *different* observables). The probability of this process is then equal to the square of the absolute value of the amplitude:.

$$P(a \rightarrow b) = |<b\,|\,a>|^2.$$

The two rules mentioned above are summarized in the following formula. Let $|b_i>$ be a complete collection of indistinguishable alternatives at some time between preparation $|a>$ and registration $|c>$. This means that the paths $<c\,|\,b_i><b_i\,|\,a>$ are all mutually exclusive and between them exhaust the possibilities (cf. the definition of "complete" for classical ensembles). Then:

$$<c\,|\,a> = \sum_i <c\;|\;b_i><b_i\,|\,a>\,.$$

If a registration of one of the alternatives were to take place at some intermediate point, thus distinguishing between these alternatives, then the probabilities $P(a \rightarrow b_i) = |<b_i|a>|^2$ would have to be computed and used in all calculations of later probabilities.

Note that, as in the classical case, all the quantum-mechanical probabilities are *conditional*; one does not ask for the probability of a final b-value *tout court* but given an initial prepared value a. Once computed, these conditional probabilities obey the laws of the classical probability calculus

based on classical logic. In contrast to the classical case, quantum-mechanical conditional probabilities cannot be attributed to ignorance but are fundamental. Without altering the physical conditions defining the process under consideration (thus producing a different process), it is impossible to further subdivide an initially prepared quantum-mechanical ensemble into subensembles, let alone into individual trajectories, for which probabilities (as opposed to probability amplitudes) can be defined. For example, a sample of initially undecayed radioactive nuclei all with the same average half-life cannot be subdivided into subensembles each with different predicted average lifetimes. (Of course, retroactively, *after* some or all have decayed, it is easy to do so.)

To complete the analogy to classical ensembles, note that the probability amplitude $<q_i, t_i \mid q_f, t_f>$, like any complex number of amplitude ≤ 1, can be written:

$$<q_i, t_i \mid q_f, t_f> = [P(q_i, t_i; q, t)]^{1/2} \exp[h/iW(q_i, t_i; q, t)],$$

where P is a real number between 0 and 1. To a first, semiclassical approximation in the classically allowed region of configuration space (see Berry and Mount 1972 for the semiclassical treatment of turning points and the classically forbidden region), W is a Hamilton principal function, and P is its Van Vleck determinant. In other words, a classical ensemble can be used to produce a semiclassical wave function for a system described by some Hamiltonian.

Prediction, Retrodiction, and State Functions

Preparation of a system usually involves a choice between one of several initial input channels a_i (e.g., the choice of that beam of atoms with given z-component of spin in a Stern-Gerlach type of experiment); and registration usually involves one of several possible outcome channels b_j (e.g., the result of a subsequent measurement of the x-component of the spin of the atoms in the chosen beam); so that one may calculate a set of amplitudes $<a_i \mid b_j>$ for these related processes. An ensemble of (real or virtual) copies of the system may then be prepared by *preselection,* based on the choice of one of an a_i. In this case the probability amplitudes will be used for *prediction* of the probabilities of each of the subsequent possible *registration* results b_j. As an aid in calculating these probability amplitudes for prediction, a *state* of the system $|c>$ is often defined for the time interval between preparation and registration. (In the Schrödinger picture, the state changes with time; in the Heisenberg picture it does not.) The possible states of a quantum-mechanical system are assumed to form a Hilbert space, and most standard accounts of quantum mechanics begin with consideration of the abstract state space or one of its representations (see Quantum Mechanics).

Usually, only preselected ensembles are considered, but an ensemble may also be *postselected* based on the choice of a unique final registration result b_j, and amplitudes introduced as aids in calculating the conditional probabilities for *retrodiction* of the various possible values of initial a_i, given a particular final value of b_j. The limited physical significance of the concept of state in quantum mechanics is indicated by the fact that at any intermediate time between preparation and selection, *different* states will be assigned to preselected and postselected ensembles for the same physical system. In contrast, the same state of a classical ensemble can be used for purposes of either prediction or retrodiction.

Classical or Quantum Logic?

As noted in the section "What Is a Quantum-Mechanical Proposition?," classical propositional logic is all that is needed to handle propositions describing a complete quantum-mechanical process. Logical problems begin when such propositions are truncated by omission of reference to preparation and/or registration. Since classical-mechanical propositions are correlated with states of the system in phase space without reference to anything outside the system, an attempt is made to correlate quantum mechanical propositions with states of the system in Hilbert space (see below). Usually, only preselected ensembles are considered, and explicit reference to both reparation and registration is dropped. Attention is focused on "the state $|c>$ of the system at time t," to which one tries to attach a significance similar to that of the state in the classical case.

The maximal goal of such an approach is to attribute a *complete* set of classical properties, e.g., *both* position *and* momentum, to a quantum system in a given state. Note that, in contrast to the classical case, here propositions, such as "The system has position q" and "The system has momentum p," are *elementary.* They are then compounded by suitably defined operations of conjunction and disjunction in an attempt to give meaning to the resulting compound propositions, even when the properties referred to in such

compound propositions are incompatible quantum mechanically. The compound propositions are assumed to have a definite truth value at any time t, and the inability to actually determine these truth values by experiments performed at this time is regarded as a purely epistemic problem. An attempt to carry out such a program while maintaining classical propositional logic would clearly fail. So some alternate, nonstandard logic is introduced, with the aid of which the program can be carried out. The earliest and most widespread such logic is based on the (non-Boolean) *orthomodular lattice of linear subspaces* of the Hilbert space associated with the system, with the claim that this results in *the* logic of quantum mechanics, that is, of the reality underlying the formalism (see "Orthomodular Lattice Logic" below).

More modestly, it may be agreed that one must restrict simultaneous attribution of properties to a system, and hence the attribution of simultaneous truth values to the corresponding sets of elementary propositions, to quantum-mechanically *compatible* sets of properties. Compounding of such properties and/or propositions is similarly restricted to compatible propositions. There are a number of ways of developing such an approach into a formal logical system, with the claim that use of (one or more of) the resulting nonstandard logic(s) aids the understanding of the quantum-mechanical formalism. The earliest and most widespread of such logic(s) *for* quantum mechanics is based on the *partial Boolean algebra of projection operators* acting on the Hilbert space associated with the system (see "Partial Boolean Algebra Logic" below).

Orthomodular Lattice Logic

As traditionally formulated since von Neumann (1927), the state space of a quantum-mechanical system is a Hilbert space (see Quantum Mechanics). In the lattice-logical approach, elementary quantum propositions are taken to correspond to one-dimensional linear subspaces (rays) of the Hilbert space, compound propositions corresponding to higher-dimensional closed linear subspaces. No reference to the circumstances of preparation or registration of the system is supposed to be included in the semantical interpretation of these propositions, which are assumed to refer exclusively to the state of the system at some time t. But, as noted earlier, an elementary proposition about a quantum system can involve only half the canonical variables of the corresponding classical system. For example, the statements 'The system has position q' and 'The system has momentum p' are each (mutually exclusive) elementary quantum propositions, and no further information about the system may be included in such elementary propositions. As a consequence (and in contrast to the classical case), the truth of an elementary quantum proposition is *not* sufficient to determine the truth value of all other (elementary or compound) propositions. If an elementary quantum proposition is true at some time, for example, it does not follow that all other elementary quantum propositions are false at that time.

To give them a determinate truth value, (most) such propositions would have to be rephrased probabilistically—for example, 'The probability that the system has a position q is x,' where x is a real number between 0 and 1—or more accurately, as conditional probability statements, such as 'If the system has momentum p, then the probability that the system has a position q is x,' and this would actually describe a process (preparation of p, registration of x). In contrast to the classical situation, the conditional probabilities occurring in such propositions cannot be eliminated by any additional knowledge about the system.

How to interpret such quantum-mechanical probabilities has been a subject of controversy since the earliest days of the theory. In particular, how is "probability" in such a proposition to be interpreted semantically? It is certainly not absolute, but conditional on the truth of some other given (usually elementary) quantum proposition (this circumstance is usually expressed in terms of a certain "preparation" of the system, or in equivalent "state vector" language). Even assuming their conditional character, are such probabilistic assertions meaningful for a single system, as propensities? Or do they hold only for an ensemble of systems, for each of which the original antecedent proposition is true ("identically prepared systems" or "systems having the same state vector"), as in ensemble interpretations of quantum mechanics?

How to treat the logic of such quantum propositions became a subject of considerable controversy with the proposal to "just read the logic off from [the atomic orthomodular lattice of closed linear subspaces of] the Hilbert space" (Putnam 1969). The atoms of this lattice are the one-dimensional subspaces of the Hilbert space, and they correspond to the elementary propositions about the quantum system discussed in the previous section. Logical operations on (elementary or compound) propositions are then defined in terms of operations on the lattice subspaces corresponding to the propositions, as indicated in the following table:

Logical operation	Closed linear subspace operation
Negation ('not,' '¬')	Orthogonal subspace ('⊥')
Conjunction ('and,' '∧')	Intersection ('∩')
Disjunction ('or,' '∨')	Span of the two linear subspaces ('Sp')

Note that the definition of "conjunction" does not differ from the classical one in the sense that applied to closed linear subspaces, set-theoretical intersection does not take us outside that class. On the other hand, the definitions of "disjunction" and "negation" cannot employ set-theoretical complementation and union: When applied to linear subspaces, each takes us outside this class. The chosen correspondence of "disjunction" with "span" (i.e., the smallest closed linear subspace containing the sums of all vectors lying in either of the two spanned linear subspaces) and of "negation" with "orthocomplement" are mutually coherent, in the sense that they enable the preservation of the form (if not its semantical content, as shall be seen below) of the *tertium non datur,* the law of the excluded middle: 'A or not-A' is a tautology, or equivalently its negation 'A and not-A' is a contradiction (see below).

As a consequence of the non–set-theoretical definitions of negation and disjunction, the resulting operations are not truth-functional (Gibbins 1987, 135–136). Indeed, no consistent assignment of truth values to all three connectives is possible that preserves the relation between tautologies and inferences (Malament 2002, 16–18) (for the semantic implications, see "Semantic Problems" below). Recently, it has also been shown (see Pavičić and Megill 1999) that there are nonorthomodular lattice models that obey all the axioms of this quantum logic.

Various other logical concepts can now be defined by closed linear subspaces or relations between them. For example:

Logical concept	Closed linear subspace or relation between them
Tautology ('T')	The entire Hilbert space ('H')
Contradiction ('F')	The zero-dim linear subspace ('{0}')
Implication ('⇒')	Inclusion ('⊆')

Notice that these definitions do not differ from the classical ones in the sense that, as sets, the entire Hilbert space and the zero-dimensional linear subspace are both linear subspaces, and as applied to closed linear subspaces, set-theoretical inclusion is still meaningful. In the resulting lattice logic, both distributive laws relating conjunction and disjunction fail. Sometimes this has been taken to be the distinctive feature of quantum logic; but it is easily seen that lattice logics can be constructed for certain classical physical systems, in which the distributive law also fails (see Stachel 1986, 236–264).

It has been shown (see Megill 2005, where it is misnamed "implication") that there are five possible definitions of a lattice quantum-logical conditional as the closest possible approximation to the classical (Boolean) material conditional. In a certain sense, it does not matter which one is chosen: Any of these conditionals, together with negation, may be chosen as the only primitive operations in setting up lattice quantum logic. But no matter which is chosen, it does not have the desired relation to implication (see "Semantic Problems" below).

Partial Boolean Algebra Logic

As mentioned above, Strauss ([1936] 1972) introduced partial Boolean algebra logics in an attempt to formalize Bohr's concept of complementarity. The form of the elementary propositions is the same as in the lattice logic approach, but such propositions are now put into correspondence not with one-dimensional subspaces of the Hilbert space, but with the one-dimensional projection operators onto these spaces, with which they are in one-one correspondence. (A Hermitean operator P is a projection operator if and only if (*iff*) it is idempotent, i.e., if $P^2 = \mathrm{P}$.) The set of all these operators forms a partial Boolean algebra (defined below); and the logic is now read off from the structure of this algebra. Only those logical operations on propositions are allowed that correspond to operations on the corresponding projection operators that do not lead out of this algebra. While the sum of two projection operators P_1, P_2 (taken in either order) is always a projection operator and their addition is associative, their product is a projection operator *iff* they commute; and they commute only if

- The corresponding subspaces are orthogonal, in which case $P_1 \cdot P_2 = P_0$, where P_0 is the operator that projects onto the zero-dimensional linear subspace $\{0\}$; or
- One subspace is contained within the other: ($P_1 \subseteq P_2$), in which case $\mathrm{P}_1 \cdot \mathrm{P}_2 = P_1$.

Conjunctions and disjunctions of commuting projection operators P_1 and P_2 are defined as follows:

$$P_1 \wedge P_2 = P_1 \cdot P_2 \quad P_1 \vee P_2 = P_1 + P_2 - P_1 \cdot P_2.$$

(Conjunctions and disjunctions of noncommuting projection operators are excluded; they could be defined only "unnaturally," by first going to the corresponding linear subspaces, using the lattice definitions for these subspaces [see previous section], and then going back to the corresponding projection operators.) The negation of a projection operator $\neg P$ is defined by the complementary projection operator $I - P$, where I is the identity operator that projects onto the entire Hilbert space.

With these definitions, the set of projection operators forms a partial Boolean algebra (*pBa*). A *pBa* is a family of Boolean algebras B_i that obeys the following conditions:

1. If B_i, B_j are two members of the family, their set-theoretical intersection $B_i \cap B_j$ is also a member of the family. This implies that there are unique common zero (P_0) and unit (I) elements that belong to each of the B_i values.
2. Given three elements, such that any pair of them belong to some Boolean algebra (possibly different ones for different pairs) in the family, then there is a Boolean algebra in the family such that all three elements belong to it.

In the resulting *pBa* quantum logic, commuting operators correspond to compatible propositions, and each set of all mutually compatible propositions forms one of the Boolean algebras in the family. Since conjunction and disjunction are defined only for compatible propositions, one cannot make simultaneous assertions about incompatible propositions. Thus a sentence like "The particle has position x and momentum p" is not a well-formed proposition, so it cannot even be called false!

Partial Boolean algebras are closely related to orthoalgebras (see Wilce 2002), which play an important role in logics based on the consistent histories approach to quantum mechanics (see below).

Semantic Problems

In the previous two sections, syntactical characterizations of two quantum logics have been given, with some hints about the semantic interpretation of their propositions. But for them to be regarded as true logics, a full semantic interpretation must be given. The results of Gleason (Hooker 1975, 123–133; Dvurečenskij 1993), Specker (Hooker 1975; 135–140), and Kochen and Specker (Hooker 1975, 263–292) present formidable obstacles to a monotonic semantic interpretation of any bivalent lattice quantum logic. In the standard propositional calculus, a truth function exists for any Boolean algebra of propositions; i.e., the propositions can all be mapped onto the set $\{T, F\}$ in such a way that once truth values have been assigned to the elementary propositions (a valuation), the usual truth tables hold for all propositional connectives. In other words, the values of truth and falsity can be consistently applied to all the propositions in a Boolean lattice.

Gleason showed that no such truth function can exist for the quantum-mechanical lattice of subspaces of a Hilbert space of more than two dimensions. So a truth-valued semantics for lattice quantum logic is out. The problem arises from the existence of "incompatible" propositions in lattice quantum logic. Classical logic assumes that any proposition that has been asserted once in an argument can be asserted again at any later stage of that argument. Yet, even in many ordinary (i.e., non–quantum-mechanical) situations, this may fail to be the case for propositions that do not include an explicit specification of the implied background conditions. For example, the various states of matter (solid, liquid, gaseous, and plasma) are incompatible with each other. So a statement such as 'The hardness of a certain sample of some metal has such and such a value' may be asserted as a proposition (correctly or incorrectly) only as long as the metal is in the solid state; if the sample is later melted or vaporized, such a statement can be regarded as either false or meaningless. One way out of such difficulties is to consider such statements as propositions only when sufficient background conditions are added to make them "eternally" true or false—for example, 'The hardness of a certain sample of some metal has such-and-such a value under such-and-such conditions of temperature and pressure.' Classical logic is perfectly adequate to treat such propositions. Alternatively, one might continue to treat the incomplete statements as propositions, and modify one's logic in a way that admits incompatible propositions, such as 'The hardness of a certain sample of some metal has such-and-such a value' and 'The viscosity of the same sample has such-and-such a value'—each of the two statements having a possibility of being true or false only when the sample is in a solid or liquid state, respectively (Stachel 1986, 249–264). While a perfectly

respectable way of handling such propositions, such a modification of logic hardly sheds new light on the existence of several incompatible states of matter, or on their respective properties of hardness and viscosity.

What Can Quantum Logic Do?

As suggested earlier (see "What Is a Quantum-Mechanical Proposition?" above), a rather similar situation is obtained in quantum mechanics. As Bohr (1958) emphasized, as long as the only statements admitted as propositions concern what he calls "phenomena," there is no need to go beyond classical logic in the treatment of such propositions. If one chooses to drop the description of the experimental arrangement and admit such "bare" statements as 'The position of the particle is x' as a proposition, then one must have recourse to a nonclassical logic in the treatment of such propositions. But, as in the classical case, it is hard to see how such recourse leads to a deeper understanding of those features peculiar to quantum mechanics often considered paradoxical.

The following example has been cited (see e.g., Putnam 1969) to show how the failure of the distributive law in lattice quantum logic leads to a deeper understanding of quantum mechanics: In this logic, as in classical logic, any statement of the form "The particle has position x and momentum p_i" (which shall be abbreviated "$X \wedge P_i$") is meaningful; but in lattice logic it is always false ($X \wedge P_i = \phi$, the absurd proposition), because $X \cap P_i = \{0\}$, the zero-dimensional linear subspace. Hence, the conjunction of such statements for all possible values of the momentum is false ($S = \sum_i (X \cap P_i) = \phi$) because the union of any number of exemplars of the zero-dimensional linear subspace is still $\{0\}$. On the other hand, the statemen: 'The particle has momentum p_1 or the particle has momentum p_2 or .... or the particle has momentum p_N,' where the list runs over all possible momenta (complications arising from a denumerably infinite or continuous set of values of quantities are ignored in the case of $\sum_i \vee P_i$), is always true ($\sum_i \vee P_i = I$), because $\sum_i Sp(P_i) = H$, the entire Hilbert space. So the statement S', "The particle has position x and (the particle has momentum p_1 or the particle has momentum p_2 or.... or the particle has momentum p_N)" ($S' = X \wedge (\sum_i P_i) = X \wedge I$) is true iff the statement "The particle has position x" is true ($S' = X$). If the distributive law held, S (which is always false) would be identical to S', which may be true or false—a clear contradiction. The failure of the distributive law means that there is no contradiction involved if S and S' fail to have the same truth value.

These formal manipulations are certainly correct. But what insight is gained in terms of the *meaning* of the relevant propositions? S' seems to assert that the particle has a definite position and *some* momentum. But this is a false appearance, due to an implicitly classical reading of the disjunction of momenta proposition. 'The particle has momentum p_1 or the particle has momentum p_2 or ... or the particle has momentum p_N' is true only because of the quantum-logical definition of "or" as the span of the relevant linear subspaces: The span of all the one-dimensional orthogonal linear subspaces representing possible values of the momentum is the entire Hilbert space; so the assertion of this disjunction proposition amounts to no more than the trivial assertion 'The system exists.' It will continue to hold true for states in which the momentum fails to have a definite value—in particular, for the state under consideration, in which the position *does* have a definite value! Thus the compound proposition S asserts no more than the simple proposition "The particle has position x," and really has nothing to do with its momentum.

An even simpler example of how the seemingly classical nature of a quantum-logical law conceals a quite perverse meaning of its quantum-logical equivalent is provided by the law of the excluded middle, $A \vee (\neg A) = T$, which corresponds to the linear subspace $A \cup \mathrm{Sp}(\perp A)$. Classically, the law asserts that either a certain property or propositional holds true of a system or it does not. But lattice-logically, since $A \cup \mathrm{Sp}(\perp A) = H$, the entire Hilbert space, which corresponds to the trivial proposition ('The system exists'), the law has nothing to do with whether one may always assert one of the two alternatives, 'The system has property A' or 'The system does not have property A.' The most it does (via its negation) is show that *if* one is able to assert one of the alternatives, then one cannot assert the other.

Finally, note that quantum logics are always weaker than classical logic, which manifests a tendency to maximal definiteness (see Waismann 1968). Indeed, Gödel (1930) proves the completeness of the classical first-order predicate calculus: Every tautology of this calculus can be proven; and addition of a further (extensionally inequivalent) proposition to the set of tautologies would lead to contradictions. In other words, classical first-order logic cannot be strengthened; any nonclassical first-order calculus can represent only a *weakening* of the classical one; that is, in such a calculus, certain

classical tautologies will be false for some valuation(s) of the primary propositions. Kochen and Specker (Hooker 1975, 263–276) showed this explicitly by construction for certain *pBa* values arising in quantum mechanics. As discussed above for the case of quantum-mechanical propositions, classical logic will always be valid if propositions are stated with sufficient attendant conditions to ensure that they will always be either true or false; and the possibility of nonstandard logics that weaken the first-order predicate calculus arises from the admission as propositions of statements that omit certain of these attendant conditions.

Operational or Dialogic Approaches

Various operational or dialogic logics, based on the temporal sequence of possibly incompatible assertions, have been proposed as aids in the interpretation of quantum mechanics. One gives up the assumption that once a proposition is asserted in an argument, it can always be reasserted at any later stage. Although there seems no reason why this need be the case, this observation has often (e.g., Lorentzen 1965) been associated with the dialogic approach to logic, which attempts to found logic on the formulation of a successful strategy to defend a proposition in dialogue with an opponent. This approach has been applied to quantum mechanics (Mittelstaedt 1978). Hintikka (2002) bases his approach on an extension of first-order logic that he argues is needed for many cases in which mutually interdependent properties are present. All of these are "logic(s) for" approaches to quantum logic:

> Putnam proposes changing logic for physics' sake; my starting point is a change in (or, rather, an extension of) basic logic for logic's sake, or more explicitly, for the sake of the expressive power of a logical language. ... [O]nce this extension has been carried out, we do not need any separate new quantum logic. (Hintikka 2002, 208)

Consistent-Histories Approach

The quantum logics considered so far start from the concept of the *state* of a system at each instant of time—or at least the state of the system's properties, or propositions about its properties, at each instant. An alternative approach to quantum mechanics (see "Probability Amplitudes and Feynman Paths" above) is based on the concept of *process*, a conditional probability being associated with the entire development of a system between two instants of time (preparation and registration). In nonrelativistic (i.e., Galilei-invariant) quantum mechanics, a unique link between the state and process approaches exists: The time interval of any process is uniquely divided into instants of absolute time, and a state is associated with each instant. But in the case of relativistic" (i.e., Lorentz-invariant) quantum mechanics or quantum field theory, such a unique division does not exist (indeed, the initial and final instants need not be parallel timelike hyperplanes, or even hyperplanes at all) in Minkowski space-time. In non–flat background space-times, timelike hyperplanes generally do not exist, so the process approach is much more natural in relativistic cases. Even in nonrelativistic quantum mechanics, the process approach has much to recommend it. As noted earlier, the basic task of any quantum-mechanical formalism is to compute a probability amplitude for a process; and the state function is an auxiliary computational device (see "Prediction, Retrodiction, and State Functions" above).

In contrast to the Feyman approach (see "Probability Amplitudes and Feynman Paths" above), the recently developed consistent-histories approach (Isham 1994, 1995, and 1997) treats quantum systems as closed; it asserts that under certain conditions, it is possible to assign *probabilities* to collections of individual paths associated with a given process, or at least to collections of subensembles of such paths, or *histories,* even if these paths cannot be distinguished within the experimental arrangement defining the process. For any two histories α, β a decoherence function $d(\alpha, \beta)$—a complex number of modulus ≤ 1—may be calculated using standard quantum mechanics as if intermediate measurements had been made. It is then assumed that this function is meaningful even in the absence of such intermediate measurements.

A set of such histories is said to be *complete* if the physical realization of any one history would exclude that of all the others; and, if this set of alternatives is chosen for testing, then one of them must be realized. The set is *d-consistent* if $d(\alpha, \beta)$ vanishes for any distinct pair in the set. If these conditions hold, the probability that any history α in the set will be realized is $d(\alpha, \alpha)$, and the sum $\sum d(\alpha, \alpha) = 1$.

There are many complete, mutually incompatible *d*-consistent sets of histories; and since the system is closed, one cannot adopt the usual Feynman interpretation and say that the choice of a preparation and registration apparatus fixes one of them. The coherent-histories proposal is to consider all of these sets together, in an interpretation of "many world-views" (Isham 1997) of quantum mechanics.

Such a collection of sets has the structure of an *orthoalgebra* (see e.g., Wilce 2002; Dvurečenskij et al. 2002), a collection of Boolean algebras pasted together into a structure similar to a partial Boolean algebra (see "Partial Boolean Algebra Logic" above). A probabilistic logic can be associated with this structure by associating a proposition with each history α, i.e., "The system followed history α during the process." The set of propositions form a nonbivalent logic that falls within the general class of intuitionistic logics, for which the distribution law holds, but the law of the excluded middle fails. Rather than valuations in which propositions are either true or false, consistent-history propositions are associated with probabilities, that is, valuations in the interval [01]. Isham proposed this "logics for" approach in the hope of developing a structure of sufficiently broad scope to be applicable to background-independent formulations of quantum gravity.

Conclusion

The final word on quantum logic may be left to Bohr (1939): "The question of the logical forms which are best adapted to quantum theory is in fact a practical problem, concerned with the most convenient manner in which to express the new situation that arises in this domain."

JOHN STACHEL

QUANTUM MEASUREMENT PROBLEM

While there are many problems surrounding the account of measurement in quantum theory, the so-called problem of measurement in quantum theory refers to a specific difficulty that has plagued its interpretation from early in its history and that continues to defy a widely accepted resolution. This entry addresses the problem primarily in terms of the relevant features of the formalism of standard quantum theory, and the usual account of measurement in quantum theory. However, as will be emphasized throughout, the problem of measurement is more generic than the terms in which it will be primarily described here, for it arises in every known quantum theory, in some form or other, regardless of the details of the formalism or the account of measurement (see Quantum Mechanics).

In briefest form, the problem is this: At the end of measurement-like interactions (between a measured system and a measuring apparatus), quantum theory sometimes (indeed, generically) assigns the "wrong" state to physical systems (henceforth "systems"), including systems that are apparently the objects of everyday observation. The wrong state of a system refers to a state whose standard interpretation fails to assign properties to the system that are apparently directly observed (for example, the property apparently enjoyed by many everyday objects of having a very well defined location in space). While the details to follow are important for a clear understanding, this simple statement of the problem should be kept firmly in mind.

Quantum States

States as Probability Measures

In quantum theory, the "state" of a system, S, is a probability measure, a function from the possible values of all physical quantities (such as position and energy, henceforth "observables") to numbers between 0 and 1, whose intended interpretation is the "chance" that S has the given value for the given observable. (How one understands these chances is a matter of interpretation, discussed below.) For each observable, the probability measure is "complete" in the sense that the sum of the probabilities for each possible value of a given observable is 1. The classical ("ignorance") interpretation of this fact would be that the system does in fact have one of the possible values, but which value it has is unknown. For example, in classical statistical mechanics, the state of a gas is a probability measure over all of the possible configurations of molecules in the gas. The usual understanding of this measure is that the gas has

just one of these possible configurations, the probabilities arising purely from our ignorance about which configuration it is. For now, however, do not adopt this interpretation, nor any other.

Mixed versus Pure States

To get started on the task of interpretation, it helps to distinguish between "mixed" and "pure" states. Given two states, σ and σ', which, recall, are probability measures, one can form their "mixture," $\sigma'' = p\sigma + (1 - p)\sigma'$, with $0 < p < 1$. The mixture σ'' is a "mixed state." (Mixtures can contain an arbitrary number of states, but two is enough for the purpose of exposition.)

One appropriate use of mixed states is to describe a system whose actual state is unknown. For example, if the system is chosen randomly from an "urn" of systems, some in the state σ and some in the state σ'', in the proportion p to $1 - p$, then one should assign the system the mixed state σ''. In the standard parlance, mixed states that arise in this way are called "proper mixtures," as opposed to "improper mixtures," considered below.

Pure states are states that cannot be written as mixtures. Reflection on this definition produces a more positive characterization of pure states. Pure states are, intuitively, states of maximal information. For present purposes, the simplest account of that notion is this: A state is pure if and only if it assigns a definite value to some maximally specific (henceforth "maximal") observable A in the sense that it assigns probability 1 to one of A's possible values, and probability 0 to the rest.

Here and below, one should not presume that the qualifier "maximal" is essential to the statement of the problem of measurement. Its presence is for technical convenience. An observable A is maximal if it is not the coarse-graining of any other observable; that is, there is no other observable B such that there is a many-to-one map, m, from the possible values of B onto the possible values of A, where for any possible value b of B, every state that assigns probability 1 to b also assigns probability 1 to $m(b)$.

In quantum theory, any state that assigns a definite value (in the sense defined above) to a maximal observable is indeed a state of maximal information (a notion that can be made mathematically precise). In classical physics, states of maximal information assign definite values to *all* observables. In quantum theory, there are, provably, no such states. Instead, every pure state assigns a definite value to some maximal observable, and assigns nontrivial probabilities (that is, probabilities that are neither 0 nor 1) to the values of other observables.

The Standard Interpretation of Pure States

For the moment, it suffices to adopt the interpretation of mixed states mentioned above, *viz.,* that they represent ignorance about the actual, pure state of a system. (This interpretation is controversial, though standard in the case of so-called proper mixtures.) Note, however, that an interpretation of the probabilities in a mixed state does not necessarily carry over to the probabilities generated by a pure state (henceforth "quantum probabilities")—indeed, there are serious obstacles to a straightforward ignorance interpretation of quantum probabilities, a point discussed below.

It is helpful to begin with a minimal interpretation of quantum probabilities, one that is often adopted in applications, the so-called "eigenstate-eigenvalue link," which is a system in the state σ has the value a for the observable A if and only if σ assigns probability 1 to a and (therefore) probability 0 to the other possible values of A. (Such a state is necessarily an eigenstate of A corresponding to the eigenvalue a—hence the name *eigenstate-eigenvalue link,* coined by Fine [1969].) The measurement problem, in a very naive form, amounts to the fact that some quantum states fail to assign definite values to the results of a measurement, given the eigenstate-eigenvalue link. This fact is intimately connected with the principle of superposition in quantum theory.

Superpositions

Consider some maximal observable A and two possible values for it, a and a'. Let the state σ assign probability 1 to a, and let σ' assign probability 1 to a'. (Such states always exist. The requirement that A be maximal is only for ease of exposition.) The principle of superposition says that one can form a third pure state, σ'', with the following properties:

1. σ'' assigns a probability to the value a for A strictly between 0 and 1, and similarly for the value a';
2. σ'' assigns probability 0 to all values of A except the values a and σ'.

In the context of the eigenstate-eigenvalue link, the principle of superposition is curious at best, for it implies the existence of a state (σ'') in which the system has neither the value a nor the value a' for the observable A, and yet the probability that it has some other value is 0.

In any case, it is crucial to keep in mind that the superposition of two pure states is itself *pure*, not mixed. Classically, too, there are states having

properties 1 and 2 given above; however, such states are necessarily mixed, and in this case, one could adopt an ignorance interpretation. On the other hand, superpositions are pure, and (at this stage of the discussion) their interpretation is given by the eigenstate-eigenvalue link. The existence of superpositions ultimately gives rise to the problem of measurement.

Measurements

Constraints on Measurement

The problem of measurement is perhaps misnamed, for it arises generically in quantum theory, not only in the context of a measurement. However, the problem is particularly clear in the context of measurements, which makes it a useful starting point.

A measurement establishes a correlation between some observable for the measured system (typically called the "measured observable") and some observable for the measuring apparatus (the "pointer-observable"—one can imagine, literally, a needle that points to a number on a scale). In the ideal case, the pointer-observable is perfectly correlated with the measured observable.

Noting that a measurement is a dynamical process, it is natural to make the following (extremely!) minimal requirement for a measurement. Let U represent the time-evolution of states during the measurement of a measured observable A by a pointer-observable B, so that if σ is the state of a system at the start of the measurement, then $U(\sigma)$ is the state after the measurement. We require: For any two states, Σ and Σ', of the compound system (the measured system plus the apparatus), if Σ and Σ' differ in their probabilities for at least one value of A, then $U(\Sigma)$ and $U(\Sigma')$ differ in their probabilities for at least one value of B. Intuitively, U renders the pointer-observable "somehow sensitive to" the measured observable B.

The Quantum-Theoretic Representation of Measurements

There are models of measurements satisfying this weak constraint. Indeed, there are models satisfying the following stronger, though still natural, constraint: Let Σ and Σ' each assign probability 1 to the (distinct) values a and a' of A, respectively; then $U(\Sigma)$ and $U(\Sigma')$ must assign probability 1 to two distinct values of B. That is, under these conditions, U establishes a perfect correlation between the values of A and B. (If the compound system's state continues to assign probability 1 to the value a for A, then the measurement is said to be "of the first kind," or "nondisturbing." In general, measurements are *not* nondisturbing.)

In general, given any time-evolution describing any sort of interaction between two systems, there will be many observables in the two systems that become correlated (though generally not perfectly) as a result of the interaction. In other words, interactions between systems will, most of the time, establish the sort of correlation that is sufficient to satisfy the weak constraint on measurements. Hence whatever problems flow from meeting this weak constraint will be quite generic to quantum theory—and the measurement problem does flow more or less directly from the imposition of this weak constraint.

On the other hand, the problem follows very directly from the stronger constraint, and it is therefore helpful to consider that more restricted version of the problem first. One should keep in mind, moreover, that there are interactions, which apparently occur in the real world, that satisfy the strong constraint. Actual measurements are not an example of such interactions, if one measures success as establishing a perfect correlation between the *intended* pointer-observable and the *intended* measured observable. However, the lack of a perfect correlation between these two observables does not imply that there are not two *other* observables (one for the measured system and one for the apparatus) between which the measurement *does* establish a perfect correlation. Indeed, one can prove that after just about any interaction between two systems, there almost always is a pair of (nontrivial) observables—one for each system—that is perfectly correlated. (The proof is by way of the biorthogonal decomposition theorem, and the point was recognized by Schrödinger [1935].)

The Problem

The State at the End of a Measurement

It is a straightforward consequence of the considerations above and the formalism of quantum theory (specifically, the linearity of the equation of motion) that if U satisfies the strong constraint, then there are initial states for the measured system (specifically, states that are superpositions of two or more eigenstates of the measured observable A) such that, at the end of the measurement, the state of the compound system is a superposition of eigenstates of B, so that, according to the eigenstate-eigenvalue link, the measuring apparatus has no definite value for the pointer-observable.

(Strictly speaking, one should say not "the observable B," but "the observable $B \times I$," which is an observable on the compound system whose value is determined solely by the value of B on the apparatus, so it "ignores the measured system.") One can conceive the reason as follows: In the context of the formalism of quantum theory, the strong constraint on measurement essentially requires that the state of a measuring apparatus must "formally mimic" the state of the system that it is measuring. When the system that it is measuring has a definite value for the measured quantity, then mimicking is exactly what one wants, of course. The problem is that when the measured system is in a superposition of definite-valued states for the measured quantity, the same requirement implies that the apparatus will, again, mimic the state of the measured system, but, alas, in this case "mimicking" means that the apparatus is itself in a superposition of definite states of the pointer-observable.

It is also worth noticing that as a result of the measurement, the measured system becomes entangled with the apparatus. While this fact is perhaps not, strictly speaking, a problem, some find it counterintuitive that merely as a result of measurement, the measured system (and apparatus) come to lack their own pure states.

Proofs of the More General Problem

Perhaps the first notable "proof" of the problem more or less as we have just considered it was von Neumann's ([1932] 1955) derivation, which demonstrated, roughly, that in a nondisturbing measurement (see above) satisfying the strong constraint, the final state of the apparatus must be a superposition of eigenstates of the pointer-observable. A series of increasingly more general proofs followed, for example from Wigner (1963), d'Espagnat (1966), Earman and Shimony (1968), Fine (1969), and Shimony (1974). A review of this history, together with arguably the simplest proof of the theorem formulated by Fine and later reconsidered by Shimony, was given by Brown (1986).

Two features of these theorems (particularly the later ones) are notable here. First, they do *not* adopt the eigenstate-eigenvalue link, but a much weaker condition on when observables have values. Second, they adopt (more or less) the weak, rather than the strong, constraint on measurements.

The interpretive condition that these theorems adopt is, roughly, that the final state of the apparatus assigns a definite value to the pointer-observable for the apparatus just in case the final state of the compound system is a mixture of states each of which has a definite value for the pointer-observable according to the eigenstate-eigenvalue link. In other words, they allow the adoption of an ignorance interpretation of mixed states of the compound system, accepting that when the compound system has the sort of mixed state just described, it is actually in one of the pure states appearing in the mixture, and therefore, according to the eigenstate-eigenvalue link, the apparatus has a definite value for the pointer-observable.

Note that the condition applies to the *compound* system, *not* to the apparatus on its own. The difference is subtle, but crucial. For example, in an ideal measurement, the apparatus by itself will *always* be in a mixture of (pure) eigenstates of the pointer-observable. It does not follow, however, that this mixture can be given an ignorance interpretation.

Why not? The short answer is that the mixture, in this case, is improper, meaning that it does not arise in the way that proper mixtures do (described above), but rather from ignoring the rest of the universe, in this case, the measured system. (Formally, the improper mixture is obtained by tracing out the degrees of freedom corresponding to the measured system.) One cannot straightforwardly adopt an ignorance interpretation of this improper mixture. The following considerations illustrate the difficulty.

Let I represent the logically trivial property possessed by all systems. For any two properties, P and Q, of two arbitrary systems, 1 and 2, let the compound property "system 1 has P and system 2 has Q" be denoted $P \wedge Q$ and the compound system be denoted $1 \wedge 2$. Consider the following, seemingly innocuous, principle: If system 1 has the property P, then $1 \wedge 2$ has the property $P \wedge I$.

This principle is violated by an interpretation that supplements the eigenstate-eigenvalue link with an ignorance interpretation of improper mixtures, for let the compound system be in a superposition of two states, each of which assigns (according to the eigenstate-eigenvalue link) a definite value for A to system 1, and a definite value for B to system 2. This superposition is, of course, a pure state, but the subsystem 2 is in an improper mixture of eigenstates of B. According to the proposed interpretation, then, subsystem 2 has a definite value for B. (Similar remarks hold for subsystem 1.) However, according to the eigenstate-eigenvalue link, the compound system does *not* have any value for the compound observable $A \times B$, thus leading to a violation of the seemingly innocuous principle above. (So-called "modal" interpretations of quantum theory attempt, in various ways, to dance around this issue and adopt an

ignorance interpretation of [at least some] improper mixtures. The literature on this topic is vast, but see Bacciagaluppi (2003) for a lengthy discussion, with plenty of references.)

Hence, if one prefers to hold on to the apparently innocuous principle, then it is advisable to allow the ignorance interpretation only for (proper) mixtures of the total, compound system, and not for the improper mixed states of the components. Brown and his predecessors took this path. Doing so at least allowed them to consider the case—more general than that considered in many expositions of the measurement problem—in which the initial state of the compound system is mixed. The point is that in this case, allowing an ignorance interpretation of mixed states for the compound system, and insisting on only a very weak notion of what constitutes a measurement, one can still show that in quantum theory, measurements can lead to states for the compound system in which the apparatus does not have any definite value for the pointer-observable.

False Starts and Discredited Answers

There are many initially appealing, but ultimately insufficient, responses to the problem of measurement. A few of the most important or prevalent are considered here.

The Ignorance Interpretation of Quantum Probabilities

Probably the most obvious response to the problem of measurement is to question the proferred interpretation of quantum probabilities. Why not adopt a straightforward ignorance interpretation, according to which each observable in fact has a definite value all of the time, the quantum probability representing ignorance about the actual value? Adopting such an interpretation would certainly resolve the problem of measurement, because all observables, and *a fortiori* all pointer-observables, always have a value.

However, various theorems, most notably that of Kochen and Specker (1967), pose serious challenges to an ignorance interpretation. Kochen and Specker derive a contradiction from a few presuppositions, including that every quantum-theoretic observable has a definite value. The presuppositions of their derivation can be understood in various ways, but no matter how they are understood, violating them is a radical move. For example, one way to violate them is to deny the logical law of distributivity. While some have taken this route, clearly it is controversial. In any case, the main point is that the theorem of Kochen and Specker renders any naive ignorance interpretation of quantum probabilities untenable.

The Collapse Postulate

The practical response to the problem is the collapse postulate: At the end of a measurement, if the compound system is in a superposition of eigenstates of the pointer-observable, the state of the compound system ''collapses'' onto just one element in the superposition, corresponding to the actual result of the measurement. Such a collapse, which is a discontinuous change of state, contradicts the (continuous) equation of motion in quantum theory. Hence one would like a systematic principle, internal to the theory, dictating when such collapses occur. While there are adequate rules of thumb about when to collapse the state, there is no such agreed-upon principle. (A further discussion of the collapse postulate, and reasons for rejecting it as an interpretive principle, is in Dickson 1998, Chs. 1–2, with references therein.)

An additional problem for the collapse postulate is that it introduces a fairly explicit form of nonlocality into the theory. Given a pair of entangled systems that are well separated in space, suppose that a measurement is made on one of them. The result, in this view, is a collapse of the state. However, such a collapse will effect the state of the distant system as well. While there are arguments about why such a collapse does not violate the letter of the law of relativity, and while quantum theory is in general nonlocal independently of the collapse postulate, nonetheless that postulate does introduce a form of nonlocality that some find objectionable.

Decoherence

An increasingly common response to the problem of measurement appeals to decoherence. Very briefly: If the description of a measurement is made to take into account the interaction of the measuring apparatus with its environment (for example, the electromagnetic radiation in the environment), one can show (given careful though admittedly idealized modeling of this interaction) that the compound system composed of the apparatus and its environment itself undergoes an approximately nondisturbing measurement-like interaction in which the pointer-observable becomes the observable measured, by the environment. But the discussion above already entails that in this case (to a high degree of approximation), the state of the

apparatus at the end of the interaction is a mixture of eigenstates of the pointer-observable. Hence, the suggestion goes, simply adopt an ignorance interpretation of this mixture, and conclude that the pointer-observable does, in fact, have a definite value.

Given the discussion above, however, the problem with this response should be clear. The mixture in question is improper, and so cannot straightforwardly be given an ignorance interpretation. Something more by way of interpretation *must* be said to justify this interpretation.

Decoherence does, however, help with (though it does not resolve) the most general form of the problem of measurement. In its most general form, the problem is that quantum theory apparently fails to assign definite values to observables that appear, on the basis of everyday observation, to have definite values. In the special case of a measurement, at least the state of the apparatus is a mixture, albeit improper, of "desired" states. A task for interpreters of the theory, then, is somehow to parlay this fact to secure the definiteness of the pointer-observable. But what about interactions that are not explicitly measurements? What can one say about the states of the subsystems involved in the interaction? Decoherence promises to secure the following: If the subsystem is "relatively large" (e.g., $>10^{-5}$cm across), its interaction with the environment will entail that (very quickly) its state will become (very close to) a mixture, albeit improper, of desired states. The qualifiers "very quickly" and "very close to" should not be ignored, but at the same time, one must admit that decoherence does seem to reduce the most general form of the problem of measurement to the more specific form that arises in explicit measurements. (An excellent discussion of decoherence, focused on explaining why it is not sufficient to resolve the problem of measurement, is in Bub 2000, 207–218.) Even so, however, this strategy has merely reduced the general problem to one that continues to elude a satisfactory solution.

QUANTUM MECHANICS

Quantum mechanics has been a subject of intense philosophical discussion for well over 75 years, and research on the philosophy of quantum mechanics continues apace. Undoubtedly, much progress has been made—especially in answering questions about the mathematical structures used in quantum mechanics. However, when it comes to spelling out the philosophical implications of quantum mechanics, there continue to be pronounced disagreements. At one extreme, some claim that the

moral of quantum mechanics is a negative one about the limited applicability of human concepts; that is, the concepts humans have developed to cope with everyday experience do not apply without restriction to the phenomena encountered in quantum mechanics. So, the upshot is that one must pay special attention to whether the proper conditions are in place for applying these concepts. At the other extreme, some claim that quantum mechanics supplies positive evidence for the existence of multiple universes, and that each time a measurement occurs, the universe divides itself again. Between these two extremes there is a wide variety of competing interpretations of quantum mechanics, and the range of philosophical options is both intimidating and exhilirating.

The Old Quantum Theory

It is often said that the introduction of quantum mechanics has brought about a radical change in our physical worldview. In particular, it is claimed, quantum mechanics is inconsistent with the intuitive picture supplied by classical mechanics. Thus, in order to understand what is supposed to be so revolutionary in quantum mechanics, it is necessary first to review the main features of classical mechanics.

Modern classical physics reached its definitive form in the "Hamiltonian" formulation of mechanics introduced in the mid-nineteenth century (see Classical Mechanics). In this formalism, the instantaneous state of a physical system is described by its generalized positions (q_i) and momenta (p_i). For example, the instantaneous state of a system of k particles is specified by $6k$ real numbers ($q_1, \ldots, q_{3k}, p_1, \ldots, p_{3k}$). The set of all such instantaneous states is called the phase space of the system. Moreover, the dynamics of systems in classical Hamiltonian mechanics is fully deterministic; that is, for any initial state $s(0)$, there is a unique state $s(t)$ for any future time t.

Classical statistical mechanics often investigates situations in which there is no certain knowledge of the precise microstate of the system. In this case, the instantaneous state of the system is represented by a probability distribution ρ over phase space. Furthermore, if the initial state is ρ, then the future state of the system can be computed by applying the deterministic dynamical laws to the individual points in phase space, and then by reapplying ρ. Thus, there is no difficulty in seeing apparent randomness at the macroscopic level as arising from a strictly deterministic dynamics of microsystems (see Statistical Mechanics).

Quantum Statistics

During the nineteenth century, classical statistical mechanics achieved many successes in explaining the macroscopic properties of bodies (e.g., the temperature of a gas) in terms of motions of their constituent atoms (which are subject to the laws of Newtonian particle mechanics). However, not all physicists were convinced of the atomic hypothesis. In particular, many believed that electromagnetism, rather than mechanics, would serve as the proper foundation for physics. As a result, efforts were being made to explain macroscopic quantities in terms of more fundamental electromagnetic quantities.

One crucial test case for this new statistics of radiation was the emission of radiation by a black-body. A black-body is the perfect mixer of electromagnetic radiation: No matter what frequency of radiation it absorbs (and it absorbs any frequency), it re-emits a range of frequencies of radiation whose intensities are a function only of the temperature of the body. The theoretical explanation for this fact is that the atoms in a black-body behave as small harmonic oscillators. When radiation is absorbed, these oscillators vibrate, each with some characteristic frequency.

Wilhelm Wien proposed that the energy density per unit frequency depends on frequency f and temperature T according to the formula $u(f, T) = af^3 \exp(-bf/T)$, where a and b are empirically determined constants. Although Wien's formula agreed with the available data (which were restricted to fairly high frequencies), its theoretical basis was suspect.

At roughly the same time, Lord Rayleigh and James Jeans showed that if classical statistical mechanics is applied to the oscillators in a black-body, the resulting distribution is given by the formula $u(f, T) = 8\pi f^2 kT$, where k is the Boltzmann constant. Clearly, the Rayleigh-Jeans formula diverges from Wien's in the range of high frequencies ($f \gg 1$), and so it disagrees with the empiricially observed values for the radiation distribution. But things get worse: the equipartition theorem of classical statistical mechanics entails that the distribution of energy over frequencies would tend toward a uniform distribution over the various degrees of freedom. But the higher frequencies are associated (classically) with higher energies, and therefore the system would tend toward an "ultraviolet catastrophe."

Experiments performed in 1900 by Lummer and Pringsheim showed that Wien's formula was inaccurate for radiation at low frequencies. In order to take account of this new data, Max Planck

proposed the distribution $u(f, T) = af^3[\exp(bf/T) - 1]^{-1}$ that agrees approximately with Wien's formula in the case of high frequencies ($f \gg 1$), and with the Rayleigh-Jeans formula in the case of low frequencies ($f \ll 1$). Planck then supplied a theoretical derivation of his formula by assuming that an oscillator of frequency f can have an energy value only in the discrete set $E = hnf$, where h is a positive constant (now known as *Planck's constant*) and n ranges over the positive integers. (The constant b in Planck's formula turns out to equal h.) Moreover, since there are fewer ways to distribute energy among higher frequencies than among lower frequencies, statistical considerations entail that it is unlikely the energy would be concentrated among the higher frequencies. Thus, the ultraviolet catastrophe is avoided.

While Planck quantized the energy of the oscillators in a black-body, he did not quantize the energy of the electromagnetic field itself. It was Einstein, in 1905, who took this more radical step. (Kuhn [1978] argues that Planck did not intend to introduce quantum discontinuity, and its origin is properly traced to Einstein's 1905 paper.) Einstein noticed that for high frequencies, the formula for the entropy of black-body radiation has the same logarithmic volume dependence as the entropy of an ideal gas. The latter dependence results directly from the fact that the energy in an ideal gas is localized in molecules. So, Einstein inferred the same for high-frequency radiation, whose energy, he proposed, could be treated thermodynamically as if it is localized in units of hf (i.e., "light quanta"). He then went on to show that the light quantum hypothesis explains phenomena such as the photoelectric effect.

Bohr's Atomic Theory

As of 1912, the best available model of the atom was Rutherford's solar system model, according to which an atom consists of negatively charged particles (electrons) orbiting a dense nucleus of positive charge. However, Rutherford's model had a fatal defect: According to classical electrodynamics, an orbiting electron will radiate at a constant rate (proportional to the square of the magnitude of its acceleration) and will thereby quickly decelerate. In fact, an orbiting electron would spiral into the nucleus on the order of 10^{-10} seconds, which would entail a radical instability of matter.

Meanwhile, it was also known that atoms emitted characteristic frequencies of light when heated. When the emitted light is passed through a prism, the resulting frequencies of electromagnetic radiation satisfy some rather simple arithmetical relations. For example, the visible spectrum of hydrogen is given by the Balmer series:

$$f(m) = R\left(\frac{1}{2^2} - \frac{1}{m^2}\right), \qquad (1)$$

where R is Rydberg's constant (approximately 109,737.3 cm^{-1}), and m is an integer greater than 2.

In a trilogy of papers in 1913, Niels Bohr proposed a "quantized" version of Rutherford's model of the hydrogen atom. Bohr's model not only solved the stability problem of Rutherford's model, but also explained the observed spectrum. Bohr's model is based on two fundamental postulates:

1. An atom has a discrete set of 'stationary states' that correspond to constant values of its total energy. In these stationary states, the mechanical properties of the electrons, (e.g., the relations between the radius, orbital angular momentum, and kinetic energy) are governed by classical mechanics. However, an atom does not emit radiation while in a stationary state (in violation of classical electrodynamics).
2. In certain circumstances, an atom will make a transition from one stationary state to another. But these transitions cannot be described by classical mechanics. Rather, during the transition the atom emits radiation of a single frequency (i.e., corresponding to one spectral line). If the energy of the initial state is $E(n)$, and the energy of the final state is $E(m)$, then the emitted radiation has frequency

$$f(n,m) = h^{-1}[E(n) - E(m)], \qquad (2)$$

where h is Planck's constant.

More concretely, Bohr determined that the energy of the nth stationary state is $2\pi^2 m_e e^4 h^{-2} n^{-2}$, where m_e is the mass of the electron, and e is the charge of the electron. It follows then from equation 2 that

$$f(2,m) = 2\pi^2 m_e e h^{-3}\left(\frac{1}{2^2} - \frac{1}{m^2}\right). \qquad (3)$$

If the known values for m_e, e, and h are plugged in, then the leading coefficient $2\pi^2 m_e e h^{-3}$ agrees with the empirically ascertained value for the Rydberg constant R. Thus, Bohr's frequency formula (equation 2) supplied a theoretical derivation of the Balmer series. Bohr's model also supplied an accurate value for the ionization energy $|E(1)|$ of hydrogen (i.e., the energy needed to remove the

electron to an infinite distance from the nucleus), and for the diameter of the hydrogen atom in its ground state. In summary, Bohr's proposal was hugely successful, and it placed the idea of quantization at the forefront of theoretical physics.

Quantum Conditions

Following Bohr's quantization of the hydrogen atom, several research groups began to pursue similar lines of inquiry. Among these groups, Arnold Sommerfeld and his collaborators in Munich are especially noteworthy for their attempts to provide a systematic and mathematically rigorous framework for quantum theory.

Sommerfeld's (1919) quantization recipe involves two steps: First, describe the classically permissible motions of the system (i.e., those that satisfy the appropriate dynamical laws). Then impose "quantum conditions" to pick out a proper subclass of permissible motions. In particular, since the laws of classical Hamiltonian mechanics are deterministic, each point in phase space lies on a unique phase orbit—i.e., the set of points that can be reached from that point by a classical trajectory. The quantum conditions rule out all but a certain subclass of trajectories. In particular, suppose that a system is described by the canonical variables $(q_1, \ldots, q_k, p_1, \ldots, p_k)$. Then the points on a permissible phase orbit satisfy the k equations $\oint p_i(q_i)d_{qi} = n_i h$, where the n_i are positive integers. [The variables' q_i values are assumed to be periodic, and the integral is taken over one period. For a system with one degree of freedom, the function $\oint p(q)dq$ evaluated at point x gives the area enclosed by the phase orbit through x and has the units of action (=energy $\times$ time).] The number n_i is called the "quantum number" of the corresponding phase orbit. Thus, each stationary state of a system with k degrees of freedom is specified by a k-tuple of quantum numbers.

For example, for an electron in a circular orbit around a nucleus, the standard choice of canonical variables are the angle $q = \theta$, and the orbital angular momentum $p = mr^2(d\theta/dt)$. In this case, $\oint p(q)dq = (2\pi)p$. Thus, the quantum condition requires that the orbital angular momentum is an integral multiple of $h/2\pi$. Combining this with the classical-mechanical equation for the kinetic energy of the orbiting electron entails that the energy of the system is $E(n) = 2\pi^2 m_e e^4 n^{-2} h^{-2}$, where n is a positive integer, in agreement with Bohr's derivation of the energy levels of the hydrogen atom.

In his original treatment of the hydrogen atom, Bohr made the simplifying assumption that the orbiting electron has one degree of freedom (corresponding to the radius of its orbit). In the more general treatment, a hydrogen atom is a system with three degrees of freedom, which can be given in spherical polar coordinates (r, θ, ϕ) for the orbiting electron. In this case, a stationary state of the atom is specified by three quantum numbers nr, $n\theta$, nϕ. Alternatively, a stationary state can also be specified by three numbers (n, k, m), where the principal quantum number $n = nr + n\theta + n\phi$ determines the energy; the azimuthal quantum number $k = n\theta + n\phi$ determines the total angular momentum; and the magnetic quantum number $m = n\phi$ determines the z-component of the angular momentum.

Sommerfeld's algorithm for quantization was succesfully applied to atoms in which a single electron orbits a positively charged shell (i.e., "hydrogenic" atoms). For example, by introducing the magnetic quantum number, Sommerfeld and Debye were able to explain the Zeeman effect, in which an atom's spectral lines separate into multiple lines ("multiplets") when it is placed in a magnetic field. However, the old quantum theory proved inadequate in application to multielectron atoms, even of the most simple sort (e.g., helium, in which two electrons orbit the nucleus). In particular, the old quantum theory gave incorrect predictions for the higher frequencies in the spectrum of helium, and for the ionization potential of helium. There were also a number of phenomena for which the old quantum theory simply could not provide any account—including the anomalous Zeeman effect (in which multiplet spectral lines recombine when the intensity of the magnetic field is increased), and the appearance of doublets in the spectrum of the alkali atoms. What is more, since there is no mechanically stable configuration for two (or more) electrons orbiting a single positively charged nucleus, the idea that the mechanical properties of stationary states can be treated classically could not be maintained. Indeed, it seemed that a more radical revision of classical physics was needed in order to supply a unified and empirically adequate account of atomic phenomena.

Quantum Mechanics

In the mid-1920s, two powerful new formalisms for quantum theory were introduced by Erwin Schrödinger and Werner Heisenberg, respectively. On the one hand, Schrödinger hoped to eliminate discontinuous transitions between stationary states by formulating a theory of "wave mechanics" in which a chargefield propagates through space

according to a deterministic equation of motion. On the other hand, Heisenberg wanted to reformulate quantum theory on the basis of observable quantities (e.g., frequencies of spectral lines) and to rid it of unobservables (e.g., electron trajectories). The resulting formalism of noncommuting observable quantities was called matrix mechanics. For a short period of time, the existence of two competing quantum theories caused significant tension within the physics community. However, it was soon shown by von Neumann that there is a mathematical isomorphism between the theories of Schrödinger and Heisenberg. In fact, both theories can be subsumed under the more general Hilbert space formalism. In this formalism, states (or wavefunctions) are represented by vectors in a Hilbert space, and physical quantities (or observables) are represented by operators in this space.

The salient features of the Hilbert space formalism can be illustrated by looking at the space V of vectors in three-dimensional Euclidean space, i.e., arrows of variable length and direction with tails fixed at the origin (0, 0, 0). (In actuality, Hilbert spaces make use of complex numbers, but that detail is not important here.) The space V is equipped with two operations. First, for every vector $v \in V$ and real number a, there is a vector av that results from "stretching" v by the length a. (If a is negative, then av points in the opposite direction than v.) Second, if u and v are vectors in V, then the vector $u + v$ is defined by the following operation: Move the tail of the vector v along u, keeping their relative angles fixed, until the tail of v lies on the head of u; then, $u + v$ denotes the vector whose head coincides with the head of the transported vector. Let $\|v\|$ denote the length of the vector v.

(Thus, if the head of v lies at the point (a, b, c), then $\|v\| = (a^2 + b^2 + c^2)^{\frac{1}{2}}$.) If u and v are vectors, then their inner product is defined by

$$\langle u, v\rangle := \|u\| \cdot \|v\| \cdot cos\theta, \tag{4}$$

where θ is the angle between u and v.

More generally, a Hilbert space $\mathcal{H}$ is a vector space over the field of complex numbers C, with an inner product $\langle \cdot\ , \cdot\rangle$, and limit points for all of its Cauchy sequences (i.e., any sequence $\{vn\}$ of vectors that become arbitrarily "close" for large n). Vectors $u, v \in \mathcal{H}$ are said to be orthogonal if $\langle u, v\rangle = 0$. A subset W of vectors in $\mathcal{H}$ is called a subspace if when $u, v \in W$ and $a \in C$, then $av \in W$ and $u + v \in W$. In other words, a subspace of a Hilbert space is a subset that is itself a Hilbert space. In the case of R^3, there are two sorts of proper subspaces: Lines passing through the origin (one-dimensional), and planes passing through the origin (two-dimensional).

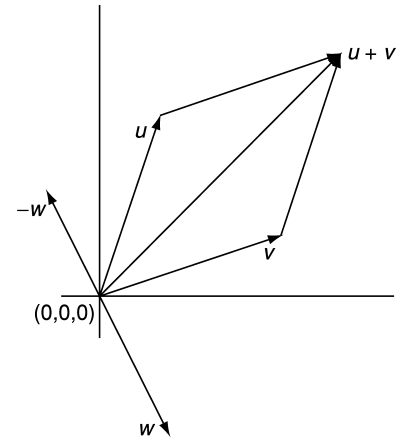

Fig. 1. Vector space operations.

An operator O on a Hilbert space $\mathcal{H}$ is a mapping that transforms vectors to vectors and that preserves linear relations. That is, $O(v + w) = Ov + Ow$ and $O(cv) = c(Ov)$ for any vectors v, w and for any complex number c. There is one special type of operator on Hilbert space that is particularly important for quantum mechanics. Let W be a fixed subspace of $\mathcal{H}$. Then for any vector $v \in V$, there is a unique closest vector $E_W v$ to v in W. (That is, $\|E_W v - v\| \leq \|w - v\|$ for all $w \in W$.) The vector $E_W v$ is called the projection of v onto W; and the mapping that takes v to $E_W v$ is called the projection operator onto W.

With this terminology in place, the "statistical algorithm" of quantum mechanics can be formulated as follows:

1. Assumption 1. Each quantum-mechanical system is associated with a Hilbert space $\mathcal{H}$, and its pure states are represented by rays (i.e., one-dimensional subspaces) in $\mathcal{H}$.
2. Assumption 2. Experimental yes-no questions (e.g., "Is the second particle located in the region Δ?") are represented by projection operators on $\mathcal{H}$.
3. Assumption 3. If the system is in state v, then the probability that an experimental question E will receive an affirmative answer is $\text{Prob}^v(E) = \|Ev\|^2$.

The projection operators that correspond to a single quantity are pairwise compatible—that is, their operator product is commutative—which is typically taken to mean that they can be measured simultaneously. On the other hand, projections corresponding to conjugate quantities (e.g., position and momentum) do not commute with each other.

Interpretations of Quantum Mechanics

Quantum mechanics and its descendant, quantum field theory, have yielded empirical predictions of unprecedented accuracy. However, quantum mechanics by itself does not supply any unconditional statements about how things are when no measurement is being performed. (As some philosophers have put it, quantum mechanics supplies only probabilities conditional upon certain measurements being performed.) Thus, quantum mechanics is analogous to an uninterpreted formal system, and an interpretation of quantum mechanics would supply a class of models that entail the conditional probabilities of quantum mechanics (Stein 1972).

It is often said that the primary obstacle to interpreting quantum mechanics is the superposition principle, which says that any two quantum states can be superposed to form another quantum state. In particular, if u and v are state vectors, then $w = c_1u + c_2v$ is a state vector (when $|c_1|^2 + |c_2|^2 = 1$), called a superposition of u and v. The state w shows different faces, depending on what measurements are performed. On the one hand, if E_u and E_v are measured, then w looks like an ignorance mixture of u and v. In particular, in a long run of experiments performed on systems prepared in w, a measurement of E_u will get a positive response in $(100 \times |c_1|^2)\%$ of the trials, and a measurement of E_v will get a positive response in $(100 \times |c_2|^2)\%$ of the trials. On the other hand, a system prepared in state w always gives a positive response to E_w, and this is a feature that no ignorance mixture of u and v can have. In particular, systems whose states are either u or v will occasionallly give a negative response to E_w, and so an ensemble of systems in states u and v is empirically discriminable from a system in state w.

The superposition principle is also the source of the nonlocality in quantum mechanics (see Locality). In particular, suppose that $v \otimes w$ is a "conjunctive" state of a pair of systems—that is, $v \otimes w$ is the state in which the first system is in state v and the second system is in state w. Suppose that x is another state of the first system, and y is another state of the second system. Then the superposition principle entails that $2^{-\frac{1}{2}}(v_1 \otimes w_1 + v_2 \otimes w_2)$ is a state of the composite system. Since, however, this state is not a simple conjunction of states of the component systems, it is called an "entangled" state.

According to the orthodox (Dirac–von Neumann) interpretation of quantum mechanics, the property represented by Ev is objectively indeterminate (i.e., neither possessed nor not possessed) when the system is in a state w such that $0 < \text{Prob}^w(E_v) < 1$. More generally, the orthodox interpretation says that a system possesses a property E only if its state assigns probability 1 to E; and E is not possessed only if the state assigns probability 0 to E. (This pair of conditions is often called the eigenstate-eigenvalue link.) When neither of these conditions hold, E is objectively indeterminate.

However, this objective indeterminacy never manifests itself directly to observers. That is, in any single case, an observer who checks for the property E will find that it either is or is not possessed by the system. Thus, although E may initially be indeterminate, it becomes determinate whenever it is measured. In order to accommodate this fact, the orthodox interpretation claims that a measurement of E forces the quantum state to "collapse" onto a state that is either completely in the range or completely in the null space of E.

- Projection Postulate. If E is measured in state v, and the outcome is positive, then the final state is $\|E_v\|^{-1} E_v$. If the outcome is negative, then the final state is $\|v - E_v\|^{-1}(v - E_v)$.

(See Dirac 1958, 36; von Neumann 1932, Ch. 6). In the absence of a measurement interaction, the state of a quantum system changes deterministically, as dictated by the Schrödinger equation. However, when $0 < \text{Prob}^v(E) < 1$, the projection postulate permits two possible postmeasurement quantum states. So, according to the orthodox interpretation, there are two types of processes in quantum mechanics: the deterministic process that occurs in the absence of measurement, and the indeterministic process that occurs as the result of a measurement (see Quantum Measurement Problem). Since quantum mechanics itself is sometimes (mistakenly) identified with its orthodox interpretation, it has been claimed that quantum mechanics is an inherently indeterministic theory (see Determinism).

The orthodox interpretation of quantum mechanics has been criticized for many reasons, but most severely for its claim that the standard rule for dynamical evolution is suspended in measurement processes. For one, there is no precise criterion for distinguishing "measurement" interactions from other physical interactions, and so invocations of the projection postulate have to rely on imprecise judgments (Bell 1990).

There are essentially three lines of response to the standard criticisms of the orthodox interpretation. First, some claim that measurements are in fact distinguished from ordinary interactions in that they involve a nonphysical object, *viz.,* the mind of a conscious being (Wigner 1962). However, this

solution has been rightly criticized as conceding the incompleteness of the quantum-mechanical description of measurement. Second, some claim that the standard dynamical law of quantum mechanics—which is linear and deterministic—never holds exactly, but is just an approximation of the true dynamical law, which is stochastic and nonlinear (Shimony 1993, I.4). It is hoped that this new dynamical law would be able to explain the appearance of a determinate macroworld by showing that when systems similar to a human observer (e.g., large, heavy) interact with microsystems, then the former end up in states that can count as having registered a definite outcome. This idea has been taken quite seriously, and as a result, there are now a number of worked-out theories of dynamical wavefunction collapse (see e.g., Ghirardi, Rimini, and Weber 1986). However, one should be clear that these theories are replacements for, rather than interpretations of, quantum mechanics. In particular, these theories do not attempt to interpret or explain microscopic superpositions. Furthermore, while these theories are in principle empirically distinguishable from standard quantum mechanics, the experiments that could decide between them would be extremely difficult to carry out in practice.

Finally, the third response to the problems with the orthodox interpretation is to reject the projection postulate altogether. Thus, according to "no collapse" interpretations, quantum mechanics applies universally to all physical systems, and since measurements do have outcomes, the eigenstate-eigenvalue link must fail. There are essentially two types of no-collapse interpretation. On the one hand, some no-collapse interpretations claim that measurements do not have unique outcomes, appearances notwithstanding. For example, Everett's relative state interpretation (Barrett 2001) and Kochen's relational interpretation (Kochen 1985) both deny that a successful measurement has a single outcome. On the other hand, those no-collapse interpretations that maintain the uniqueness of observed measurement outcomes postulate "hidden variables" in order to account for these outcomes.

Hidden Variables

As noted previously, quantum mechanics predicts that there are measurements in which the state of the system does not uniquely fix an outcome. Thus, if the quantum-mechanical state provides a complete physical description, then there are some facts, *viz.,* that one measurement outcome obtains rather than another, that simply have no physical explanation.

Einstein maintained throughout his career that the quantum-mechanical description should be considered incomplete and that physicists should be searching for a more fundamental theory that will underwrite its statistical predictions. In contrast to Einstein, Bohr maintained that the quantum-mechanical description is complete. Einstein and Bohr had a long series of debates over this question, leading eventually to Einstein's famous proposal of the Einstein-Podolsky-Rosen thought experiment (Bohr 1949).

The question of whether quantum mechanics could be supplemented with hidden variables was given a mathematical formulation by von Neumann (1932). In particular, he asked whether it is mathematically possible to enlarge the space of quantum-mechanical states so as to include states (analogous to points in phase space) that determine the answers to all experimental questions. Of course, if nothing further is required of these hypothetical completed states than that they map the projection operators into $\{0, 1\}$, then it is trivially true that such completed states exist. However, in order for the completed states to have some explanatory power, the values they assign to operators should reflect the algebraic relations of these operators (since these commutation relations are supposed to have some physical significance). For example, for any pair of orthogonal projections, a state should assign 1 to at most one of the two.

Von Neumann formulated his requirement on hidden variables in terms of expectation values. He claimed that if A and B are operators (representing physical observables), then the hidden state should assign the operator $A + B$ the sum of the expectation values that it assigns to A and B. (Of course, the expectation values of quantum states satisfy this requirement.) He then proved a representation theorem that shows that any such state (at least in the pure case) is represented by a ray in Hilbert space. Thus, there are no "hidden" states. Von Neumann (1932) concluded that

> it is therefore not, as is often assumed, a question of a reinterpretation of quantum mechanics,—the present system of quantum mechanics would have to be objectively false in order that another description of the elementary process than the statistical one be possible. (325)

John S. Bell (1966) was the first to point out explicitly that von Neumann's linearity requirement may be too stringent. Nonetheless, Bell himself went on to show that von Neumann's result

goes through—aside from the exceptional case where the state space is two-dimensional—even with a weakened version of the linearity assumption (the result was proved independently by Kochen and Specker [1967]). In particular, a hidden state is said to be partial-linear just in case it is linear with respect to simultaneously measurable observables. Bell then pointed out that it follows from Gleason's representation theorem, according to which all pure probability measures on the lattice of subspaces of a Hilbert space $\mathcal{H}$ are represented by rays in $\mathcal{H}$, that all partial-linear states are represented by rays in $\mathcal{H}$. Thus, if physical states must be represented by partial-linear functionals, then there are no hidden states.

Bell pointed out, however, that even the strengthened result has a loophole, because it assumes that hidden states are noncontextual—i.e., that propositions about systems have a truth value *simpliciter,* independent of contextual features (such as which measurements are being performed on distant systems). For example, suppose that E, F_1, and F_2 are projections such that E is jointly measurable with either F_1 or F_2, while F_1 and F_2 cannot be measured simultaneously. Now, the Bell-Kochen-Specker theorem assumes that a hidden state assigns a value (either 0 or 1) to E without any reference to whether F_1 or F_2 is measured along with E. But this can be denied; indeed, it is precisely by employing contextual value assignments that Bohm's hidden variable theory escapes the conclusion of the Bell-Kochen-Specker theorem.

The de Broglie–Bohm Theory

In his 1924 Ph.D. dissertation, Louis de Broglie proposed that for each type of physical particle (e.g., photon, electron), there is a corresponding type of wavefield that guides the particle's motion. In particular, de Broglie proposed that the equation $p = h/\lambda$ supplies the link between the momentum (p) of a particle and the wavelength (λ) of the corresponding wave. Although de Broglie's idea received some confirmation through the discovery of diffraction effects with electrons, it was soon squashed by the then-dominant orthodox interpretation of quantum mechanics. In 1952, David Bohm independently rediscovered de Broglie's idea and developed it into a full-blown (empirically equivalent) alternative to quantum mechanics. According to Bohm's theory, the quantum state ψ plays two roles: Its squared modulus $|\psi|^2$ gives a classical probability distribution over particle positions, and the gradient of its phase defines a field that guides the trajectories of individual particles. The resulting dynamics of individual processes is completely deterministic; the apparent randomness and indeterminism of quantum mechanics can be shown to follow from the impossibility of keeping track of the trajectories of individual particles.

The Bohmian probability distribution over particle positions reproduces the distribution that the quantum state assigns to the position observable Q. Thus, Bohm's theory can be thought of as the (unique) hidden variable theory, in which Q always has a definite value, regardless of the quantum state (see Bub and Clifton 1996). Moreover, Bohmians claim that operators that do not commute with Q do not represent genuine physical quantities, and purported measurements of these quantities can be interpreted as complicated position measurements (cf. Dürr, Goldstein, and Zanghì 1996).

Bohm's theory provides an explicit counterexample to any attempt to prove the impossibility of hidden variables. It also shows that quantum mechanics does not logically entail indeterminism. But critics are quick to point out that Bohm's theory has its own share of counterintuitive consequences. For one, it undermines the traditional understanding of space-time structure: there are no inertial trajectories of particles, and the nonlocal dependence of the values of hidden variables on measurement contexts violates the spirit, if not the letter, of special relativity. Nonetheless, some claim that quantum mechanics by itself is non-local, and so non-locality cannot be thought of as a peculiar drawback of Bohm's theory (Albert 1992; Maudlin 2002). But this position is by no means unanimous, and the debate over the locality issue continues (see Locality).

It has also been claimed that Bohm's theory is inconsistent with the principle of faithful measurement—that is, that the outcomes of measurements reflect the values that quantities possessed prior to measurement. (However, Bohmians will reply that this result is not surprising, since these unfaithful measurements are of pseudoquantities.) Finally, it has been claimed that Bohm's theory arbitrarily privileges position over momentum (which play symmetric roles in the canonical commutation relations). In fact, it has been claimed that one could formulate an alternative Bohmlike interpretation in which momentum is always definite (Stone 1994). However, Bohmians are likely to claim that there are good philosophical and physical reasons for privileging position over momentum (e.g., interaction terms in a system's Hamiltonian are typically functions of position and not of momentum).

Modal Interpretations: Dieks and van Fraassen

Let M be a measuring device, and let O be an object system. The state space of the composite system $M + O$ is represented by the tensor product $V_1 \otimes V_2$ of the state spaces of M and O (see Locality). A postmeasurement state v of $M + O$ will typically be entangled, in which case there is no property that O possesses with probability 1. Thus, the orthodox interpretation (which maintains the eigenstate-eigenvalue link) invokes the projection postulate to change the entangled state v into a product state.

Modal intepretations attempt to give a rule for picking out the definite properties of O without collapsing the postmeasurement state. The key move made by these interpretations is to make a distinction between the "dynamical state" of the composite $M + O$ (i.e., the state that changes deterministically, as if no special measurement process occurred), and the "value state" of the object system O (i.e., the state that determines the observed outcomes of a measurement of O). According to the *biorthogonal decomposition theorem*, for any state v of $M + O$, there is a set $\{y_1, \ldots, y_n\}$ of unit-length vectors in V_2, and coefficients λ_i (all between 0 and 1) such that

$$\text{Prob}^{v}(E) = \sum_{i=1}^{n} \lambda_i \, \text{Prob}^{yi}(E), \qquad (5)$$

for all experimental questions pertaining to the object system. So, ignoring the measuring apparatus M, the state v looks just like an ignorance mixture of $\{y_1, \ldots, y_n\}$. According to Dieks's modal interpretation, the value state of O is some y_i (which one obtains is not determined by the dynamical state), and in this case the real properties are those represented by projection operators that are compatible with E_{yi}. According to van Fraassen's modal interpretation, the value state of O can be any state x that is "possible relative to v" (i.e., not orthogonal to all of the y_i), and in this case the real properties of O are those compatible with E_x. In both cases, the set of real properties is constrained in some way by the quantum state and typically has different members at different times.

One argument put forward in favor of modal interpretations is that they solve the measurement problem by means of a "minimal" revision of standard quantum mechanics (without the projection postulate). However, it has also been argued that these interpretations do not provide a general solution to the measurement problem (Albert 1992, appendix). (For a summary of these debates, see Vermaas 1999, chap. 10.) In terms of being a minimal revision of standard quantum mechanics, it can be shown that the set of real properties in Dieks's modal interpretations is definable in terms of the quantum state alone (Clifton 1995; Vermaas 1999). Thus, modal interpretations do not need to invoke extraneous philosophical arguments for privileging certain properties over others—in contrast to Bohm's claim that position is privileged, and to Bohr's claim that the measured observable is privileged. However, modal interpretations have also been criticized for not providing a plausible dynamics for their hidden states. On the one hand, some modal interpreters (e.g., van Fraassen 1997) reply that a satisfactory interpretation of quantum mechanics does not need to supply dynamics for its hidden states. On the other hand, attempts to work out explicit dynamics for the hidden states have yielded some unpleasant results (Vermaas 1999; Dickson and Clifton 1998).

Bohr's Complementarity Interpretation

According to Niels Bohr's complementarity interpretation of quantum mechanics (see Complementarity), it is appropriate to speak about different quantities in different "measurement contexts." In particular, there are contexts in which it is appropriate to speak of an ensemble of particles with definite positions; and there are contexts in which it is appropriate to speak of an isolated system that is subject to dynamical conservation laws; but there is no single context in which it would be appropriate to employ both of these modes of description, which are complementary. Thus, to a first approximation, Bohr's interpretation can be seen as the (unique) nocollapse interpretation in which the measured observable R is always determinate (see Bub and Clifton 1996). Note, however, that in this interpretation, the set of real properties is not fixed by the quantum state (as in Dieks's modal interpretation), nor does it remain invariant (as in Bohm's interpretation). But what then determines which quantity it would be appropriate to speak about? Is the preferred determinate observable picked out by something physical (e.g., the Hamiltonian of the measurement interaction), or does it correspond merely to a perspective from which the object is viewed?

Other Interpretations

There are many other interpretations of quantum mechanics besides those previously mentioned.

Three of the most prominent are Everett's relative state interpretation (and its numerous philosophical spawn; see Barrett 2001), the consistent histories interpretation (see Griffiths 2001), and relational interpretations (see Mermin 1998; Rovelli 1996). The first two of these interpretations have been gaining ground recently among quantum cosmologists who argue that an observer-independent interpretation of quantum theory is needed in order to apply quantum mechanics to the universe as a whole.

Conclusion

Much of the landscape of contemporary philosophy of science has been shaped in some way or other by issues that arise in the foundations of quantum mechanics. Conversely, attitudes toward the interpretation of quantum mechanics reflect trends in the general philosophy of science. In particular, while many early attempts to interpret quantum mechanics (e.g., by members of Bohr's institute in Copenhagen) had operationalist overtones, more recent efforts have focused on developing "realistic" interpretations. Whether any of these realistic interpretations is adequate and plausible remains a matter of debate.

WILLARD VAN QUINE

(25 June 1908–25 December 2000)

Willard Van Quine was born in Akron, Ohio, and died in Boston, Massachusetts. He took an undergraduate degree in mathematics from Oberlin College in 1930. In 1932, he completed a Ph.D. at Harvard University with a dissertation in logic that generalized and simplified a portion of Whitehead and Russell's *Principia Mathematica.* From 1932–1933, traveling on a fellowship in Europe, Quine spent five months in Vienna, where he attended meetings of the Vienna Circle and met such notables as Schlick, Waismann, Gödel, Hahn, Reichenbach, and Ayer (see Vienna Circle). Six weeks in Prague brought the beginning of the famous personal and professional relationship between Quine and Rudolf Carnap (see Carnap, Rudolf). Quine then studied logic with Tarski, Leśniewski, and Łukasiewicz while in Warsaw for six weeks. In 1936, following three years as an inaugural Junior Fellow at Harvard, Quine took a faculty position at Harvard, teaching there (but for his service in the United States Navy during World War II) until his retirement in 1978. Quine published prolifically throughout his career until the year of his death.

Quine emerges from a tradition within analytic philosophy that has been called scientific philosophy. This tradition is characterized by a concern for the epistemology and ontology of science, logic, and mathematics; the exploitation of developments in logic and set theory; and an antipathy toward speculative metaphysics (Hylton 2001). In particular, Quine's work is best understood against the backdrop of Vienna Circle logical empiricism, especially the work of Carnap. Allowing for some necessary simplification, the logical empiricists were concerned to portray science as a unified system of knowledge, including not only logico-mathematical knowledge and the so-called hard sciences, but also psychology, sociology, and history (see Logical Empiricism). While the positivist conception of science was broader than typically portrayed, it is, of course, not the case that every claim of every discipline qualified as scientific. To so qualify, a claim or statement had to pass a test of cognitive significance by being either analytic (true solely in virtue of the meanings of constituent terms) or synthetic (empirically confirmable or disconfirmable) (see Cognitive Significance). Any claim that was neither analytic nor synthetic was considered cognitively meaningless, thus unscientific.

This conception of the analytic and the synthetic served a number of interrelated ends in the logical empiricist program. First, the claim that the truths of logic and mathematics are analytic provides an empirically respectable account of the supposed a priori status of logico-mathematical knowledge. The relevant claims are true in virtue of meaning alone, so no particular state of the world is relevant, and thus no appeal to observation is relevant. Yet neither is an appeal to special intuition or nonempirical realms required—understanding of the language is the key justifying component of such knowledge.

Second, the empiricist characterization of synthetic claims was central to providing an account of the unity of the a posteriori portion of science. In the early days it was thought that every synthetic claim would strictly reduce to (translate into) some claim in a basic observational language. This language would include vocabulary sufficient for logic, set theory, and some form of observational claim. The exact nature of the observational claims was much debated, even after strict reductionism had been abandoned. If feasible, this would show that all genuinely synthetic claims are ultimately about possible or actual observations. But strict verificationist reducibility of theoretical claims to observational claims is not to be had (see Reductionism; Verifiability). The required relation had to be loosened to some form of implication of observational claims by the theoretical (Carnap 1936–1937). In any case, the requirement that synthetic claims must be related to observable circumstances in ways to be made clear through logical analysis supports the notion of the unity of science (see Unity and Disunity of Science)—for every nonanalytic claim would bear the same (type of) relation to observational claims, and the process of confirmation would be fundamentally the same. Thus,

with no fundamental epistemological or ontological distinctions made among synthetic claims, no fundamental distinctions of methodology or ontology were made among the sciences. Whether one is considering physics, psychology, sociology, or whatever else, to be scientific, the claims of the discipline had to be either analytic or synthetic.

Third, in this understanding of legitimate theorizing, much traditional philosophy was to be swept aside as unscientific. One might wield the requirement of cognitive significance like a scythe—cutting down any claim that failed to be either clearly analytic or clearly synthetic, thereby eliminating a host of metaphysical claims and problems. Or one might take a more considered, clinical approach, as Carnap did. Many traditional philosophical disputes (idealism versus realism, for example) were seen as pseudoproblems—situations in which what appear to be contradictory claims regarding matters of fact are, according to Carnap, more fruitfully viewed as disagreements over which language (linguistic framework) should be adopted. Since adoption of a language is logically prior to the process of meaningful inquiry, nothing decidable by inquiry (that is, no matter of fact) is at issue. Rather it is a question of which language to adopt for the purposes of inquiry, and competing proposals can be assessed only on pragmatic (and, so, for Carnap, nonfactual) grounds. Thus, what traditionally would be taken as a deep dispute requiring metaphysical inquiry is cast by Carnap as a question not of truth, but of methodological and linguistic efficacy. Provided a proponent is clear about the structure of the language, tolerance reigns when considering the very loosely constrained questions of how perspicuous, simple, and fruitful the proposed framework might eventually prove.

While this view substantially deflates the status of philosophy as queen of the sciences, it does not completely relegate her to the position of intellectual handmaiden. The logical empiricists maintained a role for philosophy in the use of logic, set theory, and mathematics to analyze, clarify, and simplify the ground, structure, and results of empirical theorizing. Since those disciplines were understood to be analytic, philosophy itself is understood to be analytic (or the pragmatic investigation of analytic frameworks) and is not expected to make synthetic claims, or produce knowledge—such is the job of (and only of) unified science. Rather, philosophy is an a priori discipline of linguistic and conceptual analysis, maintaining a status independent of and methodologically distinct from empirical science. Far from playing a passive or merely organizing part, however, the analytic work of philosophy was projected to play a significant role in the advance of knowledge by illuminating the epistemology of science and helping to diagnose, cure, and prevent outbreaks of pseudoproblems.

Quine emerges from this tradition and inherits its concerns, but in rejecting the analytic/synthetic distinction he radically transforms the manner in which they are addressed. The conception of analyticity was central to the logical empiricists' semantics, epistemology, and dismissal of metaphysics; moreover, it marked the frontier between science and what remained of philosophical inquiry. In place of the picture sketched above, Quine offers a holistic semantics and epistemology that allows for only a difference of degree (not type) between so-called analytic and synthetic sentences. All meaningful sentences (including those of logic and mathematics) have at least remote observational import, not when taken individually, but only insofar as they are part of a set of claims (up to the whole of science) having observational implications. Quine's rejection of analyticity and the holistic epistemology and semantics anchor his naturalism—a view of science and philosophy as fundamentally similar in subject and method, differing only in degree of contact with empirical considerations. Mathematics and logic are viewed, not as analytic a priori, but as central strands of ongoing theorizing, thus participating in the empirical content of the whole theory. Philosophy and science (and "common sense") are on a continuum. In a sense, philosophy becomes science—though, as will be shown, this is a misleading turn of phrase.

Although Quine's importance is little disputed, there is much disagreement over the success and exact import of his rejection of analyticity and transformation of logical positivism and philosophy. Critical views of Quine range from those who aim to reject semantic holism (Fodor and Lepore 1992) and/or defend some form of the analytic/synthetic distinction (Boghossian 1997; Grice and Strawson 1956; Katz 1966) to those who read Quine as the revolutionary who could not, himself, see the full implications of his break with tradition (Rorty 2001). These disputes will be important at various points in this essay.

Two Dogmas, Analyticity, and Philosophy

Two Dogmas of Empiricism (Quine [1951] 1980) is often looked to as the decisive moment in Quine's rejection of analyticity, and, indeed, as a (if not *the*) decisive moment in the development of twentieth-century analytic philosophy. Rorty (2001), with

typical enthusiasm, hails it as the most important article of the century and writes that it "rocked the audience back on its heels." Such folkloric status is enhanced by its appearance right at the midpoint of the century—Quine presented the paper in December 1950 to the American Philosophical Association in Toronto, and it was published in *Philosophical Review* in January 1951—dividing the calendar perfectly. The date of Quine's death, moreover, nearly perfectly marks the silver anniversary of *Two Dogmas.* Yet, while it does contain the famous arguments against analyticity and the striking initial pronouncement of Quine's holism, and has been discussed and translated perhaps more than any other English-language article in philosophy, *Two Dogmas* must not be considered in isolation from its surrounding works. It constitutes only a part of Quine's attack on analyticity, and, in truth, contains only a sketchy statement of his metaphysical and epistemological views. Thus, a discussion of the article can be a starting point, but by no means an endpoint.

Quine opens *Two Dogmas* by proposing to examine the notion of analyticity (that certain truths are true in virtue of meaning and independently of fact) and the notion of reductionism (that each meaningful sentence is equivalent to some claim in an observational language). The ensuing criticisms strike at the center of the logical empiricist conceptions of science, the a priori, and philosophy.

Quine divides supposedly analytic truths into two classes: the logical truths and those that can be transformed into logical truths by appropriate substitution of synonyms (whether this classification exhausts the supposed analytic truths has been questioned; see, e.g., Boghossian 1997; Katz 1966). Quine proposes initially to take the first class for granted and focus on the second class of analytic sentences. Thus, *Two Dogmas* has very little explicit discussion of logical truths, even though his criticisms of the analyticity of logic are more fundamental than much of what goes on in *Two Dogmas*—this issue will resurface in greater detail further on. Since Quine focuses on statements that can supposedly be transformed into logical truths by appropriate substitution of synonyms, the initial problem is to gain a relevant understanding of synonymy, or sameness of meaning.

Definition is surveyed and rejected as helpful in explicating synonymy—for, Quine argues, definitions either depend on preexisting synonymies, thereby failing to explain them generally, or are explicit introductions of notational variants, again failing to explain the synonymy relation generally. Next, Quine considers the condition of interchangeability *salva veritate:* Two terms are synonymous if they can be interchanged in all contexts without change of truth value. The problem Quine finds is that in order to secure a relation stronger than mere coextension, one must either include a necessity operator in the language or modify the interchangeability requirement from preservation of truth value to preservation of analyticity. The latter is a nonstarter, as analyticity is what wants explanation. The former, though less obviously, is equally a nonstarter according to Quine. The only way he sees to make sense of a necessity operator is essentially to presuppose an understanding of analyticity; thus, again, one must presuppose what wants explaining. Quine concludes that explaining analyticity by way of synonymy fails.

Quine next considers an attempt to define analyticity directly, at least for artificial languages, via semantical rules. His complaint here is that while there are various ways of distinguishing a subset of the truths of some artificial language L and labeling them "analytic for L," this provides no understanding of what "analytic" means generally, for there is no indication of how this would generalize across languages ("S is analytic for L" with variable S and L), nor is there any indication of how the specific notion of analytic for L relates to the notion of analyticity for natural languages. Even if there were a specification of "analytic for L" that captured intuitions concerning natural language analyticities, no clarity would be gained, for the attempt to explain the natural language case was abandoned in hopes that an appeal to artificial languages would be more illuminating (though more on this below). As an alternate approach, the analytic truths of L might be specified by appeal to the semantical rules of L (for analyticity is supposed to have something to do with meaning relations). Then "S is analytic for L" (for variable S and L) becomes "S is true in virtue of the semantical rules for L." But, of course, "semantical rules for L" wants explaining in a general way, for any recursive specification of a set of truths of L could be labeled as semantical rules. Again, the proposal gives no way of identifying what the rules or analytic truths of one language supposedly have in common with those of other languages, no way of explaining a general notion of analyticity. Quine (1980, 37) concludes that belief in analyticity is an "unempirical dogma."

Quine then discusses reductionist verificationism. If, as the reductionist view claims, each meaningful statement could be translated into some statement in a logico-observational language, then

there would be an eminently clear criterion of statement synonymy (translating into the same observational claim), from which a criterion of term synonymy could be derived. This understanding of synonymy would then yield an understanding of analyticity. This strict form of semantic reductionism had already been discredited by the date of *Two Dogmas,* but Quine claims that the notion that a sentence has a specifiable content independently of other sentences still survives in the doctrine of analyticity. That doctrine encourages the idea that each sentence has a clearly specifiable content, while the idea of specifiable sentential content (left over from strict reductionism) encourages the idea that some sentences lack empirical content, that what content they have is not at all empirical but purely a question of meaning relations. Thus, discrediting the notion of specifiable sentential content discredits the notion of analyticity, for Quine sees the two as inextricably linked. Moreover, by underlining the failure of strict reductionism and extending its moral to the then current doctrines concerning the empirical content of supposedly synthetic claims, Quine is criticizing both sides of the logical empiricists' conception of the analytic/synthetic distinction.

In place of the notion of specifiable sentential content, Quine offers an early version of his semantic and epistemic holism. There is a strong remnant of logical empiricist verificationism here—Quine (1980) continues to countenance the notion of empirical content, but not of sentences taken individually: "The unit of empirical significance is the whole of science" (42). Following Duhem and Neurath (see Neurath, Otto; Duhem Thesis), Quine emphasizes the holistic nature of theory. Since no hypothesis has observational implications independently of a host of auxiliary hypotheses, there is, for Quine, no sense in which any theoretical claim is meaningful independently of the theory in which it is embedded. Moreover, since only a conjunction of hypotheses has observational implications, a failed prediction falsifies not a specific hypothesis, but a conjunction of hypotheses. Where the theory should be modified in order to defuse the implication and maintain consistency is underdetermined by the evidence. The falsification determines only that one or more of the conjuncts must be rejected or changed, but nothing determines which. On the basis of this underdetermination Quine claims that in the face of failed prediction, any sentence may, in principle, be maintained by making the necessary adjustments elsewhere in the theory. Conversely, any sentence may be revised, again, so long as the concomitant adjustments are made elsewhere. Quine even countenances the possibility of rejecting logical or mathematical laws in order to defuse the inference. All that is necessary, initially, is to block the inference leading to the false predictions. If rejection of a law of logic or mathematical claim will defuse the inference, then such an avenue is open. Since logic alone cannot determine how a theory must be revised, Quine claimed that pragmatic considerations (including conservatism and simplicity) figure into the choices made. Again, this follows Neurath's emphasis on the role of pragmatic concerns in theorizing. Neurath's conception of those concerns, however, was much broader than Quine's—for Neurath included social, economic, and political issues among the relevant considerations (Neurath 1983).

This latter claim of radical revisability is often taken as a further argument against the analytic/synthetic distinction, especially given the linkage of analyticity to apriority. For, if analyticity and apriority coincide (as the logical empiricists would have it) and if a priori claims are unrevisable (as is, perhaps, intuitive), then radical revisability would imply that there are no a priori truths, and so no analytic truths. Such a reading is encouraged by the opening of a famous paragraph of *Two Dogmas.* Quine (1980) has been discussing holism:

> If this view is right, it is misleading to speak of the empirical content of an individual statement—especially if it is a statement at all remote from the periphery of the field. *Furthermore it becomes folly to seek a boundary between synthetic statements, which hold contingently on experience, and analytic statements, which hold come what may.* Any statement can be held true come what may, if we wish to make drastic enough adjustments elsewhere in the system. Even a statement close to the periphery can be held true in the face of recalcitrant experience by pleading hallucination or by amending certain statements of the kind called logical laws. Conversely, by the same token, no statement is immune to revision. Revision even of the logical law of excluded middle has been proposed as a means of simplifying quantum mechanics; *and what difference is there in principle between such a shift and the shift whereby Kepler superseded Ptolemy, or Einstein Newton, or Darwin Aristotle?* (43) (emphasis added)

The first italicized portion suggests that Quine is appealing to mere revisability in his rejection of the analytic/synthetic distinction. But this common interpretation fails to account for the final lines of the paragraph and to take into account the views of Carnap, the main target of Quine's criticisms. Unrevisability was no part of Carnap's view of analyticity. Indeed, a central pillar of Carnap's

view was that competing analytic frameworks could be chosen or revised based on pragmatic considerations and that such changes are in principle different from changes made in the synthetic portions of theory. This is the heart of Carnap's deflation of metaphysics and the notion of the constitutive a priori. If Quine is appealing only to the revisability of supposed analytic claims, then this criticism flies wide of Carnap's conception. Thus, there must be more going on in the preceding paragraph, and it occurs in the final lines. Quine is appealing not just to revisability, but to there being no principled difference between the revision of supposedly analytic claims (e.g., logical laws) and supposedly synthetic claims (e.g., that planets move only in perfect circles).

The point for Quine is that any revision made to the overall theory is supposed to improve its fit with sense experience while maintaining as much simplicity and usability as possible. This is just what a theory is for Quine—a linguistic construct facilitating interaction with—and understanding of—the world, constrained by predictive test and pragmatic considerations of simplicity and efficacy. There is no difference of type in the considerations that might lead to the revision of a law of logic and those that might lead to the revision of a so-called synthetic claim. Rather, there are only differences of degree—a difference in how directly linked to observations a claim is, and a difference in the amount of readjustment a revision would require in the rest of the theory. The natural (and pragmatic) tendency toward conservatism and simplicity inclines theoreticians away from revising logic and mathematics and toward revising claims more closely linked to observation. Given this conservatism, revision of the more fundamental portions of theory (mathematics, logic, ontology), though always an option, will be considered only when either prediction meets with gross and extended failure in some domain, or some important and widespread gain of theoretical simplicity is in the offing (or both). Despite this difference in degree, and despite the difference in intellectual focus it occasions when revising theory, every decision to revise or accept a theory is a question not of this or that specific hypothesis, but of the whole theory. And any such decision is constrained by a combination of pragmatic and empirical considerations. Hence, for Quine, there is no difference of the kind Carnap conceived—no distinction between kinds of revision, between the analytic and the synthetic, between the purely pragmatic and the fully factual. Thus, setting aside some qualifications to be addressed below, Quine's holism and radical revisability do generate a further argument against analyticity. But it is the lack of a principled difference in kind of revision, not mere revisability itself, which is operative.

Finally, having rejected reductionism in favor of holism regarding empirical content, there is no need for analyticity as a special explanation for the supposedly nonempirical, a priori claims of logic and mathematics. Despite being linked to observation only remotely, logic and mathematics participate in the empirical content of the whole system, for they are ubiquitous in and essential to the inference of observational consequences from sets of hypotheses. The apparent unrevisability, apriority, and necessity of logic and mathematics are explained via the unwillingness to revise such central strands of theory and the usual availability of simpler revisions.

Note that despite how Quine opens *Two Dogmas,* holistic considerations do address the analyticity of logic (the first class of analytic claims). Indeed, the arguments against the semantic rule conception also address the analyticity of logic, though this may not be entirely transparent while reading *Two Dogmas.* But the full-fledged attack on the analyticity of logic and math occurs in *Truth by Convention* (Quine [1936] 1976a) and *Carnap and Logical Truth* (Quine [1960] 1976b).

It is in these pieces straddling *Two Dogmas* that some heavy work is done in attempting to dismantle Carnap's conception of analyticity. Indeed, it has been argued (most recently by O'Grady [1999] and George [2000], but see also Gregory [2003]) that *Two Dogmas* actually does very little to damage Carnap's conception of analyticity and the use to which he puts it. The main problem is that Carnap was not, ultimately, interested in explaining and grounding an analyticity distinction applicable to natural language, nor was he interested in a general definition of analyticity applicable across artificial languages. As Carnap ([1952] 1990) notes, all he himself is after is a formally articulated distinction within an artificial language that, to some extent, though by no means perfectly, captures intuitions regarding analyticity and that, more importantly, clearly delineates framework commitments from theoretical commitments. This is consonant with Carnap's overall metaphysical deflationism and his view of philosophy as a discipline of linguistic analysis aimed at clarifying and examining analytic frameworks. In order to contribute to the advance of knowledge by helping to diagnose, cure, and prevent outbreaks of pseudo-problems, a concept of analyticity may not need to be grounded in natural language or generalizable

across artificial languages. All that "analytic for L_0" need do, it seems, is adequately formalize and identify those sentences taken to be most fundamental to whatever theoretical conception is under examination. If "analytic for L_1" does the same for an alternate theoretical conception, then sufficient clarity has been gained for pragmatic issues of framework choice to be considered. If this view of Carnap's program is correct, then Quine's criticisms of analyticity for artificial languages appear simply to miss their mark. For the upshot of Quine's criticisms is that analyticity for artificial languages fails either to be nonarbitrary and generalize across languages or to capture and explain the concept of analyticity for natural languages. But on the above account, neither full generality nor explanation of natural language analyticity is required.

The situation is not so simple, however—for, along with the explication and comparison of competing theoretical frameworks, Carnap wanted to hold a deflationary stance toward the choice of analytic frameworks. As noted, such choice was understood as governed by purely pragmatic considerations such that framework decisions carry no genuine metaphysical import. Thus, the analyticity distinction is crucial to Carnap's antimetaphysical program and to the conception of philosophy as unique in its method of analysis. But it is not entirely clear that these aspects of the view evade the conjunction of the *Two Dogmas* criticisms with those extracted from *Truth by Convention* and *Carnap and Logical Truth.* In those works Quine argues (among other things) that the method of legislative postulation (as it is called in the later article), while promising to establish certain sets of sentences as true by convention or analytic, can easily be extended beyond logic and mathematics, beyond what is taken to be fundamental to a theory proposal, to include even empirical truths—indeed, every supposed truth of the theory in question. There is no principled stopping point to the legislative postulation of truths. Thus, there is no principled stopping point (on this account) to the circumscription of analytic truths. That is, if one wished, one could define the whole of a theory as analytic (this point is implicit in the *Two Dogmas* criticism of semantical rules). This is no problem for Carnap's explicative aims. One can still delineate competing theories, restricting the postulation of truths to those sets of sentences the proponents of a theory take to be most fundamental. This, surely, will facilitate understanding and pragmatic comparison of theories, thereby aiding the advance of science.

The lack of a principled analytic/synthetic distinction is, however, a problem for Carnap's metaphysical deflationism. The notion of analyticity was supposed to support the deflation of metaphysics by distinguishing sets of sentences whose acceptance is a matter of pure pragmatic decision from sets of sentences whose acceptance constitutes a judgment of truth. The former are the analytic sentences of the language, and, as their acceptance is supposed to be logically prior to all meaningful inquiry in that language, their acceptance cannot constitute a judgment of truth—rather, it is supposed to be a pragmatic decision regarding which tool to use. But if the exact delineation of a set of analytic sentences is constrained, not by some logical principle or any deep understanding of natural language synonymy, but by only what seems fundamental to the supporters of a particular proposal, then the metaphysical deflationism loses its force. This is because the distinction between pragmatic framework decision and synthetic judgment carrying metaphysical import is essentially arbitrary and can be varied at will. The whole of a theory might be defined as analytic, or none of it, or some proper portion.

If the whole is taken to be analytic, then any change in theory is supposed to count as a purely pragmatic framework decision, where such decisions are constrained by simplicity, coherence, facility of use, and the overall empirical fit of the theory. But, since the whole theory is analytic, no other kind of change can be made. So there is no distinction here between pure pragmatic decision and genuine judgment. If none of the theory is taken as analytic, then any change is supposed to count as a genuine judgment of truth. But, again, such changes will be constrained by overall simplicity, coherence, facility, and empirical fit. No real distinction is being made here either. If one of the many middle roads is taken, then nearly any proper portion of the theory may be taken as analytic. However, without some principled ground (in logic or natural language) for analyticity, all this amounts to is the assigning of provisional protected status to certain sets of sentences, such that revising *those* sentences is taken to be a more fundamental sort of revision than revising others. But, depending on current pragmatic and empirical concerns, including the intuitions of the theoreticians involved, exactly which portion of the theory is so protected can be varied at will. Such a view, Quine (1976a, b) argues, supports a distinction not of metaphysical status, but only of the theoreticians' current willingness to revise certain portions of the theory as opposed to others—a willingness that can

evolve as theory, evidence, and pragmatic concerns evolve. If this is correct, then, for want of a principled analytic/synthetic distinction, Carnap's deflationary metaphysics collapses into a view nearly identical to that of section 6 of *Two Dogmas*—a view that accords equal metaphysical import to all truths of the theory, distinguishing them mainly by the theoreticians' willingness to revise (Gregory 2003).

In addition to attempting to undermine Carnap's deflationism, Quine's rejection of analyticity is supposed to result in an erasure of the logical empiricists' distinction between philosophy and science. Quine still has a conception of the unity of science, but now this includes mathematics, logic, and philosophy—these being understood not as analytic disciplines, but as empirically meaningful in virtue of their contribution to the whole theory. Metaphysical deflationism is rejected, but Carnap's explicative aims persist. Logico-mathematical analysis of theoretical proposals is still central to the practice of philosophy, but the judgments and decisions based on such analysis are not considered devoid of metaphysical import. Thus, Quine reinflates metaphysical inquiry, but only so long as the claims of such inquiry participate in the empirical content of the whole theory. Moreover, it is not only the philosopher who recognizably engages in such philosophical activity, it is open to any self-conscious theorizer. The main differences among the layperson, the scientist, and the philosopher are simply in the frequency and degree of sophistication with which that individual engages in abstract reflective analysis. Thus, while philosophy becomes science, science is recognized as having always been philosophical.

It is not easy to be clear on what this means. There are two natural, yet polarized, ways of misinterpreting the impact of Quine's rejection of analyticity and reinflation of metaphysics. On one side, there is the view that Quine (re)instates a certain liberalism regarding metaphysics and philosophy. On the other is the view that Quine has rejected philosophy altogether in favor of a rigid scientism. In the liberalist interpretation, Quine's rejection of logical empiricist constraints on inquiry reopens the door to traditional metaphysics; or, in conjunction with his stress on pragmatism, it opens a new door to a hypertrophic pragmatism in which inquiry is constrained only by social practice. In the scientistic interpretation, Quine's rejection of the boundary between science and philosophy and his insistence on empirical significance leave no room for philosophical inquiry—all is science, and science is all.

Both interpretations mistake what Quine took to be the nature of his own views. Against the liberalist interpretation, Quine consistently maintains the importance of observational constraints on inquiry and that even despite observational underdetermination of theory, these constraints can distinguish better from worse theories (1969, 1975, and 1998). Moreover, Quine is best understood as a form of metaphysical realist—at least in the internalist sense. For Quine claims that there is no standard transcending the best scientific methodology from which to make meaningful claims of anti-realism regarding ongoing theory (Quine 1981b, d; [1990] 1992). The scientistic interpretation is closer to being accurate but ignores both Quine's attitude toward current science and the way in which he is trying to reconceive philosophy. On the first count, the charge of scientism implies a blind faith in the methodology and deliverances of science or scientists, but Quine accounts for both the possibility of large-scale theoretical change (taking even foundational commitments as tentative), as well as small- and large-scale methodological change (see below). Quine (1981c, 22–23; [1990] 1992, 20–21) even countenances the possibility of rejecting physicalism and empiricism (though not intersubjective testability). On the second count, to view Quine as plumping for science and dismissing philosophy is to maintain a simplistic distinction between the two, such that one must, by embracing science, be rejecting philosophy. But, as the discussion of analyticity begins to reveal, Quine sees no fundamental distinction between the two, and not simply because what is best or acceptable in philosophy is what is scientific. Rather, it is because scientists and philosophers alike speculate and theorize about the world in an attempt to understand it; and any such theorizing is constrained by holistic empirico-pragmatic concerns. The more closely tied to observation inquiry is, the more scientific it is; conversely, the more remote from observation, the more philosophical—it matters not what academic department one reports to. Philosophy does not disappear; indeed it is understood as ubiquitous. The grain of truth in the scientistic interpretation is that Quine was thoroughly (though in principle tentatively) committed to the findings and methodology of science. Moreover, Quine was deeply committed to the notion that as one's distance from intersubjective checkpoints increases, so does one's risk of moving beyond science or philosophy, into fantasy or gibberish. The scientistic interpretation fails, however, to recognize that Quine, via philosophical analysis and argument, maintained a unique caution and skepticism regarding science,

based in large part on his (very philosophical) recognition of how tenuous is the connection between intersubjective checkpoints and the vast theoretical structures erected upon them.

Observation, Theory, and Naturalized Epistemology

At the most general level of description, Quine has a hypothetico-deductive model of science. Hypotheses are generated and sets of them tested by the observational predictions deducible from those sets. When prediction is successful, then so far so good—confidence should always be tentative. When prediction is not successful, then new or revised hypotheses are called for. Given Quine's naturalism, understanding the details of hypothesis generation and testing is a task for science itself. Many subdisciplines will be relevant—physics, neurology, psychology, evolutionary biology, linguistics, history of science, etc.—especially on the generative side of the tale. But Quine ([1990] 1992, 2) believed he had "by means of little more than logical analysis" shed significant light on the structure of prediction and testing. The observation sentence is central to this analysis.

Observation sentences are supposed, in some sense, to be those sentences most closely associated with concurrent sensory stimulation and on which members of a language community will largely agree when presented with the same stimulus situation. To make this more precise, three criteria pick out observation sentences relative to a community of speakers. First, observation sentences are occasion sentences. That is, they are true at some times and places, and false at others (e.g., "There's a dog"). This is in contrast to standing sentences, which are true always or false always (e.g., "Electrons carry negative unit charge"). Second, a sentence is observational for an individual speaker if that speaker responds affirmatively (at the time of stimulation) for some range of stimulations of the speaker's sensory receptors, and negatively for some other range (there may also be a range in which the speaker is noncommittal). Stimulation of a subject on a given occasion is understood as "the temporally ordered set of all those of his exteroceptors that are triggered on that occasion" (Quine [1990] 1992, §2). Given this definition of stimulation, two subjects cannot share the same stimulation unless they share nerve endings. Hence, a careful way of stating the component of communitywide agreement is needed. So, third, a sentence is an observation sentence for the community if it is observational for each member individually and if community members would agree in their verdicts upon witnessing the same (or a similar) occasion of utterance (Quine [1990] 1992, §§2, 15–16). Thus, an abbreviated definition might run: An observation sentence is an occasion sentence that commands assent or dissent outright upon query in a given stimulus situation, and this pattern of assent and dissent is consistent across a community.

Observation sentences have a dual semantical and epistemological importance for Quine. Semantically, they are both the locus of empirical content and the first rung on the ladder of language acquisition. Epistemologically, they are the intersubjective checkpoints of science. The very same intersubjectivity of utterance and prompting occasion that normalizes usage and affords a way into language for the neophyte also allows for the testing of sets of hypotheses. Since hypotheses consist mainly of standing generalizations, they do not imply individual observation sentences (particular occasion sentences). Rather, sets of hypotheses imply observation categoricals. These are generalized conditionals of observation sentences (e.g., "Whenever there's an apple, then it's red"). Indeed, observation categoricals are a sort of minimal hypothesis, expressing generalized or habituated expectation. Unlike observation sentences, they are testable—one instantiates the antecedent and checks to see if the consequent obtains. If it does, then so far, so good. If not, then the conjunction of implying hypotheses is falsified, and revision is called for. Outside of his definition of observation sentences and categoricals, Quine takes a rather straightforwardly Popperian and Humean line on the logic of testing (see Popper, Karl Raimund). The testing of sets of hypotheses via the testing of observation categoricals they imply can, strictly speaking, only refute the conjunction of hypotheses. The continued success of predictions embodied in implied observation categoricals reinforces the habit of reliance on and confidence in the categoricals and their implying hypotheses (Quine 1981a, 28; [1990] 1992, §§5–6).

It is important to avoid some misunderstandings regarding observation sentences. Though Quine saw them as playing the role classical empiricists had wanted of sensory evidence, they are not Humean impressions, nor Russellian sense data. Nor, in contrast to certain logical empiricist conceptions of protocol sentences, are they reports of sensory phenomena. They are occasion sentences so strongly associated with ranges of stimulation that utterance or assent/dissent is practically immediate. Such immediacy is supposed to minimize, though by no means eliminate, reliance on learned

theory. Viewed as undifferentiated wholes (holophrastically), observation sentences are nontheoretical responses to stimuli. This is part of what allows the novice to acquire a language. But observation sentences are not simply undifferentiated wholes. They contain terms that appear in more theoretical sentences, and it is in virtue of these shared terms that observation categoricals are implied by hypotheses. This dual nature has a number of implications. First, though when taken holophrastically they appear theory neutral, observation sentences are theory laden in virtue of the inferential connections to and terms shared with theoretical sentences. Second, in addition to direct conditioning, observation sentences may be learned via description and inference. Third, observationality of a sentence is relative to the community specified. What counts as observational for one community (''That's a red giant,'' ''That's a middle C''), in virtue of the members' spontaneity of judgment in a stimulus situation, may not count so for a broader community. At any given time, however, the more specialized speakers could instruct those less specialized, in part by reverting to observation sentences common to both. It should also be stressed that observation sentences are not incorrigible. Assent to the utterance of an observation sentence may be rescinded either in the face of further observation or as the result of theoretical considerations. Thus, while observation sentences play a fundamental role in the testing of hypotheses, they are not a form of sensory given or simples forming an incorrigible foundation for knowledge.

Thus, logical analysis and some armchair psychology yield the prediction and testing side of the story, at least in outline. The generative side of the story, however, is highly unconstrained by logic and observation. Understanding the generation of expectations, projections, and hypotheses thus requires more than just logical analysis.

On the one hand, theoretical claims cannot be deduced from observations because there is no logic of ampliative inference, nor do logical constraints determine how to revise in the face of failed prediction. On the other hand, the rejection of analyticity, apriority, and reductionism involve repudiating both the Cartesian goal of externally justifying scientific methods and the Carnapian goal of rationally reconstructing the logico-empirical structure of science (Quine 1969). The natural sciences themselves are to be used to ''address the question how we, physical denizens of the physical world, can have projected our scientific theory of that whole world from our meager contacts with it'' (Quine 1995, 16). Thus, it is not that ampliative inference is devoid of all system or structure. Rather, what system or structure can be imputed to it will be largely extralogical—a matter of the evolution of innate similarity standards in the species, in the cognitive development of individuals, and in the community's ongoing theorizing. In the earliest pronouncements, such as ''Epistemology Naturalized,'' Quine (1969) focuses especially on psychology as the science wherein this project is to be pursued. In later writings, such as *Pursuit of Truth* (Quine [1990] 1992), neuroscience, evolutionary genetics, and the history of science are included. The epistemologist is to investigate the complex and various ways humans actually do arrive at theories, including neurological, psychological, sociological, and historical factors.

Interestingly, despite arguing in favor of the naturalization of epistemology, Quine engaged in no hands-on investigation of the sort he urged. Perhaps this was a consequence of his professed dislike of laboratory work and enjoyment of popular science literature (see Hahn and Schilpp 1998, 5, 43; Quine 1985, 37). He did, however frequently theorize on how to gather behavioral evidence of a subject's similarity standards and their evolution, including, of course, the development of language (see e.g., Quine 1974 and 1981c). Foley (1994) takes this as a sign that Quine was not doing epistemology in any new way, but unless one accepts a naive distinction between philosophy and science, it should not be expected that all naturalistic epistemologists be lab rats as opposed to abstract theorizers.

Three interrelated objections have typically been raised regarding Quine's naturalized epistemology—the circularity objection, the normativity objection, and the change-of-subject objection. As the responses to these objections are also interrelated, it is worth considering them en masse. If epistemologists are to engage in a scientific study of science, then it seems that the results must be circular, thereby vitiating the normative/justificatory project of epistemology (the circularity objection). Given the circularity issue, and the fact that science is a purely descriptive endeavor, no scientific epistemology could ever be a normative epistemology, but the normative aspect is a crucial part of any philosophical epistemology (the normativity objection). While the epistemology Quine advocates may be of interest to psychologists, it is not a properly philosophical epistemology, since, being circular and purely descriptive, it fails to address the fundamental normative questions of traditional epistemology—Quine is simply changing the subject. These will be addressed in reverse order.

It is correct that in some sense Quine is attempting to change the subject, to motivate a departure from or reconception of traditional epistemology, but it is naive to conclude that naturalized epistemology is no longer philosophical, losing all contact with traditional issues. This maintains the simplistic dichotomy between science and philosophy that Quine was repudiating, and it seems to treat traditional formulations of questions as somehow sacrosanct. Quine's importance, and that of his naturalism, rests in the attempt to reconfigure the field of inquiry in a philosophically and scientifically fruitful manner. Hence the change-of-subject objection has the air of mere dismissal, as opposed to critical engagement.

The normativity objection presupposes that science is purely descriptive, that all a scientific investigation of belief and theory formation can do is list the various and sundry things that go on. But scientific theory and practice have significant normative dimensions, as evidenced by idealizations used in theory development and testing and the normative role of theory in engineering. Moreover, these norms are applied to scientific practice itself, allowing differentiation of practices according to their measure along different parameters. As these measures of instrumental efficacy are theoretical claims, they are fallible and open to revision. Quine cited predictive success as the ultimate parameter. So, naturalized epistemology is the assessment of the instrumental value of cognitive and social practices toward the goal of predictive success. Quine supports this through his analysis of the structure of theory and evidence, which reveals that prediction of intersubjectively available checkpoints is the fundamental norm of science. Since, as science reveals, information comes through the five senses, success in sensory prediction is the "final arbiter." As mentioned during the discussion of his alleged scientism, Quine ([1990] 1992, 20–21) recognized the possibility of admitting sources of information and testing other than the senses (extrasensory perception, revelation), were this ever warranted. He stopped short of speculating about giving up on intersubjective predictive tests altogether.

One further point bears mentioning. Clearly, to say that predictive success is the end against which methods are assessed is not to say that predictive success is the goal of science or cognition. It is likely one of the goals, but truth, understanding, and aesthetic enjoyment are surely others. Finding value in various practices, even if only distantly or loosely connected to predictive success, is entirely consistent with taking predictive success as the test parameter.

The obvious circularity of this approach is not a problem from Quine's point of view. The rejection of analyticity and apriority and the view of common sense, science, and philosophy as continuous imply that inquiry (epistemological or otherwise) cannot begin from a position independent of all theory. Hence any such inquiry is ultimately circular. But this is not to be understood as defeatist resignation. It is not that the demand for an independent justification of science and its methods is well grounded, but, alas, it cannot be met. Rather, the point is that such a demand is itself based in a misconception of the nature of theory and language—a misconception of epistemology. Quine tried to offer a better conception. There is a further worry that because natural epistemology begins from within ongoing scientific theory, it is doomed to reinforce the norms already at work in science. But this, while not impossible, is as unlikely as the possibility that no new theories will be developed, because all inquiry begins from within ongoing theory. Theory changes in the light of new evidence and new understandings of old evidence and theory. Methodological norms are fallible and may change with developing theory. It is no more likely that natural epistemology will become stuck in a loop of blind stagnation than that science in general will. For Quine, the epistemology of science is on a par with science itself (Gregory 1999; Quine 1969 and [1990] 1992).

Conclusion

It is worth illuminating points of contact with a few other philosophies of science. There are, of course, the connections to and departures from logical empiricism. The stress on falsification links Quine with Popper, as noted above, though Quine never maintained a sharp criterion of demarcation between science and pseudoscience. Quine's recognition of a lack of purely logical constraints on theory change, his assertion of the theoretical nature of normative constraints, his holism, and his stress on conservatism while recognizing the possibility of fundamental revisions—all these suggest that theory development will usually be a rather mundane affair but that given extended and serious failure in some domain, dramatic and very loosely constrained change will occur. This is all perfectly consonant with Kuhn's account of normal science and paradigm change (see Kuhn, Thomas). Of course, Quine's view idealizes theories as formal linguistic structures and conceives of theory change as modification of such structures. Kuhn's view of theory change is much richer, paying detailed

attention to sociological, technological, and practical issues. Moreover, in Quine's view, revolutionary change is more highly constrained (mainly by predictive test) than in the typical reading of Kuhn. Finally, views of philosophers such as Lakatos (1977), who distinguish portions of theory that are less apt to be revised and are revised only under special circumstances, are less in tension with Quine's views than it might appear. Quine's views can countenance distinctions among sentences of more or less protected status, and naturalized epistemology is supposed to illuminate the nature of those distinctions. Tensions arise only insofar as such distinctions are taken to ground metaphysical and epistemological conclusions antithetical to Quine's naturalism. This is not to deny the presence of tensions between Quine's views and others' or to deny the possible value in rejecting Quine's naturalism. But it is important to note that while Quine is notorious for rejecting or blurring conceptual boundaries, his views can countenance certain kinds of distinctions.

Quine's criticisms of analyticity heralded the waning of logical empiricism. His holistic naturalism offers a unique view of philosophy as progressive, metaphysically committed, and continuous with science. His articulation of a version of naturalized epistemology was one of the major impetuses for the development, in philosophy, of naturalistic studies of science and cognition. Whether one accepts his naturalism in detail, in outline, or not at all, Quine's importance cannot be overestimated. Willard Van Quine shaped philosophy and philosophy of science in the second half of the twentieth century.

R

FRANK PLUMPTON RAMSEY

(22 February 1903–19 January 1930)

Frank Plumpton Ramsey made important contributions to philosophy, economics, logic, and mathematics. The son of a Cambridge mathematician, from an early age he was well known to members of the Cambridge intellectual community. He received a degree in mathematics from Trinity College in 1923, became a Fellow of King's College in 1924, and in 1926 he was made a University Lecturer in Mathematics, the post he held until his untimely death in 1930. Ramsey was an original thinker and no one's disciple, but his work clearly shows the influence of Russell, Keynes, Wittgenstein, Moore, W. E. Johnson, and Peirce. (Biographical information on Ramsey can be found in Mellor 1995, Sahlin 1990, and the introductory sections of Ramsey 1931 and 1990.)

Ramsey's earliest publications include a criticism of Keynes' theory of probability (Ramsey [1922] 1989) and a critical notice on Wittgenstein's ([1922] 1961) *Tractatus.* From 1925 to 1927, he published the philosophical papers "The Foundations of Mathematics," "Universals," "Mathematical Logic," and "Facts and Propositions" (Ramsey 1927). In 1927–1928, he published two influential papers in economics, "A Contribution to the Theory of Taxation" and "A Mathematical Theory of Saving," and his single mathematical publication, in which was introduced what is now known as Ramsey's theorem, "On a Problem in Formal Logic." Shortly after his death, the collected works of Ramsey (1931) appeared, containing all of the aforementioned works except the economics papers and the discussion of Keynes. It also contains writings unpublished until then, including the paper "Truth and Probability," written in 1926, and papers dating from 1928–1929 such as "Theories" and "General Propositions and Causality." Similar collections of Ramsey's work have also been published (Ramsey 1978 [which has the economics papers] and 1990). Two more recent books (Ramsey 1991a, b), contain material from the manuscripts in the Ramsey Collection at the University of Pittsburgh's Archives of Scientific Philosophy. The most comprehensive treatment to date of Ramsey's philosophical work is by Sahlin (1990).

The significance of some of Ramsey's work—for example, his contributions to the foundations of mathematics—was quickly appreciated. But it

took time for many of Ramsey's ideas to become widely known and appreciated (on this, see Ramsey 1990, xi–xxiii, and Mellor 1995). As one encounters those ideas, it is worth remembering that they were all produced before his twenty-seventh birthday, which he did not live to see. Some are expressed in papers or notes not meant for publication and not developed to a point that fully satisfied him. It is remarkable how much illumination has been found, and how much can still be found, by studying the work that Ramsey had time to produce.

Logic and *The Foundations of Mathematics*

Ramsey was well acquainted with Whitehead and Russell's (1910) *Principia Mathematica* (*PM*), and with Wittgenstein ([1922] 1961). He commented on and corrected the proofs of the second edition of *PM*, and he was the major contributor to the first English translation of the *Tractatus.* In his lengthy "The Foundations of Mathematics (FM)" and the subsequent paper "Mathematical Logic (ML)," Ramsey strongly argued that the system of *PM* needed serious revision in order to remain true to the project of capturing mathematics within logic (see Russell, Bertrand). He identified three crucial shortcomings of the system that, in his view, undermined both the legitimacy of its fundamental principles and the system's adequacy as a basis for mathematics. As Sullivan (1995) observes, there is a correspondence between the three fundamental problems that Ramsey found and the three problematic axioms of *PM* with which Russell struggled—the axioms of choice, reducibility, and infinity. The upshot of the solutions Ramsey offered was that the formal system of *PM* was drastically reinterpreted but largely preserved; changes were confined to a simplification of its theory of types and the elimination of one of its axioms (reducibility). In the course of doing this, Ramsey drew a distinction that has become a standard way of classifying the various paradoxes that Whitehead and Russell cataloged in *PM*. Only brief indications of Ramsey's criticisms and proposals can be given here. (For background and more thorough discussion, see Sullivan 1995 or Grattan-Guinness 2000; the latter contains an extensive bibliography of further sources.)

At the heart of Ramsey's revisions to the system of *PM* is a move toward extensionality, based on an understanding of logic strongly influenced by Wittgenstein. Ramsey followed the *Tractatus* in taking propositions to be truth functions of atomic propositions. He divorced propositions from the symbolic formulas that express them; a single proposition (truth function) may be expressed by many different formulas, and some propositions may not be expressible at all. The same is true for propositional functions. (In *PM*, propositional functions are, roughly, what yield propositions when all their occurrences of free variables are bound or replaced by names. In Ramsey's conception, they turn out to be functions from individuals to propositions.) Some truth functions with infinitely many arguments can be expressed by use of the quantifiers, which Ramsey understood as convenient ways of writing infinite conjunctions and disjunctions. Given infinitely many atomic propositions, however, many possible truth functions of the set of atomic propositions will not be directly expressible, though they are relevant to the truth or falsehood of universally and existentially quantified propositions.

In the system of *PM*, every class (set whose members all have the same type) is defined by a symbolically expressible propositional function, or defining property. Ramsey's *first criticism* was that this is too restrictive for mathematics, which at least leaves open the possibility of infinite classes not definable by the propositional functions of *PM*. So the system of *PM* misinterprets important mathematical assertions about some or all classes, including the axiom of choice (*PM*'s multiplicative axiom) (*FM,* §II). Given the restricted availability of classes in *PM*, this would be an empirical truth rather than a logical truth, if it is true at all. In Ramsey's reconstruction of *PM*, many classes were available beyond those definable by *PM*'s propositional functions, and he regarded the axiom of choice as an obvious tautology, a necessary truth.

Paradoxes and the Theory of Types

Ramsey's *second criticism* of *PM* is now the one best remembered. Whitehead and Russell had cataloged seven logical contradictions that the system of *PM* must avoid; these included the existence of Russell's class of all classes not members of themselves, the liar sentence, and Richard's construction of a decimal that both is and is not finitely definable. They attributed a common source to the contradictions—"a certain kind of vicious circle"—and they invoked a *vicious circle principle*: "Whatever involves *all* of a collection must not be one of the collection" (*PM,* introduction, Ch. 2). The system of *PM* adhered to this principle through its theory of ramified types.

Ramified type theory arranged propositional functions into a twofold hierarchy of orders and of types within individual orders. The *type* of a propositional function was determined by the

members of its domain. Individuals, monadic functions of individuals, monadic functions of monadic functions of individuals, and so on, had distinct and increasing types, which might be labeled 0, 1, 2, and so on. (Types of relations, and of classes defined with them, were more complex.) A function was only meaningful when applied to entities of type one less than itself, and it was not meaningful to say that classes defined by such functions either contain or fail to contain themselves as members. The hierarchy of *orders* of propositional functions was generated by how the functions were defined—specifically, by what quantifications over functions (think of them as quantifications over properties) were used in their definitions. In keeping with the vicious circle principle, the idea was that the definition of a propositional function could not quantify over all functions, or even over all functions of its own type. This restriction generated functions of increasing order: Those whose definition involved no quantification over functions were order zero (Ramsey called these *elementary*), those whose definition involved quantification over elementary functions were first-order, those whose definition involved quantification over first-order functions were second-order, and so on. It was not meaningful to quantify over propositional functions of all orders, and Whitehead and Russell showed that the dual hierarchy of ramified type theory defused the threat posed by the contradictions to the system of *PM*.

But the complications that the hierarchy of orders brought to type theory presented a serious problem for *PM*'s adequacy as a foundation for mathematics. The example Ramsey emphasized most fully in *ML* is crucial to real analysis. The least upper bound of a set of real numbers would be defined in *PM* by a function having an order greater than the order of a function defining the class of real numbers, so that it would fail to be a member of that class, that is, fail to be a real number itself. Whitehead and Russell introduced their *axiom of reducibility* to deal with such problems. It asserted that to each propositional function within a given type, there corresponded an equivalent function of lowest order for that type, so that the same class was defined by both functions. By invoking the axiom, then, real numbers and least upper bounds could be defined by functions of the same (lowest) order. Ramsey forcefully asserted, however, that the axiom of reducibility is far from obvious, and certainly not a principle of logic. Ramsey followed Peano in pointing out that the logical contradictions on Whitehead and Russell's list are dissimilar. (He added to the list Grelling's "heterological" contradiction, which he attributed to Weyl.) Ramsey placed them in two groups—(1) contradictions that could arise within a logical system and (2) contradictions that "cannot be stated in logical terms alone; for they all contain some reference to thought, language, or symbolism, which are not formal but empirical terms" (*FM*, Ramsey 1990, 183). The latter "all involve some psychological term, such as meaning, defining, naming, or asserting. They occur not in mathematics, but in thinking about mathematics" (*ML*, Ramsey 1990, 239). This has come to be known as a distinction between logical paradoxes and semantic paradoxes. Ramsey argued that those in the first group, including the contradictions of Russell's set and Burali's greatest ordinal, can and must be avoided by features of the logical system; in the case of *PM*, the theory of types, without ramification, would do the job. The second group of contradictions included the paradoxes of the liar, the least indefinable ordinal, the least integer not definable in fewer than nineteen syllables, Richard's finitely undefinable decimal, and Grelling's property "heterological." These are what motivated *PM*'s very general vicious circle principle and the ramified theory of types and orders.

How did Ramsey deal with the semantic paradoxes (which he described as "epistemological") and dispense with reducibility? Consider reducibility first. Ramsey agreed that a propositional function's type, determined by the members of its domain, was a real feature of it. But he thought of *PM*'s orders as features of the particular symbolic expressions that point to functions, rather than as features of the functions themselves. Since the functions themselves served to define classes, there was no need to regard their orders as relevant to the definitions of classes, and so no need for the unwanted axiom of reducibility. In taking this direction, Ramsey departed from *PM*'s strict observance of the vicious circle principle, which he regarded as much too broad. He treated definitions as ways of specifying particular functions and classes, rather than as ways of constructing them. It can be acceptable, in the course of successfully specifying what an entity is, to refer to the whole of a class of which that entity is a member. Whatever circularity is involved need not be vicious. This approach relies, of course, on the idea that the entities are already somewhere out there to be selected by the specifications. The Platonistic flavor of his account led Carnap (1931) to label it "theological mathematics," in contrast to the "anthropological mathematics" of the intuitionists. Ramsey later moved away from the account and this particular aspect of it.

What, then, about the semantic paradoxes? They all exploit the relation of *meaning* between symbols

and propositional functions they express. Orders are no longer features of functions themselves and no longer play a role in defining classes, but it does make sense to think of orders as features of symbolic expressions that reflect levels of quantificational complexity—over individuals, or over functions (properties or relations) of individuals, or over functions of functions of individuals, and so on. In a move resembling later treatments that developed hierarchies of languages, Ramsey argued that relation(s) of meaning (and so of definability) are ambiguous for symbolic expressions of different orders. The meaning relation that holds for an elementary function is distinct from the meaning relation that holds for a first-order function, and so on up the hierarchy of orders. He further argued that when one keeps track of the distinct meaning relations, each of the semantic paradoxes can be shown not to yield a real contradiction (*FM*, §III).

Impredicative Functions, Infinity, Abandonment of Logicism

Ramsey pushed the extensionality of his system quite far. As mentioned earlier, he arrived at the point of regarding propositional functions as functions from individuals to propositions, rather than as open symbolic expressions. Ramsey called all propositional functions that are truth functions of atomic propositions *predicative* functions (this is not the same meaning that Whitehead and Russell gave the term). Predicative functions include more than just functions of individuals; Ramsey shows that all of the propositional functions of *PM* are predicative in his sense. But in Ramsey's extensionalization of *PM*, there are more propositional functions than this: *Impredicative* functions are those among the mappings from individuals to propositions that cannot be built up as truth functions of atomic propositions. In Ramsey's system, quantification over propositional functions is understood to range over all *functions in extension*, predicative and impredicative.

Ramsey's *third criticism* of *PM* was directed at its treatment of identity. In *PM*, identity was defined by appeal to a principle of indiscernibility of elementary properties. But it is no truth of logic, Ramsey said, that two things cannot share all elementary properties. He instead took *sameness of individual* as a primitive nonlogical idea, and made use of the rich collection of functions in extension to give an account of the propositional function $x = y$. The proposition that *PM* interpreted as saying that indiscernible individuals are related by '=' was instead interpreted as saying that '=' holds between individuals that share all functions in extension, predicative or impredicative. The latter include all mappings from individuals to propositions, however arbitrary, and this amounts to saying that '=' holds among individual(s) that are the same. In this interpretation, the assertion (ϕ_e) $(\phi_e\, x \equiv \phi_e\, y)$, where ϕ_e ranges over functions in extension, does turn out to be a tautology exactly when $x = y$, and Ramsey took it, so understood, to be the defining condition for $x = y$. Ramsey applied this account to *PM*'s axiom of infinity, which, in Whitehead and Russell's interpretation, asserted that there are infinitely many individuals distinguishable by predicative functions (in Ramsey's sense of 'predicative'). Ramsey regarded that as at best an empirical claim. Since his reconstruction included functions in extension, his interpretation of the axiom just amounted to the assertion of the existence of an infinity of individuals, whether distinguishable by predicative functions or not. Ramsey acknowledged that this may still appear to be an empirical claim, but he used his account of identity to argue that, though the axiom is unprovable, it is a tautology (necessary) if it is true. At the end of *FM* he advocated adopting it, both on these grounds and because it is indispensable to mathematics.

This is still not an entirely satisfactory result for a logicist theory of mathematics, and Ramsey increasingly departed from that view after the publication of *FM*. The paper *ML* appeared one year later, and in it he still defended a generally logicist outlook against the alternative approaches of Hilbert, Weyl, and Brouwer. In *ML* Ramsey remained dissatisfied with the status of the axiom of infinity, yet he was still convinced that it is needed. There is evidence, however, that his views soon began to change. Braithwaite reports that in 1929 Ramsey "was converted to a finitist view which rejects the existence of any actual infinite aggregate" (Ramsey 1931, xii), and among the notes written in the last years of his life there is clear evidence of his strong interest in finitism (Ramsey 1991a, notes 53 and 54). There is also this statement, written in 1929 at the end of an unpolished set of notes on theories:

> It is obvious that mathematics does not require the existence of an infinite number of things. We say at once that imaginary things will do. . . . But there are no imaginary things, they are just words, and mathematicians and physicists who use the infinite are just manipulating symbols with some analogy to propositions. (Ramsey 1991a, note 58)

There is no further indication how he thought to dispense with an axiom of infinity.

Ramsey's Theorem

All of Ramsey's work in logic and the foundations of mathematics predated the dramatic developments of the 1930s. Who can say how his views would have continued to evolve if he had lived? Before moving on to other topics, it is worth mentioning Ramsey's most lasting contribution to mathematics itself, Ramsey's theorem. In the paper "On a Problem in Formal Logic," Ramsey took up Hilbert and Ackermann's Decision Problem and proved a special case, the decidability of validity for $\exists\forall$-form sentences with identity. In 1936 Alonzo Church showed that the problem for full predicate logic is unsolvable. As a preliminary to the main topic of his paper, however, Ramsey established a remarkable result in combinatorics that has proved seminal to a great deal of subsequent mathematical research. Details can be easily found in mathematical sources on *Ramsey theory* or *Ramsey numbers.*

Probability and Partial Belief

Ramsey's greatest influence on the philosophy of science today is through his work on probability and degrees of belief. His writings on laws and theories introduced other important ideas that are now well remembered and widely used (see below), but Ramsey lacked the opportunity to develop them as fully as the ideas in the remarkable paper "Truth and Probability" (TP). The paper was not widely appreciated prior to Savage's (1954) work, but Ramsey and Bruno de Finetti are now recognized as the two key figures in the origin and early development of contemporary accounts of subjective, or Bayesian, probability. *TP* is a rich paper and cannot be covered fully here (see also Zabell 1991, Jeffrey [1965] 1983, Skyrms 1990, Sahlin 1990, and Galavotti 1991). The paper has five sections—Braithwaite (Ramsey 1931, introduction) says that at one time Ramsey planned to add a sixth, on probability in science, and to publish the paper separately. He later developed plans to include it in a book, or books, on logic, truth, and probability. Drafts of other portions of that project, chapters devoted mainly to truth and judgment, have been published (Ramsey 1991b), and other works contain notes on probability, degrees of belief, and chance (Ramsey 1931 and 1991a).

Ramsey opens *TP* by allowing that there may be two distinct interpretations of probability, one appropriate to logic, the other to statistics and physical science, and he made clear that his subject was the former. The framework he had in mind began by conceiving of logic as the science of rational thought, subdivided into what he called the 'logic of consistency' and the 'logic of truth.' The former contains formal deductive logic and mathematics. Most of *TP* is devoted to developing the idea that the logic of consistency also contains a theory of probability, and to explaining that the sort of probability it must contain is *subjective.* In the final section, Ramsey turned to the logic of truth with the observation that "we want our beliefs to be consistent not merely with each other but also with the facts." Conformity to the logic of consistency gives no guarantee of that, so there is room for a broader human logic, "which tells men how they should think" or what it would be reasonable to believe (Ramsey 1990, 87). Ramsey's remarks on the logic of truth will be discussed in a later section.

Ramsey sets the stage for his own account with a review of the two rival interpretations of probability that were familiar to his readers. (Zabell 1991 is particularly good on the background and context of Ramsey's theory.) One is the frequency account, and the other is J. M. Keynes' logical interpretation of probability. Ramsey made no attempt to refute a frequency interpretation of probability—it is clearly mathematically viable and appears to be useful to science. It turns out not to be a suitable basis for a logic (of consistency) for partial belief, however, and he set aside frequencies until he later took up the logic of truth. Keynes' interpretation, on the other hand, was clearly meant to be a part of logic, and Ramsey gave serious attention to its shortcomings. Keynes advocated the view that a probability is an objective logical relation holding between one proposition and another. He held that such logical relations are unanalyzable, yet they are at least sometimes perceivable, and they serve as guides to rational belief. The degree of belief it is rational to have in an unknown proposition p is given by the probability relation that holds between the proposition describing what one knows and p. Keynes' degrees of probability were not generally quantitative, but in some cases, by appeal to the principle of indifference, they could be compared and calculated. Especially since the failure of Carnap's sophisticated later attempts at a similar approach, accounts like this are today no longer widely held. Suggestions for their resurrection still emerge from time to time in areas of philosophy where this history is not well known, and Ramsey's criticisms of Keynes remain relevant. They begin with the straightforward observation that

> there really do not seem to be any such things as the probability relations [Keynes] describes. He supposes that, at any rate in certain cases, they can be perceived; but speaking for myself I feel confident that this is not true. . . . [M]oreover I shrewdly suspect that others do not perceive them either, because they are able to come to so very little agreement as to which of them relates any two given propositions. (Ramsey 1990, 57)

Ramsey developed this criticism thoroughly in the second section of *TP*. Later, after the presentation of his own view, three further criticisms of Keynes' theory were given in the fourth section of *TP*. Keynes' account (a) failed to make clear why the logical relations should obey the axioms of probability, (b) attempted to lay down a priori logical constraints such as the principle of indifference to generate what are surely empirical probability values in science, and (c) did not recognize or explain "a probable belief founded not on argument but on [uncertain] direct inspection," since the logical relation indicates the probability of a proposition based only on what is *known* (Ramsey 1990, 86). Ramsey thought it clear that his own theory had none of these flaws.

Degrees of Belief

The third section of *TP* is its longest and most significant. It introduced, as well as anything written since, a conception of *degrees of belief* that is now widely used. Ramsey offered two lines of justification for taking *rational* degrees of belief to be probabilities. One was based on a betting model of action, and led to the Dutch Book Argument. The second provided a groundbreaking generalization of the betting model. Ramsey stated an axiomatic theory of rational preference and derived from it an expected utility theory that put the agent's degrees of belief in the role of probabilities (it is considered in the next section).

What *are* degrees of belief, and why think that they can be quantified? Ramsey developed an account that applies to dispositional beliefs as much as to occurrent beliefs. He considered and rejected the suggestion that the degree of a belief corresponds to the strength of an introspective feeling one might have about it, proposing instead that it must be a causal property of the belief, "which we can express vaguely as the extent to which we are prepared to act on it. This is a generalization of the well-known view, that the differentia of belief lies in its causal efficacy" (Ramsey 1990, 65). Ramsey did not deny, of course, that beliefs are sometimes accompanied by feelings of various intensities—say, of various degrees of conviction. The apparent advantage of such feelings is that they can be known through introspection, which supports the view that one knows how strongly one believes things. But Ramsey doubted that one always knows how strong belief is, and suggested another way of judging a belief's strength that need not rely on internal observation of some belief-feeling: One imagines how one would act in various hypothetical circumstances. Even if there were some quantitative scale on which feelings could be measured, unlikely as that is, he argued, they contribute little to the role of belief as a basis for action.

In its focus on their action-guiding role, Ramsey's account of partial beliefs fits well with his wider perspective on belief, which was strongly influenced by his study of Peirce. That will be neglected here, except to note that in other writings (Ramsey 1927; 1991b, esp. Ch. 3), he offers a broadly functionalist account of a belief's content, or, in his terms, its *propositional reference.* Several discussions of Ramsey's treatment of belief appear in Mellor (1980). Ramsey clearly thought it a good working hypothesis that internal patterns of relevant causal properties or dispositions are present and susceptible of measurement, though he was under no illusion that such measurement is easy. He repeatedly drew analogies between the difficulties of measuring these causal properties and the complications that arise in physical measurements of, for example, length or electric current.

A person's degree of belief in p is a causal property contributing to the belief's influence over that person's choices and actions. A familiar "old-established" technique for measuring it, which Ramsey regarded as "fundamentally sound," is to offer that person bets on p and see what bets, at what odds, that person is willing to accept. The person's willingness to give high odds on p indicates a high degree of belief in p; an insistence on receiving high odds indicates that the person's degree of belief is low. More precisely, if the least favorable bet that the person is willing to make on the truth of p is one where the person pays \$$a$ if p is false and wins \$$b$ if p is true, the person's degree of belief in p is the betting quotient $a/(a + b)$. A conditional degree of belief in *p given q* is similarly measured by the odds of the least favorable conditional bet—a bet on p that is in effect only if q is true. (A degree of belief in *p given q*, Ramsey said, is not always the same as the degree to which one would believe p if one believed q for certain.) Ramsey noted that there are many complications that undermine the generality and precision of the method: the diminishing marginal utility of money or of whatever goods are the payoffs, the possibility that one has

particular eagerness or reluctance to make bets, the possible disturbance of one's opinion by the act of making the offer, and so on. Ramsey compared these to similar difficulties in carrying out physical measurements—it can be difficult to isolate one out of a number of forces at work, and measurement may require a physical intervention that alters the system being measured. The use of the betting model to characterize strength of belief predates Ramsey—it was used by Borel (1924) and de Finetti (1937), for example.

The betting model has since been the subject of much discussion and criticism, yet it remains the best way of getting across the idea on which contemporary Bayesian theory is founded. Explicit wagering is a specialized form of activity, and most persons engage in it only occasionally. But the model has the two advantages of familiarity and flexibility, since one can readily imagine betting on a wide variety of propositions. So in a theoretical effort to understand the action-guiding role of degrees of belief, betting makes a good, though hardly perfect, stand-in for actions of all sorts. Many actions can be regarded as expressions of implicit wagers, "Whenever we go to the station we are betting that a train will really run, and if we had not a sufficient degree of belief in this we should decline the bet and stay at home" (Ramsey 1990, 79). Ramsey's own remarks about the usefulness and limits of the idealized model are more sensible than a great deal of what has come after. According to the model, a given person at a given time has *a single* (definite) degree of belief in the proposition *p*. This involves assumptions of both *precision*—degrees of belief have precise numerical values—and *stake-insensitivity*. The latter holds that the action-guiding strength of a belief is unaffected by the size of the stakes involved in the actions so guided (or, at least, unaffected over some significant range of stakes). The degree of belief one has, for example, in "It will storm this afternoon" is unaffected by whether the stakes involve the inconvenience of carrying an umbrella, or more seriously, the risk of death in a small sailboat. There is no doubt that the magnitudes of the stakes affect how one makes choices, but Ramsey's theory and its descendents locate the effects not in changes to the strengths of one's beliefs, but in the interplay between beliefs and desires that yields choice (this point is further discussed in Armendt 1993).

The Logic of Consistency for Degrees of Belief

The fundamental claim is that *rational* degrees of belief satisfy the principles of probability. The argument Ramsey actually presented for it is based on his axiomatic theory of rational preference. But he also stated, for the first time, what has since become known as the Dutch Book Argument. That argument concludes that when degrees of belief violate the axioms of probability, they are flawed, because under their guidance the believer who holds them would be willing to accept a combination, or book, of bets that together yield a sure loss to him, whatever turns out to be true and however the bets pay off—a Dutch Book. Ramsey (1990) did not fill in the argument, but he clearly could have: "If anyone's mental condition violated these laws ... he could have a book made against him by a cunning bettor and would then stand to lose in any event" (78). He also stated the conclusion of the Converse Dutch Book Argument:

> Having any definite degree of belief implies a certain measure of consistency, namely willingness to bet on a given proposition at the same odds for any stake. ... Having degrees of belief obeying the laws of probability implies a further measure of consistency, namely such a consistency between the odds acceptable on different propositions as shall prevent a book being made against you. (Ramsey 1998, 78–79)

Both the argument and its converse also appear in de Finetti (1937). In the voluminous later literature on the Dutch Book Argument, Skyrms best addresses the heart of the topic (see e.g., his essay "Higher Order Degrees of Belief" in Mellor 1980; Skyrms 1990, Ch. 5). The key element of Skyrms' interpretation, in keeping with what seems to be Ramsey's own, is that the Dutch Book is a dramatic device. The believer's susceptibility to a Dutch Book illustrates the presence of a flaw in his beliefs; it does not in itself constitute the flaw. Armendt (1993) follows Skyrms' interpretation and further discusses the relationship between the betting model and axiomatic preference theories.

Ramsey used the betting model to present the intuitive idea of degree of belief, but his general account of subjective probability as a norm for degrees of belief really comes from his preference theory, only an overview of which can be given here (for further details, see Jeffrey [1965] 1983 or Sahlin 1990). Ramsey replaced betting with the more general device of a *gamble*. A gamble yields one outcome or another, say α or β, depending on whether a proposition p is true. The outcomes α, β were taken to be states of the world very fully specified with respect to things that the believer or agent cares about. In a nutshell, the account was this: The agent has a systematic set of preferences among various outcomes, as well as among a large set of imaginable gambles on them. His preferences

are subject to certain principles, which Ramsey stated as axioms of the system and its preference relation. Some axioms are richness assumptions—the system includes preferences among fine-grained arrays of gambles on every proposition in which the agent has a degree of belief. To the extents that this richness is an acceptable idealization and the other axioms (e.g., transitivity and connectedness) are plausible components of a model of rationality, systems that satisfy the axioms can be regarded as systems of rational preference. Ramsey showed that for any such system, two appropriately unique, and so nonarbitrary, measures can be derived. One is a real-valued measurement of the values of the outcomes and gambles (a utility function, though he did not call it that), and the other is a numerical measurement of the propositions that is provably a probability function. The two measures together obey a principle of expected utility, and Ramsey interpreted the probability function as the measure of the agent's degrees of belief. Ramsey's account provides a foundation for both the theory of subjective utility and the theory of subjective probability, though the latter is what he emphasized in *TP*. The theory is a forerunner of many later axiomatic treatments of belief, utility, and decision developed by philosophers, economists, statisticians, and others. The later literature is immense and impossible to survey here. Savage's (1954) theory was extremely influential, and it contributed to the later recognition of Ramsey's work; particularly well known among philosophers is Jeffrey's ([1965] 1983) theory.

The Logic of Truth

Ramsey took the result just described to establish the legitimacy of a logic of consistency for partial beliefs. When the account is regarded as a decision or utility theory, its direct inclusion of degrees of belief clearly makes it an *epistemic* account. When viewed either as a doxastic theory or a utility theory, it is also *subjective*, in that the constraints applying to degrees of belief and preferences are internal to the system, not imposed by what is true or objectively desirable in the world. In later subjective probability theory, and especially in the *radical probabilism* of de Finetti, Jeffrey, and others, subjectivism is fundamental to the account—the apparent objectivity of some probabilities is held to be explicable by the dynamic behavior of interacting systems of subjective (conditional) probabilities. Ramsey himself expresses such a view in the later note "Chance" (Ramsey 1990). The remaining part of *TP*, however, does not contain an explicit commitment to radical probabilism. Here Ramsey sought a fuller account of good epistemic practice, one that goes beyond the logic of consistency by ascertaining the standards and sources of successful belief. On the other hand, in this most exploratory part of the paper, Ramsey asserted little or nothing with which a radical probabilist need disagree.

What is the connection between probability in the sense of (rational) degrees of belief, and probability in the sense of frequencies, or "class-ratios"? While still considering the logic of consistency, Ramsey (1990) allowed that "experienced frequencies often lead to corresponding partial beliefs, and partial beliefs lead to the expectation of corresponding frequencies" (83), but he denied that a general connection along such lines can be made out. What can be said to connect the interpretations is that, "supposing goods to be additive, belief of degree m/n is the sort of belief which leads to the action which would be best if repeated n times in m of which the proposition is true" (84). This is the sense in which the calculus of frequencies was linked to a calculus of consistent partial beliefs. (In the later note, "Reasonable Degree of Belief" [Ramsey 1990], he explores difficulties and refinements associated with this idea.) C. S. Peirce's pragmatism greatly influenced Ramsey's approach to the question of what, beyond consistency, makes degrees of belief reasonable. The *habits* by which one arrives at and maintain beliefs should be at the focus of attention. This led Ramsey (1990) to regard inductive inference as a central topic in the logic of truth, which is not to say that the logic of consistency is silent concerning induction:

> [I]f p is the fact observed, my degree of belief in q after the observation should be equal to my degree of belief in q given p before. ... When my degrees of belief change in this way we can say that they have been changed consistently by my observation. (88)

Beyond conditionalization, though, what inferential habits produce reasonable beliefs, and what standards guide judgments about them? A richer account of induction than Ramsey's, based on the idea of exchangeable sequences of events, was soon given by de Finetti (1937). As to goals and standards, *always fully believe the truth* comes to mind, but it is not very helpful for human belief or for the habits followed in the many predicaments where certainty would be misplaced. A better standard, Ramsey proposed, is that a habit should yield partial beliefs whose strengths correspond to the frequencies with which relevantly similar beliefs are true. He illustrated the point with an example concerning the wholesomeness of toadstools; one

might also think of weather forecasts. A habit that yields a degree of belief in p equal to x is reasonable when the frequency with which such beliefs are true is x. (For a discussion of how this proposal may be linked to deeper decision-theoretic standards of success, see Adams 1988).

Ramsey's further remarks in *TP* are a prolegomenon to the logic of truth, rather than a development of it. He asserts that scientific inductive reasoning will be indispensable to the project of identifying and assessing mental habits—judging when and how well they work. Induction is itself such a habit, and a useful one. To understand it better, and to determine how useful it is, one cannot avoid employing it. There is a circle here, but as Ramsey conceives the point of the project, nothing vicious about it.

The Value of Knowledge

TP is by far Ramsey's most substantial and polished effort in the area of partial belief, decision, and probability, but a number of other notes on related topics are among his papers. Two were mentioned above; another particularly interesting note is "Weight or the Value of Knowledge" (Ramsey 1991a, 285–287), in which Ramsey demonstrated a result that was independently rediscovered by Savage and by I. J. Good. Can a decision maker generally expect to be better off by acquiring more information before making a choice? Ramsey showed, in the context of his decision theory, that when free information is available, acquiring it will not lower, and may increase, the expected utility of the decision. Skyrms (1990, ch. 4) points out that the setting Ramsey uses in his treatment suggests that he may also have partly anticipated the generalized form of belief updating developed by Jeffrey ([1965] 1983) known as *probability kinematics.*

Scientific Theories, Laws, and Causality

During 1928–1929, Ramsey wrote several notes and papers on these topics that contain ideas of lasting influence. Since the papers are unfinished, and his views were in some respects clearly evolving and unsettled, the focus here will be on their general direction and on several ideas that were later taken up and developed more fully than Ramsey himself had opportunity to do. One theme that runs through the papers is an instrumentalist view of laws and theories.

The 1929 paper "Theories" investigated the formal structure of scientific theories. Ramsey's approach reflected his study of recent work by Nicod, Carnap, and Russell; he was interested in the content of theoretical assertions and in how such content is related to the observational assertions that the theory explains. Assume for the moment that the two sorts of assertions can be clearly distinguished. An idea attractive to logical positivists was that, in principle, anything expressed by theoretical assertions could also be expressed in a more roundabout way by observational assertions alone. One way to do this is to show that theoretical terms are explicitly definable from observational ones and that the definitions can be inverted. Ramsey presented a simple, toy example and explored what would be required to show this. He concluded that it might be done, but only in a way so complex and cumbersome that it would never be worth doing. That was not surprising, but a more significant problem is that the theory obtained by the method of explicit definition is too rigid. Further observations might suggest additions to the theory, but additions cannot be made without altering the definitions and thereby changing the meanings of its terms (this point was further developed by Braithwaite 1953, Ch. 3).

Ramsey offered another proposal. Assume a theory T that is axiomatized in first-order logic, with a distinct theoretical vocabulary whose terms appear in T and in a set C of correspondence rules (or as Ramsey says, a dictionary) relating theoretical and observational assertions. Conjoin all the axioms of T and all the rules of C, replace the occurrences of each distinct theoretical term with a second-order variable, and introduce for each distinct variable a second-order existential quantifier that binds its occurrences. The resulting sentence contains only observational terms, it is entailed by $(T \wedge C)$, and the particular observation sentences it entails are the same as those entailed by $(T \wedge C)$. This device is now known as the *Ramsey sentence* of the theory, and it has since been widely used in diverse treatments of the content, meaning, and truth of theories (see e.g., Hempel 1958, Carnap 1966, and Lewis 1970; there are many others). One notable area in which Ramsey sentences have been widely used is in the philosophy of mind. Functionalists in particular, following Lewis (1972), have often advocated employing Ramsey sentences to characterize mental states.

How much is accomplished or shown by any particular use of the Ramsey sentence technique clearly depends upon the application. Is the matter at hand one in which a relationship between two distinct linguistic, syntactic systems is really the main target of interest? Proponents of semantic or model-based approaches to understanding theories generally

think that this is not the significant issue, and believe that more light can be shed on theories by thinking of set-theoretic or model-theoretic structures.

Ramsey explored two ways of thinking of causal laws. The brief 1928 note "Universals of Law and of Fact" (Ramsey 1990) explains the difference between universals of law and universals of fact (between lawlike and accidental generalizations) by appeal to an ideal future system of complete knowledge about the world. If one knew everything, Ramsey said, one would want to organize that knowledge in a deductive system in a way that strives for simplicity. The general axioms of the system would be the fundamental laws of nature, and the generalizations derivable from them without reference to facts of existence are derivative laws of nature. The choice of axioms "is bound to some extent to be arbitrary, but what is less likely to be arbitrary if any simplicity is to be preserved is a body [of such generalizations]" (Ramsey 1990, 143). This is as close as Ramsey came to a uniqueness claim, and he did not invoke a set of independently natural properties, or ways of carving up the world, that the ideal theory need capture. "As it is," he said, "we do not know everything; but what we do know we tend to organize as a deductive system and call its axioms laws, and we consider how that system would go if we knew a little more and call the further axioms or deductions there would then be, laws" (ibid). In this unpublished note, Ramsey did not cite him, but the account may well have developed from Ramsey's familiarity with John Stuart Mill's work. In any case, within a year Ramsey discarded the view. Its influence has endured, however, in the work of more recent philosophers, notably Lewis (1973) and Earman (1986) (see Laws of Nature).

The paper "General Propositions and Causality" contains Ramsey's second, revised treatment of causal laws. It was written in 1929, at a time when Ramsey had frequent conversations with Wittgenstein, who had just moved to Cambridge. The new view was that a law is not a summary of propositions about particular events; its causal force lies in our trust of it as a guide to inferences about particular events. Causal generalizations "are not judgments but rules for judging 'If I meet a ϕ, I shall regard it as a ψ.' This cannot be *negated* but it can be *disagreed* with by one who does not adopt it" (Ramsey 1990, 149). To assert a causal law is to assert a formula from which one can derive propositions about particular events. Its *causal* character lies in the temporal ordering of the events (ψ does not precede ϕ). The special importance attached to rules for judgments so ordered is traceable to how one thinks about one's actions; in deliberation one gives special importance to forward-looking rules, those that look to the future. Ramsey's views here have affinities to a number of subsequent treatments that strive for pragmatic, reductive accounts of causal necessity; a noteworthy example is Skyrms (1980).

This article concludes by mentioning a suggestion Ramsey (1990) made in a footnote to a discussion of conditionals in "General Propositions and Causality," at a point where he was distinguishing "hypotheticals" from material implications: "If two people are arguing 'If *p,* will *q*?' and are both in doubt as to *p*, they are adding *p* hypothetically to their stock of knowledge and arguing on that basis about *q*. ... We can say that they are fixing their degrees of belief in *q* given *p*" (155). The idea is that the acceptability of an indicative conditional corresponds to the acceptability of its consequent after the antecedent is hypothetically added to one's beliefs. Ramsey took the latter to be measured by the conditional probability of the consequent on the antecedent. The idea has been extensively developed by Adams (1975). In later philosophical literature on conditionals, Ramsey's suggestion, known as the *Ramsey test*, is widely embraced, at least up to a point. Precise characterizations of the idea vary, however, as do opinions about the scope of its adequacy. The large body of literature cannot be covered here (a recent survey of much of it is in Bennett 2003).

RATIONAL RECONSTRUCTION

Philosophers of science do many things. Nevertheless, the demand arises on occasion for them to give a general account of the relation of the work of philosophy of science to work in the sciences. To this demand, there are several responses (e.g., logical analysis of scientific and metascientific concepts, an explicit account of scientific method). One answer that has been employed in various places and times since the twentieth century is that philosophy of science engages in a rational reconstruction of science. This seems to raise as many questions as it answers. Does not the need for a "rational reconstruction" of science at the hands of philosophers seem to indicate that science as practiced is in some important sense not (wholly) rational? What is it about science that needs to be reconstructed in order to better exhibit its rational structure? What are the proper tools for reconstructing science?

This article seeks to provide a brief but balanced account of the point of rational reconstruction in the two projects that most importantly advanced that understanding of the proper business of philosophy of science: logical empiricism and Imre Lakatos's methodology of scientific research programs (see Logical Empiricism; Research Programs). Rational reconstruction is connected with many central issues of philosophical method within analytic philosophy of science. Arguments over rational reconstruction connect also to large debates about proper method in philosophy generally and, in particular, to the debates in the late

nineteenth and early twentieth centuries over the relations of philosophy to psychology and sociology (for excellent introductions to these debates, see Kusch 1995 and 1999).

Logical Empiricism

Within analytic philosophy of science, Rudolf Carnap's *Der logische Aufbau der Welt* [The Logical Construction of the World] of 1928 is the work often cited as first articulating an understanding of the business of philosophy of science as rational reconstruction (see Carnap, Rudolf). Carnap's project in the *Aufbau* is a rational reconstruction of the objects of science through exploitation of the technical resources of the new mathematical logic. He sketches a system of logical definitions that shows how all proper scientific claims can be translated back into a language that makes reference only to experience. Logical definition and inference are, of course, exemplary rational procedures, and thus the constructional system rationalizes psychologically attained knowledge, exhibiting its objective conceptual meaning.

It is sometimes suggested that rational reconstruction was introduced by the young Carnap (Reichenbach 1938) and is an expression of a radical break between early logical empiricism and the German epistemology that was pursued in the generations before it. Carnap's use of 'rational reconstruction' [*rationale Nachkonstruktion*] in the *Aufbau* was, in fact, a move within a well articulated debate among neo-Kantians, phenomenologists, positivists, Marxists, and others over the proper methods of epistemology (Richardson 1999). For example, the positivist Theodor Ziehen (1914), in his meta-epistemological work *Zum gegenwärtigen Stand der Erkenntnistheorie* [On the Present State of Epistemology], distinguished between two methods used in the epistemology of his day. He called the first the 'genetic method,' since it traced representations used in judgment back to their psychological origins; and he called the second the 'reconstructive method' because it "to a certain extent reconstructs the world of impressions from representations and judgements" (29). That is, the proponents of the reconstructive method say that the world of impressions is not the content of knowledge but is itself only an object of knowledge when placed within a system of representations and judgments. Ziehen associated the genetic method with positivism and naturalism, and the reconstructive method with neo-Kantianism.

Within this general framework, 'reconstruction' was closely associated with 'rational.' Indeed, some neo-Kantians used the language of reconstruction and tied it directly to the rationalizing of the experiential world. For example, Jonas Cohn (1908), in his *Voraussetzungen und Ziele des Erkennens* [Presuppositions and Goals of Knowing], calls pure mathematics an a priori "constructive" science because it constructs its own objects. Pure experience is not, for him, the source of knowledge so much as is the rationally opaque starting point of knowledge that is brought under rational control through mathematized natural sciences. These sciences use the resources of mathematics to rationalize and objectify experience:

> All reconstruction is partial rationalization. The concepts of the particular reconstructive sciences are also, considered in and of themselves, constructions and, as such, fully transparent. But the new epistemic task that they serve gives them a close relation to the inexhaustible and opaque experiential reality . . . . One can say, therefore, that the particular reconstructive sciences concern themselves with individuals only insofar as these can be captured under general determinations. (Cohn 1908, 342)

Carnap's articulation in 1928 of the point of epistemology as rational reconstruction of the results of cognition is a move, therefore, in an ongoing meta-epistemological debate. The formal logic of Russell and Whitehead's *Principia mathematica* was to be used to show how the objects of knowledge that are picked out by ordinary cognitive processes and the more articulated processes of science can be arrived at logically and discursively. Thus, the process of rational reconstruction has a curious feature: It yields the results independently already attained in science but replaces rationally opaque processes with transparently rational definitions and inferences:

> The fact that we take into consideration the epistemic relations does not mean that the syntheses or formations of cognition [*Erkenntnis*], as they occur in the actual process of cognition, are to be represented in the constructional system with all their concrete characteristics. In the constructional system, we shall merely reconstruct these manifestations in a rationalizing or schematizing fashion; intuitive understanding is replaced by discursive reasoning. (Carnap 1967, 89)

Rational reconstruction replaces the rationally opaque psychological processes by which knowledge is typically attained with explicit logical

definitions and inferences that show how the results of those processes are genuinely objects of rational knowledge.

The rational reconstructionism of the *Aufbau* fits into two more disputes central to German epistemology at the time. The first was over the rational status of metaphysical claims. Carnap's principal philosophical use of rational reconstruction is not so much positive regarding the sciences as negative regarding metaphysics. Carnap argues that the claims of the metaphysicians *cannot* be rationally reconstructed: Such talk has no touchstone in experience and no rational control from logic; it is without content and form. The second dispute was the by-then long-standing question of the relation of epistemology to psychology. Carnap's rational reconstructionist epistemology distinguishes the questions of the objectivity of knowledge that are properly epistemological from the workings of cognition in the causal order that are a matter for empirical study of psychology. These two debates come together, since presumably there is some psychosocial causal story about why some people talk about metaphysical matters such as the relation of *Dasein* and Nothingness. Carnap's view was that whatever causal story there is that explains the existence of such talk in a culture, the talk itself cannot be rationalized and has no meaning. Thus, the task of rational reconstruction is not simply to reproduce willy-nilly whatever the results of any psychological process may be. By 1932, Carnap (1959) explicitly claimed that the processes giving rise to metaphysical talk were affective or conative, not cognitive, psychological processes.

The first logical empiricist work in English to make much of the notion of rational reconstruction was Hans Reichenbach's (1938) *Experience and Prediction*. In this work, the need to properly distinguish epistemological from psychological concerns is very much in the foreground, and rational reconstruction is marshaled exactly here:

> Epistemology does not regard the processes of thinking in their actual occurrence; this task is entirely left to psychology. What epistemology intends is to construct thinking processes in a way in which they ought to occur if they are to be ranged in a consistent system; or to construct justifiable sets of operations which can be intercalated between the starting-point and the issue of thought-processes, replacing the real intermediate links. Epistemology thus considers a logical substitute rather than real processes. For this logical substitute the term *rational reconstruction* has been introduced; it seems an appropriate phrase to indicate the task of epistemology in its specific difference from the task of psychology. (5f)

Indeed, Reichenbach (1938) introduces his famous distinction between the contexts of discovery and justification as a "more convenient determination" (6) of the notion of rational reconstruction. He stresses the way in which the justification of scientific claims is a matter of public communication, whereas the psychology of scientific discovery can be a subjective and intuitive matter. Only the former is the proper concern of epistemology, and even in this area, epistemology substitutes a fully logically articulated structure for the more inchoate and suggestive arguments actually found in the writings of scientists engaged in reasoned persuasion. Following Reichenbach, the term 'rational reconstruction' was routinely employed by logical empiricists to explain the point of their philosophical enterprise.

Logical empiricist rational reconstruction was not without its critics. The most famous is, of course, Willard Van Orman Quine (1969), who argued that once logical empiricists themselves rejected radical reductionism, "the translation of all significant discourse into the language of experience," there was no further point for rational reconstruction:

> To relax the demand for definition, and settle for a kind of reduction that does not eliminate [the defined terms], is to renounce the last remaining advantage that we supposed rational reconstruction to have over straight psychology; namely, the advantage of translational reduction. If all we hope for is a reconstruction that links science to experience in explicit ways short of translation, then it would seem more sensible to settle for psychology. Better to discover how science is in fact developed and learned than to fabricate a fictitious structure to a similar effect. (78)

Quine's move toward psychology and naturalism here has been widely followed (see Quine, Willard Van). However, one can read Carnap's movement away from the term 'rational reconstruction' to 'explication' as a sort of response to Quine (see Explication). The point of philosophical work is not to find out how science has developed and been learned, but to provide precise resources for its future development through the conceptual tools of logic. That is, for Carnap, rational reconstruction or explication consists not so much of forensic norms for the purpose of understanding and evaluating how things have gone in science, but of deliberative resources for aiding in a clearer language of science for the future. This is, in fact,

how he connected rational reconstruction and explication in the preface to the second edition of the *Aufbau* in 1961:

> By rational reconstruction is here meant the searching out of new definitions for old concepts. The old concepts did not ordinarily originate by way of deliberate formulation, but in more or less unreflected and spontaneous development. The new definitions should be superior to the old in clarity and exactness, and, above all, should fit into a systematic structure of concepts. Such a clarification of concepts, nowadays frequently called ''explication'', still seems to me one of the most important tasks of philosophy. (Carnap 1967, vi)

Rational reconstruction, especially when deployed as a strict distinction between scientific discovery and justification, has been subject to other important objections. Thomas Kuhn and others in the historical philosophy of science have stressed a continuity of discovery and justification; Kuhn (1977) remarks, for example, ''considerations relevant to the context of discovery are then relevant to justification as well; scientists who share the concerns and sensibilities of the individual who discovers a new theory are ipso facto likely to appear disproportionately frequently among that theory's first supporters'' (328). Indeed, Kuhn's work on multiple discovery suggests an even deeper lesson: In the absence of successful justification, scientific discovery has not even happened (see Kuhn, Thomas). Discovery is generally assigned to whomever can best marshal the resources of persuasion, and a claim that is not substantiated in the scientific community is not a scientific discovery at all.

Lakatos

The second major attempt to explain philosophy of science as rational reconstruction was at the very center of the historical philosophy of science that had rejected logical empiricist rational reconstructionism. Imre Lakatos importantly revived the notion of rational reconstruction in a new setting, with his view that philosophy of science engaged in the rational reconstruction of the history of science (see Lakatos, Imre). Lakatos argued that any history of science begins with a prior normative sense as to what counts as a scientific achievement in the first place, and this normative sense is an implicit or explicit philosophy of science. An explicit philosophy of science is, thus, an account of the constitutive norms of scientific achievement, and a history of science based on such a philosophy presents an internal history of scientific rationality according to this norm. Lakatos (1978b) summarizes his view of the relation of philosophy of science and the history of science:

> [P]hilosophy of science provides normative methodologies in terms of which the historian reconstructs ''internal history'' and thereby provides a rational explanation of the growth of objective knowledge; (b) two competing methodologies can be evaluated with the help of (normatively interpreted) history; (c) any rational reconstruction of history needs to be supplemented by an empirical (socio-historical) ''external history.'' (102)

A philosophy of science thus determines what internal history of science is, which in turn determines which historical questions about science are relegated to an external, social, and psychological history. Philosophical presuppositions, therefore, set the problems that a historian must solve in order to write a history of the rational development of science while simultaneously assigning some problems to a nonrational or even irrational external history. For example, a falsificationist methodology of science can assign a rational meaning to an experiment only if it can find a theory that the experiment attempts to falsify. Thus, if an experiment is presented by the scientists who designed it as independent of theory, the falsificationist historian must find hidden in the historical record a theory that the experiment in fact tested. In the absence of such a theory, the falsificationist cannot assign a rational point to the experiment. If no such theory can be found, then the falsificationist must assign both the scientist's own account of science and the experimental activity to a nonrational external history—perhaps a history of false consciousness due to faulty scientific pedagogy.

It does seem plausible that a historian of science would have to go to the historical record with certain presumptions about which activities are properly scientific. What Robert Boyle did with his air pump is part of the history of science; what Robert Boyle had for his breakfasts and what his butler did with the air pump are neither of them events properly in the history of science. Lakatos's pronouncements on how to write history, however, struck many as so theory laden as to require a deliberate falsification even of what was obviously internal to science. For example, in a famous passage, Lakatos (1978b) writes:

> Internal history is not just a *selection* of methodologically interpreted facts; it may be, on occasions, their *radically improved version*. One may illustrate this using the Bohrian programme. Bohr, in 1913, may not have even thought of the possibility of electron spin. He had more

> than enough on his hands without the spin. Nevertheless, the historians, describing with hindsight the Bohrian programme, should include electron spin in it, since electron spin fits naturally in the original outline of the programme. Bohr might have referred to it in 1913. Why Bohr did not do so is an interesting problem which deserves to be indicated in a footnote. (119)

When called upon to diagnose Lakatos's curious attitude toward history, some theorists, notably Hacking (1981) and Koertge (1976), have, quite rightly, pointed to Lakatos's lingering Hegelianism. Unlike most empirically minded Anglo-analytic philosophers, who think that the set of historical events is simply the set of all things that have happened, Hegelians have a teleological sense of history, and any event that does not fit into the thread of the story is not part of history. To have a diagnosis of Lakatos's attitude is not yet to convince anyone else to adopt his view. Many have found Lakatosian rational reconstructions of history of science to be grotesque parodies that cover up more than they reveal about the dynamics of science. Kuhn indicated, indeed, how Lakatosian rational reconstructions (which must have looked like highly theoretical versions of the textbook histories of science he inveighed against) violate the norms that historians work within:

> The problem is not that philosophers are likely to make errors—Lakatos knows the facts better than many historians who have written on these subjects, and historians do make egregious errors. But a historian would not *include in his narrative* a factual report which he *knew* to be false. If he had done so, he would be so sensitive to the offense that he could not conceivably compose a footnote calling attention to it. (Kuhn 2000, 151)

Conclusion

Philosophy of science has been, and continues to be, motivated in large measure by a desire to explain the rationality of science. Rational reconstruction was, to an important degree, a response to the demise of inductivist accounts according to which science was rationally constructed via an inductive method. Rational reconstruction worked together with conventionalism and hypothetico-deductivism to grant a freedom and creativity to the work of scientists while rescuing the rationality of science, which was now located in *post facto* rational evaluation. Debates over rational reconstruction are thus ultimately debates about whether philosophers should be defending the rationality of science and what resources are available to do so.

REALISM

Realism in the philosophy of science is basically the thesis that unobservable entities posited by empirically successful theories exist (see Theories). Theoretical posits, like electrons or genes, are not just useful ideas but real entities. Realism takes the explanatory and predictive success of theories to warrant an ontological commitment to the existence of the entities they posit. But it is certainly possible for theoretical posits to be useful even if the entities posited do not exist. Scientists themselves use many theories that they disbelieve. Antirealism claims that the explanatory and predictive success of theories testifies only to the utility of their posits and cannot warrant the belief that the posited entities are real. At issue is the reach of empirical evidence (see Instrumentalism).

Virtually all the positions and arguments advanced in the debate over scientific realism are implicated in this statement of the issue. Interpretive problems will be addressed first so as to construct a defensible formulation of the realist thesis. Subsequent sections will evaluate the major arguments.

Formulating the Realist Thesis

Components of Realism

Scientific realism, as described, has semantic, metaphysical, and epistemic components. Semantically, it claims referential success for theoretical concepts and truth for existence claims of theories. This much semantics is redundant. It reduces to the metaphysical claim that posited entities exist. To assert that p is true is to assert that p, and to assert that a refers is to assert that there are as. These disquotational properties eliminate 'true' and 'refers' from contexts where p and a are explicit.

But realism makes a further commitment to the descriptive success of theories. Whether or not reference to an unobservable entity requires describing it truly, realism must attribute some truth to a theory's description of the entity if evidence for the theory is to warrant realism's metaphysical claim. For, as the entity is unobservable, its mere existence, independently of its nature and relations to other entities, carries no observable consequences. So the realist believes not only that the entity exists, but also that it has certain properties. Because theories develop and change in response to new evidence, and competing or successive theories sometimes differ in the properties they attribute to the same entity, this further realist commitment is vague and inconstant. It is therefore doubtful that the semantic component of realism can be made entirely redundant.

It is instructive, on this point, to contrast the thesis of "entity realism" advocated by Ian Hacking (1983). Hacking eschews all talk of truth and all theoretical description; his realism is exclusively metaphysical, committed to the entities alone in virtue of their technological applications in the study of yet more speculative aspects of nature. He believes that electrons exist because scientists say they use them to study other things, but he professes no theoretical beliefs as to the nature of electrons. As Hacking disallows himself the

resources to explain how a theoretical entity manages to be technologically useful, deference to how scientists describe their own practice is his only means of identifying the entities to which his realism is committed. This leaves him wide open to an antirealist reading of such description as a useful manner of speech without ontological import.

A viable realism must endorse some theoretical properties as well as a theoretical ontology. The difficulty, to which Hacking's minimalism is responsive, is to make this further commitment specific. Characteristically, realism speaks of there being "some truth" to theory, but declines to be fully explicit as to what this truth is. Realism claims that there is truth enough to account for the predictive and explanatory effectiveness of unobservable posits. But not knowing how much truth or what truth is enough, realism cannot cash its truth attributions in for specific theoretical assertions.

Epistemically, realism claims that empirical evidence justifies theoretical beliefs. This component is, again, only partially redundant. Specification of the propositional content of the beliefs justified can constitute the realist thesis without adverting to justification. But the denial that any specific theoretical proposition is justified is not yet antirealism. Antirealism claims not that particular propositions are unjustified, for the realist could agree and endorse others, nor even that *no* theory is justified, for the realist could attribute this to a contingent lack of evidence, perhaps to lack of resources or diligence. Antirealism claims that it is not in the nature of empirical evidence to justify theoretical belief. Realism and antirealism divide over the *capacity* of the kind of evidence in principle available to warrant beliefs as to the existence and nature of entities that cannot, in principle, be observed. To claim that theoretical beliefs are epistemically justifiable is already realism, and this claim does not reduce to any endorsement of a particular theory.

Of course, realists characteristically claim much more. They claim that many theories in fact enjoy an evidential warrant sufficient to show that the unobservable entities they posit exist. But then they meet the additional argumentative burden that this additional commitment incurs with vacillation or vagueness; the favored theories are unspecified or their specification is disputed. Typically, they are identified only as the "best supported" theories of current science, without specifying a standard of support or determining the degree of support of any particular theory. This has not mattered much to the debate. The principal arguments for and against realism are largely insensitive to differences among its semantic, metaphysical, and epistemic components.

The Observational-Theoretical Distinction

The distinction between observation and theory is crucial to realism, and it might seem that the whole debate is obviated by the disrepute into which this distinction has fallen (Maxwell 1962; Churchland 1985) (see Observation). If the distinction is denied, then the alternative to realism is an expansion of antirealism into a thoroughgoing skepticism. The antirealist needs the distinction to delimit such incredulity. But surely some, at least rough and ready, distinction is allowable; its difficulties go not so much to showing that the distinction is untenable as that there are too many ways to draw it, none of them neat. An epistemically pristine concept of observability independent of science is elusive in principle. And if one follows science in countenancing theory-mediated methods of observation, then the boundary of the observable is ever-shifting (Leplin 1984b; Shapere 1982). Atoms and microbes used to be examples of unobservable entities; now the status of atoms is unclear. Elementary particles seem safe, unless one begins to worry about whether they are rightly conceived of as "entities" at all and whether it makes sense even to entertain their observability (see Particle Physics).

One can only assume that the issue is rightly joined at some point, for in claiming that empirical evidence can warrant theoretical belief the realist is not predicting that all objects of such belief will become observable. Whatever the point of engagement, beliefs on the observational side are not in dispute. The realist need not account for their justification but is entitled to assume it in defending the justifiability of beliefs on the theoretical side. Conversely, an argument strong enough to impugn observational beliefs is out-of-bounds to the antirealist. It is not the burden of realism to refute skepticism.

The Scope of Realism

Realism's obvious attraction, and motivation, is to side with science. Realism brooks no philosophical impediment to what science discovers. This advantage depends on delimiting the range of theoretical entities, and propositions about them, that realism endorses. For science itself declines to treat many of its theoretical posits realistically. If it is not to disagree with science, realism must disqualify some entities.

Empirical success *tout court*—explanatory and predictive utility—does not seem an adequate basis for doing so. Stipulating that success be uniform—uncompromised by failure—disqualifies replaced theories of continuing utility, but this stipulation is both too strong and too weak. The records of entrenched, credible theories are not unblemished; there are reasons for tolerating empirical problems rather than blaming the theories that face them, nor is there any expectation that the best theories scientists could ever have would be trouble free. And theories at the frontiers of research, theories too speculative and underdeveloped to believe, may, for a time at least, face no empirical difficulty whatever. They may be supported by all available evidence simply because too little pertinent evidence is available. Worse, rival theories may all be successful; the realist must not be ontologically indiscriminate where science is skeptical.

The standard solution is to restrict realism to mature, entrenched, well-tested, current theories. This is inadequate on several counts. Not all the entities such theories posit are meant to have ontological standing. Some are conceptual devices that the theory is not committed to. And their status can change. Scientists come to interpret realistically entities originally introduced as artifacts of mathematics or aids to computation—positrons and quarks, for example. And entities originally intended realistically get reinterpreted as conceptual devices whose existence is prohibited by theory—electron orbits, for example (see Chemistry, Philosophy of). Some theoretical entities are part of a conceptual background assumed in interpreting a theory but uninvolved in the application of the theory to observable situations—the electromagnetic ether, for example. The conceptual framework may be dispensable or replaceable without empirical cost. Some entities are conceptually anomalous to the point that commitment to them is unreasonably precipitous however well the evidence supports them and however indispensable to the progress of science they appear—gravitational mass, for example. A defensible realism must somehow unburden itself of a profusion of theoretical entities that scientists—whose epistemic ambitions are entangled with pragmatic, aesthetic, and heuristic interests philosophically infected by sociology—admit into their best theories.

To address these problems, the following statement of scientific realism is proposed:

> *SR*: Theoretical entities that are needed to explain or predict empirical results, and that are posited by well-supported theories free of empirical or conceptual difficulties, exist and have those of the properties these theories attribute to them that enable them to fulfill their explanatory and predictive roles.

To motivate the unusual complexity of *SR*, it will be contrasted with two popular versions of realism.

Contrasting Formulations

According to Bas van Fraassen (1980), realism is the thesis that science aims at truth and that acceptance of a theory includes believing that it is true (see Empiricism). Notice that this version acquiesces totally in realism's propensity for vagueness as to what, exactly, one is to be realist about. Van Fraassen's realist is not explicitly committed to anything epistemic or metaphysical. He is, however, semantically profligate; truth is the defining concept. He is also, like Hacking, committed to a particular reading of scientific practice. Van Fraassen's realist need not believe that any theory is true but that the scientist believes this in accepting a theory. *SR*, by contrast, is a thesis about what science achieves, regardless of its aims or epistemic attitudes. Science's predominant interest and direction could be nonepistemic, so far as *SR* is concerned. They could be indecipherable or as diversified as the proclivities of individual scientists. Unwilling to defer to the supposed values of science as an institution, *SR* must itself specify the conditions for metaphysical and epistemic commitment.

An older realist tradition, associated with Hilary Putnam (1978) and Richard Boyd (1984), holds that successful theories are approximately true (see Putnam, Hilary). The qualification leaves room for theory change and refinement. This version is epistemically profligate. *SR* achieves the same flexibility with much less generosity. A theory does not have to be "approximately" true or "close" to the truth to be empirically successful. It can contain lots of falsity that fails to make a difference at the observational level. So *SR* endorses only those entities and only those of their property attributions needed to make sense of what transpires at that level. *SR* is irreducibly semantic and epistemic because it is difficult to specify what these entities and properties are. They must be determined case by case through analysis of the evidence, of how the evidence is predicted or explained, and of whether alternative modes of prediction and explanation, invoking different entities or properties, are open.

Arguments for Realism

The Burden of Argument

Debates over realism are complicated by disagreement, usually implicit, about the argumentative burden. Does it fall upon the antirealist because realism's endorsement of science gives it an initial plausibility? This appears to be the presumption of Philip Kitcher (1993), who thinks that realism wins if antirealist arguments are countered. Or does it fall upon the realist because realism makes the stronger epistemic commitment? This is generally the view of antirealists, notably van Fraassen, who recommends antirealism for its epistemic minimalism. Since many realists, in the tradition of Putnam and Boyd, accept the burden of argument, it seems appropriate to begin with pro-realist argumentation.

This priority does not, however, reduce the antirealist's burden to criticism. Because of an important asymmetry in the opposing positions, antirealism requires an independent line of argument. It was noted that theoretical entities are given varying and changeable roles within science. Their ontological standing is subject to dispute, uncertainty, and investigation. A good example is electron orbitals. The original quantum theory required them, and experimentalists have claimed to observe them (Scerri 2001). Yet quantum mechanics denies their existence; only stationary states of the atom as a whole are real (see Chemistry, Philosophy of). Realism reflects this diversity in circumscribing the range of its intended applicability. Antirealism, by contrast, counsels a sweeping ontological skepticism with regard to theoretical entities as such, apart from any scientific issues affecting their interpretation. Only autonomous philosophical reasoning, presumed to trump debates within science, could ground so indiscriminate a position.

The Explanationist Strategy

The main line of argument for realism is "explanationist" or abductive. This means, essentially, that the explanatory achievements of theories count favorably in their epistemic evaluation (see Abduction). The need to advance theoretical hypotheses to explain empirical results is justification for believing the hypotheses, that is, for taking them to be true. In Putnam's version, if there were no truth to theory, one would be at a loss to explain, not just what is observed, but also the success of theory in explaining and predicting what is observed. In Boyd's version, truth attributions to theory derive from the success of the scientific method in generating empirically successful theories. To explain the success of method, one must suppose it grounded in a fundamentally correct picture of nature.

As it stands, this line of argument is seriously deficient. Just as realism is selective in the entities and properties it endorses, so must it be selective in the explanatory and predictive successes in which it invests epistemic import. For many, if not all, such successes admit of nonrealist explanation. Scientific method recognizes this. Scientists do not claim epistemic warrant from all the empirical results that a theory predicts. Experiments capable of warranting a theory must be carefully designed to make errors in the theory detectable. If this cannot be done, the theory is not warranted, however rich its explanatory and predictive success.

Thus, it was clear to Mendel that his laws of dominance and segregation, and the unobservable hereditary particles they introduced, got no support from the ratios of dominant and recessive traits in third-generation plants (see Genetics). That is why he designed the "backcross test," which predicted new ratios uninvolved in the construction of those laws. Watson and Crick did not recommend their helical model of DNA for the amount of water that it accommodated, although the amount of water accompanying DNA was important information that an acceptable model would have to provide. They needed x-ray photographs. Some empirical information is built into theories. Some is predictable by rival theories. Some is explainable by theories—in geology and evolutionary biology, for example—that could also be used to explain contrary results. An explanatory argument for realism must identify those scientific successes that realism is needed to explain.

Novel Prediction

The most promising strategy is to focus on predictive novelty (Leplin 1997a). Scientific practice accords special probative weight to a theory's successful prediction of results that were unknown, unexplained, unappreciated, unanticipated, uninvolved in the theory's construction, unrelated to previous tests, unlikely or counterindicated on the basis of rival theories, unpredictable apart from the theory—a host of loosely related ideas are encapsulated in the scientific conception of novelty. The prediction of gravitational deflection of starlight by general relativity is a paradigm case of a novel result highly influential in the evaluation of a theory by scientists. The prediction from Fresnel's wave theory of a bright spot in the center of the shadow cast by a circular disk in spherical diffraction is a favorite example of philosophers (Giere 1983).

These examples suggest that novelty matters because it represents discovery, which is the business of science. A successful novel prediction is generally the discovery of a new phenomenon. But as the variations in the cognates of the notion suggest, this simple desideratum is incomplete. Sometimes what is discovered is not the phenomenon itself but how it is to be explained. A known phenomenon may continue to be regarded as novel so long as it defies theoretical explanation. For philosophical purposes, an understanding of novelty is needed that will advance the distinctively epistemic interest of licensing theoretical belief, rather than the loose and variable understanding of the scientist concerned to learn about the natural world.

The twentieth-century philosopher who made the most of novelty was Imre Lakatos (1970) (see Lakatos, Imre). Novelty was his criterion of the progressiveness of science; new theories must make new predictions. This is instructively ambiguous: Is the newness in what is predicted or in the prediction of it? Lakatos's conception of progress was primarily methodological, not epistemic. As it takes no account of a theory's conceptual coherence or negative evidence, Lakatosian progress cannot assure an advance in knowledge or truth. What the realist wants from novelty is a property that requires realist explanation. A novel empirical result must be one whose successful prediction by a theory requires the existence of the theory's unobservable posits to explain.

For this purpose it is unnecessary that the result be previously unknown, nor even uninvolved in constructing the theory, for its involvement could have been innocent. Perhaps, although the theorist used it, it need not have been the case; its use was incidental in that its omission would not have affected the theory's development. Perhaps the result was like a superfluous premise in a valid argument. It may have had heuristic importance, but without it the same conclusion would eventually have been reached. Conversely, that a result be totally unknown, new in every respect, does not guarantee novelty. For the result might instantiate a general principle assumed in developing the theory, or be interchangeable in the theory's development with known results that were crucial in determining the theory's predictive capacities. In these cases, the theory's provenance is such that it would naturally predict the result whether its posits warrant a realist interpretation or not.

Novelty requires that a result have a certain kind of *independence* from the provenance of the theory predicting it. Neither the result nor any general law or principle that subsumes it can have a role in determining what the theory will predict. Then the realist can argue that the theory's successful prediction of the result was not foreordained, but requires special explanation. This form of independence captures the idea of unexpectedness or distinctiveness ingredient in the common conception of novelty.

A remaining barrier to supposing that realist explanation is needed is that the result might also be predicted by rival theories with respect to which it is also independent. The realist must not endorse incompatible theories, and might lack a principled basis for favoring one over others. A number of additional measures pertaining to the weight or quantity of evidence might be introduced to handle this problem. But the simplest expediency is to make it a condition of a result's novelty for a theory that no viable rival theory predicts the same result. Then the realist can argue that the only available explanation of the theory's predictive success is to be found in the theory's own epistemic merits. This is a *uniqueness* condition. It captures the idea that, not only is a novel result in fact unexpected, but it is one that scientists had no, even unrecognized, reason to expect.

This requirement is clearly historical. Either novel status is historically variable or it must be indexed to a particular state of science. Given the realist's epistemic purposes, it is best to relativize novelty to the theories available at a particular time. A result R is *novel* with respect to a theory T if it satisfies the independence condition with respect to T and, at the time that T first predicts it successfully, no viable rival to T also predicts it. Then, the later development of rivals that predict R affects not R's novelty for T but its epistemic weight in the evaluation of T. Empirical results that satisfy the independence and uniqueness conditions for novelty are the ones whose successful prediction the realist claims provide warrant for theoretical beliefs.

Defending SR

With this delimitation of the range of scientific successes to which to apply his explanationist strategy, the realist's argument for *SR* is straightforward. The theoretical entities and properties that a theory uses to achieve predictive success are *needed* to achieve this success if this success is novel, for novel success is explainable neither on the basis of a theory's provenance nor on the basis of rival theories. A novel predictive success provides some reason to think that the theoretical entities used to achieve it are real, for if they are fictitious, if the theory is wholly wrong in positing and

describing them, then one is at a loss to understand how the theory manages to achieve this success.

Notice that realism's explanandum here is not a novel result as such, or its prediction, or the truth of this prediction. The result is a fact about the world; the theory explains that. The theory's prediction of the result is explained by the theory's semantic content and the logical relations of this content to a statement of the result. The explanation of the prediction's truth is that this is the way the world is observed to be. What the truth of the theory is invoked to explain is the complex relational fact that the theory predicts the result *successfully*; that is, it yields the prediction and the prediction proves correct. How the theory manages to do this is unexplained by its semantic content or the observable way of the world.

A number of philosophers have argued that the appeal to truth gains the realist no explanatory advantage. They point out that the reality of theoretical entities adds nothing to their explanatory resources. Reality, according to Hacking (1983, 54), is not part of a theory's explanation of anything. A theory never explains anything just "by being true" (Levin 1984, 126). Such objections are beside the point, because realism's explanandum is not that of the theory, but is a second-order fact about the theory.

That a theory is sufficiently rich to yield novel predictions and that some such predictions prove true might be unremarkable. At what point appeal to chance becomes intellectually inadequate is disputable. But surely a sustained record of novel success unblemished by failure invites theoretical belief. To persist in agnosticism in the face of such ever-mounting achievement would seem to be a position that refuses to acknowledge the very possibility of evidence against it, thereby preempting its own eligibility for support. It is also a position at odds with scientific method, which seeks explanation not only of properties of the physical world but also of the success of theories in predicting and explaining these properties. Understanding why theories work as well as they do and no better is necessary for improving them. Unless the antirealist thinks there are a priori reasons to prefer methods of inquiry different from those found to be successful in experience, the project of understanding the success of theories cannot very well be rejected. But to the extent that such success is novel, realism is the outcome of this project.

The Antirealist Response

The antirealist's response to the sort of argument sketched is to attack abductive reasoning. Van Fraassen claims that explanation is a pragmatic rather than an empirical virtue; that is, the reasons for which it is valued have nothing to do with the realist's epistemic aims. Explanatory success cannot betoken truth, because it is impossible for empirical evidence to decide whether a theory's claims about its unobservable posits are true. No evidence available in principle can distinguish a theory's truth from its utility and reliability in prediction. The weaker, nonrealist hypothesis that a theory is empirically adequate—that it gets the observable facts right—is the strongest hypothesis testable. As a stronger hypothesis, realism is untestable and cannot be warranted.

One might wonder whether anyone but the skeptic can accept van Fraassen's constraints on the reach of evidence. Van Fraassen himself is certainly prepared to advance theses, like the empirical adequacy of a theory, that are stronger than alternatives among which observations cannot discriminate. Why is the thesis that a theory gets the *observed*, rather than the observable, phenomena right not the strongest thesis warrantable?

But a more fundamental question to ask is whether van Fraassen's reasoning argues against abduction or just presupposes that abduction is illegitimate. The realist contends that a theory's predictive and explanatory success is evidence for it. Van Fraassen contends that only the empirical facts themselves—not the fact that they were predicted successfully or explained, nor their novelty—are evidence for anything, and these facts can have no differential bearing on a theory's truth as against its mere empirical adequacy. Van Fraassen has given no reason for this limitation of the scope of relevant evidence. But he might ask whether the realist is any better off. Why should how the empirical facts are predicted or explained be an evidential matter? The criticism would then be that it is incumbent upon realists to defend their expansion of the scope of evidence.

There is a naturalistic answer to this challenge. Explanatory reasoning is indispensable in ordinary life. People leave the room by the door rather than the window, not because over extended trials people have had better results the one way than the other, but because they believe general laws that explain experience. Neither enumerative nor eliminative induction without abduction can make sense of the warrant for commonplace, practical decisions. Explanatory reasoning is equally indispensable within science. The progress of modern science depends squarely on the "method of hypothesis," the willingness to advance theoretical hypotheses and to judge theories by their explanatory

resources. Recognizing that the methods and standards for investing credence have no a priori warrant, the naturalist relies on those that have been found successful in experience. Abduction works.

Arthur Fine (1984) thinks that this defense of abduction is circular. Because abduction is used in science to decide what conclusions to draw about the world, it must not be used in the philosophy of science to judge the epistemic status of these conclusions. This would be to *pre*judge their legitimacy. If philosophy is to judge the methods of science, it must not presume the reliability of those very methods. According to Fine, whether or not realism is correct, abduction is bound to support it, because realism is an explanatory hypothesis and abduction simply assumes that explanation betokens truth. If it does not, then the consistent abductive reasoner is systematically deceived. Only methods of reasoning that, unlike abduction, are potentially sensitive to a disconnection between truth and explanation could ground realism, because only they are capable of delivering a nonrealist conclusion.

There are a number of replies to this criticism, their theme being that Fine's requirements for a permissible realist argument are unreasonably stringent. Since abduction is used successfully in science to reach conclusions about observable phenomena, there is an immediate danger that Fine's requirements amount to skepticism. If theoretical beliefs are preempted by their abductive basis, so are many beliefs about observables. Could beliefs about observables be recovered on some other basis? Van Fraassen (1989) thinks so. But Leplin (1997a, Ch. 5) has argued that abduction is as fundamental as other forms of ampliative inference and that its inclusion in one's inferential repertoire is necessary to block paradox. In particular, enumerative induction is legitimate only for properties connected by an explanatory relation. More generally, the reply to Fine is that one cannot investigate scientific practice with methods more fundamental than those of science, because there are no more fundamental methods; indeed, there are no known methods at all of any plausibility and reliability that science does not already use. Hence, skepticism is the only alternative to the innocence of such circularity as there may be in the realist strategy.

Arguments Against Realism

Underdetermination and Empirical Equivalence

Because the relation of empirical evidence to theory is ampliative, any body of evidence is strictly consistent with the falsity of any theory. As it is not open to the antirealist to reject ampliation altogether—that produces skepticism—the antirealist cannot fault the realist for believing a theory on the basis of evidence that leaves open the possibility that some rival theory is true instead. Nevertheless, the possibility of unrefuted rivals has been used to mount an attack on realism. The key is to claim not only that any given body of evidence leaves alternatives to the realist's preferred theory open, but the stronger thesis of empirical equivalence:

> *EE*: Every theory T has a rival theory T' whose observable consequences are identically the same as those of T.

According to *EE*, the existence of T' is not merely a logical possibility but a fact. A multiplicity of theoretical options are invariably available, whatever the observable evidence. Moreover, observations used to support T cannot in principle discriminate T from T'; it is not just that they fail to do so presently, so that a warranted choice requires further evidence. Transitory evidential indecisiveness is a perennial situation; in it scientists attempt to design new experiments capable of discriminating among the contending theories. According to *EE* they may thereby eliminate some contenders, but can never reduce the options to a single theory. Frequently it is claimed that all theories have indefinitely many or infinitely many empirically equivalent rivals, so that crucial experimentation necessarily leaves a multiplicity of options (Kukla 1998, chap. 5). But if realism can contend with *EE* as formulated, these bolder versions need not be addressed. *EE* is a basis for claiming that theories are underdetermined by all possible evidence:

> *UD*: No amount of evidence suffices to warrant any theory.

It is supposed that, given *EE*, no evidence for any theory can support it over some rival (see Underdetermination of Theories). And it is further supposed that if rival theories are equally supported by the evidence, then a choice between them can be justified only pragmatically and cannot be epistemically warranted. If *UD* is correct, then realism—*SR* in particular—is indefensible.

As *EE* is stronger than the uncontested logical inconclusiveness of evidence, it requires argument. One approach is to cite cases. A Newtonian theory in which gravitation is fundamental may predict the same particle trajectories as an Einsteinian theory in which space-time is curved (Earman 1993). Standard von Neumann quantum mechanics may be empirically equivalent to a Bohmian formulation of quantum mechanics with hidden variables

(Cushing 1994). But the realist has no interest in denying the possibility of empirical equivalence, and it is unclear how a few real cases can generalize into anything like *EE*. What impresses one about real cases are the tentativeness and complexity of the judgment that empirical equivalence is irremediable, and the difficulty of formulating a rival theory that achieves it.

A more general argument exploits the leeway some important theories leave open for fixing certain of their parameters. Van Fraassen (1980, chap. 3) points out that any theory differing from Newtonian theory only in ascribing a nonzero constant absolute velocity to the center of mass of the universe is empirically equivalent to Newtonian theory. John Earman argues that the global topologies of some cosmological models allowed by general relativity are empirically indeterminable in principle. Rival hypotheses about the compactness of space, for example, will be empirically equivalent. As these examples depend on accepting a substantial body of theory, the realist should welcome them (Laudan and Leplin 1991; Stanford 2001). As shown, the realist has no interest in claiming that successful theories are to be believed in every detail or that every theoretical issue must be epistemically resolvable.

The most influential defense of *EE* is algorithmic. For example, define $T' = \neg T \wedge O(T)$, where $O(T)$ says that T's observable consequences are true. This approach substitutes artifactual cases for real ones to achieve generality. But it is unclear whether *EE* can be sustained artifactually. The antirealist cannot claim that the mere logical indecisiveness of evidence establishes *UD*, for then the result is skepticism. For *EE* to advance beyond the logical indecisiveness of evidence, the rival whose existence it guarantees must be a theory. Is $\neg T \wedge O(T)$ a theory? Impatient with the controversy this question stirs up (Leplin and Laudan 1993; Kukla 1998, Ch. 5), one might become inclined to dismiss it as "semantic." This would be a mistake, for what is really at issue is whether *EE* is capable of underwriting *UD* (Leplin 1997b). It is *UD* that threatens realism, not *EE* as such. If *EE* is read simply as asserting the consistency of $\neg T$ with $O(T)$ (or with all possible evidence for $O(T)$), if, in other words, $\neg T \wedge O(T)$ is to count as the rival theory that *EE* promises, then any underdetermination consequent upon *EE* is too sweeping for the antirealist to embrace. Either no underdetermination of real theoretical belief follows from *EE*, or any belief logically stronger than the observational evidence in hand is underdetermined. The first option sustains realism; the second is skepticism.

There is, in fact, no algorithm for generating theories, and it is by no means clear that theoretical alternatives are always available. And where they are available, there is no general impediment in principle to observational discrimination. Apart from the profligacy of its promise to deliver theories without end, there are two grounds for suspicion about *EE*.

The observational consequences of a theory depend on auxiliary information with which it is conjoined to generate predictions. One worry is that this information is inconstant, augmentable, and defeasible in unforeseeable ways. Equivalence with respect to one state of auxiliary knowledge may give way to decidability with respect to another. Unless the potential scope of auxiliary information is somehow delimited, equivalence has no guarantee. Even an equivalence of the idealized "total" theories of a final science is in principle amenable to changes in auxiliary knowledge (Leplin 1997b).

The second worry is that if *UD* were true, the theoretical auxiliaries needed to generate observational consequences from a theory would have no epistemic warrant. As different observational consequences are obtainable with different auxiliaries, the inability to privilege any specific auxiliaries leaves the theory's class of observational consequences indeterminate. But then *EE* itself is indeterminate, and cannot be used to infer *UD*. Thus either *UD* is false and there is no warrant for theoretical beliefs as realism contends, or *EE* is undecidable, in which case *UD* is unsupported. Either way, the antirealist's argument from underdetermination fails.

The Skeptical Historical Induction

A more serious challenge to realism is to be found in the historical record of once successful theories that science has come to reject. If successful theories have regularly proven to be false, then the success of a theory cannot be evidence that it is true. Larry Laudan (1981) has compiled a list of once prominent theories whose unobservable posits are unacceptable to contemporary science. Included are electromagnetic and optical ether theories, phlogistic chemistry, and the caloric and vibratory theories of heat. He invites the induction that the unobservable posits of contemporary science will in turn be rejected by future science, challenging the realist to explain why theoretical entities that happen to be current should be held exempt from the lessons of history.

Laudan's list, though embarrassing to realist intuitions, is not immediately generalizable. Even

if many successful theories are false, success may yet indicate truth if its frequency among false theories is low. It may be that during the historical periods from which Laudan's examples come, virtually all theories were false. It is the small minority of successful ones that require notice. Perhaps success is far more frequent among true theories, which predominate in contemporary science, than among false ones. After all, the realist thinks not only that the best confirmed theories are at least partially true, but also that methods of theorizing and protecting against error have improved with scientific experience. It is a natural corollary to the realist position that truth is more frequent among current theories than past ones. But this is speculation. At best it prevents Laudan's argument from being definitive; it does not prevent it from shifting the burden to the realist.

A number of realist responses suggest themselves. The original response was Putnam's restriction of the abductive argument for realism to "mature" science. But of course the criterion of maturity cannot be currency. If realism is to claim any naturalistic grounding, if it is to be responsive to the historical record rather than imposed a priori, then its delineation of what is relevant in this record must not disqualify negative evidence. There must be an independent standard that Laudan's examples fail, a standard of experimental objectivity or severity of testing, some methodological stricture whose violation disqualifies the examples as the sort of successes that warrant realist explanation. Perhaps it can be argued that the quantum-mechanical revolution extends even to the criteria for theoretical success, so that it is simply a mistake to credit Laudan's examples with success whatever their coeval estimation. Short of that, it will be difficult to disqualify major theories of nineteenth-century physics. But with that, it will be difficult not to forecast further changes of method that disqualify contemporary physics. If standards of success have shifted to the point that scientific judgments of it are unreliable, then current science cannot be privileged. Either way, the induction goes through.

A different response is to point to the presupposition of current science in the determination that past theories have proved wrong, for, in denying the existence of previous theoretical entities, Laudan assumes a contemporary perspective. But to assume this perspective is to declare current science true and referential. The realist can ask for no more.

Whether Laudan's examples can be reinstated on a basis less congenial to realism is a difficult issue largely unexplored. If past theories were simply refuted by further evidence, they may be pronounced false without endorsing successor theories. But then, they may no longer be pronounced, on balance, successful, and it is unclear that realism need apply to them. Alternatively, one might fashion a new induction from the fact that once-successful theories eventually proved unsuccessful to the eventual decline of current theories. Another possibility is to appeal to inconsistencies among successful theories to argue that some of them must be false regardless of which, if any, are true. Then success is no guarantee of truth, and the realist's abduction fails. But judgments of logical relations among theories have been historically variable; a definitive judgment usually requires a contemporary perspective. And if somehow sustained, such judgments will deplete Laudan's list, weakening the induction.

A variant on the induction due to Kyle Stanford (2001) finesses these problems. Stanford connects the induction to the thesis of evidential underdetermination by propounding a transitory form of empirical equivalence. Instead of claiming that an equivalent rival exists for any theory, he claims that any body of evidence supporting a theory supports some rival theory equally well. The rival need not be available; indeed, Stanford's induction to the existence of such rivals in general is based on cases in which it was *unavailable* over a substantial period of the theory's success. That is, he induces from cases of theory succession rather than theory competition. The development of science exhibits a pattern in which successful *unrivaled* theories are eventually replaced by new theories that predict and explain all the evidence that, before they existed, supported their predecessors. One is to infer that the evidence for the best current theories is equally supportive of some alternative theory as yet unidentified, so that the best current theories are underdetermined.

Some critics of realism respond to the difficulties of *EE* by founding *UD* on something weaker: At any particular time the observable consequences of *T* are the same as those of some rival or other, possibly of different rivals at different times (Kukla 1998, Ch. 5). The trouble has been that no general argument, such as the algorithmic strategy attempts, has been advanced for this thesis; it appeared as an ad hoc reaction to challenges to *EE*. Stanford's induction appears to supply such an argument, if only availability of the rival is not required.

There is a serious difficulty with the argument, however. Many philosophers and historians contend that successor theories do *not* predict or

explain the evidence for their predecessors. There are explanatory losses as well as gains in theory change; according to the more radical voices (Kuhn 1962), successive theories address altogether different questions and cannot recognize any common body of evidence at all.

But even with Stanford's more traditional view of progress (see Scientific Progress), it is problematic to maintain that the evidence explained by a new theory supports this theory as well as it supported its predecessor. In paradigm cases the new theory posits different, more powerful predictive machinery whose acceptance depends on new empirical successes. The original evidence that warranted the old theory would not be sufficient to warrant the new. How, then, can it be decided that the *extent* of the support it offers the new equals that which it offered the old? The only ready answer is to assimilate the notion of warrant or evidential support to that of subsumption; both theories subsume the old evidence. But status as a consequence of a theory is not the sole determinant of an observation's evidentiary weight with respect to the theory. It is an error, which the inference from *EE* to *UD* commits and *SR* is formulated to avoid, to assume that all of a theory's predictive successes support it at all, let alone equally. Novel ones count more, for example. In effect, Stanford supposes that since evidence supporting a theory is recoverable by inference from any stronger theory, it must support a stronger theory as well. This thesis generates well-known paradoxes of confirmation (Hempel 1965, 3–51) (see Confirmation Theory; Induction, Problem of).

The skeptical induction is designed to be naturalistic: The success of science is supposed to warrant realism, whereas the actual record of successful theories manifestly does not. As an argument from history, the induction takes at face value historical judgments of successfulness. But of course these judgments respond to multiple desiderata, pragmatic as well as epistemic. The realist will wonder whether counterexamples from history exhibit the kind of success for which realism is the appropriate explanation, and whether, if they do, the realist commitments they require are actually defeated. Even if the skeptical induction refutes a realism that infers theoretical truth from success straightaway, it may fail against a more discriminating thesis like *SR*.

To tell against *SR*, the inductive basis must include the particular theoretical entities and properties that were needed to achieve predictive success. Only if these have regularly been rejected by subsequent science, so that they were not simply misdescribed or incompletely understood but nonexistent, is *SR* in jeopardy. Moreover, the realist may require that the success achieved be novel, on the grounds that otherwise realism is not needed to explain it. Whether a significant record of novel success may be credited to many of the theories and entities from which antirealism is induced is questionable. More to the point, where novel success was achieved it is questionable whether the entities invoked to achieve it are rejected by current science.

A number of realists, including Kitcher (1993), Leplin (1997a), and Psillos (1999), respond to the skeptical induction by claiming referential success for some of the posits of abandoned theories, or at least for some specific predictive and explanatory applications of these posits. In certain experimental situations, the use of the term 'dephlogisticated air' by practicing chemists referred to the oxygen present before them, which they misdescribed. In saying that dephlogisiticated air sustained combustion, it was oxygen that they were referring to. Psillos goes so far as to identify the luminiferous ether, Laudan's prime example, with the electromagnetic field. This is a principled but risky strategy for the realist. Admitting the legitimacy of the induction, it makes its stand on what the historical evidence proves to be.

The resolution of this question depends on how reference to unobservable entities is fixed. The realist's strategy assumes that referential success does not require descriptive success, or at least that it tolerates some descriptive failure; a theoretical entity can be real although the theory that posits it is wrong. The best current theory of reference, the causal theory originated by Saul Kripke (1980), is the natural foundation for this strategy. But apart from internal problems, this theory requires an ostensive access to the referent, which is unavailable in the case of theoretical posits. Evidently, some degree of descriptive accuracy is required for theoretical reference. Pending a better understanding of the theory of reference, it is unclear how much discarded science the realist must resurrect to answer the skeptical induction.

REDUCTIONISM

Reductionism is the thesis that the results of inquiry in one domain—be they concepts, heuristics, laws, or theories—can be understood or are explained by the conceptual resources of another, more fundamental domain (Nagel 1961; Sarkar 1998). Thus chemistry is supposed to be reducible to physics (see Chemistry, Philosophy of); within physics, thermodynamics is supposed to be reducible to the kinetic theory (see Kinetic Theory); Mendelian genetics is supposed to be reducible to molecular genetics (see Genetics; Molecular Biology); and so on. Reductionism can be viewed both as describing a research strategy or heuristic (how research should be pursued) and as a claim that the results of such research justify the assertion that one domain is being reduced to another. This article will concern both these aspects.

From the mid-1930s to the mid-1970s, philosophers commonly regarded reduction as a relation among theories, theoretical vocabularies, and laws.

Nagel's (1961) influential analysis reflected the then contemporary linguistic orientations: One theory reduced to another if the theoretical vocabulary referring to its entities and properties were definable, and its laws (logically) derivable, from that of the other—connected by empirical identifications, correlations, or reconstructive definitions (see Nagel, Ernest). Essentially this model of reduction extends the deductive-nomological model of explanation to the situation in which the explanandum is itself a law (of the reduced theory) (see Explanation; Hempel, Carl Gustav). Nagel also added "nonformal," or pragmatic, conditions that had to be satisfied for a reduction to be scientifically valuable. These conditions are perhaps the most lasting contributions of Nagel's account, but in the 1960s and 1970s, they were seldom noted—the formal properties were of central concern.

Schaffner (1967) extended Nagel's account to allow approximations and "strong analogies" in connecting theories—situations in which theories did not match exactly after a putative reduction, agreeing in some predictions but diverging in others: when one theory succeeded another, or a higher-level theory was explained and corrected by a more exact lower-level account. Theories at different levels of phenomena could supposedly thereby be successively reduced to those of the lowest compositional level or most fundamental theory, indicating the derivative character and the *in principle* dispensability of the things reduced.

This familiar philosophical gambit should invite suspicion: Whatever else it accomplishes, an in principle claim reliably indicates that it has not yet been achieved in practice. Should science be satisfied with such in principle claims? If so, how are these ever to be established? If not, what alternatives should be explored (Wimsatt 1976)? Typically, "methodological" reductionists urge the superiority of reductionist aims but seldom discuss methods—no practical reductionist problem-solving heuristic, or anything from the supposedly irrelevant "context of discovery." These are bothersome lacunae: If scientific work is reductionist, it should be discernible in the practice of science.

This unitary account of reduction has long dissolved, leaving a polyphonic disunity. Wimsatt (1979), Hooker (1981), and Sarkar (1998) review the relevant literature. On the one hand, studies from different sciences have become needlessly decoupled, seldom citing one another; on the other, they have become more responsive to actual scientific practice—especially in biology. This article concentrates on biology, but the analysis is intended to extend to mechanistic explanations throughout the cognitive, social, and physical sciences (see Explanation; Mechanism).

The perceived unity of the Nagel-Schaffner account was an artifact of the focus on structural or logical rather than functional features, when interest in reduction served foundationalist aims of increasing philosophical rigor, epistemological certainty, and ontological economy. These philosophical goals seldom matched the goals of scientific research even within contexts in which that research explicitly involved the pursuit of reductions (Schaffner 1974; Wimsatt 1976). Sarkar (1998) distinguished three important types of scientific reductions (see also Nickles 1973):

- Intralevel reduction, including successional reduction (Wimsatt 1976), the type of reduction involved in theory succession;
- Abstract interlevel reduction, in which levels of organization are distinguished, and upper-level features explained, using lower-level ones; and
- Spatial interlevel or strong reduction, in which the levels of organization are defined compositionally in physical space.

Prior formal accounts commonly conflated these three different types of reduction. Scientific reductions of any of these sorts are not the global and complete systematizations traditionally envisioned by philosophers. They are usually partial, local, conditional, and context dependent—that is, dependent on the specific mechanisms involved, and their associated *ceteris paribus* conditions (for interlevel reductions), or on the character and conditions of approximation used (for intralevel reductions). Thus, reductions do not necessarily lead to the unification of the sciences into a whole that satisfies traditional philosophical criteria for coherence and unity (see Unity and Disunity of Science).

Intralevel reductions are common in mathematically expressed theories and models. The most important type of intralevel reductions are successional reductions (see below under "Intralevel Reductions"). These typically localize formal similarities and differences between earlier and later, or more approximate and exact, theories of the same phenomena through mathematical transformations, thereby aiding succession and elaboration of the later theory and delimiting conditions for safe and effective heuristic use of the former.

In abstract interlevel reductions, levels of organization are distinguished in an abstract space. For

instance, in classical genetics before the molecular era (see Genetics), the genome was represented hierarchically from a single allele to multiple alleles at a single locus, to linkage groups, and finally to the entire multilocus genotype (Sarkar 1998, Ch. 5). Properties of the entire multilocus genotype (that is, the whole organism) were supposed to be reducible to those at lower levels of this hierarchy. In condensed matter physics (Batterman 2002), hierarchical models of physical systems in phase space provide another potential example of such reductions. In biology, abstract interlevel reduction is typically a prelude to spatial interlevel reduction (for instance, from classical genetics to molecular biology). However, in physics, these abstract reductions often occur in phase-space representations and, thus, do not show the same pattern. This type of reduction does not raise any unique significant philosophical concerns not shared by the spatial type of interlevel reduction and will not be discussed further here (for more discussion, see Sarkar 1998, Chs. 3 and 5); from here on, interlevel reduction will be taken to mean spatial interlevel reduction.

Spatial interlevel reductions are compositional—localizing, identifying, and articulating mechanisms that explain upper-level phenomena and entities, all represented as entities in physical space. Reductionist accounts in complex sciences are commonly interlevel—for instance, explaining Mach bands in terms of lateral inhibition in neural networks (von Bekesy 1967), behavior of genes in terms of DNA (Sarkar 1998), or gases in terms of clouds of molecules (see Kinetic Theory). Reductions of this sort have also traditionally been called *mechanistic explanations* in the literature (Nagel 1961) (see Mechanism). *Aggregativity*, the claim that the whole is nothing more than the sum of its parts, is also commonly associated with such interlevel reductions. It is the proper opposite to *emergence* (see Emergence). Like interlevel reductions, aggregative relations are compositional. But aggregativity requires more. System properties that are aggregates of parts' properties represent degenerate cases where the organization of parts does not matter: They are invariant over organizational rearrangements. It is—roughly—a reduction without a mediating mechanism. Mechanistic models often start with many aggregative simplifying assumptions but add organizational features as they develop. As with intralevel replacements, some things (the aggregates) seem dispensable, though for different reasons: They are not required *in addition* because they are "nothing more than" the reducing things.

Intralevel Reduction

In intralevel reductions, the representation of the system being investigated is not assumed to be hierarchical or otherwise organized into levels. For instance, in biology, during heritability analysis (Sarkar 1998, Ch. 4), phenotypic variation in populations is presumed to be at least partly explainable by, or reducible to, genotypic variation: No assumption is made about the structure and organization of the genotype. The reduction of geometrical optics to physical optics similarly involves no claim about organization (see Schaffner 1967); the reduction of Newtonian gravitation to general relativity concerns all of space-time and makes no claim about hierarchical organization (see Space-Time).

The most interesting type of intralevel reduction is successional reduction, where one theory succeeds another and the earlier theory gets reduced to the later one. These reductions relate theories or models of entities at the same level of organization or theories that are not level specific. They are relationships between theoretical structures where one theory or model is transformed into another (often via limiting approximations) to localize similarities and differences between them. Since such derivations involve approximations, they are not truth-preserving deductions (see Approximation). 'Derivations' in this context is not the logical notion of deduction: In one sense, it is weaker insofar as it requires weaker formal assumptions; in another sense, it is stronger because the approximations and idealizations involved typically make implicit empirical assumptions (Leggett 1987 provides a discussion, though limited to the context of physics).

A terminological issue about the use of 'reduction' in contexts of theory succession should be noted: Sometimes, it is said that the later, more exact, or more complete theory *reduces in the limit* to the other (Nickles 1973). Thus, special relativity 'reduces' to classical mechanics in the limit as $v/c \rightarrow 0$ (where v is the velocity of a body and c is the velocity of light); either by letting velocity of the moving entity, $v \rightarrow 0$ (a "real" engineering approximation for velocities much smaller than the speed of light, c) or by letting $c \rightarrow \infty$ (a counterfactual transformation yielding Newton's conception of instantaneous action at a distance). This usage of 'reduction' is nonstandard in scientific contexts and parasitic on that of reduction in mathematics to indicate the specification of a particular value to a variable that can range over a set of values or some other operation that shows that one problem is a

special case of another problem. There is obviously no question of the predecessor theory explaining its successor.

Localizing similarities by successional reduction and differences between theories (in aspects not captured in the reduction and in the transformations used) serves multiple functions in the succession of the newer theory (Wimsatt 1976; Nickles 1973). It co-opts the evidence for, and legitimates the use of, the older theory where they agree (as $v \rightarrow 0$ in the case of Newtonian mechanics and special relativity); may establish conceptual connections between them (as $c \rightarrow \infty$ in the same case); and locates contexts to pursue confirmation, testing, and elaboration of the newer theory where they disagree. Limiting conditions show where the older theory is a valid approximation and how rapidly it breaks down.

Finally, successional reduction is a kind of similarity relation. A series of pairwise successional reductions will usually be intransitive: Differences accumulate in theoretical successions because of approximations and idealizations, ultimately becoming too great to manage. Also, reductionist transformations involve scientific work, and are not achieved gratuitously. Since their scientific functions usually require relating the new theory only to its immediate predecessor, one rarely goes any further. (There is no scientific relevance in tracing special relativity back to Aristotelian physics!) Thus, successional reduction is often intransitive by default, even when possible otherwise—which it often is not, because of cumulative differences. If mappings are too complex to construct transformations relating immediate successors, then reduction fails, and the older theory and its ontology may be discarded. Instead of reduction, there is theory replacement. So this kind of reduction can be eliminative—but characteristically only when it fails (Wimsatt 1976). Ramsey (1994) and Batterman (2002) elaborate such reductions, and Batterman's discussion of the role of singularities shows another way in which reductions can fail without being eliminative. Sarkar (1998) discusses approximations, and Wimsatt (1987) connects these issues to related uses of false models.

Interlevel Reduction

By contrast, interlevel reductions generally do not relate theories (Sarkar 1992). They are driven by referential identities (Schaffner 1967; Wimsatt 1976) or localizations (Bechtel and Richardson 1993; Sarkar 1998) between entities at the reduced and reducing levels, and not theoretical similarities. These identities or localizations comprise what were called bridge laws or "reduction functions" in traditional accounts of reduction. Darden and Maull (1977) envision the construction of a single theory tying together two domains or levels but do not require prior theories. Interlevel reductions explain phenomena (entities, relations, lawlike regularities) at one level through the operations of often *qualitatively* different mechanisms at a lower level—such qualitative differences sometimes lead to claims of emergence (see Emergence).

Such mechanistic (or "articulation-of-parts") explanations (Kauffman 1972) are paradigmatically reductionist in biology (Wimsatt 1976; Glennan 1996; Sarkar 1998). They are compositional—upper- and lower-level accounts are supposed to refer to the same thing. Unlike the similarity relations of successional reductions, these references are transitive across levels, though the explanations may not be. Levels are defined by spatial inclusion of parts in a whole. For instance, Mendel's factors were successively localized through mechanistic accounts

(a) in chromosomes by the Boveri-Sutton hypothesis (Wimsatt 1976; Darden 1991),
(b) relative to other factors (now genes) in the chromosomes by linkage mapping (Wimsatt 1992)
(c) to bands in the physical chromosomes by deletion mapping, and finally
(d) to specific sites in chromosomal DNA.

Identities and localizations are powerful hypothesis generators in the reductionist's heuristic toolkit, suggesting new predictions at one level from properties or relationships at the other, with ample cues for how to construct explanatory accounts (Bechtel and Richardson 1993; Wimsatt 1976). In contrast, more traditional "correspondence theories" (Kim 1966) lack these resources and look "empirically equivalent" to identificatory theories only in static ad hoc comparisons made after the fact. (Work in scientific discovery motivates more realistic dynamical rather than merely static accounts of these processes. They are often revealingly different.) When genes were tentatively localized to positions on chromosomes, it spawned a research program dedicated to the elucidation of what different regions of chromosomes did and consisted of. Subsequent identification of genetic specificity with DNA sequences led to projects of sequencing parts of and eventually the entire genomes of organisms (see Molecular Biology).

Localizations are not logically as strong as identities: If two entities are identical, then *any* property

of one is a property of the other. But localizations preserve all relevant spatiotemporal properties of identities, and thus all of their local mechanisms. Consequently, contrary to Schaffner (1967), identities are not required for successful reductions. For identities or localizations, interlevel reductions are transitive when compositional claims preserve boundaries between entities, and functional localization fallacies (attributing a system property to what is only a very important part of that system) often result when they do not. Sarkar (1998) explicates this point about identities more formally, showing that claims incorporating localizations may have the form of conditional statements and yet allow reductions to be achieved; they need not have the form of biconditionals, which identities must.

Boundaries between entities sometimes change for good reasons, and explanations may be intransitive for other reasons (e.g., different interests at different levels). But transitivity of explanation (and its central connection to compositional relations) is still reflected in the *modus tollens* form: Failures to explain upper-level phenomena in lower-level terms are inevitably blamed (by reductionists) on incomplete or incorrect descriptions of the relevant system at one level or another, generating expectable mismatches.

As noted earlier, failed successional reductions may eliminate objects of an older theory, but failures of interlevel reduction make upper-level objects and theory indispensable—there is typically no other way to organize the phenomena. Interlevel reductionist explanation—successful or not—is never eliminative. A mythical philosophical invention, eliminative reduction, reflects older aims of ontological economies since abandoned (Wimsatt 1979). There is no evidence for such elimination in the history of science, and there is no reason—in terms of scientific functions served—to expect it in the future. Claims to the contrary (see, e.g., Churchland 1986) may arise through conflations of successional and interlevel reduction. Designers of optical instruments continue to use geometrical optics rather than physical optics, though they may need to make corrections due to diffraction or exploit the phenomenon of polarization in some contexts, for instance, to eliminate the effects of glare (Batterman 2002). Engineers designing combustion engines use thermodynamics, not the kinetic theory of matter.

Analyses of reduction presuppose (and should provide) correlative analyses of levels whose objects, properties, and relationships are supposed to be related. These typically show that robust (multiply detectable) higher-level entities, relations, and regularities (Wimsatt 1981) do not disappear wholesale in lower-level scientific revolutions. Conceptions of them transmute, add (or occasionally subtract) dimensions, or turn up in different ways but do not disappear (Wimsatt 1994). In the case of interlevel reductions, claims of eliminativism rest upon exaggerations of unrepresentative cases.

Importantly, reductionist explanatory mechanisms are not themselves—nor directly legitimated by—exceptionless general laws. Exceptionless generalizations would be unmanageably complex. Useful, simple, broadly applicable generalizations about composed systems are richly qualified with *ceteris paribus* exceptions explicable in terms of mechanisms operating under an open-textured variety of applicable conditions (Glennan 1996). Mechanisms are not pragmatically translatable into laws (Wimsatt 1976; Cartwright 1983) (see also Laws of Nature; Mechanism).

How successful is interlevel reductionism? Historically, as characterized here, it goes back to the mechanical philosophy of the seventeenth century, according to which properties of extended bodies were to be explained by the contact interactions of their constituent parts (Sarkar 1992). The mechanical philosophy was recognized to have failed as a universal epistemology for physics by the nineteenth century, but the reductionist program continued to be pursued, though only in a piecemeal fashion. Its major nineteenth-century achievement was the kinetic theory of matter (see Kinetic Theory), in particular, Boltzmann's mechanical interpretation of the second law of thermodynamics. Einstein's kinetic account of Brownian motion in 1905 was another major success (see Sarkar 2000). While details of these—and other—reductions in physics continue to be debated, the general philosophical point, that reductions have been successful in many areas of physics, remains correct.

The major success of interlevel reductionism since the twentieth-century, as often alluded to earlier in this article, has been in biology, with the advent of molecular biology in the 1940s and 1950s (see Molecular Biology). In chemistry, meanwhile, the putative reduction of chemistry to physics has been both defended and challenged (see Chemistry, Philosophy of). In the social sciences, interlevel reductionism is usually called *methodological individualism*; it too has been both defended and challenged (see Methodological Individualism). Unexpectedly, within physics, interlevel reductionism has become controversial, with quantum entanglement often being interpreted as presenting a challenge to reductionism because it denies any standard individuation of the parts (see Jaeger and

Sarkar 2003) (see Locality; Quantum Mechanics). (For more extended discussions of reductionism in contemporary physics, see Shimony 1987 and Batterman 2002.)

Multiple Realizability and Supervenience

The concept of a level of organization figures centrally in two concepts that have played a central role in discussions of reduction and reducibility in philosophy of psychology, and the lessons one would draw from case studies in biology or physics run counter to the antireductionist views commonly asserted there. The very stability of higher levels of organization, relative to the more rapidly changing dynamics at the lower level, essentially guarantee multiple realizability. The lower level characteristically has many more variables and exponentially more possible states than the more macro level; so, there will inevitably be many-one mappings between microstate and macrostate.

But the relative stability of the macrostates generates something even stronger, which Wimsatt (1981) calls "dynamical autonomy," whereby the vast number of dynamical changes at the micro level map to the same or to neighboring macrostates, else macrostate fluctuations would be constantly observed—as they are in fact with "between-level" phenomena like Brownian motion (Wimsatt 1994; Sarkar 2000). This means that the most effective way of making a macro change in a system is virtually always to manipulate the macro variables. Thus macroscopic causality is safe in a reductionist world, and multiple realizability is no argument against reduction, but a very robust feature of the natural world.

But it is characteristic of any interlevel compositional reductionist explanations that there are exceptions to the upper-level regularities when these are mapped in the most natural ways to the micro level. (Note that there may be more than one such way.) For instance, fluctuation thermodynamics essentially concern continuous fluids, with exceptions having the right statistical characteristics. These upper-level exceptions may be negligible, as in statistical mechanics, or much more common, for instance, in relations between classical and molecular genetics. Even very reliable mechanisms have a fairly large and distinct number of ways of breaking down (which grows with increasing complexity and may also be open-ended). This open-endedness arises naturally in a mechanistic perspective, since it is easy to conceptualize in a systematic way how any proposed mechanistic intervention would act, but not possible to list systematically all possible mechanistic interventions.

Claims of supervenience, roughly, hold that there can be no change at the upper, or macro, levelf without a change at the lower, or micro, level but that there is no other systematic relationship between levels. The intuitions driving supervenience in interlevel cases are that there are multiply realizable macro-level properties that have no systematic micro-level account, in part because it is thought that a micro-level account would be wildly disjunctive and that there would be an open-ended class of exceptions to any attempt at a lower-level unity (see Supervenience). The characteristics of mechanisms described earlier appear to satisfy these conditions, but without denying reductionist explanations—and the dynamical autonomy of macro-level variables gives even more of what is needed to justify the autonomy of the "special sciences." It might be that the search for the apocalyptic completeness that would eliminate exceptions has motivated the idea of supervenience (see below), but this is an artifact of thinking of reductions in terms of laws rather than in terms of mechanisms—at least in the compositional sciences.

As used by philosophers of psychology, the formulation of supervenience (whether interpreted ontologically or epistemologically) commonly utilizes the relation between macro states and micro states *as revealed in terms of some future complete apocalyptic physics and psychology* (see Psychology, Philosophy of; Supervenience). But this leaves the discussion in an embarrassing situation: Can it now even be said that anything is supervenient? Not having the future sciences, it would appear that nothing can be said at all.

Interestingly, another concept and approach due to Levins renders something like supervenience immediately usable and widely applicable. Levins' (1966) concept of a "sufficient parameter" was originally elaborated for levels of organization but applies more broadly:

> It is an essential ingredient in the concept of levels of phenomena that there exists a set of what, by analogy with the sufficient statistic, we can call sufficient parameters defined on a given level ... which are very much fewer than the number of parameters on the lower level and which among them contain most of the important information about events on that level. (428–429)

He then provides an example of a causally potent robust property derived and caused in multiple ways. Levins' approach avoids dubious, in-principle arguments and assumptions about future physics and psychology and substitutes a thoroughly

heuristic methodology tolerant of approximations and exceptions and better fitting actual scientific practice (Wimsatt 1994).

Aggregativity and Emergence

Opponents of reductionism usually fear what Dennett (1995) calls "greedy reductionism": explaining upper-level things in lower-level terms without intervening mechanisms mediating emergence of qualitatively different phenomena at higher levels (as Dennett says, "without cranes"). Greedy reductionism goes with "nothing but" talk, as reflected in Sperry's (1976) worries that to reductionists "eventually everything is held to be explainable in terms of essentially nothing." But this does not happen in an interlevel reduction. One moves to smaller and smaller parts in successive reductions, but in each transition, much of the explanatory weight is borne by the *organization* of those parts into a larger mechanism that explains the behavior of the higher-level system. (Those parts' properties explanatorily relevant to the behavior of the larger mechanism also provide the basis for judgments of multiple realizability and functional equivalence—roughly, any part[s] realizing those properties will do.)

But what if some properties of the parts were also manifested by the system—and were invariant no matter how one cuts up or rearranges its parts? For such properties, organization would not matter. Such properties are picked out by the most general conservation laws of physics but apparently not by any other scientific generalizations. These properties meet very restrictive conditions: For any decompositions of the system into parts, they are invariant over appropriate rearrangements, substitutions, and reaggregations, and their values scale appropriately under additions or subtractions to the system. For these aggregative properties, one is presumably willing to say that the mass of an animal considered as a subject by an artist for an anatomical drawing is nothing more than the mass of its parts. And the blame is on the artist—not vanished emergent interactions—for any shortfalls in what is represented in the drawing (Wimsatt 2000).

Essentially all other systemic properties partly depend upon the organization of parts, are in that sense emergent, and, according to reductionists, are mechanistically explainable. Within practical scientific contexts, emergence and reduction are not usually regarded as opposites; and nonadditive, organizational, and context-dependent interactions are the domain of emergence (see Emergence). Given these differences, it is not appropriate for interlevel reduction to be tarred with the ontologically corrosive reputation of aggregativity. Nevertheless, assumptions of aggregativity do play a role in initiating a reductionist research program; this may account for the confusion of aggregativity with reductionism.

Multiple conditions for aggregativity, each requiring invariance of system properties under different decompositions and operations on the system's parts, make aggregativity a degree property. In developing explanations, one starts with simple models. Simpler theories—ignoring higher-order interactions—typically look more aggregative. Few properties are aggregative in all respects for all decompositions, but many are aggregative or approximately so for some. Such decompositions are particularly simple and fruitful—more nearly factoring systems into modular parts with monadic, intrinsic, context-independent properties.

Such decompositions show varying success for different problems. Decompositions with more solutions get more attention, and it becomes tempting to accept "nothing but" statements that are really context bound and approximate, as if they were truly general. Bad decompositions for a problem produce functional localization fallacies, biases, and conceptual confusions (Bechtel and Richardson 1993). Powerful reductionist problem-solving heuristics can systematically lead to decisions to ignore or underestimate context dependence (Wimsatt 1980). This is one bias that epistemologically successful reductionist research must self-consciously guard against. Analyzing complex systems often requires simultaneous use of multiple decompositions, boundaries, and contexts—treacherous fields for functional errors: Reductionist heuristics must be deployed with special care in all such contexts (Wimsatt 1974 and 1994).

HANS REICHENBACH

(26 September 1891–9 April 1953)

Hans Reichenbach was born in Hamburg, Germany, a seaport and open-minded commercial town. He went to the *Oberrealschule,* where, chiefly, mathematics, natural sciences, and modern languages were taught. As a result of this schooling, in his later life he became more interested

in science than in history. Reichenbach initially studied engineering in Stuttgart for a year, before studying mathematics, physics, and philosophy at Munich, Berlin, and Göttingen, respectively. Among his academic teachers were the physicists and mathematicians M. Planck, A. Sommerfeld, P. J. W. Debye, and D. Hilbert, and the philosophers E. von Aster, E. Cassirer, A. Riehl, G. Simmel, C. Stumpf, and E. Husserl. Von Aster and Cassirer impressed him the most (for details of Reichenbach's life, see Gerner 1997).

As a student Reichenbach was one of the leaders of the Freistudenten movement. Students who were active in this movement were influenced by the Wandervogel and other groups of the *Jugendbewegung* (youth movement). Members of this movement went hiking, sang, played musical instruments, did folk dances, and, in general, tried to find a new way of life. Reichenbach gave numerous talks and published many articles in student journals such as *Die freistudentische Idee: Ihr Inhalt als Einheit* (Reichenbach 1977–1999, vol. 1, 108–123). Reichenbach's noncognitivist ethics stem from the ideals he acquired from the Freistudenten movement (see below).

In March 1915 soon after the beginning of World War I, Reichenbach enlisted in the German army. Military service damaged his health, and in September 1917, he left the army for a job in the Gesellschaft für Funktelegraphie, which developed radio-telegraphy technology of military importance. In November 1918 a revolution shook Germany, and Reichenbach joined the Sozialistische Studentenpartei Berlin. He became one of the leaders of the organization and helped draft its program. In 1919 he became one of the first students to attend Einstein's lectures on the theory of general relativity, which strongly influenced his philosophical development. In 1920 Reichenbach became assistant, and later *Privatdozent*, for physics at the Technische Hochschule Stuttgart. There he developed the main ideas of his philosophy and wrote, in addition to important articles, his most ingenious work, which was later translated as *The Axiomatization of the Theory of Relativity* ([1924] 1969). Six years later, Reichenbach succeeded, with Einstein's help, in becoming an *außerordentlicher Professor* (roughly, an associate professor) for natural philosophy in the faculty of natural science. The job paid poorly, and Reichenbach wrote many articles, frequently on relativity for newspapers and popular journals, to supplement his income. Relativity was a popular subject for almost everyone at this time, and Reichenbach gave lectures on the radio, which later appeared as popular books, *From Copernicus to Einstein* ([1927] 1942) and *Atom and Cosmos* ([1930] 1932).

In 1923 Carnap, who had previously corresponded only with Reichenbach, organized the first meeting of "exact philosophers" at Erlangen. Besides Reichenbach, also participating were K. Lewin, H. Behmann, Paul Hertz, and others. There were many subsequent conferences and congresses of "Logical Empiricists," as they later called themselves. From 1923 until his death, Reichenbach remained in close contact with Carnap (see Carnap, Rudolf; Logical Empiricism). After the meeting, they both tried to found a journal for exact philosophy. It was, however, not before 1930 that Reichenbach was successful in taking over the *Annalen der Philosophie*, which became *Erkenntnis*, initially coedited with Carnap and Neurath (see Neurath, Otto).

The years in Berlin were Reichenbach's most productive. In 1928, he published what was later translated as *Philosophy of Space and Time* ([1928] 1958), but, after this, his work focused on probability theory. This eventually led to the publication of *Wahrscheinlichkeitslehre* ([1935] 1949). In 1929 Reichenbach replaced Joseph Petzold as president of the Gesellschaft für empirische Philosophie, which was very active in organizing talks and discussions. A smaller informal group, called the Berliner Kreis [Berlin Circle], was the counterpart of the Vienna Circle and included the philosophers Kurt Grelling and Walter Dubislav, the psychiatrist Alexander Herzberg, and the psychologist Kurt Lewin (see Vienna Circle).

In 1933, Hitler became chancellor of Germany, and some months later Jewish and so-called half-Jewish public servants, including professors, were dismissed from civil service. Reichenbach had to leave the university because his father was of Jewish descent. The same year, Kemal Atatürk refounded the University of Istanbul and replaced most of the Turkish professors with emigrants from Germany. Reichenbach had to stop lecturing in Berlin during the summer of 1933, but fortunately he could start teaching in Istanbul that October. During his lectures in Istanbul, Reichenbach was accompanied by an interpreter who translated the lectures, sentence by sentence, into Turkish. Reichenbach did not suffer as a result of exile as many others did. He was so inspired by logical empiricism that the uncomfortable political situation did not stop his research. Reichenbach remained editor of *Erkenntnis* for some years, until Felix Meiner, the publisher, was forced by the German authorities to

discontinue the journal. During this period, Reichenbach met philosophical friends at many congresses: 1934 in Prague, and 1935 and 1937 in Paris. With the help of Charles W. Morris, Reichenbach received a chair at the University of California at Los Angeles (UCLA) in 1938. There, for the first time in his life, Reichenbach found ideal conditions for scientific work: He felt he was in the biblical "Land of Promise" far away from the dreadful war taking place in Europe. At UCLA, he wrote some of his most important books (Reichenbach 1944, 1947, [1935] 1949 [with about 50% new text], 1951, and 1954). On April 9, 1953, Reichenbach suffered a heart attack and died some hours later.

Space and Time

Reichenbach's reaction to Einstein's lectures motivated his first book, translated as *The Theory of Relativity and A Priori Knowledge* ([1920] 1965). The main idea of this work is that Kant's synthetic a priori principles are not uniquely determined by human understanding and pure intuition, but can be freely chosen or replaced by alternative principles: "Kant's concept of *a priori* has two different meanings. First it means 'necessarily true' or 'true for all times', and secondly 'constituting the concept of the object' " (48). Reichenbach rejected the first but retained the second meaning. Similar to Poincaré, throughout his life, Reichenbach held the view that knowledge is composed by empirical evidence and a contribution of reason, consisting of conventional principles, definitions, or rules (see Poincaré, Henri; Conventionalism).

Reichenbach called these conventional principles "coordinating principles." Examples include the principle of special relativity and the principle of the Euclidean character of space. The coordinating principles can become incompatible with the observed facts. It is a task of the theoretical physicist to find a set of coordinative principles that leads to a consistent picture of nature in agreement with the empirical data (see Kamlah 1985, 161–162). In private correspondence, however, Schlick convinced Reichenbach that he had left Kantianism by writing this book (see Gerner 1997, 54) (see Schlick, Moritz). From that time on, Reichenbach regarded himself as an anti-Kantian, even if he inherited more of Kant's tenets than he admitted.

Until 1928 Reichenbach studied primarily space and time. He wrote two books on that subject (Reichenbach [1924] 1969, essentially the mathematical theory of four-dimensional [light-ray or first signal] geometry; and [1928] 1958, which is less technical). In *Axiomatization*, Reichenbach axiomatized space-time geometry using three kinds of objects: space-time points or events, world-lines, and the relation of causal influenceability of one event by another, the *signal relation.* With these concepts Reichenbach formulated axioms aimed at showing that the inertial systems of special relativity and the corresponding coordinate systems can be constructed uniquely. The mathematical details of Reichenbach's light-ray geometry will not be discussed here, but there are interesting epistemological remarks that fill some of the crucial gaps later left by the *Philosophy of Space and Time.* The following discussion treats the two books together.

In the early 1920s, Reichenbach developed a theory of *coordinative definitions*, which replaced coordinating principles. Unfortunately, Reichenbach makes some confusing remarks about how these definitions endow signs with meaning. An expression is defined either by pointing at things ("This is a horse," "This is a bicycle," etc.) or by uttering a sentence that contains, together with other words, the expression to be defined. The first is a so-called ostensive definition, the second, a linguistic definition. Ostensive definitions are used to teach children some of their first words, while linguistic definitions presuppose an existing language. Reichenbach ([1924] 1969) writes: "Physical definitions, therefore, consist in the coordination of a mathematical definition to a 'piece of reality' " (8), which suggests that coordinative definitions are ostensive definitions for Reichenbach. With the exception of the definition of the meter by a standard rod in Paris, however, all definitions given by Reichenbach are linguistic definitions. Reichenbach's paradigm for linguistic definition is Einstein's definition of 'simultaneity' (45): "Let a first signal be sent from A at the time t_1; reflected at B, let it return to A at time t_3. Then its time of arrival at B will have the following value: $t_2 = \frac{1}{2}(t_3 - t_1)$." This definition has a linguistic character, but since its *definiens* refers to physical entities, it indirectly coordinates a concept to certain things.

The role of Reichenbach's coordinative definitions is essentially the same as the role of Poincaré's conventions (see Conventionalism). Poincaré distinguished "crude facts" from "scientific facts" (Poincaré 1958, 115–122). Crude facts are described in a language already known (a kind of observational language). With the aid of conventions, statements about scientific facts must be translated into the language that describes the crude facts. Analogously, Reichenbach's coordinative definitions define the scientific terms in the language in which observations are described.

Reichenbach ([1924] 1969) calls these just "facts," but it is clear from section 1 of *Axiomatization* that he means *empirical facts*.

Reichenbach (1977–1999, vol. 2) considered the separation of factual statements and definitions as one of the most important tasks of philosophy of science:

> Coordinative definitions are used at many points in the study of physics. It is not always easy to recognize them as such and to distinguish them from assertions of facts, and some well-known scientific disputes stem from seeking empirical knowledge where definitions belong. . . . We have a certain freedom of employing definitions and facts. It is only when a definition is given in one place that another assertion becomes an assertion of fact; conversely, the second may be regarded as a definition, which makes the first into an assertion of fact. (161–162)

Reichenbach's treatment of physical geometry, measurement of length, and simultaneity illustrate this task, and he considered his axiomatized theory of light geometry as a model for the semantics of physics.

Since definitions are arbitrary, the semantic analysis of science can be performed in different ways by splitting a theory into definitions and descriptions of facts differently. This yields pairs of different *equivalent descriptions* that have the same truth value. Reichenbach ([1928] 1958) originally called this thesis the 'epistemological' or 'philosophical theory of relativity' (177) and later the 'theory of equivalent descriptions' (1951, 133). If it is assumed that the same language is used in all descriptions of the observational facts (Reichenbach's "facts" and Poincaré's "crude facts"), this restricts the arbitrariness of the choice of alternative descriptions. The nontrivial content of the theory of equivalent descriptions is that under this condition, different equivalent descriptions are possible. This position can be accurately labeled 'nontrivial conventionalism.'

Reichenbach's conventionalism arises from epistemological issues and differs from his ostensible follower Grünbaum (1973). If the observational language is extended by theoretical terms, the latter must be defined in a partly arbitrary way. Grünbaum demands beyond this that nonconventional terms are "intrinsic," which he does not identify with "observable." Since Reichenbach's followers no longer shared the historical presuppositions of Reichenbach's generation, they had difficulty recognizing that his *philosophical relativity* was something new and interesting. Reichenbach's analysis responded to the neo-Kantian and iconic realist positions. According to Kant, humans are equipped with a system of a priori concepts, categories, pure intuitions, and derived concepts, and science cannot be conceived outside of this conceptual frame. Thus, an arbitrary choice of any definition of simultaneity is impossible. According to iconic realism, there is a single true picture of the world, and any different image is false. True knowledge means to have this picture in one's mind. Seventeenth-century philosophers would have said that at least God sees the world as it really is, even if human beings are unable to obtain its true picture. Thus, there is no way to choose between two different equivalent descriptions of nature. At least one of them has to be false. In contrast to both neo-Kantianism and iconic realism, Reichenbach emphasized that arbitrary definitions are needed to describe the world. It is important to note that in Reichenbach ([1928] 1958) the "theory of relativity of geometry" appears in the context of the refutation of neo-Kantianism. Reichenbach's rejection of iconic realism will not be discussed here (but see Kamlah 1979).

Against Kant, Reichenbach first shows that geometry itself is conventional. One can always introduce physical forces, which are said to compress or expand measuring rods in such a way that the same rods, if undistorted, would lead to a given metric or geometry. As Einstein had already stated, Reichenbach emphasized the point that it is not geometry alone, but geometry plus physics that is empirically testable (Reichenbach 1953b). Yet, neo-Kantians could respond: "Since geometry is given by pure intuition, one must always choose physics in such a way that it agrees with geometry and with the empirical evidence." Reichenbach's response was to develop a theory of geometrical intuition that did not permit this response; this is one of his most interesting achievements ([1928] 1958, §9–13). Reichenbach distinguished *physical* and *mathematical visualization* (82). The former is the anticipation of a possible perception described by Helmholtz (1962): "By the much abused expression 'to represent' . . . I understand . . . that we are able to imagine the series of perceptions we would have, if something like it occurred in an individual case" (277). Reichenbach showed how a non-Euclidean world can be visualized, and therefore that intuition does not acknowledge only Euclidean geometry. For instance, consider a movie that shows how it is to live in a non-Euclidean environment. Such a movie is possible only if some physical assumptions are made: Light has to travel in straight lines and solid bodies must obey the condition that during

transportation, their length adapts to the metric of the geometry that is simulated.

While watching the non-Euclidean movie, however, neo-Kantians may be unconvinced that these experiences are veridical. They could argue that solid bodies are shrinking or growing in a quite unusual way, while the true geometry is still Euclidean. Pure intuition forces the use of only Euclidean physical models for the world. Neo-Kantians are committed to *mathematical intuition*, which is used to produce a model or picture of a state of affairs in the mind as to how it really is and not how it appears. In Reichenbach's spirit one may show that, by using physical models, pictures may be used that are either much bigger than the portrayed objects (e.g., atoms) or much smaller (e.g., the planetary system). Hence, the principle of geometrical similarity, which was already used as an axiom by Wallis in the seventeenth century in physical modeling, is an example of the fact that the axioms of Euclidean geometry are unconsciously used as a constraint for visual thought experiments. Reichenbach ([1928] 1958) called this the *normative function of visualization* (42).

In spite of Reichenbach's frequent assertions that coordinative definitions are arbitrary and that, therefore, many equivalent descriptions of nature are possible, he admitted that, as a practical rule, a single description may be superior to all others. Reichenbach (1951) called this the *normal system* (137, 180). Thus, in geometry, physicists normally define congruence by the transport of rigid rods. Yet, in nature, only solid rods are found, and rigid rods are obtained by correcting for the influences of deformatory forces such as temperature change or elastic forces. Reichenbach ([1928] 1958) proposed a definition of rigid rods that he believed was unique. He first distinguished between *universal* and *differential forces* (13). Universal forces act on all bodies in the same way, while differential forces (like temperature change) act on them differently. Hence, differential forces can be measured by comparing bodies of different kinds, while universal forces depend on the assumed geometry. Utilizing universal forces can "explain" why solid bodies do not follow the metrics of that geometry. Therefore, if it is assumed that all universal forces disappear, the metric of the space can be determined. However, there is no guarantee that in each set of equivalent descriptions a normal system exists; if quantum mechanics is true, a *normal system* for microphysics cannot be found (see below).

Finally, Reichenbach's theory of *simplicity* constituted a progress compared with Mach and Poincaré (see Mach, Ernest; Poincaré, Henri). If two equivalent descriptions of a physical system differ in simplicity, this is irrelevant for their truth. They are either both true or both false, differing only in *descriptive simplicity*. If, however, they are not empirically equivalent, they differ in *inductive simplicity*, and the simpler description is more likely to be true than the other one (Reichenbach 1977–1999, vol. 2, 163–164).

Realism and Meaning

After leaving neo-Kantianism, Reichenbach claimed to be a realist for the remainder of his life, but it is unclear what kind of realist. There are many different epistemological theories that are called 'realism,' and the arguments used in any particular case must be studied carefully in order to find out what kind of realism is being defended by each proponent (see Realism).

For Reichenbach, the distinction between realism and logical empiricism was intimately connected with the explication of the concept of meaning. Meaning can be defined in different ways. According to Reichenbach (1938), there is the *truth theory of meaning* and the *probability theory of meaning* (among others not mentioned here). The first says:

> Two sentences have the same meaning, if they obtain the same determination as true or false by every possible observation. (3)

The second says:

> Two sentences have the same meaning, if they obtain the same weight, or degree of probability, by every possible observation. (ibid)

It cannot be said beforehand which of these explications of meaning is correct. A decision between them must be made, which Reichenbach (1938) called a *volitional bifurcation* (10). This decision is not arbitrary, since it leads to different consequences in each case. It is not difficult to see that the *probability theory of meaning* allows more sentences to be confirmed than the *truth theory of meaning*. Reichenbach erroneously attributed the latter to the Vienna Circle (see Vienna Circle), because of an alleged commitment to the slogan: "The sense of a sentence is the method of its verification" (see Verifiability). Since most theoretical sentences cannot be strictly verified in the sense that they follow logically from observations, those people who decide to accept the truth theory of meaning are practically incapable of surviving, since they cannot empirically verify any important

sentence about events in the future. By definition, all these sentences will have the same meaning as a contradiction (70–71). Reichenbach preferred the *probability theory of meaning*, and he called those who took the same position "realists." Thus, probability is indispensable to knowledge. Reichenbach believed that his *realism* differed from *positivism*, since, for the latter, knowledge came from observation and logic alone. For Reichenbach, probability and induction are additionally needed.

Reichenbach defended this theory until about 1938. Later, in *Philosophical Foundations of Quantum Mechanics*, he adopts yet another kind of realism: realism by convention, which claims that humans are normally committed to the following principle:

> The laws of nature are the same whether or not the objects are observed. (Reichenbach 1944, 19)

Reichenbach (1977–1999, vol. 2) called this convention an 'extension rule' (249). If it is not accepted, a tree that an observer looks at may double if the observer's eyes close or the observer looks in another direction before returning to the original state of attention. Similar to other conventions, realism for Reichenbach (1953b) depended on a "volitional decision" (§II.8).

Probability and Causality

Probability remained central to Reichenbach's work from 1915, when he wrote his dissertation, until at least 1949, when the English edition of *Wahrscheinlichkeitslehre* was published. Reichenbach's dissertation defended the frequency theory of probability at a time when, at least in Germany, textbooks still used Laplace's *Théorie de la probabilité* as their model. Two years later, in his *Staatsexamensarbeit*, Reichenbach discussed the possibility that fundamental physical laws were statistical (Kamlah 1998, 35). Thus, Kant's concept of causality must be replaced by a statistical relation between cause and effect. In 1923 Reichenbach (1977–1999, Vol. 2) tried to work out in detail a theory of statistical causality (345–371). It may be the case that even with complete knowledge of all boundary conditions of a physical process, single events can be predicted only with a probability, $p < 1$. In this case causality is irreducibly statistical. Probability, however, does not only appear in natural laws. It also plays a predominant role in the process of corroborating scientific theories and in any kind of induction. Without a probabilistic theory of induction, natural science is not possible. Logic and observation alone are not sufficient.

Until 1933 Reichenbach thought that logical empiricism could not justify scientific knowledge, which consists predominantly of general sentences. At that time Reichenbach was a *logical probabilistic empiricist:* The theory of probability and induction was the third pillar on which knowledge rested, besides empirical evidence and logic (1977–1999, Vol. 5, 435–436; see also Kamlah 1985, 166–167). Every kind of induction rests directly or indirectly on the *principle* or *rule of induction*, which makes estimation of a probability from a series of events f^n possible. Reichenbach (1953a) formulated this rule in the same year:

> If in a finite section [of a series of events] given we have observed a certain frequency f^n [of events having a certain property A], we posit that the frequency on further continuation, will converge towards a limit f^n (more precisely: within the interval $f^n \pm d$). We posit this; we do not say that this is true. (466)

Reichenbach considered this rule to be metaphysical and, later, analytical in some sense. However, in the winter of 1932–1933, the idea of a pragmatic justification of induction suddenly came to him: It cannot be shown that the rule will lead to success, but there is nothing to lose by applying it. Either the rule will help, or nothing else will do. Therefore, the rule is treated as a posit or a wager, and every conclusion that is logically dependent on it will be a posit. He called those posits that are direct results of the rule *blind posits.* Reichenbach (1953a) illustrated their nature by analogy to decisions made in ordinary life:

> We are often confronted by similar situations in daily life. We want to reach a certain aim and we know of a necessary step, which we shall have to take in order to attain this aim, but we do not know whether this step is sufficient. The businessman who keeps his store well stocked, so that he can sell something when a customer comes in, ... the shipwrecked man who climbs a cliff, although he does not know whether a rescue ship will spot him—all these persons find themselves in an analogous situation; they satisfy the *necessary* conditions of reaching an aim without knowing whether the *sufficient* conditions are satisfied. (472)

However, in practical situations, the application of this rule is rather the exception. In most cases pre-existing knowledge is combined with the inductive appraisal of empirical evidence. Reichenbach (1938) called the result of such a procedure an 'appraised posit,' in contrast to a *blind posit*, with which any experience has to start (352).

Reichenbach believed that this pragmatic justification solved Hume's problem (see Induction, Problem of). He presented this justification to the

Vienna Circle in February 1933, days after Hitler's seizure of power in Germany. It was typical for the members of the Vienna and the Berlin Circle that they continued to discuss their philosophical problems seemingly unaffected by the dangerous political situation at that time. Reichenbach wrote to E. von Aster:

> It is only now that I feel to be entitled to defend a radical empiricism, since I have shown that the principle of induction does not contain any synthetic a priori components, and since I have been successful by applying probability logic and the concept of posit to give a satisfactory theory of statements about the future. (Quoted in Kamlah 1994, 191)

Reichenbach now no longer needed a metaphysical principle to justify induction, but the philosophical cost was high. Strictly speaking, there was no longer room for scientific knowledge in Reichenbach's epistemology, only a system of posits that could be used as directives for action.

The Direction of Time

After an ingenious attempt to solve the problem of the source of the directionality of time in 1925, with interesting but half-finished results, Reichenbach left work on this issue until late in his life. What interested him most was the difference between the past and the future. When Reichenbach died, he left an almost completed book that was later edited for publication by his wife, Maria Reichenbach. The book contains philosophical observations on subjects such as traces left by physical processes, human memory, the order of playing cards in a deck, registering instruments, the measure of information, and other processes that undergo temporal change.

The following discussion treats, though only qualitatively, the *principle of common cause*, whereas Reichenbach (1956) used the theory of probability to treat the matter exactly. He wrote:

> Suppose two geysers which are not far apart spout regularly, but throw up their columns of water always at the same time. The existence of a subterranean connection of the two geysers with a common reservoir of hot water is practically certain. (158)

He subsumed this example under the following rule:

> If an improbable coincidence has occurred, there must exist a common cause. (157)

A more precise formulation is obtained by considering two events or series of events A and B that are both improbable alone and very similar to each other at two different places and at the same time. There is a high probability that a third earlier event or series of events C is the common cause of both (see Figure 1, case 1). Reichenbach (1956, Ch. 4) then asked whether the time-mirrored counterpart also exists, the common effect D (see Figure 1, case 2). The answer is yes only if A and B share a common cause C (see Figure 1, case 3). Hence, there is another asymmetry between the past and the future besides those generally arising from physics.

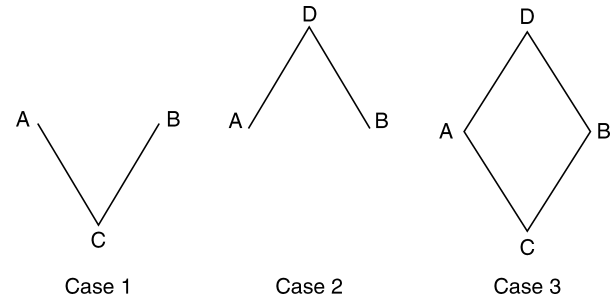

Fig. 1. Common cause and effect in a space-time diagram.

Chapter 4 of the *The Direction of Time* is full of ingenious but raw ideas waiting to be worked out by future philosophers; it is not a precise presentation of philosophical results. It is this character of the book, and of many other writings of Reichenbach, that makes his work valuable.

Logics

When Reichenbach taught logic, he looked for examples in natural language as exercises. In this way he reconstructed pronouns and tenses in first-order (predicate) logic. His theories of tenses and pronouns are well known as first attempts at formalizing natural languages with the aid of formal logics (see Reichenbach 1947, Ch. 7).

Quantum Mechanics

Twenty years after Einstein's special theory of relativity, a second revolution took place in physics. In 1925 Heisenberg's first paper on matrix mechanics was published, followed by Schrödinger's paper on wave mechanics in 1926 (see Quantum Mechanics). Reichenbach tried to understand this new microphysics, now called quantum mechanics. After 1938, he became intensively occupied with it and, in 1944, published *Philosophic Foundations of Quantum Mechanics*, which drew the attention of both physicists and philosophers.

Reichenbach (1944) did not significantly address the standard problem of the philosophy of quantum mechanics—the measurement problem (see Quantum Measurement Problem). Instead, he tried to integrate quantum mechanics into his *theory of equivalent descriptions.* Reichenbach thought that in quantum mechanics, a normal system (see "Space and Time" above) can no longer be found. Instead, the *wave* or the *particle interpretation* of quantum mechanics can be used (§8) (see Complementarity). The first construes Schrödinger's wave function as a real entity. Reichenbach does not clearly explain the second: Quantum systems are described as particles, but a formalism that would describe the quantum process in detail is not given. For Reichenbach, neither of the two descriptions can be considered a normal system. Only if one pays the price of accepting causal anomalies do either of the two interpretations describe the complete process.

To understand this point, consider the famous double slit thought experiment (Reichenbach 1944, 30). A particle starts from a source, passes through a diaphragm with two slits, and finally hits a screen or a photographic plate. If it passes slit A (see Figure 2), it will hit certain points on the screen with a certain probability. If the experiment is repeated many times, a certain density distribution of hits on the screen can be calculated using quantum mechanics. Now if slit B is also open, the density distribution will be different from that of an experiment in which both slits are open at different times (with the same duration). This causal process seems to violate the principle of action by contact. Slit B influences the particle in a nonlocal way (see Locality). The microprocess can thus be explained only if a *causal anomaly* is accepted.

Yet, electrons, protons, and other particles may behave as wave packets. A wave can pass both slits at once and interfere if both slits are open. If only one slit is open, the wave that leaves the diaphragm is different. At the moment the wave hits the screen, it suddenly shrinks to a point from which a new wave starts. Again, the principle of action by contact is violated. The breakdown of the wave is an instantaneous process. With infinite velocity, the wave is concentrated at one single point.

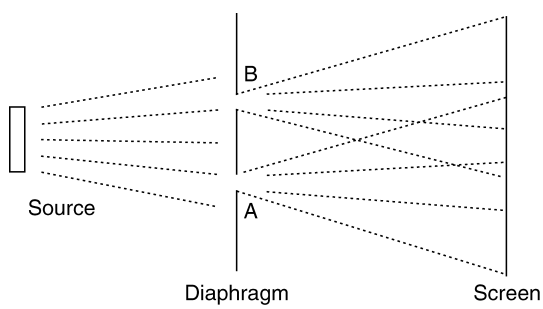

Fig. 2. The double slit experiment.

Reichenbach concluded that a choice must be made between two equivalent descriptions in which causal anomalies occur: the particle or the wave description. Neither of these can be called a normal description, since in both cases an important principle of everyday physics is violated. Reichenbach (1944) claims that Bohr and Heisenberg try to avoid this problem by using a third *restrictive interpretation* (33). They do not consider the *interphenomena*—those which happen between the measurements—as real physical processes. Therefore, statements about these *interphenomena* are meaningless for them. According to Reichenbach, they regard the quantum-mechanical formalism simply as an instrument for calculating predictions on the basis of past observations. Only observations really exist. It is also clear that this *restrictive interpretation* cannot avoid causal anomalies.

There is a fourth possibility that also agrees with the experimental findings. The microphysical *interphenomena* can be described in a language with a three-valued logic. Besides the truth values *true* and *false,* a third value, *indeterminate*, is introduced (Reichenbach 1944, 42). If a particle passes the diaphragm with two open slits A and B, it is *indeterminate* whether it goes through slit A. If a measurement of the position at the moment when the particle passes the slit is made and it is found in slit A, it is *true* that it is in A. Reichenbach's own interpretation of the third value, *indeterminate*, does not agree with the way he applied it, which suggested another explication (which, however, applies only if the quantum system is in a so-called pure state):

> Let U be the possible result of a measurement, then one defines: If the probability of the result that U will be measured as true is $p = 1$, U is indeed *true*, if $p = 0$, U is *false*, and if $0 < p < 1$, U is *indeterminate.*

This interpretation agrees more with the approach to this topic by many contemporary authors (see Reichenbach 1977–1999, vol. 5. 401–8). Even if Reichenbach's interpretation of quantum phenomena in terms of three-valued logics is problematic, it avoids causal anomalies with this logic. When the wave function changes instantaneously during the measuring process, many statements that have been *true* before now become

indeterminate, and others that were *indeterminate* become *true* or *false.* There is no true statement in such cases, which does not accord with the *principle of action by contact.*

Ethics

Reichenbach, Carnap, and some other logical empiricists did not believe that a philosopher could establish a system of ethical rules that could be held universally obligatory. How can Reichenbach's radical position be understood? As mentioned before, Reichenbach was a student leader of the Freistudenten movement. The movement was characterized by anti-authoritarianism, and it is unsurprising that Reichenbach (1977–1999, Vol. 2) wrote:

> The individual may give his life whatever form he finds to be of value and may set for himself particular goals. . .. The individual may do whatever he considers to be right. Indeed he ought to do it; in general, we consider as immoral nothing but an inconsistency between goal and action. (110)

Later Reichenbach sent his children to the Montessori school in Berlin, where the main educational principle was that students should find their own way: Learn something if they want to do that and organize common activities themselves.

Reichenbach believed that his values were identical to those of many people in contemporary civilization. Thus, he says in *The Rise of Scientific Philosophy* (1951, 295): "I even have some fundamental moral directives, which, I think, are not so very different from yours." Reichenbach's belief that human beings will develop ethical directives useful for social life even if they are not taught to do so was later supplemented by logical analysis of ethical utterances. For him, these were not statements that can be true or false, but rather commands or directives, utterances of human will. These sentiments cannot be logically derived from empirical statements or from a priori principles. If a person commits a crime, that person will certainly be imprisoned if caught. The murderer's will conflicts with the will of the majority, but it *cannot be shown that the murderer is wrong.* Reichenbach was blind to the fact that in society there is vivid rational discourse on ethical questions. He cannot even discuss questions of justice based on his own standpoint, which, however, philosophers and others frequently do.

Reichenbach published only one discussion of ethics (1951, Ch. 17). Nevertheless, it is not possible to ignore this issue altogether. Reichenbach's writings frequently contain expressions like "arbitrary decision" and "volitional decision" in an epistemological context. These decision-indicating conventionalist terms have something to do with a deep-rooted desire for freedom, which is also found in Reichenbach's noncognitivist treatment of morals. Reichenbach had been a conventionalist in ethics even before he attended Einstein's lectures in 1919 and became a conventionalist in epistemology.

RESEARCH PROGRAMS

Popper claimed that a theory is scientific if and only if it makes predications that can be tested by experiment or observation. Thus (Popper argued), genuine sciences, like physics, may be distinguished from pseudo-sciences, like astrology. On this basis Popper developed a cyclic picture of the scientific process: A theory is proposed; its empirical consequences are deduced; these consequences are empirically tested; some of these consequences are found to be false; a new theory is proposed that does not make these false predictions; this new theory is tested empirically; and so on. However, as it stands, this cyclic pattern allows scientists to repair refuted theories in an ad hoc fashion. One ad hoc strategy is to supplement a refuted generalization with a list of its known exceptions. Another is to hedge the theory with vague conditions such as 'normally' or 'other things being equal.' Popper

needed to prevent such ad hoc repairs. To this end he specified a rule governing the replacement of an old, refuted theory by a new one. This rule employed the technical concept of *empirical content*. Popper defined the empirical content of a theory as the range of possible circumstances that the theory rules out. A typical scientific law has infinitely many such "potential falsifiers," that is, infinitely many ways in which it might be refuted. With this definition, Popper could specify the required rule: When a new theory replaces an old one, the new theory should have at least as much empirical content (so defined) as its predecessor.

In sum, a scientific discipline, for Popper, is one that does not use ad hoc maneuvers to preserve its theories from refutation at the expense of their empirical content. This apparently innocuous development permanently changed the character of normative philosophy of science. First, it required philosophers to consider the temporal sequence of theories. Popper's immediate predecessors had conceived the connection between a theory and the relevant evidence as an *atemporal* logical relation, like that between a mathematical theorem and the premises of its proof. In Popper's view, however, the reasons for accepting a theory T_n should include the fact that T_n is a content-increasing successor to T_{n-1}. This requirement, that philosophers should consider sequences of theories (T_{n-1}, T_n, T_{n+1}, etc.), helped pave the way for later collaboration between philosophers and historians of science. Second, Popper's original question, "Which theories are scientific?" has become "Which *sequences of* theories are scientific?" In other words, what makes for scientific respectability is the manner in which one develops and nurtures a cluster of thoughts over time, rather than any purely logical feature of an individual theory. Nevertheless, Popper remained convinced that individual theories may be assessed for verisimilitude. Thus in Popper's view the question of scientific status is put to sequences of theories, while the unit of epistemological appraisal remains the individual theory.

Imre Lakatos was a colleague of Popper's at the London School of Economics (see Lakatos, Imre). His early philosophical work was in the philosophy of mathematics, but in the late 1960s he turned to the philosophy of science. His target was the alleged relativism and irrationalism of Thomas Kuhn's *Structure of Scientific Revolutions* (see Kuhn, Thomas). Kuhn's model of scientific activity posed a problem for rationalist philosophers such as Popper and Lakatos because it seemed to offer a more historically accurate account of science than did any of its rationalist or realist competitors. Lakatos' aim was to offer a normative philosophy of science that combined Popper's rationalism with Kuhn's historical sense.

Lakatos attempted to solve the problem with his *methodology of scientific research programs*. One of the difficulties with Popper's view is that, in Lakatos' phrase, all theories are born into a sea of anomalies. That is, all scientific theories are, strictly speaking, false, if only because they are approximate. Moreover, most important scientific theories have "open problems" that, if they were to remain unsolved, would constitute refutations. But if all theories are false, how is one to know which to adopt as the current scientific orthodoxy? Lakatos' solution was to recognize sequences of theories (T_{n-1}, T_n, T_{n+1}, etc.) as the units of appraisal, rather than individual theories. All theories are false, but some sequences of theories seem to be heading toward the truth, while others seem to go nowhere. One should accept and support the former and abandon the latter. To use Lakatos' language, some sequences *progress* while others *degenerate*. His task was to specify criteria by which progress and degeneration could be distinguished. However, the Popperian notion of a sequence of contingently related theories is not adequate for this purpose, as it does not capture the thought that the same leading idea informs each successive theory of the sequence. In other words, one requires a unit of scientific appraisal that can maintain its identity as it changes.

Lakatos' suggestion for this role is the "research program." In his sense, a research program is the sum of the various stages through which a "leading idea" passes. This leading idea provides the "hard core" of the research program, that is, a set of commitments that cannot be abandoned without abandoning the research program altogether. Lakatos offers as an example the three laws of motion and the law of gravitation as the hard core of Newton's research program (Lakatos 1978a, 179). In addition to the hard core, a research program must have a "heuristic." A program's heuristic is its collection of characteristic problem-solving techniques. To continue with Lakatos' favorite example, the heuristic of Newton's program chiefly consisted in its mathematical apparatus: the differential calculus, the theory of convergence, and differential and integral equations.

What, then, is it for a program to progress? For Lakatos, change comes to a progressive program from its own inner logic, whereas a degenerating program changes in response to external criticism.

Newton first worked out his program for a planetary system with a fixed point–like sun and one

single point–like planet. It was in this model that he derived his inverse square law for Kepler's ellipse. But this model was forbidden by Newton's own third law of dynamics; therefore the model had to be replaced by one in which both sun and planet revolved round their common center of gravity:

> Then he worked out the programme for more planets as if there were only heliocentric but no interplanetary forces. Then he worked out the case where the sun and planets were not mass-points but mass-*balls* . . . . Having solved this 'puzzle', he started work on *spinning balls* and their wobbles. Then he admitted interplanetary forces and started work on *perturbations*. (Lakatos 1978a, 50)

This is the paradigmatic research program: a sequence of theories representing stages in the development of a central idea. The important point is that the successive modifications were not forced on Newton by awkward empirical facts. Indeed, Newton scarcely glanced at the facts at all. Rather, the modifications were prompted by internal logical problems (such as the inadmissibility of infinite density in Newton's system), which were solved using the program's heuristic (i.e., Newtonian mathematics). Newton was able to ignore the fact that none of these models was empirically adequate because the program held out the promise that if he continued in the same vein, he would eventually produce a model that would not only respect the empirical evidence but also explain it.

This leads to the third and final element of the research program: a "protective belt" of auxiliary hypotheses. If empirical evidence requires changes to the program, they should be made here rather than to the hard core. In Newton's program, for example, this role was played by (amongst other things) geometrical optics and Newton's theory of atmospheric refraction (Lakatos 1978a, 179). Moreover, such changes must be "in the spirit of the heuristic" (ibid)—otherwise they would be ad hoc.

Thus, in a progressive research program, the central idea is developed and refined using the resources of the heuristic. Anomalies can and should be ignored in the hope that they will be accommodated and explained by a later stage of the program. That hope evaporates when the heuristic encounters problems that it cannot solve. Then, the program enters a degenerating phase, marked by ad hoc efforts to protect the hard core from criticism with the aid of devices external to the program. So long as successive changes to the protective belt of auxiliary hypotheses are in the spirit of the heuristic, the program is said to make *heuristic progress*.

Heuristic progress alone is not enough, however. A heuristically progressive program may ignore its anomalies, but it must also make *empirical progress*. Empirically progressive programs predict facts that are not only new but undreamt of. Lakatos' favorite example is Einstein's theory predicting that the distance measured between two stars would vary according to the time of day. Einstein's program gets as much credit for suggesting the experiment as it does for getting the prediction right (Lakatos 1978a, 5). In general, a program is *theoretically progressive* if it makes novel predictions, and it is *empirically progressive* if some of these are corroborated. Notice that the order of events matters: An empirically progressive program successfully predicts future empirical results, while *the same changes to the program* would signal degeneration if they came about after the results emerged.

This, in outline, is Lakatos' solution to the demarcation problem. Notice that the definition of heuristic progress is in fact a schema that gives a different specification for each program. Modifications to a program must be driven by its heuristic—but the meaning of this formula depends on the program in hand. Thus, the heuristic of a program plays a double role: It provides a logic of discovery for the scientists working on the program and at the same time sets the standard by which the program is to be evaluated (since fidelity to the spirit of its heuristic is a criterion of progress in a program). Thus, for Lakatos, the history of science is one of extended wars of attrition between research programs, some of which are progressing, while others are degenerating. A discipline is scientific so long as progressive programs triumph over degenerating ones.

The most effective critic of the methodology of scientific research programs was Paul Feyerabend, who claimed that any rigid account of the scientific method would eventually inhibit scientific progress (Feyerabend 1993, 14). Lakatos agreed, but he argued that his methodology was sufficiently flexible to escape this criticism. However, he had earlier argued that a program may recover from a degenerating phase to become progressive again *and* that degenerating programs should be starved of funds and support. Feyerabend had to point out only that Lakatos' methodology, if enacted as policy, would prevent a degenerating program from entering a new, progressive phase by killing it off too soon. The methodology of scientific research programs had another problem: Empirical progress requires the prediction of novel facts, but the

Copernican revolution made no such predictions. Rather, the heliocentric theory offered better explanations of already existing data. Thus, Lakatos was unable to explain why Copernicus' program was an improvement on Ptolemy. Lakatos was able to fix this problem by adopting an insightful suggestion by Elie Zahar. Zahar suggested that a program can achieve dramatic empirical success by explaining a fact that, though previously known, was not among the phenomena that the program was designed to explain. However, Zahar's suggestion, though insightful, was ad hoc with respect to Lakatos' philosophical program. By its own criteria, the methodology of scientific research programs fell into degeneration. This, together with the general decline of normative philosophy of science, may explain why it now has few adherents. Nevertheless, it will remain of interest so long as the question, "What is science?" retains its cultural and intellectual importance.

BERTRAND RUSSELL

(18 May 1872–2 February 1970)

"Almost everything that distinguishes the modern world from earlier centuries is attributable to science." With these words, Bertrand Arthur William Russell (1945) begins his chapter on "The Rise of Science" in his expansive *History of Western Philosophy*; and using this insight, he helped revolutionize not only twentieth-century logic, but philosophy itself.

Although known to many outside the academy primarily as a social critic, Russell contributed significantly to philosophy of science, in both a narrow and a broad sense. In the narrow sense, along with Gottlob Frege, Alfred North Whitehead, David Hilbert, and Kurt Gödel, Russell is responsible for groundbreaking work in two important subfields within twentieth-century philosophy of science: symbolic logic and philosophy of mathematics (see Hilbert, David). In the more broad sense, Russell is among those who originally championed connections among modern logic, mathematics, and science and between what he called the "scientific outlook" (Russell 1931) or "scientific temper" (Russell [1922] 1928, 172) and knowledge more generally.

Russell's most significant contributions include his refining and popularizing of Frege's predicate logic (upon which so many insights in philosophy of science have been based), his discovery of the paradox that bears his name, his introduction of the theory of types (his way of avoiding paradoxes), and his defense of logicism (the view that mathematics is in some important sense reducible to logic). Equally significantly, Russell, along with G. E. Moore, developed what would eventually become known as analytic philosophy, encouraging the view that science, mathematics, logic, and philosophy are all interconnected and all have something to learn from one another. Both in theory and in practice, Russell championed the view that progress in every intellectual sphere (science, philosophy, politics, education, etc.) depends on the scientific outlook, or as he also sometimes put it, "the liberal outlook" (Russell [1947] 1950, 15–16).

Born in 1872, Russell was the second grandson of Lord John Russell, the reform politician who twice served as prime minister to Queen Victoria. Following the death of his mother (in 1874) and of

his father (in 1876), Russell and his brother went to live with their grandparents. Although Russell's father had granted custody of his sons to two atheists in order that they not be raised within the church, Russell's grandparents had little difficulty in getting his will overturned. Following the death of his grandfather (in 1878), Russell was raised primarily by his grandmother, Lady Russell. Educated at first privately and later at Trinity College, Cambridge, Russell obtained first-class degrees in both mathematics (1893) and the moral sciences (1894).

While at Cambridge, and like other later-to-be-famous intellectuals such as John Maynard Keynes, G. E. Moore, Henry Sidgwick, Alfred Lord Tennyson, Alfred North Whitehead, and Ludwig Wittgenstein, Russell became a member of the secret undergraduate association, the Society of the Apostles. As Sidgwick described it, "The essential value of the Society is a belief that we can learn, and a determination that we will learn, from people of the most opposite opinions" (Deacon 1985, 43).

Although appointed a Fellow of Trinity College in 1895 and elected to the Royal Society in 1908, Russell's career at Trinity appeared to come to an end in 1916 when he was convicted and fined for antiwar activities. He was dismissed from the College as a result of the conviction. The details of the dismissal are recounted in G. H. Hardy's book, *Bertrand Russell and Trinity* (Hardy 1942). The British government also refused to issue him a passport, which would have enabled him to lecture at Harvard. Two years later he was convicted a second time. This time he spent six months in prison. It was while in prison that Russell (1919) wrote his well-received *Introduction to Mathematical Philosophy* and began work on *The Analysis of Mind* (Russell 1921). In 1920 he traveled to both the Soviet Union and China. Although sympathetic to the socialist goals of the Bolsheviks, in the Soviet Union he became convinced that little good could come from the communist revolution. As he put it, "I see no reason whatever to expect equality or freedom to result from such a system, except reasons derived from a false psychology and a mistaken analysis of the sources of political power" (Russell [1920] 1962, 78–79). He did not return to Trinity until 1944, supporting himself and his family in the interim through a string of temporary lectureships and as a writer. Married four times and notorious for his many affairs, Russell also ran unsuccessfully for Parliament in 1907, 1922, and 1923. Together with his second wife, Dora Russell, he opened and ran an experimental school during the late 1920s and early 1930s. He became the third Earl Russell upon the death of his brother in 1931.

While teaching in California in the late 1930s, Russell was offered an appointment at City College, New York. The appointment was revoked following a large number of public protests and a judicial decision in 1940 stating that he was morally unfit to teach at the College. Nine years later, he was awarded the Order of Merit. He received the Nobel Prize for Literature in 1950. In making the award, the Nobel Committee explained that it was its intention to honor Russell "as one of our time's brilliant spokesmen of rationality and humanity, as a fearless champion of free speech and free thought" (Frenz 1969, 451). In 1953, perhaps recalling the 1940 New York court decision, Russell was also elected an Honorary Associate of the New York National Institute of Arts and Letters.

During the 1950s and 1960s, Russell spent much of his time encouraging scientists to participate in various antiwar and antinuclear activities. As a result, he became something of an inspiration to large numbers of idealistic youth around the world. Together with Albert Einstein, he released the Russell-Einstein Manifesto in 1955, calling for the curtailment of nuclear weapons. In 1957, he was a prime organizer of the first Pugwash Conference, which brought together scientists concerned about the proliferation of nuclear weapons. He became the founding president of the Campaign for Nuclear Disarmament in 1958 and was once again imprisoned, this time in connection with antinuclear protests, in 1961. Upon appeal, his two-month prison sentence was reduced to one week in the prison hospital. In 1960, he announced the launching of two foundations: the Bertrand Russell Peace Foundation and the Atlantic Peace Foundation. He remained a prominent public figure until his death 10 years later at the age of 97.

Russell's Contributions to Logic and the Philosophy of Mathematics

"Bertrand Russell's claim to be remembered by history," says his obituary in *The Times* of London, "rests securely on his work in mathematical and symbolic logic and in philosophy, on which his influence was pervasive and profound. The story of symbolic logic and of philosophy of mathematics in the twentieth century is the story of the expansion of the edifice which Russell and Frege founded. There have been major reconstructions, but they are reconstructions from within" ("Earl Russell" 1970).

This assessment is no doubt correct. In fact, when discussing Russell's intellectual life, it is useful to distinguish between events leading up to the publication of *Principia Mathematica*—Whitehead and Russell's (1910–1913) main contribution to logic and philosophy of mathematics—and those that came afterward. As Russell (1967–1969) himself has remarked in his *Autobiography*, completion of this project served as something of a turning point for him intellectually: "At the age of eleven, I began Euclid, with my brother as my tutor. This was one of the great events of my life, as dazzling as first love. I had not imagined there was anything so delicious in the world. ... From that moment until I was thirty-eight [the year the first volume of *Principia* appeared], mathematics was my chief interest, and my chief source of happiness" (37–38).

Principia Mathematica thus served as the culmination of years of work in both logic and mathematics. Along the way, Russell had accepted and then rejected idealism as the proper approach to mathematics; discovered what has since become known as Russell's paradox; introduced and then modified several versions of his theory of types; defended a new, robust version of logicism, thereby improving upon the work of Leibniz, Dedekind, and Frege; and refined and popularized Frege's newly invented quantificational logic.

His move to realism, not just in mathematics but generally, occurred only after first being exposed to the absolute idealism of J. M. E. McTaggart and F. H. Bradley at Cambridge. As Russell saw it, absolute idealism depended crucially upon the doctrine of internal relations, which holds that any relational fact (e.g., that x is related to y) is really a fact about the natures of the related terms. In this view, if x is greater than y, then being greater than y is a part of the nature of x. Object y is thus, in some sense, a part of x, and x is similarly a part of y. Given the complexity of relations in the world, it then turns out that all objects will be related to all objects. Hence there exists a single, all-encompassing unity. Further, since, if one is aware of x, x must also (in this view) be a part of one's mind, it follows that everything conceivable is a part of consciousness.

Initially, Russell used this idealist framework in his approach to mathematics (e.g., Russell 1897). However, he became disenchanted with idealism once he realized how incompatible the view was with his developing view of mathematics. In Russell's emerging view, geometrical points, for example, could be individuated only by their relations. But according to absolute idealism, relations depended in turn upon the individual, intrinsic natures of their relata. Forced to choose between idealism and mathematics, Russell unhesitatingly chose mathematics, replacing idealism with realism and replacing the doctrine of internal relations with a new doctrine of what he called "external relations," the view that relations, like objects, have a reality independent of the objects they relate. The change would lead, in the short term, to his next major work (Russell 1903) and, in the long term, to his commitment to pluralism, antipsychologism, the importance of science, and the emergence of analytic philosophy as a replacement for idealism.

It was in this context that Russell discovered, in the spring of 1901, the paradox that bears his name. In 1900, he had attended the Mathematical Congress in Paris and had been impressed by the work in mathematical logic by Giuseppe Peano and his students. As a result, he began studying both Peano's and Frege's logic in detail. A year later, he stumbled across a puzzling contradiction. The contradiction arose in connection with the set of all sets that are not members of themselves. Such a set (or collection), if it exists, will be a member of itself if and only if it is not a member of itself. To see this, it helps first to observe that some sets (such as the set of all Englishmen) are not members of themselves. In contrast, other sets (such as the set of all non-Englishmen) are members of themselves. It follows that if any property (or predicate) is sufficient to pick out a set in this way, then a new set, R, can be picked out using the property of not-being-a-member-of-itself. Immediately it follows that if R is a member of itself, then by definition it cannot be a member of itself; and if R is not a member of itself, then by definition it must be a member of itself.

The significance of the paradox follows, because in classical logic, all sentences are entailed by a contradiction. (For example, assuming both P and $\neg P$, one can prove any arbitrary proposition, Q, as follows: From P one can obtain $P \vee Q$ by the rule of addition; then from $P \vee Q$ and $\neg P$ one can obtain Q by the rule of disjunctive syllogism.) In the eyes of many mathematicians, including David Hilbert and Luitzen Brouwer, it thus appeared that no proof could be trusted. Once it was discovered that the logic and set theory apparently underlying all mathematics was contradictory, no mathematical claim was secure. A large amount of work throughout the early part of the twentieth century in logic, set theory, and the philosophy and foundations of mathematics was thus prompted. Russell wrote to Frege with news of his paradox on June 16, 1902. The paradox was relevant to Frege's logical work, because in effect, it showed that the axioms Frege was using to formalize logic

were inconsistent. Specifically, Frege's rule 5, which states that two sets are equal if and only if their corresponding characteristic functions coincide in values for all possible arguments, requires that a propositional function such as $f(x)$ be considered both a function of the argument f and a function of the argument x. In effect, it was this ambiguity that allowed Russell to construct R in such a way that it could both be and not be a member of itself.

Russell's letter arrived just as the second volume of Frege's ([1903] 1964) *Grundgesetze der Arithmetik* was in press. Immediately appreciating the difficulty the paradox posed, Frege hastily added an appendix to the *Grundgesetze* to discuss Russell's discovery. In this appendix Frege ([1903] 1964) observes that the consequences of Russell's paradox are not immediately clear. For example, "Is it always permissible to speak of the extension of a concept, of a class? And if not, how do we recognize the exceptional cases? Can we always infer from the extension of one concept's coinciding with that of a second, that every object that falls under the first concept also falls under the second? These are questions," Frege notes, "raised by Mr Russell's communication" (127).

Because of these kinds of worries, Frege eventually felt forced to abandon many of his logical and mathematical views. Russell himself was also concerned about the paradox, and so, like Frege, he hastily composed an appendix for his soon to be released *Principles of Mathematics*. Entitled "Appendix B: The Doctrine of Types," the appendix represents Russell's first attempt at developing a workable theory of types. Russell's basic idea was that reference to troublesome sets (such as R) could be avoided by arranging all sentences into a hierarchy, beginning with sentences about individuals at the lowest level, sentences about sets of individuals at the next lowest level, sentences about sets of sets of individuals at the next lowest level, etc. Then, using the "vicious circle principle" (VCP) introduced by Henri Poincaré, together with his so-called "no class" theory of classes (Whitehead and Russell 1927, 37f, 187f), Russell was able to explain why propositional functions, such as the function "x is a set," should not be applied to themselves: because self-application would involve a vicious circle (see Poincaré, Henri). In other words, it is possible to refer to a collection of objects for which a given condition (or predicate) holds only if they are all at the same level or of the same "type."

Although first introduced by Russell in his *Principles*, his theory of types eventually found its mature expression in his 1908 article "Mathematical Logic as Based on the Theory of Types" and in *Principia Mathematica*. Thus, in its details, the theory admits of two versions, the "simple theory" and the "ramified theory." Both versions of the theory later came under attack. For some they were too weak, since they failed to resolve all of the known paradoxes. For others they were too strong, since they disallowed many mathematical definitions that, although consistent, violated the VCP. Russell's response to the second of these objections was to introduce, within the ramified theory, the axiom of reducibility. Although the axiom successfully lessened the VCP's scope of application, many claimed that it was simply too ad hoc to be justified philosophically (see Ramsey, Frank Plumpton).

Other responses to Russell's paradox include those of David Hilbert and the formalists (whose basic idea was to allow the use of only finite, well-defined, and constructible objects, together with rules of inference that were deemed to be absolutely certain) and of Luitzen Brouwer and the intuitionists (whose basic idea was that one cannot assert the existence of a mathematical object unless one can also indicate how to go about constructing it). Yet a fourth response was contained in Ernest Zermelo's 1908 axiomatization of set theory, **Z**. **ZF**, the axiomatization generally used today, is a modification of Zermelo's theory developed primarily by Abraham Fraenkel. All four responses helped logicians develop an explicit awareness of the nature of formal systems and of the kinds of metalogical results that are today commonly associated with them. Of equal significance during this same period was Russell's (1903) defense of logicism, the theory that mathematics is in some important sense reducible to logic. As he put it: "The fact that all Mathematics is Symbolic Logic is one of the greatest discoveries of our age; and when this fact has been established, the remainder of the principles of mathematics consists in the analysis of Symbolic Logic itself" (5). Initially, this meant showing that all mathematics was derivable from symbolic logic. It also meant discovering, so far as possible, the principles of symbolic logic itself. Later, in *Principia Mathematica*, it became clear that logicism would have to include two more precise theses. The first is that all mathematical truths can be translated into logical truths or, in other words, that the vocabulary of mathematics constitutes a proper subset of that of logic. The second is that all mathematical proofs can be recast as logical proofs or, in other words, that the theorems of mathematics constitute a proper subset of those

of logic. Like Frege, Russell's basic idea for defending logicism was that numbers were to be identified with classes of classes and that number-theoretic statements were to be explained in terms of quantifiers and identity. Thus the number 1 would be identified with the class of all unit classes, the number 2 with the class of all two-membered classes, and so on. Statements such as "There are two books" would be recast as "There is a book, x, and there is a book, y, and x is not identical to y." It followed that number-theoretic operations could be explained in terms of set-theoretic operations such as intersection, union, and the like. In *Principia Mathematica*, Whitehead and Russell were then able to provide detailed derivations of many major theorems in set theory, finite and transfinite arithmetic, and elementary measure theory. A fourth volume on geometry was planned but never completed.

However, unlike Frege, Russell drew a quite different philosophical moral from the logicist reduction. As Frege saw it, if the principles of logic were understood to be self-evident, and if the laws of arithmetic can be shown to be derivable from them, arithmetic will have become epistemologically justified. According to this type of reduction, arithmetic would become just as certain as logic itself. In contrast, in Russell's view, the order of epistemic justification is exactly the reverse, as explained in the introduction to the first volume of *Principia* (Whitehead and Russell 1910–1913):

> But in fact self-evidence is never more than a part of the reason for accepting an axiom, and is never indispensable. The reason for accepting an axiom, as for accepting any other proposition, is always largely inductive, namely that many propositions which are nearly indubitable can be deduced from it, and that no equally plausible way is known by which these propositions could be true if the axiom were false, and nothing which is probably false can be deduced from it. If the axiom is apparently self-evident, that only means, practically, that it is nearly indubitable; for things have been thought to be self-evident and have yet turned out to be false. And if the axiom itself is nearly indubitable, that merely adds to the inductive evidence derived from the fact that its consequences are nearly indubitable: it does not provide new evidence of a radically different kind. Infallibility is never attainable, and therefore some element of doubt should always attach to every axiom and to all its consequences. In formal logic, the element of doubt is less than in most sciences, but it is not absent, as appears from the fact that the paradoxes followed from premisses which were not previously known to require limitations. (62)

Thus, like any of the other sciences, logic and mathematics are justified more by induction and coherence than by a *priori* reason. In the introduction to *Principia*'s second edition, Russell's comments are to much the same effect when he mentions the "purely pragmatic justification" of the axiom of reducibility (Whitehead and Russell 1927, xiv). This view of the relation between science and mathematics stayed with Russell throughout his career. For example, in his essay *Logical Atomism*, Russell (1924) again explains his position as follows:

> When pure mathematics is organized as a deductive system ... it becomes obvious that, if we are to believe in the truth of pure mathematics, it cannot be solely because we believe in the truth of the set of premises. Some of the premises are much less obvious than some of their consequences, and are believed chiefly because of their consequences. This will be found to be always the case when a science is arranged as a deductive system. It is not the logically simplest propositions of the system that are the most obvious, or that provide the chief part of our reasons for believing in the system. With the empirical sciences this is evident. Electrodynamics, for example, can be concentrated into Maxwell's equations, but these equations are believed because of the observed truth of certain of their logical consequences. Exactly the same thing happens in the pure realm of logic; the logically first principles of logic—at least some of them—are to be believed, not on their own account, but on account of their consequences. The epistemological question: 'Why should I believe this set of propositions?' is quite different from the logical question: 'What is the smallest and logically simplest group of propositions from which this set of propositions can be deduced?' Our reasons for believing logic and pure mathematics are, in part, only inductive and probable, in spite of the fact that, in their logical order, the propositions of logic and pure mathematics follow from the premises of logic by pure deduction. I think this point important, since errors are liable to arise from assimilating the logical to the epistemological order, and also, conversely, from assimilating the epistemological to the logical order. (361–362)

According to the mature Russell, logic and mathematics differ from the natural sciences only as a matter of degree, not as a matter of kind.

Russell's Contributions to Philosophy of Science

In much the same way that Russell used logic in an attempt to clarify issues in the foundations of mathematics, he also used logic in an attempt to clarify issues in philosophy more generally. These attempts, together with his attempts to connect science to logic and philosophy, took center-stage following the appearance of the first volume of *Principia* in 1910.

As one of the founders of analytic philosophy, Russell made significant contributions to a wide variety of areas, including metaphysics, epistemology, ethics, and political theory, as well as to the philosophy of science. In the philosophy of science, he advanced discussion in a large number of areas, putting forward often-novel theories of mind, perception, causality, scientific method, and laws of nature. On the issue of causality, for example, Russell recognized that science demands more than simple observations of the form "*A* caused *B*" (see Causality). Instead, science regularly states causal laws of the form "*A* causes *B*." However, when it comes to applying this conjecture to real-world cases, the scientist does not mean that *A* always causes *B*, since there are always potential factors that may override *A*. For example, Newton's first law does not state that every object in a state of uniform motion will always remain in that state of motion. Rather, it states that every object in a state of uniform motion will remain in that state of motion unless it is acted upon by an external force. But how is the scientist to know whether such a law obtains if it is always possible to postulate such countervailing factors? As Russell (1948) puts it:

> We cannot take account of all the infinite complexity of the world, and we cannot tell, except through previous causal knowledge, which among possible circumstances would prevent *B*. Our law therefore becomes: "*A* will cause *B* if nothing happens to prevent *B*." Or, more simply: "*A* will cause *B* unless it doesn't." (474–475)

But as Russell points out, "This is a poor sort of law, and not very useful as a basis for scientific knowledge" (475) (see Laws of Nature). Russell's own solution was to rely upon a combination of scientific instruments (such as differential equations and statistical regularities) and metaphysical assumptions (concerning the quasi-permanence of logically constructed physical entities).

In books such as *The Scientific Outlook*, Russell (1931) also was one of the first to discuss the many social influences of modern developments in science and technology. Underlying these various projects lay not only Russell's use of logical analysis, but also his long-standing goal of discovering whether, and to what extent, knowledge is possible. Thus, Russell (1912) began the opening chapter of his *Problems of Philosophy* with the question "Is there any knowledge in the world which is so certain that no reasonable man could doubt it?" For Russell, this was the most central of all philosophical questions. Russell's various contributions to philosophy were thus unified by his views concerning both the centrality of scientific knowledge and the importance of an underlying scientific methodology common to both philosophy and science (see Carnap, Rudolf; Logical Empiricism). In the case of philosophy, this methodology expressed itself through Russell's use of logical analysis. So central was this methodology that Russell often claimed that he had more confidence in his methodology than in any particular philosophical conclusion.

As Russell explained it, his philosophical methodology consisted of the making and testing of hypotheses through the weighing of evidence (hence Russell's comment that he wished to emphasize the scientific method in philosophy), together with a rigorous analysis of problematic concepts using the machinery of first-order logic. For example, even in the application of elementary arithmetical concepts, one might come across difficult or marginal cases. As Russell (1942) explains,

> Two dogs and two dogs are certainly four dogs, but cases arise in which you are doubtful whether two of them are dogs. "Well, at any rate there are four animals," you may say. But there are microorganisms concerning which it is doubtful whether they are animals or plants. "Well, then living organisms," you say. But there are things of which it is doubtful whether they are living organisms or not. You will be driven into saying: "Two entities and two entities are four entities." When you have told me what you mean by "entity," we will resume the argument. (39)

In short, it was Russell's belief that conceptual analysis, together with the new logic of his day, would help philosophy exhibit the underlying "logical form" of natural language statements. A statement's logical form, in turn, would help philosophers resolve problems of reference associated with the ambiguity and vagueness of natural language. Thus, just as one can distinguish three separate senses of 'is' (the *is* of predication, the *is* of identity, and the *is* of existence) and exhibit these three senses by using three separate logical notations (Px, $x = y$, and $\exists x$, respectively), one will also discover other ontologically significant distinctions by being made aware of a sentence's correct logical form. In Russell's view, the subject matter of philosophy is then distinguished from that of the sciences only by the generality of philosophical statements, not by the underlying methodology of the discipline. In philosophy, as in mathematics, Russell believed that it was by applying logical machinery and scientific insights that advances would be made. Russell's most famous example of his analytic method concerns denoting phrases. In

his realist *Principles of Mathematics*, Russell (1903) had adopted the view that every denoting phrase (for example, 'pi,' Sherlock Holmes, the number two, the golden mountain) denoted, or referred to, an existing entity. By the time his landmark article "On Denoting" appeared two years later, Russell (1905) had modified this extreme realism and had instead become convinced that denoting phrases need not possess a single theoretical unity.

According to this new view, logically proper names (words such as 'this' and 'that,' which refer to sensations of which an agent is immediately aware) always have referents associated with them. In contrast, descriptive phrases (such as 'the smallest number less than pi') should be viewed as a collection of quantifiers (such as 'all' and 'some') and propositional functions (such as 'x is a number'), which may or may not succeed in referring. As such, they are not to be viewed as referring terms but, rather, as "incomplete symbols." In other words, they should be viewed as symbols that take on meaning only within appropriate contexts but that in isolation remain meaningless. For example, consider the sentence 'The number between six and eight is prime.' Here the definite description 'the number between six and eight' plays a role quite different from that of a proper name such as 'seven' in the sentence 'Seven is prime.' Letting S abbreviate the predicate 'is a number between six and eight' and P abbreviate the predicate 'is prime,' Russell assigns the sentence 'The number between six and eight is prime' the logical form

There is an x such that
(i) Sx,
(ii) for any y, if Sy then $y = x$, and
(iii) Px.

Alternatively, in the notation of the predicate calculus, one has:

$$\exists x[(Sx \wedge \forall y(Sy \rightarrow y = x)) \wedge Px].$$

In contrast, by allowing s to abbreviate the name 'seven,' Russell assigns the sentence 'Seven is prime' the very different logical form Ps.

This distinction between logical forms allows Russell to explain three important puzzles. The first puzzle relates to true negative existential claims, such as 'The number postulated between seven and eight does not exist.' Here, by treating definite descriptions as having a logical form separate from that of proper names, Russell is able to give an account of how a speaker may be committed to the truth of a negative existential without also being committed to the belief that the subject term has reference. In other words, a claim such as 'Seven does not exist' is false, since the proposition $\neg\exists x(x = s)$ is self-contradictory. This is so because there must exist at least one thing that is identical to s, since it is presumably a logical truth that s is identical to itself. In contrast, the claim 'The number postulated between seven and eight does not exist' can be true because by allowing B to abbreviate the predicate 'is postulated between' and e to abbreviate 'eight,' there is nothing contradictory about the proposition $\neg\exists x(Bxse)$.

The second puzzle concerns the operation of the *law of excluded middle* and how this law relates to denoting terms. According to one reading of the law, it must be the case that either 'The largest prime is even' is true or 'The largest prime is not even' is true. But if so, since both sentences appear to entail the existence of a largest prime, this will clearly yield an undesirable result. Russell's analysis shows how such a result can be avoided. By appealing to his earlier analysis, it follows that there is a way to deny 'The largest prime is even' without being committed to the existence of a largest prime: by analyzing 'The largest prime' as a definite description rather than assuming it is equivalent to a proper name. Thus, the negation of 'The largest prime is even' becomes 'It is not the case that there exists a largest prime which is even,' rather than 'The largest prime is not even,' and the truth of the former can be asserted without controversy.

The third puzzle concerns the *law of identity* as it operates in so-called opaque contexts. For example, even though 'The positive square root of nine is three' is true, it does not follow that the two referring terms 'The positive square root of nine' and 'three' are interchangeable in every linguistic context. Thus although 'Alfred wanted to know whether the positive square root of nine was three' may be true, the similar sentence 'Alfred wanted to know whether three was three' is, presumably, false. Russell's distinction between the logical forms associated with the use of proper names and definite descriptions shows why this is so.

To see this, let t abbreviate the name 'three,' let n abbreviate the name 'nine,' and let P abbreviate the two-place predicate 'is the positive square root of.' It then follows that the sentence $t = t$ is not at all equivalent to the sentence

$$\exists x[Pxn \wedge \forall y(Pyn \rightarrow y = x) \wedge x = t].$$

Russell's emphasis upon logical analysis also had consequences for his metaphysics. In response to

the traditional problem of the external world, which, it is claimed, arises because the external world can be known only by inference, Russell developed his famous distinction between "knowledge by acquaintance and knowledge by description" (Russell 1910). He then went on, in his lectures on logical atomism (Russell 1918, 1919), to argue that the world itself consists solely of a complex of logical atoms (such as "little patches of colour") and their properties. Together they form the atomic facts that, in turn, are combined to form logically complex objects. What are normally thought to be inferred entities (e.g., enduring physical objects) are then understood to be "logical constructions" formed from the immediately given entities of sensation with which people are directly acquainted, *viz.,* "sensibilia" (Russell 1914a and 1914b). It is only these latter entities that are known noninferentially and with certainty. Similar constructions allowed Russell to reduce points and instants to ordered classes of volumes and events, and classes to propositional functions.

According to Russell, a large part of the philosopher's job is to discover a logically ideal language. This logically ideal language will exhibit the true nature of the world in such a way that the speaker will not be misled by the casual surface structure of natural language. Just as atomic facts (the association of properties and relations with an appropriate number of individuals) may be combined into molecular facts in the world itself, such a language would allow for the description of such combinations using logical connectives such as 'and' and 'or.' In addition to atomic and molecular facts, Russell also held that general facts (about all members of a given class) were needed to complete the picture of the world. Famously, he vacillated on whether negative facts were also required.

Unlike Leibniz, Russell believed there was more to scientific, mathematical, and philosophical knowledge than getting the concepts right. Even so, just as Leibniz had wanted to develop a logically ideal language (or *characteristica universalis*), together with an instrument of universal deductive reasoning (his *calculus ratiocinator*), Russell believed that modern logic would help us represent the world as it actually is and reason about it without fear of error. As Russell himself translates one of Leibniz's most famous quotations:

> We should be able to reason in metaphysics and morals in much the same way as in geometry and analysis. . . . If controversies were to arise, there would be no more need of disputation between two philosophers than between two accountants. For it would suffice to take their pencils in their hands, to sit down to their slates, and to say to each other (with a friend as witness, if they liked): Let us calculate. (Russell 1900, 169–170)

Conceptual analysis may not have the air of empirical discovery about it, but it is just as crucial to the scientific enterprise as observation and experiment.

With this observation in mind, it is thus worth recalling that after reviewing the history of the interplay between science and philosophy, Russell (1945) ends his *History of Philosophy* with these words:

> In the welter of conflicting fanaticisms, one of the few unifying forces is scientific truthfulness, by which I mean the habit of basing our beliefs upon observations and inferences as impersonal, and as much divested of local and temperamental bias, as is possible for human beings. To have insisted upon the introduction of this virtue into philosophy, and to have invented a powerful method by which it can be rendered fruitful, are the chief merits of the philosophical school of which I am a member. The habit of careful veracity acquired in the practice of this philosophical method can be extended to the whole sphere of human activity, producing, wherever it exists, a lessening of fanaticism with an increasing capacity of sympathy and mutual understanding. In abandoning a part of its dogmatic pretensions, philosophy does not cease to suggest and inspire a way of life. (836)

S

MORITZ SCHLICK

(14 April 1882–22 June 1936)

Friedrich Albert Moritz Schlick was born the third and youngest son of Protestant parents. His father, who owned a factory, descended from a Bohemian family of noble lineage, and his mother from the family of the poet Ernest Moritz Arndt, after whom Schlick was named. He attended primary and secondary school in Berlin. As a sickly schoolchild, Schlick was interested in philosophy, art, and poetry at the Luisenstädter Gymnasium, but he went on to study natural science and mathematics at universities in Heidelberg, Lausanne, and Berlin. In 1904, he completed his Ph.D. under Max Planck, who regarded him as one of his favorite students, with the thesis *Über die Reflexion des Lichtes in einer inhomogenen Schicht* [The Reflection of Light in an Inhomogeneous Layer] in mathematical physics. Schlick spent the following three years doing scientific research at the universities in Göttingen, Heidelberg, and Berlin. After the appearance of his first book, whose title is translated as *Life Wisdom* (Schlick 1908), Schlick spent two years studying psychology in Zurich. In 1907, he married Blanche Hardy and, after a short sojourn in Berlin, completed his habilitation in 1911 at the University of Rostock with a study "Das Wesen der Warheit nach der modernen Logik" (Schlick 1910).

During his next ten years of academic activity, Schlick worked on the reform of traditional philosophy against the backdrop of the revolution in natural science. He became friends with Einstein and was one of the first to study the theory of relativity from a philosophical perspective. During World War I, he served two years at a military airport.

In 1917, Schlick began teaching at Rostock, and was granted the official title of associate professor, with a teaching position in ethics and natural philosophy, in 1921. During the Weimar Republic, Schlick backed university reform as a member of the Union of Progressive Academics and completed his major study, *Allgemeine Erkenntnislehre* (Schlick [1918] 1974). In the summer of 1921 Schlick moved to the University of Kiel as full professor, where he taught for one year.

After the Rostock and Kiel periods, the then 40-year-old Schlick was appointed in 1922 to the chair for natural philosophy (philosophy of the inductive sciences) in Vienna, in the tradition of Mach and

Boltzmann (see Mach, Ernest). The mathematician Hans Hahn, who was the teacher of Karl Menger and Kurt Gödel, was mainly responsible for this innovative step (see Hahn, Hans). This move also represented an attempt to provide an institutional platform and an intellectual leader for the further development of the scientific philosophy of the so-called "first Vienna Circle" (with Frank, Hahn, and Neurath) (Uebel 2000). In Vienna, in 1924, at the suggestion of his students Herbert Feigl and Friedrich Waismann, Schlick began organizing a regular discussion group that first met privately, and then in the rear building of the Institute of Mathematics in Vienna.

This forum remained in existence up until Schlick's death and later went down in the history of philosophy and science as the "Vienna Circle." This institutionalization of the Circle between 1924 and 1929 was characterized by the discussion and encounter with Wittgenstein's early philosophy and finally with Rudolf Carnap's ([1928] 1969) *Scheinprobleme in der Philosophie,* which was inspired by neo-Kantianism, Gestalt theory, and set theory, based on Mach and Russell (see Carnap, Rudolf). The formation of the circle was most lucidly described by Philipp Frank, Einstein's successor in Prague (Frank 1949) (see Vienna Circle). In addition to his extensive research and academic teaching duties, Schlick was also active in adult education as a member of the Ethical Society and, most importantly, from 1928 to 1934, as chairman of the Verein Ernest Mach. In spite of his efforts, it was dissolved February 12, 1934, for political reasons.

Beginning in 1926, Schlick came in personal contact with Ludwig Wittgenstein, who influenced him significantly. At his students' request, in 1929 Schlick refused an attractive job offer at Bonn. He spent several months in California as a visiting professor in Stanford and later (1931–1932) in Berkeley. As a professor in Vienna, Schlick's publications and lectures led to relationships with scientific communities in Berlin, Prague, Göttingen, Warsaw, England, and the United States. Together with Philipp Frank, he published the series *Schriften zur wissenschaftlichen Weltauffassung* from 1929 to 1937.

At the apogee of his influential life as a scholar, on June 22, 1936, Moritz Schlick was murdered on the steps of the University of Vienna by a former student. The student received early release by the Nazis and lived as a free citizen in Austria after 1945. Schlick's murder marked the definitive demise of the Vienna Circle, whose remaining members were forced to emigrate after the German anschluss of Austria in 1938.

Between Natural and Cultural Philosophy

Schlick thought philosophy had an important and independent function in relation to the natural and social sciences. He also embodied the prototype of a liberal, cosmopolitan intellectual in the midst of a "national-socialist revolution." Intellectually, it is difficult to accurately characterize Schlick, who clearly sympathized with American pragmatism and its commonsense thinking. Archival evidence indicates an early desire to liberate himself from traditional philosophy and dedicate himself to the exact sciences. Equally important in his work was an attempt to deal with the natural and cultural world (ethics) simultaneously.

A revealing entry by Schlick in the *Philosophen-Lexikon* begins with the following programmatic claim: "Schlick attempts to justify and construct a consistent and entirely pure empiricism." However, unlike earlier forms of empiricism, Schlick thought that the doctrine could be justified only by applying the techniques of modern mathematics and logic to reality. The entry continues:

> From there, and with the help of an analysis of the process of knowledge, the 'General Theory of Knowledge' arrives first at a clear distinction between the rational and the empirical, the conceptual and the intuitive. Concepts are mere symbols that are attributed to the world in question; they appear in 'statements' ordered in a very particular way, by which these are able to 'express' certain structures of reality. Every statement is the expression of a fact and represents knowledge insofar as it describes a new fact with the help of old signs—in other words, with a new combination of terms which have already been used in other regards. The ordering of reality ... is determined solely by experience, for which reason there exists only empirical knowledge. The so-called rational truths, then, purely abstract statements such as the logical-mathematical ones, ... are nothing more than rules of signs which determine the syntax of the language (L. Wittgenstein) which we use to speak about the world. They are of purely analytic-tautological character and therefore contain no knowledge; they say nothing about reality, but it is for precisely this reason that they can be applied to any given fact in the world. Thus, knowledge is essentially a reproduction of the order, of the structure of the world; the material or content belonging to this structure cannot enter it; for the expression is, after all, not the thing itself which is being expressed. Therefore, it would be senseless to attempt to express the 'content' itself. Herein lays the condemnation of every variety of metaphysics; for it is precisely this that metaphysics has always wanted, in having as its goal the cognizing of the actual 'essence of being.' (Schlick 1950)

This short text has its origins in Schlick's Viennese period, as the reference to Wittgenstein

indicates. It also represents the essence of his most important work on epistemology, his *General Theory of Knowledge* (Schlick [1918] 1974), which manifests a specific sort of interaction between philosophy and the sciences. As Schlick (1950, 463) concludes:

> Philosophy is not a science, even though it pervades all sciences. Because while these latter consist of systems of true assertions and contain knowledge, philosophy consists in the search for the meaning of the statements and creates understanding, which leads to wisdom.

These statements do not entail any relation of priority between nature and culture, or between theoretical and moral philosophy. According to Schlick (1950), no priority exists because ethics and aesthetics can be done in congruence with his concept of "consistent empiricism." Hence, "It makes no sense to speak of 'absolute' values; only the evaluative behaviors actually practiced by human beings can be the object of study. Based on this standpoint arises a new justification for a kind of eudaimonism, which moral principle reads more or less so: Increase your happiness!" (463).

This ethical claim clearly distinguishes Schlick's view of ethics from Wittgenstein's philosophy of the ineffable, and from those members of the Vienna Circle and the Berlin Group who regarded moral-philosophic issues as unimportant. Schlick's view of ethics is elaborated in detail in *Lebensweisheit*, *Fragen der Ethik* (Schlick 1908 and 1930), and numerous autobiographical fragments (up to 1922) scattered throughout his writings. Moreover, throughout his life, Schlick was interested in the idea of a lifelong balance between nature, culture, and art.

Schlick claimed that even early in his life, he had begun "to philosophize before I even knew that philosophy existed. All sorts of doubts eventually drove me to metaphysics, but after having read Kant, I was calmed and done with metaphysics" (Schlick 1900, 1). Later, Schlick began studying the human sciences, which he "always thought to be less of a philosophy than a *natural* science" (ibid). These early claims anticipate Schlick's later view that the Cartesian unity of nature and humanity is manifested in modern natural science. Schlick had adopted a sort of monist conception of the world. Precisely this conception of nature led him to believe that the ultimate goal and principle of ethics was "happiness." It is unsurprising, then, that he juxtaposed Kantian ethics with the obligation of a eudaimonist "ethics of charity" and proposed the mindless play of youth as a paradigm for an everyday morality.

Returning to epistemology, Schlick described his intellectual development prior to Rostock in an unpublished manuscript (Schlick CV): "The endeavor towards universality and the most general principles of knowledge and science," he wrote, "distinguishes philosophy from the special sciences. Searching for answers to the great questions of life, not just working the theoretical fields of knowledge, are the tasks of scientific philosophy." Schlick does not claim to be a philosopher by virtue of his work on the epistemological foundations of inductive science. Rather, his dual interests in knowledge of nature and of the personal life remained constant and significant throughout his career. There is here a parallel to Ernest Mach (see Mach, Ernest).

Central to Schlick's early conception of philosophy was a belief that metaphysics was trivial and a distrust of pure speculation. Schlick thought a peaceful and friendly coexistence between philosophy and natural science was possible, and a passion and ambition for this ideal formed the foundation of his academic career. He initially elaborated this ideal in a pragmatic conception of truth: "that truth is merely another name for the utility of a judgment, and nothing more; in other words, that the utility of a judgment is not a consequence of its truth—it is rather the very essence of the truth" (Schlick CV, 15). This pragmatic view is also displayed in Schlick's fondness for American philosophy (which prompted him to visit Stanford and Berkeley).

Later, however, he rejected the pragmatic theory of truth (Schlick 1910). This rejection depended upon a distinction between content and form, which Schlick developed in detail during a lecture series at the University of London in 1932. The purely formal structure of the system of facts is the same as that of a system of (logical) judgment. The contents of a system reflected the empirical world. The domains of reality and thought are thus separated and can be correlated only by the assignment of content to "sign" of the formal system. This was neither rationalism nor extreme empiricism, and therefore rejected the neo-Kantian reconciliation of the two around the turn of the century.

Schlick began exchanging letters with Einstein on a regular basis in 1915. Initially, Einstein thought Schlick was *the* philosophical interpreter of the theory of relativity. Later, Einstein himself was seen, along with Russell and Wittgenstein, as a model of the *Wissenschaftliche Weltauffassung* ([1929] 1973), particularly regarding his claim that "[i]nsofar as the statements of mathematics refer to

reality, they are not certain, and insofar as they are certain, they do not refer to reality'' (Einstein 1921, 119f).

Schlick produced one of the most important early philosophical interpretations of Einstein's work, *Space and Time in Contemporary Physics* ([1917] 1920), but began disagreeing with Einstein after turning to Wittgenstein's philosophy of language in the 1920s. In the early 1920s, Schlick read Wittgenstein's *Tractatus* in seminars held by the mathematicians Hans Hahn and Hans Reidemeister. He also studied Russell's philosophy of logical atomism and neutral monism (McGuinness 1985). Wittgenstein and Schlick's later differences concerned realism, conventionalism, and causality (Schlick 1932–1933). Wittgenstein's philosophy, focused primarily on linguistic analysis, viewed the problem of reality as a pseudo-problem in the sense of Carnap ([1928] 1969).

By 1924, the intellectual and institutional foundations of the Schlick Circle (that is, the later Vienna Circle) had been laid. Before Schlick's (1925) publication of the second edition of *Allgemeine Erkenntnislehre*, he was committed to a form of critical realism. After the 1930s, furthermore, he and Waismann constituted the wing of the Circle inspired by Wittgenstein. Schlick continued to conceive of philosophy as a system for expressing the most general principles inherent in the sciences. However, philosophy was seen as a clarifying activity, involving the logical analysis of statements within particular sciences that would overcome metaphysics and provide a clearer account of meaning. Schlick initially endorsed a realistic position, via verificationism, but later he adopted a more liberal position, but still based on a correspondence theory of truth. This view distanced Schlick from Neurath's ''nonphilosophical'' physicalism based on a coherence theory of truth, and from Neurath's project of an encyclopedia of unified science, which emerged from the controversial debate about protocol sentences.

Last Years

With the rise of fascism and the threat of National Socialism in Vienna, Schlick was prompted, like the mathematician Karl Menger, to focus on the threatening intellectual situation of his time. Within such an environment, Schlick developed what he called a ''consistent individualism'' as a correlate to consistent empiricism. The omnipotent state was to be dissolved in favor of a league of nations to promote the happiness of all people, but not in the guise of Social Darwinism. Accordingly, Schlick criticized nationalism as destructive. Specifically, he saw the National Socialist state as contrary to liberal democracy (Schlick [1930] 1962, 44ff). Schlick also reflected on the concept of the state. He developed a conception of a nonterritorial state as a concrete utopia that would be defined by the population that was to become citizens of different states by their own free will. Peaceful coexistence of several ''invisible states'' would be possible in the same territory; such an organization would make absurd any nationalist social organization (Schleichert 2003). Schlick argued that the only basis for a union of individuals into states being reliable are ethical qualities, such as character, and the peaceful voluntary nature of individual political and religious affiliations (Schlick [1930] 1962, 107).

Schlick worked on a book, *Natur und Kultur*, which was not completed due to his untimely death. It was published in a posthumous redaction, and in it Schlick (1952) said that in the last years of his life, he had been interested mainly in problems of cultural philosophy and ethics, on which he had lectured. The central issue of the book was suffering caused by culture, particularly existential need, tribulations of love, and the mind. Only the first part was completed.

Schlick's last works show that he was attempting a programmatic synthesis of nature and culture. It was a modern variant of a monistic world view that tries to situate the realm of facts and values in a humanist and cosmopolitan context, or in Schlick's words: ''Art is a desire for nature. Culture is a bridge on both ends of which nature rests'' (Schlick A 110).

SCIENTIFIC CHANGE

Epistemology, as the theory of knowledge, may refer either to the process of knowledge acquisition in an individual or to the growth of knowledge in general (see Epistemology). If scientific knowledge is accepted as a valid form of knowledge, then scientific change is central to the second aspect of epistemology. Scientific change is the process by which scientific knowledge is accumulated, transformed, and, possibly, lost. Understanding scientific change then becomes part of epistemology. To the extent that scientific knowledge is privileged over other forms of knowledge, no epistemology would be complete without an account of scientific change. Explicit interest in scientific change, as distinct from epistemology in general, emerged with empiricism, and especially with inductivism and interest in the scientific method (see Induction, Problem of). By the time of the Enlightenment, scientific change was widely taken to be progressive, resulting in the cumulative and monotonic growth of knowledge. It was also viewed as a collective enterprise with its methods and results available for public scrutiny. Implicit theories of scientific change were widespread by the late nineteenth century—for instance, in Comte's positivism, as well as in British natural philosophy, associated with figures such as Mill and Pearson. For Peirce, abduction provided the mechanism of scientific change (see Abduction). The twentieth century saw both philosophical theories of scientific change and many attempts to model the process. Many of the articles in this encyclopedia deal with particular models and theories of scientific change—this essay will provide a brief overview and a guide to the others.

Traditional Objectivism

With respect to scientific change, the logical empiricists distinguished between contexts of discovery and contexts of justification (Reichenbach 1938, 6–7). For justification, the logical empiricists hoped to find a systematic theory that, in Carnap's case, became inductive logic or the logic of confirmation (see Carnap, Rudolf; Confirmation Theory; Inductive Logic). The project of inductive logic remains incomplete. During roughly the same period, Popper and Reichenbach produced their own variants of frameworks for justifying theories (see Corroboration; Popper, Karl Raimund; Reichenbach, Hans). One feature that unites all these approaches is that the process of justification is *supposed* to be guided by a priori principles; thus, they reject a naturalized epistemology, at least with respect to justification. This option allows the straightforward introduction of normative principles into theory acceptance. Meanwhile, during the last few decades, going beyond the work of Popper and the logical empiricists, there have been more promising attempts to develop justificatory frameworks more consonant with the standard use of statistical reasoning within science—for instance, classical and Bayesian inference (see Bayesianism).

Beyond justification, is there a logic of scientific discovery? The use of "logic" suggests that scientific discovery is a rational process. While explicit claims of the existence of such a logic were rare in the first half of the twentieth century, several mechanisms of theory change (e.g., theory reduction and unification) can be seen as rational procedures that form part of such a logic (see Reductionism; Unity and Disunity of Science). However, for most logical empiricists, as also for Popper, discovery was a psychological category for which there could be no philosophical theory. The process of discovery was thus at best orthogonal to the aims of epistemology. Whether or not it is rational is simply not interesting from this perspective.

Irrationality and Relativism

Even philosophical theories of scientific change are about actual historical episodes and must partly appeal to empirical features for their justification. Thus, detailed case studies of episodes in the history of science become central to the study of scientific change. However, until the 1950s, most philosophically oriented histories of science paid little attention to the sociological and institutional contexts of scientific work. That situation changed in the 1960s, especially with the publication of Kuhn's (1962) *Structure of Scientific Revolutions*. Over the years, different commentators have taken different lessons from Kuhn's work (see Kuhn, Thomas). What is uncontroversial about it is that according to Kuhn's model, science does not proceed by cumulative progressive changes. There may be drastic shifts of perspective, with participants from divergent positions sometimes being unable to communicate with each other (see Feyerabend, Paul; Incommensurability; Hanson, Norwood Russell).

Whether or not Kuhn intended it, this view of science challenges many traditional assumptions about the rationality of the scientific process. What is critical here is that such rationality is being challenged in the context not only of discovery but also of justification. Meanwhile, Feyerabend and others denied the validity of the distinction between the contexts of discovery and justification, strengthening the claim of irrationalism.

Kuhn's work has been seen as suggesting an evolutionary model for scientific growth. Partly independently of Kuhn, many others, including Popper (1972) and Toulmin (1972), also argued for such a model; Hull (1988) offers what is probably its most detailed application to an actual example of scientific change (see Evolutionary Epistemology). Kuhn's work is also associated with the view that scientific "truths" are relative, not only to the empirical evidence, but to social ideologies (see Feminist Philosophy of Science; Social Constructionism). Extreme versions of this view even deny that scientific knowledge is privileged *qua* knowledge over other cultural products. And he is seen as denying that the history of science can be viewed as one of cumulative progress. This claim challenges the most central tenet of beliefs about scientific change since the Enlightenment (see Scientific Progress).

Each of these positions continues to be debated and developed to the present day. (For Kuhn's own doubts about such interpretations of his work, see Kuhn 2000; Hacking 1981.) Lakatos and Musgrave (1970) and Laudan (1977) made important early responses, each developing novel accounts of scientific change that at least partly preserved traditional assumptions of rationality and progress (see Lakatos, Imre; Research Programs).

Modeling Discovery

The best antidote to claims of irrationalism, whether it be with respect to the discovery or the justification of scientific claims, is to model these processes explicitly from rational principles. One strategy is to use detailed historical case studies, as Kuhn and his followers had done, but with

explicit attention to the presumed mechanisms of change. Donovan, Laudan, and Laudan (1988) collect many such cases from chemistry, geology, and physics from the seventeenth to the twentieth centuries. They find wide agreement on a variety of theses, connected with issues of theory acceptance, the presence of anomalies, and innovation and discovery. This work seems to justify many traditional ideas, such as the role of predictive success and the resolution of anomalies in generating acceptance of theories. Lakatos' work on research programs can also be viewed as being of similar intent and more general in scope, including considerations of both acceptance and discovery of theories (see Research Programs). However, what remains unclear from such case studies is whether particular principles gleaned from them ever adequately address the normative aims of epistemology: When *should* scientific claims be accepted or rejected?

An even more powerful method to study scientific change, especially discovery, is to model it computationally. This approach to scientific discovery was pioneered by Simon (1977; see Buchanan 1982). Science was viewed as a problem-solving activity using heuristics that could be equally applied to historical and contemporary situations. Techniques from artificial intelligence were brought to bear on the problem of generating explanatory hypotheses given a body of evidence (see Artificial Intelligence). The first expert system to be designed for this purpose was DENDRAL (Lindsay et al. 1980); it hypothesized the presence of specific chemical compounds from mass spectrographic data. Of only slightly later vintage, a system devised by the group around Simon, BACON, sought patterns in numerical empirical data. Going beyond traditional curve-fitting, BACON was based on the (metaphysical) assumption that an entity's relational properties were caused by its intrinsic properties (Langley et al. 1987). STAHL, also designed by the same group, used theory-driven discovery. Another product, KEKADA, successfully modeled the patterns of reasoning in the work of the biochemist Krebs (Kulkarni and Simon 1988). Taken as a whole, this work helped dispel that view that scientific discovery was a mysterious process, relying on serendipity or some special inspiration. It also made plausible the case that with improving heuristics, there would be a discernible logic of scientific discovery. In a recent review of this collective work, Langley (1998) argues that the best results are obtained when there is interaction between an expert system and human agents (that is, automation is not total). Throughout, the problem that has generated most controversy within the field is the choice of representation of the domain, that is, how the basic conceptual entities should be modeled. This is where human agents may play a crucial role. Critics of this body of work include Gillies (1996), who has argued that researchers have focused on laws and regularities already known, which may have artificially inflated the success of the approaches.

The last twenty years have seen many other computational frameworks entrenched in scientific contexts. Some were spawned from these pioneering frameworks. Glymour (e.g., 2001) and others have advocated the use of Bayesian causal networks to model cognitive processes, including those of scientific innovations. Many of the new frameworks draw on general learning and search algorithms (including metaheuristic algorithms such as genetic algorithms and neural networks) as well as data mining methods (see Fayyad et al. 1996). These have been especially valuable in the biological and environmental sciences. In these fields, the large quantities of data that are generated (e.g., from DNA sequencing projects, from remote sensing via satellites) require automated analysis (see Molecular Biology). What remains to be seen is whether such automated analysis can lead to genuine scientific innovation.

What has also become unclear, though, is whether these techniques of "discovery" are, in any sense, plausibly similar to the methods used by human agents for scientific discovery. (The contrast here is with the earlier methods from the 1970s and 1980s, which typically used heuristics gleaned from human reasoning.) However, from a normative perspective, the question of similarity is irrelevant: if the automated methods generate correct results, they are the ones that should be used irrespective of whether they capture human reasoning. Thus, while it may be the case that no new understanding of the historical processes of scientific discovery are being achieved by these new methods, they may well become staples of the process of such discovery in the future. The situation calls for more normative analysis of automated reasoning.

SCIENTIFIC DISCOVERY

See **Scientific Change**

SCIENTIFIC DOMAINS

According to empiricism, all our concepts and beliefs are based on observation, which is equated with sense perception. This doctrine has been widely criticized on two grounds: first, that it fails to specify what counts as an observation, free of any presupposition that should, according to it, be based on observation rather than presupposed by observation; and second, that it fails to delineate the sense in which all our nonobservational concepts are "based on" observation. However, deeper defects exist, showing that even if these two objections were overcome, empiricism, so conceived, would still have distorted or ignored aspects of science that are arguably far more central thereto

than those on which empiricists focused. Some of these defects stem not from the difficulty of delineating the class of observation terms but rather from the fact that most empiricists classified all the leftovers—all nonobservational concepts—indiscriminately as "theoretical." When coupled with the later (logical) empiricist emphasis on meaning and logic, this meant that nearly every issue examined concerned definitional and logical relations between the two classes, and the functions, if any, of theoretical concepts.

Consider accounts of observational and theoretical terms in twentieth-century logical empiricism. Theoretical terms were first conceived as definable and therefore eliminable via observational terms. Where meaningful at all, theoretical terms served only some practical function, perhaps as tools for economically organizing a mass of empirical data, or as suggestive scaffolding, useful in seeking empirical correlations but to be discarded once those relations were found. In conformity with the antimetaphysical roots of empiricism, they had nothing to do with the world; science was said to be concerned, fundamentally, only with correlating observations. Later, when this thesis of definability failed, theoretical terms were seen relative to their place in the logical structure of a theory, but still only as links between observation terms, which were correlated with the world as theoretical terms were not.

It was precisely here that the empiricist program, as applied to science, revealed its drastically restricted scope. For increasingly since science became a critically developing tradition, deep changes have occurred in what scientists spoke and wrote of as the subject matters of their investigations. In the seventeenth and eighteenth centuries, scientists widely engaged in studying and attempting to explain such subject matters, or portions thereof, as heat, light, electricity, magnetism, motion, and the properties of physical matter. By the end of the twentieth century, the ensuing sequence of developments resulted in scientists' specializing in studies of various levels of specificity and delineation of such areas, or parts thereof, as nuclear physics, weak interactions, dark matter, neutrino astrophysics, quantum gravity, genomic mapping, archaea, and mantle convection.

An example of one type of such change is the development of the concept of atoms in the nineteenth and twentieth centuries. Dalton proposed that atoms could account for the laws governing the proportions in which elements enter into compounds. After much resistance to such unobservable entities, Einstein's predictions about Brownian motion, and their experimental verification by Perrin, led to scientific acceptance of atoms, and they themselves became objects of study. The atom was found to consist of a nucleus with "orbiting" electrons, and quantum mechanics made it necessary to describe these entities (if such they could be called) in terms far removed from those of sense experience. The nucleus in turn became a subject for study, as did particles outside the nucleus; these particles in turn came to be seen as excitations of a quantum field rather than fundamental particles, and as having all the quantum idiosyncrasies.

In this sequence of reconceptions, what was originally the focal "theoretical" idea in an explanation of a subject matter (elemental proportions in compounds) took on a new status, becoming itself a subject matter for investigation and explanation. Insofar as terms like 'fact' and 'observation' refer to what is accepted and sometimes requires explanation, then at a certain point (roughly, Perrin's experiments) the theory of atoms passed from being "theoretical" to assuming this characteristic of the factual or observational, as having to do with a subject matter requiring study and explanation.

Such transitions occurred repeatedly in this specific case and in general throughout science. Thus, within the class of theoretical terms or concepts there exists a considerable degree of structure and function; and as a result of a change of status, these terms sometimes take on features usually associated with fact or observation. The structure is dynamic, subject to alteration. Indeed, scientists say that, at least as a general rule, the changes in status, description, and organization of subject matters are brought about for scientific reasons; and they are able, as a general rule, to detail those reasons in particular transitions.

Such facets of science were far beyond the central concerns of logical empiricism and its antecedents. The source of this neglect lay in the very conception of the empiricist program, in terms of the distinction between the observational and the theoretical, and how to analyze each. Much of the reasoning that occurs in science was masked by the empiricists' focus on this distinction, their indiscriminate classification of all nonobservational concepts as theoretical, and their attempt to treat all theoretical concepts solely in terms of definitional or logical relations to observational concepts. In effect, this combination suggested that scientists are not really, and cannot be, studying what they think and say they are studying. The real work of science is with observations (sense perceptions) and their interrelations, delusions stemming from the use of theoretical terms notwithstanding. Thus empiricist

doctrine discouraged any analysis of the reasoning involved in the changes of status, description, and organization of theoretical terms. The idea that, in these respects, concepts in the theoretical category were in flux, and that changes might be made for reasons, went unconsidered.

A few philosophers did propose that the "observational-theoretical" distinction was oversimple, that the distinctions of theoretical from nontheoretical and observational from nonobservational were not coextensive, or that some terms are both theoretical and observational, depending on context (Achinstein 1968; Maxwell 1962; Putnam 1962). However, these proposals remained primarily critical of how things were being done and did not generate systematic attempts to carry out the proposals constructively. Most important, they did not encourage examination of the reasons why the two alleged classes overlap or the more fundamental ways in which the status of theoretical terms depends on context.

Critics of empiricism such as Hanson (1958), Kuhn (1970), and Feyerabend (1978) did little better. Despite offering some important insights, their emphasis on the "theory-ladenness" of observation perpetuated the focus on the observational/theoretical distinction. They departed from empiricism chiefly in regard to theory as being prior to observation rather than based thereon. This, however, appeared to deny the basic empiricist insight that if prior beliefs influence observation, objectivity is violated. Attention therefore tended to concentrate on issues stemming from this denial, such as whether the view was committed to relativism and incommensurability of alternative sets of presuppositions.

Thus, for both empiricists and their critics, the question of changes in subject matter in science was obscured by the distinction between observational and theoretical concepts. In light of this neglect, it is appropriate to separate questions about subject matters and their changes from the observational/theoretical distinction by using a new term, 'domain,' to refer to what is being studied by scientists at a given stage. This term focuses attention on how subject matters of inquiry are described and conceived, the reasons for studying them, the ways and reasons domains become reconceived and reorganized, and the implications of those changes for understanding science.

As presented here, the motivation behind the domain concept resides solely in the fact that important issues about variety and change in theoretical terms have been ignored, and this neglect is traceable largely to the standard formulation of the empiricist program. It is independent of the fact that transitions in domain description and organization often proceed from the sensory to the nonsensory, from the familiar to the unfamiliar, or from the descriptive to the explanatory. Nevertheless, analysis of domains and domain change does have important implications for a number of philosophical issues. For example, analysis of domain change is concerned with what are taken to be reasons for such changes and can generate an account of why those considerations are justified as reasons. (This is what distinguishes the inquiry as philosophical rather than only exclusively historical.) Since the topic is concerned with what is seen as requiring explanation, understanding of the reasons given for such a requirement can illuminate problems about scientific explanation. And finally, since the process of altering descriptions and functions of domains builds on what has been learned through inquiry regarding domains, light can be thrown on issues of realism and reference.

An Example of a Domain, Seventeenth Through Early Nineteenth Centuries

Among the major domains investigated widely from the seventeenth through the early nineteenth centuries were the motion of bodies, light, heat, magnetism, electricity, "airs" (gases), and various types of material substances. Light provides a good example, partly because the items included in it are readily presentable but also because it was the subject of Newton's (1952) *Opticks*, which became an early model for investigation of domains. The items of this domain included rectilinear propagation of light from source to recipient, the laws of reflection and refraction, the colors produced when light passes through a prism, diffraction bands outside the geometrical shadow of thin objects, the finite velocity of light, double refraction in Iceland spar crystals, and the colors of thin films. Some of these properties had been known since ancient times; others were discovered later. They were considered to be related, as having to do with a particular experientially identifiable aspect of visual experience, light, along with color.

Light as a domain played two important roles: first, as a domain of *investigation* to be studied, and second, as a domain of *responsibility* for any explanatory theory of the domain. Regarding the latter role, although in the seventeenth century most workers were not familiar with every one of these items of the domain, the expectation grew that a satisfactory theory of light must account for all of them.

Chief Characteristics of Domains

Four properties of domains are discussed here:

1. *Domains could be studied in isolation from other subject matters, or at least it was assumed that they could*. This fundamental tenet of the approach could in principle have been false, as is brought out by an analogy with gravity. If gravity remained constant at all distances, the paths of planets and projectiles could not be calculated, as the effects of all other bodies in the universe would enter equally into the calculations. If the same had proved true of the factors ignored in studying individual domains, treatment of them as isolated subject matters would have been impossible.
2. *Domains were to be studied for the sake of "understanding"("explaining") them*. That is, they were not to be studied for their everyday uses and purposes. Much debate in the seventeenth century was shaped by earlier doctrines regarding fundamental explanation. For ancient philosophers influenced by Parmenides, fundamental explanations must be in terms of what is unchanging. Newton's atoms were of this nature, changing not in their intrinsic properties but only in their positions and velocities. In contrast, for Leibniz (as for Anaximenes, Heraclitus, and the Stoics) a fundamental explanation must be in terms of the intrinsically active, and therefore space, time, and matter cannot explain. Initially, then, expectations about explanation were quite general and were relevant chiefly to fundamental explanation. As science developed, requirements for explanation became increasingly more specific in the light of inquiry.
3. *Domains were derived primarily from classifications made in everyday life and language, mainly for practical ("applied") purposes, and descriptions of the domain and its items were given in terms of everyday language*. In the domain of light, for example, descriptions of properties were generally given in everyday sensory terms. (These descriptions were thus independent of the received views of explanation.) This claim depends not on there being a universal and unchangeable "observation language" but only on there being descriptive language common enough for mutual understanding within a particular community existing at a particular time and place, with regard to the most common objects, events, and properties. Thus the properties of light were described in terms of paths of travel, speeds, order of colors, alternating bands of light and darkness, appearances of sticks partially submerged in water, etc. Some properties, like the periodicities manifested in Newton's rings, could be experienced but, not being immediately apparent to the senses, had to be drawn out by close investigation. But even those were describable, naturally and unproblematically, in terms of the common language for talking about familiar objects, events, and properties in the everyday experience and exchanges of a given community. This is not surprising: At that early stage of concerted study of nature, what else could description be? This feature probably served as a model for empiricist philosophers, although they misconstrued such description as some fundamental and universal "given" in experience and, further, failed to take into account the departures from familiar description that characterized subsequent scientific change.

   From the beginning, there were presumptive exceptions. Even with light, geometry appeared in descriptions of reflection and refraction, and perhaps such terms do not qualify as having to do with "everyday sensory" properties. Other ideas, such as Newton's force of gravity, seemed "occult," and Newton himself often portrayed this force in purely sensory terms, as the manner in which two bodies move in each other's presence. But over the following centuries, scientific departures from common everyday descriptions became increasingly radical. This brings us to the fourth characteristic of domains.
4. *In the course of inquiry, the classification of items under domains and the description of the domains and their items are subject to change*. Such change can be of several types, as discussed below.

Types of Domain Change

That domains are dynamic entities, undergoing various types of change, is their most important property for illuminating the knowledge-seeking enterprise. It is what primarily distinguishes domains from ordinary classifications.

Certain types of change tend to occur early in the development of a science and are often generated by close study of the domain independently of whether an explanation of it has been proposed.

These include changes in ways of describing a domain to avoid the vagueness and ambiguity of everyday language. Sometimes preexplanatory investigation of a subject matter brings about revision of the descriptive language, either by adding to it (diffraction and double refraction), by abandoning other such language (as with the gradual replacement of alchemical vocabulary), or by modifying the concepts without altering the language of description (as with distinguishing the motion of falling bodies from that of projectiles). Other changes result from discoveries of new items of the domain, as with the double refraction of Iceland spar. Close study of a domain occasionally leads to dividing it into separate domains; for instance, hazy patches in the sky came to be viewed not as one sort of thing but as being either clouds of gas or galaxies, henceforth to be studied as separate specialties. Conversely, two domains can be joined as a result of closer study, as when preexplanatory experiments by several workers, culminating with Faraday, showed that what had seemed to be different sorts of electricity were all of the same type.

Other types of change are brought about by proposed or accepted explanations of a domain. The language for dealing with a particular domain can be substantially revised by an explanation, the most remarkable instance being the revision of the language of chemistry by Lavoisier and his associates in the light of his proposed explanatory theory. Occasionally, older descriptions survive, divorced from their original contexts. Thus early explanations of heat and electricity as fluids introduced a descriptive vocabulary (''flow,'' ''current'') into descriptions in those domains. When the fluid theory of heat, for example, was replaced by the kinetic theory, the fluid-based language was largely retained as descriptive of the domain but not as explanatory—the explanation lay in a different theory. Explanations can also lead to splitting of domains (bacteria versus archaea).

Unifications and Transformations of Science

All of the above types of changes in description and organization of domains, and their explanations, were concerned with single domains, studied and explained in isolation from one another. In that process, once a domain is given an acceptable explanation, the conceptual or descriptive reform can lead to that explanation's being given a deeper explanation. What was explanatory thus itself becomes a domain, to be studied and explained. Sometimes such deeper explanations result in unification of previously separated domains.

Although domain unifications had been achieved earlier (e.g., Newton's fusion of terrestrial and celestial physics), the process of unification became more and more prominent in the nineteenth and twentieth centuries (see e.g., Shapere 1991). In one degree and manner or another, unifications and other interrelationships of previously distinct areas of inquiry profoundly transformed the ways in which scientific domains are studied and explained. The transformations can be understood as follows.

There is an appearance of relativity about what counts as a domain. Even in the seventeenth century, some investigators concentrated on the study of different items of a particular domain. At an opposite extreme were those (e.g., advocates of the ''mechanical philosophy of nature'') who sought grand theories unifying all domains. The scope and focus of investigation, even of single domains, could vary. Despite this, and despite the fact that whether some item belonged in a particular domain could be debated, domains maintained a recognized objectivity as subject matters of investigation and explanatory responsibility: Researchers could be identified as concerned with agreed-on domains like electricity or light. With the establishment of interrelationships between domains and their explanations, new approaches to inquiry arose. A particular subject matter could be examined from any one or more of several different perspectives; conversely, one perspective could conceive and organize its subject matter in ways different from other approaches to roughly the same subject matter. Thinking in terms of domains of investigation and domains of responsibility remains instructive. But the deepening interrelationships among explanatory theories and among the subject matters investigated make the concept of a domain vastly more flexible and raise philosophical issues going far beyond the traditional empiricist focus on relations between observation and theory.

SCIENTIFIC METAPHORS

For centuries, in both the philosophical and the scientific literatures the value of the use of metaphors has been repeatedly denied, discouraged, or dismissed. Bacon, Hobbes, Locke, and Berkeley established the so-called literal-truth paradigm: Philosophers and scientists should abstain from metaphors altogether. In the twentieth century it did not help matters that the philosophical orthodoxy turned to language both ordinary and scientific. The so-called linguistic turn has proved in this respect too narrow an approach to understanding the world and how it is known, let alone a broader range of scientific practices. In the philosophy of science, the formalist orthodoxy that gave logical empiricism its backbone placed special emphasis on language as a symbolic calculus of logical relations and on observational language as the main source of cognitive significance. Within that framework, metaphors were considered as, at best, paraphrases of structural analogies within or between theories.

It was with the emergence of post–logical empiricist philosophies of science that the relations between language, cognition, and the world were understood differently and metaphors were given more attention and found to play a more important role. Renewed attention to history acknowledged the value metaphors were given by scientists such as Darwin, Maxwell, Einstein, and Bohr. Views of the role of metaphors changed accordingly.

In particular, Black (1962) rejected the comparison view that reduced metaphors to similarities and replaced it with an interaction view: Instead of formulating a preexisting similarity, metaphors allow one system to be "seen" through the frame of the second, and thereby similarities are instead created.

In her classic *Models and Analogies in Science* and subsequent works, Hesse (1966, 1993, and 1995) is concerned with the relation between models, metaphors, and truth and concludes that metaphors are explanatory redescriptions of

phenomena. Hesse argues that models and analogies contribute to the interpretation and testability of theoretical hypotheses. Just as she sees models as interpretations of explanatory theories of phenomena in her account of models and analogies, in her account of metaphors, Hesse argues that a term in an explanatory model shifts its meaning to describe a new system that is to be explained. This borrows from Black's interaction account of metaphors and replaces Hempel's deductive account of explanation. Meaning shift involves a change in referent as well as in use and associated ideas and is inextricable from the explanation. An advantage of this view is that it bypasses the difficulties associated with meaning invariance and derivability of corresponding rules that plague deductive accounts of explanation (see Explanation). Another advantage, according to Hesse, is that it preserves a certain form of realism, or truth value, within the context dependence of language use (see Realism).

Finally, Hesse defends the rationality of the role of metaphors in science, characterizing rationality as the continuous adaptation of language and beliefs to a continually expanding world. Rationality rests on the prior creativity, or generativity, of metaphors; this is one of the most important features associated with the role of metaphors in science. This role can be viewed as a matter of method (a heuristic) or a matter of understanding (a cognitive standard such as concrete images or mechanical models). For Hesse, the analogy created by metaphors is linked to the heuristic fertility— the testability—of theories based on models.

Realism and explanation are also central to Boyd's (1993) approach to scientific metaphors. Boyd argues that there is an important distinction between pedagogical and theoretically relevant metaphors and that important metaphors are "theory-constitutive." In particular, according to Boyd, they are devices not just for introducing a new vocabulary but also for accommodating language to the causal structure of the world. They provide "epistemic access," introduce a causal mechanism for fixing the reference of scientific terms, and advance guiding explanatory hypotheses leading to causal theories. Hence, Boyd couples the pursuits of a causal theory of reference and a causal theory of the world. In his view, the progress of science leads inexorably to the true theory of nature in terms of a final set of natural kind terms.

Kuhn's (1993) view of metaphors constitutes a rejoinder to Boyd in the spirit of his own view of scientific language and evolution (see Kuhn, Thomas; Scientific Revolutions). Kuhn rejects the distinction between pedagogical and theory-constitutive metaphors and claims that both share the same metaphorical mechanism. Metaphors, according to Kuhn, are central to the understanding, development, and use of scientific theories. Scientific metaphors are like natural kind terms in that they bring out features of kinds of systems or phenomena but, because of their open-endedness, they also challenge and relativize the alleged inexorability of a rigid taxonomy of natural kinds. Like Hesse and Boyd, Kuhn accepts that metaphors establish links between language and the world, but this link is constitutive, in an almost Kantian sense, since there is no determined way in which the world is outside a language. This view falls in line with the post–logical empiricist theory-ladenness of observation and description. In the light of Feyerabend's and Kuhn's views of theory dependence of meanings and incommensurability, McCormach (1971) suggested that metaphors express the unknown new use (new semantically relevant properties) of an old term with known semantically relevant properties (such as 'length' in relativity theory). With a dual role of capturing familiar analogies and connotations and suggesting new theoretical possibilities, metaphors would bridge incommensurable gaps between old and new theories (see Feyerabend, Paul).

Along the lines of the idea of an underlying shared metaphorical mechanism, some authors have attempted to make sense of the role of metaphors by introducing considerations from the philosophy of rhetoric. It has been argued, for instance, that Black (and hence also Hesse) was initially wrong in assuming a reference, or extensional, theory of meaning. Metaphors organize the scientists' thoughts, but they do so by means of the sense, or intensional meaning, of the metaphorical term (closer to Black's [1993] later thoughts on the subject) (Soskice and Harre 1995). Ultimately, metaphors, suggested by models, act as probative tools that enable scientists to introduce meanings, and possibly reference to new entities, outside the conditions of experience in a given domain of phenomena. The educational, creative, and organizing view of metaphors has been espoused by Holton (1986). He sees metaphors also at the center of, or cutting across, "themata," or quasi-universal, *Gestalt*-like modes of scientific thought such as synthesis versus analysis, wave versus particles, and determinism versus indeterminism.

A large number of philosophers and especially historians of science have since the 1980s documented the use and role of metaphors in specific sciences, thereby illustrating in more detail, testing,

and enriching general accounts. The outcomes range from the emphasis on concept formation and theoretical continuity to the extension of theory-ladenness to value-ladenness and the denunciation of ideological agendas. In the relation between the natural and social sciences the interaction has been shown to work both ways: Social theories developed out of mechanistic and physiological discourses in the natural sciences (''social hygine,'' ''flow of capital,'' etc.), and biologists and physicists borrowed from political economy (''competition,'' ''natural selection,'' ''survival of the fittest,'' ''minimum work,'' ''least action,'' ''value,'' ''dissipation,'' ''waste,'' etc.) (Mirowski 1989).

In biology, Keller (1985), for instance, has drawn attention to the fact that through metaphors the language of gender has carried into science certain norms and values that contribute to its shape and growth. From a feminist point of view, such norms and values are epistemologically limiting as well as ideologically unacceptable. Keller has noted also that different metaphors give rise to different cognitive perspectives, different aims, different questions, and even different methodological and explanatory preferences. She has illustrated this important point with examples from genetics, development, and evolutionary biology (e.g., ''selfish gene,'' ''gene action,'' ''competition,'' ''self-regulation''). Most recently, she has followed Hesse in emphasizing the role of models and metaphors in explanation (Keller 1995). Johnson and Tuana (1986) have discussed the case of Hans Selye's research in the 1920s on metabolic stress. Selye's shift from mechanical to organic metaphors for categorizing the body changed in a very definite manner the way in which his medical experience,expectations, theorizing, and treatment were structured as coherent units.

In cognitive psychology many theoretical terms are metaphorically borrowed from computer science: ''information processing,'' ''memory storage capacity,'' etc. Chemical language has been rife with metaphors from the time of alchemy to the modern naming of elements and their kinds, using terms such as ''reaction,'' ''chemical equation,'' and ''chemical balance'' (Radman 1995).

In physics the metaphorical character of concepts relating to time, space, matter, and causation has been discussed in general terms. References to ''bodies,'' ''work,'' ''electric flow,'' ''electron clouds,'' ''electric tension,'' ''black holes,'' ''worm holes,'' and ''strings'' have become pervasive. The use of metaphors as central to physicists' researches has been documented in the works of, for instance, Kepler, Newton, and Maxwell (Cantor and Christie 1987). Maxwell's case is unique in having provided explicit discussion of, as well as having championed, the application of metaphors and analogies in physics connecting scientific method with experimental culture, logic, psychology, and philosophy of language (Cat 2001). Thus, projectile metaphors for light in the eighteenth century drove attempts to determine its mechanical momentum. In high-energy physics, anthropomorphic metaphors are superimposed onto theoretical language, describing detectors to enhance the expression and demarcation of the objective ontology of entities under study (by enhancing a subject/object distinction); detecting machines are described with behavioral, physiological, and moral metaphors such as ''response,'' ''reaction,'' ''talk,'' ''noise,'' ''seeing,'' ''blindness,'' ''dead,'' ''poisoning,'' ''life expectancy,'' ''misbehaving,'' ''trustable'' (Knorr-Cetina 1995). The use of nonliteral, nontechnical, or nonformal languages in science is also relevant in explaining its intersubjective and social nature. By the use of metaphors, trust and communication are enhanced within a particular community as well as across communities, such as between experimenters and theoreticians.

A general spirit behind the interest in scientific metaphors has been the perception that science is not an isolated intellectual part of human culture (Leatherdale 1974). An important consequence of the discovered value of metaphors in science is a more sophisticated understanding of language as well as the awareness of its theoretical and practical consequences. Actions, after all, are conceptualized and valued under specific descriptions. From a cognitive point of view, another consequence is that it leads to the recognition of the value of the role of the imagination in science. In any event, since the role of metaphors in scientific activity appears both important and practically inevitable, the recent historical and philosophical analyses should impress upon scientists a heightened recognition of metaphors and responsibility in their use.

SCIENTIFIC MODELS

Models are of central importance in many scientific contexts. Cases in point are the roles played in their respective domains by the MIT bag model of the nucleon, the billiard ball model of a gas, the Bohr model of the atom, the Pauling model of chemical bonds, the Gaussian-chain model of a polymer, the Lorenz model of the atmosphere, the Lotka-Volterra model of predator/prey interaction, agent-based and evolutionary models of social interaction, and general equilibrium models of markets.

This importance has been increasingly recognized by philosophers. As a result, the philosophical literature on models has been growing rapidly over the last decades, and with it the number of different types of models that philosophers recognize. Some of the notions used as categories have created phenomenological models, computational models, developmental models, explanatory models, impoverished models, testing models, idealized models, theoretical models, scale models, heuristic models, caricature models, didactic models, fantasy models, toy models, imaginary models, mathematical models, substitute models, iconic models, formal models, analog models, and instrumental models. The key to coming to terms with this variety is to realize that these different categories pertain to these different issues that arise in connection with models:

1. Semantics: What is the representational function that models perform?
2. Ontology: What kind of things are models?
3. Epistemology: How does one learn with models?
4. Models and theory: How do models relate to theory?
5. Models and other debates in the philosophy of science:
   (a) Models and the realism versus antirealism debate
   (b) Models and reductionism
   (c) Models and laws of nature
   (d) Models and scientific explanation

Semantics: The Representational Functions of Models

Models can perform two fundamentally different representational functions. On the one hand, a model can be a representation of a selected part of the world (the ''target system''). Depending on the nature of the target, such models are either models of phenomena or models of data. On the other hand, a model can represent a theory in the sense that it interprets the laws and axioms of that theory. These two notions are not mutually exclusive and scientific models can at once be representations in both senses.

Representational Models I: Models of Phenomena

Many scientific models represent a phenomenon, where 'phenomenon' is used as an umbrella term covering all relatively stable and general features of the world that are interesting from a scientific point of view. Well-known examples of models of this kind include the billiard ball model of a gas, the Bohr model of the atom, the double helix model of DNA, the scale model of a bridge, the Mundell-Fleming model of an open economy, and the Lorenz model of the atmosphere. The representational function of these models is widely acknowledged among philosophers; but despite the ubiquity of representation talk in the literature on models, the issue of scientific representation as regards models has barely been recognized, much less seriously discussed.

A first step toward a discussion of this issue is to realize that there is no such thing as the problem of scientific representation. Rather, there are different but related problems. It is not yet clear what the specific set of questions is that a theory of representation should come to terms with, but two problems in particular seem to occupy center stage in tackling the issue (Frigg 2003, chap. 1). The first problem is to explain in virtue of what a model is a representation of something else; or more formally: What fills the blank in '*M* represents *T* if and only if _____,' where *M* is a model and *T* a target system? Somewhat surprisingly, this question did not attract much attention in twentieth-century philosophy of science.

The second problem is concerned with representational styles (see Scientific Style). It is a commonplace that one can represent the same subject matter in different ways. Weizsäcker's liquid-drop model represents the nucleus of an atom in a manner very different from the shell model, and a scale model of the wing of an airplane represents the shape of the wing differently from how a mathematical model does. What representational styles are there in the sciences?

Although this question is not explicitly addressed in the literature on the so-called semantic view of theories (see Theories), two answers seem to emerge from its understanding of models. One version of the semantic view posits that a model and its target have to be isomorphic (Suppes 2002) or partially isomorphic (da Costa and French 2003) to each other. Another version drops isomorphism in favor of similarity (Giere 1988). This approach enjoys the advantage over the isomorphic view that it is less restrictive and also can account for cases of inexact and simplifying models.

Furthermore, one can understand the discussions about certain types of models as contributions to an investigation into representational styles.

Iconic Models An iconic model is supposed to be a naturalistic replica or a truthful mirror image of the target. Paradigm cases of iconic models are scale models such as wooden cars or model bridges, which are either enlarged or downsized copies of the original. More elaborate examples of iconic models can be found in the life sciences, where one particular organism (or group thereof) is investigated in order to find out something about the species to which it belongs. In a clinical trial, for instance, a certain number of patients are administered a drug, their reaction(s) to this drug is monitored, and the result is supposed to show how humans in general react to this drug.

What criteria does a model have to satisfy in order to qualify as an icon? Although there seem to be strong intuitions about how to answer this question in particular cases, no theory of iconicity for models has been formulated yet.

Idealized Models An idealization is a deliberate simplification of something complicated with the objective of making it more tractable. Most idealizations fall into either of two classes.

One class consists of cases in which idealization amounts to ''stripping away'' all properties from a concrete object that are believed not to be relevant to the problem at hand. This allows one to focus on a limited set of properties in isolation. An example from economics is the Philips curve, which specifies a relationship between inflation and unemployment, disregarding all other economic factors. This process of stripping away is often referred to as 'Aristotelian abstraction,' 'method of isolation,' or 'use of negligibility assumptions.'

The other class comprises idealizations that involve deliberate distortions. Physicists build models consisting of point masses moving on frictionless planes; economists assume that agents are perfectly rational; biologists study isolated populations, and so on. It was characteristic of Galileo's approach to science to use simplifications of this sort whenever a situation was too complicated to tackle. For this reason one can refer to this process as 'Galilean idealization' (cf. McMullin 1985).

Galilean idealizations are beset with riddles. What does a model involving distortions of this kind say about the world? How does one test its accuracy? In reply to these questions, Laymon (1991) has put forward a theory that understands idealizations as ideal limits: Imagine a series of experimental refinements of an actual situation that approach the postulated limit and then require that the closer the properties of a system come to the ideal limit, the closer its behavior has to come to the behavior of the ideal limit (monotonicity). But these conditions need not always hold, and it is not clear how to understand situations in which no ideal limit exists.

Galilean and Aristotelian idealizations are not mutually exclusive. On the contrary, they often come together. For instance, this happens in what is sometimes called 'caricature models,' which isolate a small number of main characteristics of a system and distort them into an extreme case.

Analogical Models Stock examples of analogical models include the hydraulic model of an economic system, the billiard ball model of a gas, the computer model of the mind, and the liquid-drop model of the nucleus. At the most basic level, two things are *analogous* if there are certain relevant similarities between them. Hesse (1963) distinguishes different types of analogies according to the kinds of similarity relations in which two objects enter. A simple type of analogy is based on shared properties. There is an analogy between the Earth and the moon based on the fact that both are large, solid, opaque, spherical bodies, receiving heat and light from the sun, revolving around their axes, and gravitating toward other bodies. But sameness of properties is not a necessary condition. An analogy between two objects can also be based on relevant similarities between their properties. In this more liberal sense, one can say that there is an analogy between sound and light because echoes are similar to reflections, loudness to brightness, pitch to color, detectability by the ear to detectability by the eye, and so forth.

Analogies can also be based on the sameness or resemblance of relations between parts of two systems rather than on their monadic properties. It is in this sense that some politicians assert that the relation of a parent to children is analogous to the relation of the state to citizens. The analogies mentioned so far have been what Hesse calls 'material analogies.' A more formal notion of analogy can be obtained by abstracting from the concrete features the systems possess and focusing only on their formal setup. What the analog model then shares with its target is not a set of features, but the same pattern of abstract relationships. This notion of analogy is closely related to what Hesse calls 'formal analogy.' Two items are related by formal analogy if they are both interpretations of the same formal calculus. For instance, there is a formal analogy between a swinging pendulum and an oscillating electric circuit because they are both described by the same mathematical equation.

A further distinction due to Hesse is among positive, negative, and neutral analogies. In comparing properties or relations between two items, positive analogies consist in those they share (both gas molecules and billiard balls have mass), while negative analogies consist in those they do not (billiard balls are colored, gas molecules are not). The *neutral analogy* comprises the properties not yet known to belong to either the positive or the negative analogy (do gas molecules obey Newton's laws of collision?). Neutral analogies play an important role in scientific research because they give rise to questions and suggest new hypotheses.

Phenomenological Models Phenomenological models have been defined in different, though related, ways. A standard definition takes them to be models that represent only observable properties of their targets and refrain from postulating hidden mechanisms and the like. Alternatively one can define phenomenological models as being independent of general theories. These two definitions, though not equivalent, often coincide in practice because hidden mechanisms or theoretical entities are commonly brought into a model via a general theory.

Each of these notions has its internal problems. But more pressing is the question of how the different notions relate to each other. Are analogies fundamentally different from idealizations, or do they occupy different areas on a continuous scale? How do icons differ from idealizations and analogies? At the present stage the answers to these questions are not known. What one needs is a systematic account of the different ways in which

models can relate to the world and of how these ways compare with each other.

Representational Models II: Models of Data

Another kind of representational model is the *model of data* (Suppes 2002). A model of data is a corrected, rectified, regimented, and in many instances idealized version of the data gained from immediate observation, the so-called raw data. Characteristically, one first eliminates errors (e.g., removes points from the record that are due to faulty observation) and then presents the data in a "neat" way—for instance, by drawing a smooth curve through a set of points. These two steps are commonly referred to as data reduction and curve fitting. When investigating the trajectory of a certain planet, for instance, one first eliminates erroneous points from the observation records and then fits a smooth curve to the remaining ones. Models of data play a crucial role in confirming theories because it is the model and not the often messy and complex raw data that is compared with a theoretical prediction.

Both steps in the construction of a data model raise serious questions. How does one decide which points on the record need to be removed? And given a clean set of data, what curve can be fitted to it? The first question has been dealt with mainly within the context of the philosophy of experiment (see Experiment). At the heart of the latter question lies the so-called *curve fitting problem*, which is that the data themselves do not indicate what form the fitted curve should take. Traditional discussions of theory choice suggest that this issue is settled by background theory, considerations of simplicity, prior probabilities, or a combination of these. Forster and Sober (1994) point out that this formulation of the curve fitting problem is a slight overstatement because there is a theorem in statistics due to Akaike that shows (given certain assumptions) that the data themselves underwrite (though do not determine) an inference concerning the curve's shape if it is assumed that the fitted curve has to be chosen so that it strikes a balance between simplicity and goodness of fit in a way that maximizes predictive accuracy.

Models as the Thing Represented: Models of Theory

In modern logic, a model is a structure that makes all sentences of a theory true, where a *theory* is taken to be a set of sentences in a formal language, and a *structure* a set of objects along with the relations in which they enter. The structure represents the abstract theory in the sense that it interprets it and provides an object that embodies its essential features. As a simple example, consider Euclidean geometry, which consists of axioms (e.g., Any two points can be joined by a straight line) and the theorems that can be derived therefrom. Any structure of which all these statements are true is a model of Euclidean geometry.

Many models in science carry over from logic the idea of interpreting an abstract calculus. This is particularly pertinent in physics, where general laws—such as Newton's equation of motion—lie at the heart of a theory. These laws are applied to a particular system (e.g., a pendulum) by choosing a special force function, making assumptions about the mass distribution of the pendulum, etc. The resulting model, then, is an interpretation (or realization) of the general law.

Ontology: What Are Models?

Physical Objects

Some models are straightforward physical objects. These are commonly referred to as material models. The class of material models comprises anything that is a physical entity and that serves as a scientific representation of something else. Among the members of this class are wooden models of bridges, planes, and ships; analog models of neural systems resembling electric circuits or of an economy resembling lengths of pipe; and Watson and Crick's model of DNA. But material models also lend themselves to more cutting-edge cases, especially from the life sciences, where certain organisms are studied as stand-ins for others.

Material models do not give rise to any ontological difficulties over and above the well-known quibbles in connection with objects, which metaphysicians deal with (e.g., the nature of properties, the identity of objects, parts and wholes, and so on).

Fictional Objects

Many models are not material models. The Bohr model of the atom, a frictionless pendulum, or isolated populations are in the scientist's mind rather than in the laboratory, and they do not have to be physically realized and experimented upon to perform their representational function.

It seems natural to view them as fictional entities. This position can be traced back to the German neo-Kantian Vaihinger and has been advocated more recently by Giere (1988, Ch. 3), who calls them 'abstract entities.' The drawback of this suggestion is that fictional entities are notoriously

beset with ontological riddles. This has led many philosophers, most prominently Quine, to argue that there are no such things as fictional entities and that apparent ontological commitments to them must be renounced (see Quine, Willard Van). This has resulted in a glaring neglect of fictional entities, in particular among philosophers of science.

Set-Theoretic Structures

An influential point of view takes models to be set-theoretic structures. This position can be traced back to Suppes' work in the 1960s and is now, with slight variants, held by most proponents of the semantic view of theories (see Theories).

This view of models has been criticized on different grounds. One pervasive criticism is that many types of models that play an important role in science are not structures and cannot be accommodated within the structuralist view of models, which can account neither for how these models are constructed nor for how they work in the context of investigation (Cartwright 1999; Morgan and Morrison 1999). Another charge held against the set-theoretic approach is that it is not possible to explain how structures represent a target system that forms part of the physical world without making assumptions that go beyond what the approach can afford (Frigg 2003, Chs. 2 and 3; Suárez 2003).

Descriptions

A time-honored position has it that what scientists display in scientific papers and textbooks when they present a model are more or less stylized descriptions of the relevant target systems.

This view has not been subject to explicit criticism. However, some of the criticisms that have been marshaled against the syntactic view of theories equally threaten a linguistic understanding of models. First, it is a commonplace that one can describe the same thing in different ways. But if one identifies a model with its description, then each new description yields a new model, which seems to be counterintuitive. Second, models have different properties than descriptions. On the one hand, one can say that the model of the solar system consists of spheres orbiting around a big mass or that the population in the model is isolated from its environment, but it does not seem to make sense to say this about a description. On the other hand, descriptions have properties that models do not have. A description can be written in English, consist of 517 words, be printed in red ink, and so on. None of this makes sense when said about a model.

Equations

Another group of things that are habitually referred to as models, in particular in economics, consists of equations (which are then termed 'mathematical models')—for instance, the Black-Scholes model of the stock market and the Mundell-Fleming model of an open economy.

The problem with this suggestion is that equations are syntactic items, and as such they face objections similar to the ones put forward against descriptions. First, one can describe the same situation using different coordinates and as a result obtain different equations; but one does not seem to obtain a different model. Second, the model has properties different from the equation. An oscillator is three-dimensional, but the equation describing its motion is not. Equally, an equation may be inhomogenous while the system it describes is not.

Gerrymandered Ontologies

The proposals discussed so far have tacitly assumed that a model belongs to one particular class of objects. But this assumption is not necessary. It might be the case that models are a mixture of elements belonging to different ontological categories.

Epistemology: Learning with Models

Models are vehicles for learning about the world. By studying a model one can discover features of the system the model stands for. This cognitive function of models has been widely acknowledged in the literature, and some even suggest that models give rise to a new style of reasoning, called 'model-based reasoning' (Magnani and Nersessian 2002). This leaves one with the question of how learning with a model is possible.

Hughes (1997) provides a general framework for discussing this question. According to his "DDI" account of modeling, learning takes place in three stages: *d*enotation, *d*emonstration, and *i*nterpretation. One begins by establishing a representation relation (denotation) between the model and the target. Then one investigates the features of the model in order to demonstrate certain theoretical claims about its internal constitution or mechanism; i.e., one learns about the model (demonstration). Finally, these findings have to be converted

into claims about the target system; Hughes refers to this step as 'interpretation.' It is the latter two notions that are at stake here.

Learning About the Model: Experiments, Thought Experiments, and Simulation

Learning about a model happens at two places, in the construction and the manipulation of the model (Morgan and Morrison 1999). There are no fixed rules for model building, and so the very activity of figuring out what and how a model fits together affords an opportunity to learn about the model. Once the model is built, one learns about its properties not by looking at it, but by using and manipulating it to elicit its secrets.

Depending on what kind of model one is dealing with, building and manipulating a model employs different activities demanding a different methodology. Material models seem to be unproblematic, as they are commonly used in the kind of experimental contexts that have been discussed extensively by philosophers of science (the model of a car is put in the wind tunnel to measure its air resistance). This is not the case with fictional models. What constraints are there to the construction of fictional models, and how does one manipulate them? The natural response seems to obtain an answer to these questions by performing a thought experiment. Different authors have explored this line of argument but they have reached very different and often conflicting conclusions as to how thought experiments are performed and what the status of their outcomes is (Hitchcock 2004, Chs. 1 and 2).

An important class consists of mathematical models. In some cases it is possible to derive results or solve equations analytically. But quite often this is not the case. It is on this point that the invention of the computer has had a great impact, as it allows one to solve equations that are otherwise intractable by making a computer simulation. Many parts of current research in both the natural and social sciences rely on computer simulations. To mention only a few examples, computer simulations are used to explore the formation and development of stars and galaxies, the detailed dynamics of high-energy heavy-ion reactions, aspects of the intricate process of the evolution of life, and factors determining the outbreak of wars, the progression of an economy, decision procedures in an organization, and moral behavior.

What is a simulation? Simulations characteristically are used in connection with dynamic models, i.e., which involve time. The aim of a simulation is to solve the equations of motion of such a model, which is designed to represent the time evolution of its target system. So, one can say that a simulation represents one process by another process (Hartmann 1996; Humphreys 2004).

It has been claimed that computer simulations constitute a genuinely new methodology of science, or even a new scientific paradigm (Humphreys 2004). Although this contention may not meet with univocal consent, there is no doubt about the practical significance of computer simulations. In situations in which the underlying model is well confirmed and understood, computer experiments may even replace real experiments, which has economic advantages and minimizes risk (as, for example, in the case of the simulation of atomic explosions). Computer simulations are also heuristically important. They may suggest new theories, models, and hypotheses, for example, based on a systematic exploration of a model's parameter space.

But computer simulations also bear methodological perils, as they may provide misleading results. In many cases the relevant variables are continuous. But due to the discrete nature of the calculations carried out on a computer, they do not allow for an exploration of the full range of the variables, and therefore may not reveal certain important features of the model.

Converting Knowledge About the Model into Knowledge About the Target

Once knowledge about the model is available, it has to be "translated" into knowledge about the target system. It is at this point that the representational function of models becomes important again. Models can provide information about the nature of their target systems only if one assumes that (at least some of) the model's aspects have counterparts in the world. But if learning is tied to representation and if there are different kinds of representation (analogies, idealizations, etc.), then there are also different kinds of learning. If, for instance, one has a model that is taken to be a realistic depiction, the transfer of knowledge from the model to the target is accomplished in a different manner than when one deals with an analog model or a model that involves idealizing assumptions.

What are these different ways of learning? Although numerous case studies have been made of how certain specific models work, there do not seem to be any general accounts of how the transfer of knowledge from a model to its target is

achieved (with the possible exception of theories of analogical reasoning; see references above). This is a difficult question, but it is one that deserves more attention than it has received so far.

Models and Theory

One of the most perplexing questions in connection with models is how they relate to theories. The separation between models and theory is a very hazy one, and in the jargon of many scientists it is often difficult, if not impossible, to draw a line. So the question is: Is there a distinction between models and theories, and if so, how do they relate to one another?

In common parlance, the 'model' and 'theory' are sometimes used to express someone's attitude toward a particular piece of science. The phrase "It's just a model" indicates that the hypothesis at stake is asserted only tentatively, while something is awarded the labeled 'theory' if it has acquired some degree of general acceptance. However, this way of drawing a line between models and theories is of no use to a systematic understanding of models.

The Two Extremes: The Syntactic and the Semantic View of Theories

The syntactic view of theories, which is an integral part of the logical empiricist picture of science, construes a theory as a set of sentences in an axiomatized system of first-order logic (see Theories). Within this approach, the 'model' is used in both a wider and a narrower sense. In the wider sense, a model is just a system of semantic rules that interpret the abstract calculus, and the study of a model amounts to scrutinizing the semantics of a scientific language. In the narrower sense, a model is an alternative interpretation of a certain calculus. If, for instance, one takes the mathematics used in the kinetic theory of gases and reinterprets the terms of this calculus so that they refer to billiard balls, the billiard balls are a model of the kinetic theory of gases. Proponents of the syntactic view believe such models to be irrelevant to science. Models, they hold, are superfluous additions that are at best of pedagogical, aesthetical, or psychological value (cf. Bailer-Jones 1999).

The semantic view of theories reverses this standpoint and declares that one should dispense with a formal calculus altogether and view a theory as a family of models (see Theories). Although different versions of the semantic view assume a different notion of model, they all agree that models are the central unit of scientific theorizing.

Models as Independent of Theories

One of the most perspicuous criticisms of the semantic view is that it mislocates the place of models in the scientific edifice. Models are relatively independent from theory, rather than being constitutive of them; or to use Morrison's (1998) phrase, they are "autonomous agents." This independence has two aspects: construction and functioning (Morgan and Morrison 1999).

A look at how models are constructed in actual science shows that they can be derived entirely from neither data nor theory. Theories do not provide algorithms for the construction of a model; model building is an art and not a mechanical procedure. The London model of superconductivity is a good example: The model's principal equation has no theoretical justification and is motivated solely on the basis of phenomenological considerations (Cartwright 1999).

The second aspect of the independence of models is that they perform functions that they could not perform if they were a part of, or strongly dependent on, theories.

Models as Complements of Theories A theory may be incompletely specified in the sense that it imposes only certain general constraints but remains silent about the details of concrete situations, which are provided by a model (Redhead 1980). A special case of this situation is if a qualitative theory is known and the model introduces quantitative measures. Redhead's example for a theory that is underdetermined in this way is axiomatic quantum field theory, which imposes only certain general constraints on quantum fields but does not provide an account of particular fields.

While Redhead and others seem to think of cases of this sort as somehow special, Cartwright (1983) has argued that they are the rule rather than the exception. In her view, fundamental theories such as classical mechanics and quantum mechanics do not represent anything at all, as they do not describe any real-world situation. Laws in such theories are schemata that need to be concretized and filled with the details of a specific situation, which is a task that is accomplished by a model.

Models Stepping in When Theories Are Too Complex to Handle Theories may be too complicated to handle. In such a case a simplified model may be employed that allows for a solution (Redhead 1980). Quantum chromodynamics, for instance, cannot easily be used to study the hadron structure of a nucleus, although it is the fundamental theory for this problem. To get around this difficulty,

physicists construct a tractable phenomenological model (e.g., the MIT bag model) that effectively describes the relevant degrees of freedom of the system under consideration (Hartmann 1999). A more extreme case is the use of a model when there are no theories available at all—take Bohr's model of the atom at the time he proposed it. The models scientist then construct to tackle this situation are sometimes referred to as "substitute models."

Models as Preliminary Theories The notion of models as substitutes for theories is closely related to "developmental models," which consist of cases in which models are some sort of a preliminary exercise to theory. A closely related notion is that of probing models (also known as 'study models' or 'toy models'). These are models that do not perform a representational function and that are not expected to provide information about anything beyond the model itself. The purpose of these models is to test new theoretical tools that are used later to build representational models (cf. Wimsatt 1987).

Models and Other Debates in the Philosophy of Science

The debate about scientific models has important repercussions for other debates in the philosophy of science. The reason for this is that traditionally the debates about realism, reductionism, explanation, and laws were couched in terms of theories, because only theories were acknowledged as carriers of scientific knowledge. So the question is whether, and if so how, discussions of these matters change when shifting the focus from theories to models. Up to now, no comprehensive model-based accounts of any of these issues have been developed, but models did leave some traces in the discussions of these topics, and it is these traces that will be dealt with in this section.

Models and the Realism Versus Antirealism Debate

It has been claimed that the practice of model building favors antirealism over realism (see Instrumentalism; Realism). Antirealists point out that truth is not the main goal of scientific modeling. Cartwright (1983), for instance, presents several case studies illustrating that good models are often false. Realists reply that a good model, though not literally true, is usually at least approximately true. In this vein, it has been argued that by relaxing idealizations (de-idealization) the predictions of the model typically become better, which is taken to be evidence for realism (cf. McMullin 1985; Nowak 1979).

Apart from the usual complaints about the elusiveness of the notion of approximate truth, antirealists have criticized this reply as flawed for two related reasons. First, there is no in-principle reason to assume that one can always improve the model by adding de-idealizing corrections. Second, it seems that the outlined procedure is not in accordance with scientific practice, in which it is unusual for scientists to try to repeatedly de-idealize an existing model. Rather, they shift to a completely different modeling framework once the needed adjustments get too complicated. A further difficulty with de-idealization is that most idealizations are not "controlled." For example, it is not clear in which way one has to de-idealize the MIT bag model to eventually arrive at quantum chromodynamics, the supposedly correct underlying theory.

The antirealist "incompatible models argument" takes as its starting point the observation that scientists often use several incompatible models of one and the same target system for predictive purposes. There are, for example, numerous models of a gas or the atomic nucleus. These models seemingly contradict each other as they ascribe different properties to the target system. This seems to cause problems for realists, as they typically hold that there is a close connection between the predictive success of a model and its being at least approximately true. But if several theories of the same system are predictively successful, and if these theories are mutually inconsistent, they cannot all be true.

Realists can react to this argument in three ways—first, by challenging the claim that the models in question are indeed predictively successful; second, by defending a version of perspectival realism, according to which each model reveals one aspect of the phenomenon in question; and, finally, by denying that there is a problem in the first place, because scientific models, which strictly speaking are always false, are just the wrong vehicles to make a point about realism.

Models and Reductionism

The existence of a multiplicity of models raises the question of how different models are related. A simple picture of the organization of science along the lines of Nagel's model of reduction or Oppenheim and Putnam's pyramid picture does not seem to be compatible with the practice of modeling (see also Reductionism). But which picture of science is?

Cartwright (1999) and others have suggested a picture of science according to which there are no

systematic relations between different theories and models. All theories and models are tightened together only because they apply to the same domain of phenomena but do not enter into any further relations (deductive or otherwise). One is confronted with a patchwork of theories and models, all of which hold, *ceteris paribus*, in their specific domains of applicability. Some argue that this picture is at least partially incorrect because there are various types of interesting relations that hold between different models or theories. These relations range from those of controlled approximations over a singular limit to rather loose relations. Some have even argued that, at least within the context of biology, models play an essential role in a reductionist enterprise (Sarkar 1998). These suggestions have been made on the basis of case studies, and it remains to be seen whether a more general account of these relations can be given and a deeper justification for them provided (e.g., in a Bayesian framework) (see Bayesianism).

Models and Laws of Nature

It is widely held that science aims at discovering laws of nature. Philosophers, in turn, have been faced with the challenge of explicating what laws of nature are (see Laws of Nature). According to the two currently dominant accounts—the best-systems approach and the universals approach—laws of nature are understood to be universal in scope, meaning that they apply to everything that there is in the world. This take on laws does not seem to square with a view that assigns models a center stage in scientific theorizing. What role do general laws play in science if models are what represent what is happening in the world?

One possible response is to argue that laws of nature govern entities and processes in a model rather than in the world. Fundamental laws, in this approach, do not state facts about the world but hold true of entities and processes in the model (cf. Cartwright 1983).

Models and Scientific Explanation

Laws of nature play an important role in many accounts of explanation, most prominently in the deductive-nomological model and the unification approach (see Explanation). Unfortunately, these accounts inherit the problems that beset the relationship between models and laws. This leaves two options. Either one can argue that laws can be dispensed with in explanations, an idea employed both in van Fraassen's pragmatic theory of explanation and in certain causal accounts of explanation. Or one can shift the explanatory burden on models. A positive suggestion along these lines is Cartwright's (1983) "simulacrum account of explanation," which suggests that one explains a phenomenon by constructing a model that fits the phenomenon into the basic framework of a grand theory (chap. 8). In this account, the model itself is the explanation that is sought. This squares well with basic scientific intuitions but leaves the question of what notion of explanation is at work. Other accounts of explanation do not seem to be more hospitable to models. Causal or mechanistic accounts of explanation (see Explanation, Mechanism) do not assign models an explanatory function and, at best, regard them as tools to find out about the causal relations that hold between certain parts of the world.

Conclusion

Models play an important role in science. But despite the fact that they have generated considerable interest among philosophers, there remain significant lacunae in the philosophical understanding of what models are and of how they work.

SCIENTIFIC PROGRESS

The concept of 'progress' presupposes some aim or end against which progress can be measured. In order to talk meaningfully about the progress of science, one must have in mind some concept of the aim of science. What, then, is the aim of science? In Francis Bacon's famous phrase, "Knowledge is power." Insofar as that dictum was taken as the catchword of the emerging Scientific Revolution, it was understood to mean the power to accurately predict, manipulate, and control the natural world. There can be no question that in this sense more is now known than in past generations and that science, so understood, has progressed from its beginnings to the present. The future prospects appear bright as well, although perhaps not unlimited.

Predictive power is an important part of the story of scientific progress but it cannot be the whole story. Were there access to an infallible oracle, the power to predict would be unlimited, but one would still not be inclined to call it science. For one thing, there would be no understanding of why the oracle always got it right. So, scientific progress is tied up with the notion of increased understanding of how the world works. This understanding typically takes the form of some story, theory, or narrative. 'Understanding,' in turn, seems to be connected to the question of truth. Producing a coherent narrative about some sequence of events is not sufficient to guarantee understanding. One wants to know that the narrative is true or, at least, approximately so. Hence, another measure of scientific progress is an increase in or convergence to truth. For progress to occur, one demands that successor theories or narratives be truer than their predecessors. However, if two accounts appear to be equally true, the notion of explanatory power may be invoked. In this dimension, progress occurs when a less explanatory account is replaced by a more explanatory account. Many have argued not only that science progresses but that the progress is "rational." The most trenchant criticisms of Kuhn's (1973) analysis of scientific revolutions were directed toward the alleged "irrationality" of scientific change. The rationality of scientific progress, in turn, is taken by some to be grounded in a commitment to scientific realism (see Realism). So, for some realists,

progress occurs in virtue of scientists' accounts getting closer to the truth about how the world is. The explanatory power and predictive accuracy of accounts is alleged to rest in the fact that these accounts are getting at the way the world is, more or less. When it comes time to spell out this picture in detail, however, things become problematic. In what follows, some of the major themes that have emerged in the twentieth-century discussion of the scope and limits of scientific progress will be sketched.

The Logical Positivists

The positivists are perhaps best remembered for their efforts to promote the unity of science, a project that culminated in the *International Encyclopedia of Unified Science* (Neurath, Carnap, and Morris 1952). The project promoted the idea that there was one language of science, a unity of method that became codified as the hypothetico-deductive method. This is often interpreted to imply that there is also a unity of laws that generated a reductionism with physics as the most basic science serving as a foundation for chemistry, biology, and psychology and the other social sciences (see Reductionism; Unity and Disunity of Science). Correlative with this reductionist worldview was a commitment to what became known as the covering-law model of scientific explanation (see Explanation). Associated with the covering-law model of explanation is a hierarchical model of explanatory connections that has been labeled the "layer cake" model. The basic idea is that there is an observational base that contains singular statements reporting observational facts, for example, about charge distributions, chemical reactions, embryonic developments, animal behaviors, social groups, and so on. At the next level up, there will be empirical generalizations about these phenomena. The third stage will include even more general statements connecting the generalizations at the first level. At some stage, theoretical constructs will be introduced. At some level, the sociological laws and theories will be subsumed under the psychological laws and theories, and they in turn will be subsumed under biological laws, and these in turn will be subsumed under laws of chemistry and finally under laws of physics. This procedure is conceived as continuing indefinitely. Each rise in level brings greater systematization to the body of established scientific knowledge and constitutes scientific progress.

In the Aristotelian model and in the rationalist tradition, this process of looking for more and more general laws would eventually end at some very general laws that are "self-evident." This is one aspect of what some logical empiricists have called the "search for certainty," which characterized traditional philosophy. For the modern empiricists, the highest-level laws always function as "unexplained explainers." Thus, the search for ever more general laws continues, in principle, indefinitely. Even if one was to arrive at some "final theory," whatever that might mean, the fallibilism of the empiricists would preclude one's ever recognizing it. The net effect is a view of endless progress (see Logical Empiricism).

The Popperian View

In the 1930s, Karl Popper developed an alternative to the positivist picture of science (see Popper, Karl Raimund). Popper accepted the positivists' view of the nature of theories and the importance of the hypothetico-deductive method but parted company with them on what he saw as the crucial question of how scientific claims are to be validated. The positivists adopted the view that theories were to be validated by being confirmed by evidence. Measures of confirmation were generally taken to be probability measures of some sort. In a choice between two theories, the rule was: choose the theory that is most probable given the evidence. Popper rejected this approach in favor of emphasizing the falsifiability of scientific claims. In this view, the job of the scientist is to subject hypotheses and conjectures to the severest possible tests and to provisionally accept those that passed the most severe (Popper 1961, 1968).

For Popper, the philosopher of science is a methodologist whose job it is to propose a series of methodological rules that will promote the growth of knowledge, that is, the discovery of general laws. These methodological choices are partially a matter of adopting certain conventions based on value assumptions about the aim and nature of science. For Popper, the appropriate choice is the methodology that maximizes the solution of interesting problems. The result encourages methodologies that involve bold conjectures and severe testing of hypotheses. The severe tests to which hypotheses are to be put is a reflection of a critical method that promotes rational change. Indeed, Popper identifies 'being rational' with 'being critical.' In this way, the progress of science, insofar as it is produced by a critical evaluation of hypotheses, is a rational endeavor.

Popper's evolutionary model of scientific change consists of conjectures and refutations. Problems

give rise to hypotheses that are then subjected to severe tests. If the hypothesis fails to pass those tests, it is rejected and another conjectured takes its place. The cycle of testing and assessing begins anew. If the hypothesis passes one severe test, then there will always be others more severe yet. Theories or conjectures that pass such severe tests are said to be *corroborated*. The degree of corroboration of a theory is a measure of how well it has stood up to severe tests in the past. But it says nothing about the likelihood of the theory withstanding future tests. So, in what sense is the most highly corroborated theory the best choice in a given situation? Popper's argument for identifying the most highly corroborated theory as the best goes along lines like these:

1. The rational choice is the best choice.
2. It is always rational to choose that option that has been most severely tested and survived, because those theories are the ones that have been subjected to the severest criticism. (Recall that, for Popper, to be rational is to be critical.)
3. In the case of theories, it is rational, then, to choose that theory among the competing options that is most highly corroborated. Therefore,
4. The best theory is the most highly corroborated (see Corroboration).

The most highly corroborated theories also "track" the truth, in the sense that Popper argued that a measure of closeness to the truth that he called "verisimilitude" could be defined. With such a measure, it would be possible in principle to determine which of a set of alternative conjectures represented genuine scientific progress. This proposal generated an extensive literature designed to refine and validate such a measure. For the most part, such attempts to construct viable measures of verisimilitude have come to naught, although there are still defenders of this approach as the best method for gauging scientific progress (cf. Miller 1974; Niiniluoto 1999) (see Verisimilitude).

The Kuhnian View

Thomas Kuhn's (1962) influential *Structure of Scientific Revolutions* was seen at the time as a radical challenge to traditional views about the nature of science and the prospects of scientific progress. It is well to remember that *Structure* was in fact the last number in that canon of logical positivism, the *International Encyclopedia of Unified Science*. Nonetheless, it is fair to say that Kuhn in the 1960s saw himself as breaking with that tradition. Over the years, he came to see the continuity that existed between his views and those of the later positivists. He also came to refine and modify his views in the light of what he took to be the excessive lengths to which some of his readers took them. The central themes remain, however, much as he laid them out in the 1960s (see Kuhn, Thomas).

The growth of a scientific discipline, in Kuhn's view, follows a standard pattern of different stages. In his earliest formulation of this stance, it is possible to distinguish five stages that characterize the progress of science. These are:

1. Immature science
2. Mature (normal) science
3. Crisis science
4. Revolutionary science
5. Resolution; normal science resumed.

The cycle then repeats itself through stages 2–5 indefinitely. Central to Kuhn's view is the notoriously slippery concept of a "paradigm," or "disciplinary matrix." A disciplinary matrix is the overall collection of methods, formulae, rules, procedures, and commitments that govern scientific research. Kuhn came to distinguish four major components of disciplinary matrices: symbolic generalizations, models, values, and exemplars. These are the shared standard examples that give "content" to the abstract principles of the disciplinary matrix. The exemplars are the fundamental units in the matrix and are the basic tools by which the scientist working in a normal science tradition advances the range of phenomena rendered lawlike by the basic principles and theories of the tradition.

In *Structure*, immature science is characterized as preparadigmatic. Later, Kuhn argued that no research occurs in the absence of paradigms. Immature science is science that is characterized by paradigms, which for some reason or other, fail to generate a "puzzle-solving" tradition. The shift from immature to mature science is then seen as a shift from a paradigm that "leads nowhere" to one that provides a context of unsolved puzzles and problems such that some hope exists for their solution.

Mature (normal) science is thus a problem-solving tradition. According to Kuhn, most scientists spend most of their lives working in such traditions. The normal science tradition seeks to extend and entrench tried-and-true theories and practices. Progress at this stage consists in increasing the number of systems that can be understood in terms of the fundamental exemplars of the theory. However, no theory (or paradigm) successfully solves all its problems. Problems that resist

assimilation to the techniques of the paradigm are labeled 'anomalies.' When the failure of a paradigm to reduce anomalies to lawfulness is perceived (by scientists) to be as great or greater than the power of the paradigm to force nature into its mold, a crisis results.

Crisis science is characterized by a general recognition that the ruling paradigm is no longer functioning effectively. This recognition may come from the community of scientists working within the tradition of the disabled paradigm, or it may come from without. With the paradigm breakdown comes a proliferation of new ideas, theories, methods, and alternative paradigms.

When one of the new paradigms begins to emerge as a contender for succession, the result is a conflict between the new and the old paradigm. Since paradigms are pervasive in determining worldviews, the ground rules for deciding among competing paradigms are not the same as those that operate within a single tradition. Kuhn argues that not only are the worldviews of different paradigmatic traditions different, but, in a sense, the *world itself is different* for the practitioners in different paradigmatic traditions.

The ultimate resolution of paradigm conflicts results in the emergence of a new normal science tradition. According to Kuhn, such resolutions involve something akin to a Gestalt shift. Critics were quick to conclude that, for Kuhn, scientific progress from one paradigm to another is a fundamentally irrational process, since the standards and values of one paradigm need not be shared by its successor. In responding to his critics, Kuhn sought to soften this implication by pointing out that there were certain values characteristic of science, such as simplicity, predictive accuracy, and requirements for consistency, that transcended particular disciplinary matrices. Thus, he argued, revolutionary science was both progressive and rational.

Post-Kuhnian Developments

Among the post-Kuhnians was Imre Lakatos, who developed a blend of Kuhnian and Popperian elements that he labeled the 'methodology of scientific research programs' (see Lakatos, Imre; Research Programs). He argued that the fundamental unit of assessment should be a research tradition such as Newtonian mechanics, rather than a single hypothesis or conjecture. These research programs consisted of a "hard core" of central symbolic generalizations, along with a "protective belt" of auxillary hypotheses. Programs were either progressive, when they made bold and stunning predictions, or regressive, when they focused on protecting the core from refutation. The resulting model of scientific development was claimed to be a sophisticated falsificationist version of Popper's program that offered a response to what Lakatos saw as Kuhn's irrationalist view of scientific change. (For critical assessments, see Dilworth 1994 and Laudan 1977.)

Larry Laudan proposes that scientific progress be measured in terms of the problem-solving capacity of a research tradition. His conception of a research tradition is, despite protestations, similar to Kuhn's conception of a disciplinary matrix. Laudan suggests that instead of understanding progress as a rational activity, one defines rationality in terms of progress. So, given two problem-solving research traditions, the rational choice is to choose that which is most progressive in terms of its problem-solving ability. Problems, on Laudan's view, are either empirical or conceptual. Empirical problems are either solved, unsolved, or anomalous. Conceptual problems are either internal or external to the tradition. The degree of progressiveness is taken to be a measure of the solved problems minus the unsolved and anomalous. This approach presumes that problems can be characterized more or less independently of the traditions that address them. This is certainly true for a large group of problems, but not for all. To the extent that problems are identified with the traditions within which they occur, the attempt to compare alternative traditions in terms of their problem-solving capacity is compromised. In any case, this analysis succeeds no better than any of the others in providing an effective procedure for determining scientific progress.

Philip Kitcher (1993) argues that the traditional positivist picture, which he dubbed "legend," while flawed, is basically correct in its picture of the progressive unifying nature of science. By exploring the multidimensional practices that constitute scientific inquiry, he paints a broadly realistic conception of science that allows for objective, rational progress.

Ilkka Niiniluoto opts for a "realist" measure of progress based on the notion of verisimilitude, or "nearness" to the truth (see Verisimilitude). He rejects Laudan's problem-solving criterion on the ground that no truth-independent criterion can be a suitable measure of progress, although it may serve as a truth indicator. But the argument for this appears to be a presumption that the aim of science is to arrive at the truth. Indeed, if the aim of science is to produce true theories, then no truth-independent criterion of success or progress will be adequate. But what does this mean to a defender of a criterion of pragmatic problem solving capacity for the success of science?

Does scientific progress entail convergence to the truth? Kuhn (1962) hinted that the growth of scientific knowledge should be viewed more along the lines of aimless biological evolution rather than as a teleologically directed process (cf. Laudan 1977). He subsequently backed off from the more radical implications of this claim, but a preliminary sketch of a similar view was given by Stephen Toulmin (1972). Unfortunately, the promised development of this sketch never appeared. At the same time, however, Donald Campbell was developing an evolutionary model of scientific change that he called "hypothetical realism" (Campbell 1974). David Hull (1988) presents a gripping picture of science progressing to the truth as a result of the struggle between scientists for credit and acclaim in the open market of ideas (see Evolutionary Epistemology).

The Price of Progress

For the most part, those who endorse the progressive character of science see it continuing forever. There are exceptions, but these are in the minority (e.g., Horgan 1996). The problem with postulating the end of science is that those who profess it are extrapolating current conceptual and technological capacities in a way that history belies. Since the last century, Big Science has come into its own, first in physics but now in other fields as well. Making discoveries costs money, and no extended principled discussion of who should pay and who should benefit has yet been undertaken (cf. Rescher 1978; Kitcher 1993). At the beginning of the last century, Poincaré argued that science for its own sake was justification enough (Poincaré 1958). In the light of the development of weapons of mass destruction and the social implications of advances in biotechnology, to name just two areas of concern, this is a conceit that the twenty-first century can ill afford to harbor.

SCIENTIFIC REVOLUTIONS

Since an explicit definition of 'scientific revolution' in terms of necessary and sufficient conditions is out of the question, this article will instead characterize revolutions by contrasting them with normal science and evolutionary development, by considering exemplary cases of revolution, and by noting the history of the the term 'revolution.'

Origins of the Idea of Scientific Revolution

The concepts of political and scientific revolution have been intertwined almost from the beginning. Hatto (1949) and Cohen (1985) have assembled the most thorough collection of historical sources. The ancients and medievals had no term for political revolution in the modern sense. However, they already drew an analogy to revolution in the sense of celestial orbits (*orbis* = cycle, circle, wheel), since they sometimes supposed that a city or state cycled through the gamut of political constitutions, from tyranny to democracy. Thus a revolution was a return to a previous state rather than something new and progressive. Such cycling was often considered natural or even fated, by the turn of the wheel of fortune, and therefore outside of human control. Astrological beliefs abetted the linking of political and celestial turnings. In the Italian Renaissance, Machiavelli and a few others suggested that states were at least partly artificial and that revolutions could be humanly made. Meanwhile, the Vulgar Latin 'revolutio' came to designate celestial revolution, and an analogy to the wheels of the new clockwork machinery apparently helped propagate the term into political contexts.

The title of Copernicus's work of 1543, *De revolutionibus orbium coelestium*, implied a cyclic return, a sense retained in early modern political contexts, as when the Stuart monarchy replaced the Rump Parliament in Britain in the Restoration of 1660. But soon after, 'revolution' came to suggest a political-structural change away from the status quo, as in the Glorious Revolution of 1688, although this, and the American Revolution a century later, could still be considered a return to an imagined previous condition. The French Revolution stabilized the sense of rejection of an old regime for something new. This meaning in turn passed back, metaphorically, into science, where Newtonian mechanics became the paradigmatic revolution in replacing both Aristotelian and Cartesian philosophy. During the nineteenth century the new chemistry of Lavoisier and Dalton and, later, Darwin's theory of evolution inspired talk of revolution; but it was not until the twentieth century that 'scientific revolution' became common parlance.

The shocking double revolution in physics (relativity and quantum mechanics) as well as the Russian Revolution stimulated thinking about revolution early in the century. Meanwhile, Burtt (1932), Koyré ([1939] 1978 and later writings), and Butterfield (1949) integrated the work of Copernicus, Kepler, Galileo, Descartes, and Newton into a single, extended event, dubbed the 'Scientific Revolution,' a label that came to name a historical period, which in turn became the central locus of historical research. Butterfield's *Origins of Modern Science* was especially accessible to a general audience. He contended that the Scientific Revolution was the emergence of modern science itself, not simply a revolution within science; and, moreover, that it was the most significant event since the rise of Christianity. The new discipline of history of science was therefore fundamentally important. (See Lindberg and Westman 1990 and Cohen 1994 for critical accounts of the historiography of the Scientific Revolution.) In addition, Butterfield presented the history of modern science as a *series* of conceptual revolutions, including the revolution in chemistry (with Lavoisier as the central figure) and the Darwinian revolution. Historians also began to speak liberally of technological "revolutions," such as the agricultural revolution, the print revolution, and, of course, the Industrial Revolution.

Since 1950, with the maturation of history of science as a discipline, and especially since the publication of Thomas Kuhn's (1962) *The Structure of Scientific Revolutions*, talk of scientific revolutions has proliferated (see Kuhn, Thomas). Notoriously, Kuhn incorporated some aspects of political revolutions in his account of scientific revolutions, and so the interplay continues. Historians and historical philosophers soon discovered

other revolutions, for example, the revolution in wave optics (Young and Fresnel), the ongoing revolution in heat theory (Carnot, Kelvin, Clausius, Maxwell, Boltzmann), the revolution in electromagnetic theory (Faraday, Maxwell), the nineteenth-century revolution in probabilistic and statistical techniques, the Second Scientific Revolution around the turn of the nineteenth century, and so on. Meanwhile, revolutions in geology (plate tectonics) and molecular biology were taking place. Social scientists sought their own revolutions, leading some to announce a Chomskyan revolution in psycholinguistics (see Chomsky, Noam).

Attitudes toward both scientific and political revolutions have changed historically. The Restoration was controversial, while the Glorious Revolution was generally welcomed. Both the French and Russian upheavals gave revolutions a bad reputation as excessively violent rejections of old forms of life and culture. This negative association carried over to talk of scientific revolution in the ensuing decades. Old-guard scientists sometimes sounded rather like Edmund Burke in his conservative reaction to the French Revolution. The relativity and quantum revolutions were especially shocking epistemologically, for they did not replace prescientific speculation. On the contrary, they overturned classical mechanics, the very paradigm of scientific knowledge. They thereby destroyed the conception of science as foundational, as yielding virtually certain conclusions, and as the one truly cumulative institution there is. Today, however, revolution enjoys a generally positive image associated with liberation and opportunity for dramatic improvement. At least in the West, where political stability is unquestioned, this positive attitude is reflected in popular slogans and advertising, such as ''Challenge authority'' and ''We broke all the rules and created new rules.''

Unlike 'rebellion,' 'revolution' is an achievement term rather than a process term. It connotes a community's success in freeing itself from an established order and instituting a new order. Thus 'revolution' implies significant innovation. This application of the term is modern, for there can be no genuine revolutions as long as a divinely established order makes radical, humanly instigated change impossible and as long as significant innovation of any kind seems beyond human capacity. As a rejection of an established constitution, revolution also implies a normative struggle. Revolutionaries typically appeal to reason and justice, arguing that the old order is arbitrary, irrational, and inefficient and that it gratuitously thwarts human freedom and blocks progress. Thus it is not surprising that the modern idea of revolution emerged during the Enlightenment. In simplest terms, Enlightenment thinkers set reason and autonomy in opposition to history and tradition. However, this Enlightenment understanding is challenged by later revolutions that undermine previous, clearly modern scientific and political paradigms themselves.

Hegel attempted to overcome the dualism of reason and blind historical forces by positing transcendental reason or the Absolute as an agency that subtly harnesses myriad contingent events in such a way that a rational pattern emerges. Hegel and Marx developed conflict theories of profound social change, where tensions arise from the old structure rather than from external forces. Modern and postmodern thinkers generally accept a dynamical conception of human history and of the history of particular fields. One mark of modernity is the idea of essential social change, especially deliberately instituted progressive change. One mark of postmodernity is the denial that deep historical change is indisputably progressive and rational and that it fits a single, coherent narrative. As indicated, historical change becomes a threat to the claim that the sciences cumulatively reveal the timeless and culturally neutral truth about the universe.

The positivist-empiricist model of scientific change is ahistorical and only minimally dynamic, for it conceives scientific change as cumulative empirical and theoretical change within a stable but expanding conceptual framework. Conflict between established results is to be avoided at all costs. By contrast, evolutionary models postulate continuous but potentially transformative change over time. In them the conflict tends to be widely distributed and less intense than in revolutionary models, which work best when there exists a central core of ideas and practices to overthrow. Thus postmodern critics' decentralization of community power structures problematizes revolutions of the classical kind, yet the postmodern sympathy for disunity also inspires talk of discontinuity or rupture, that is, revolution.

The following sections survey how historians and philosophers of science have dealt with the problem of understanding deep scientific change.

Revolution as a Unit for History of Science

There are several additional reasons why revolution has become a popular topic, some of which raise the question as to what extent revolutions are artifacts or illusions of professional historical and

philosophical research. These reasons include the following:

1. The amount of material to be gathered, analyzed, and cast into narrative form is potentially overwhelming. Thus some form of cognitive economy in the form of problematic and thematic organization is necessary to render this material humanly intelligible, to both historians and their readers. The idea of revolution has been a fruitful organizing principle for history and philosophy of science as well as for social-political history—perhaps the more so as recent history of science has turned away from internalist to social history. There are historiographical and epistemological reasons for this shift, including the difficulty of treating large quantities of highly technical material. On the other hand, this very complexity can challenge the identification of discrete revolutions.
2. The idea of revolution is well suited to the narrative forms that historians prefer. Story is one of the primary ways in which complex meshes of human events are made both interesting and intelligible. Revolutions are event-like or process-like and thus fall naturally into Aristotelian narrative form as having a beginning, middle, and end. Moreover, with scientific revolutions the story can be made dramatic, even heroic. Possible story lines full of human interest easily suggest themselves: the fall of the mighty; the triumph of the underdog, ridiculed outsider, or creative genius; achievement of the impossible; the discovery of a vast new territory; and so on. So depicted, science is no longer a boring, grinding affair of piling up experimental facts in an emotionless manner.
3. As a discipline, history of science came to intellectual and professional maturity under the guidance of such leaders as Koyré, who turned the history of science into an agonistic field of big intellectual ideas (e.g., Platonic vs. Aristotelian), that is, a story of clashing intellectual positions, in which human beings are merely the carriers or the agents. As Burtt had before him, Koyré combated the standard, positivist-empiricist view that it was a turn to empiricism that produced the Scientific Revolution for the revolution involved little new empirical information (they said) and was primarily the reorganization of already available material around a new set of philosophical and metaphysical ideas. The Scientific Revolution was an intellectual revolution. To a large degree, Thomas Kuhn would extend this analysis to revolutions in general, as Butterfield also had suggested.
4. Kuhn's *The Copernican Revolution* (1957) and *The Structure of Scientific Revolutions* (1962) further challenged conservative conceptions of science, illustrated the organizing and narrative power of revolution by turning the history of science into a drama of profound and unexpected conceptual change that was fascinating to a wide audience, and had immense impact on several fields of thought and action. The new history of science together with the philosophies of science described in the next section created a battle of the "big systems" and ultimately, with the advent of the new sociology of science, the "science wars" (see Social Constructionism).
5. Mature history of science features sensitivity to cultural context, as against the old "whiggish" histories that arranged all of the history of science within the same, cumulatively growing conceptual and cultural framework. Professional historians taking a biographical approach place a premium on identifying cultural differences and on capturing the subjective problem contexts of individual scientists such as Galileo, Newton, Faraday, Darwin, and Einstein. It is as if the discipline of history, like some high-tech imaging technologies, contains built-in contrast enhancers that magnify sensitivity to conceptual change and thereby turn every subtle change into a major explanatory problem. Such sensitivity can heighten the appearance of revolutionary thinking.
6. The institutionalization of history and philosophy of science in graduate schools further magnified this sensitivity, for it provided a way in which young historians and graduate students could emphasize the importance and originality of their historical subjects. Again, carried to an extreme, the smallest variation can be made to look revolutionary.
7. Yet, revolutions can also be constructed in historical writing by going to the opposite extreme of telescoping previous developments so that they appear to be more episodic and less evolutionary than they in fact were. Such revolutions can be whiggish illusions insofar as they are construed as sudden breaks from tradition. Butterfield (1931) had already warned that general history inevitably produces whig fallacies.

8. Among the factors that incline historians and philosophers toward a revolutionary conception of scientific change are intellectual commitment to stage theories of psychological, social, or scientific development; rigid, rule-based accounts of human cognition and/or social organization (e.g., various forms of structuralism); logical empiricist assumptions about the logico-linguistic structure of science; and romantic accounts of creativity. All such approaches render evolutionary accounts of stage transitions implausible. In addition to some logical empiricist assumptions, Kuhn was influenced by the developmental psychology of Jean Piaget, a stage theorist, while others were influenced by Freud's account of development, another stage theory. Many historians have been influenced by French historico-philosophical thought, e.g., that of Gaston Bachelard and Michel Foucault, with their emphasis on long-term epistemological formations and their ruptures.

On the other hand, mature historians rightly reject "deus ex machina" explanations of profound change such as appeal to genius or divine inspiration. Instead, they seek to understand major developments as the culmination of many previous events in their cultural and institutional contexts. Thus, good historians no longer see Galileo's or Newton's or Einstein's work as dropping miraculously from the sky. They view it as sustained exercises in problem solving, based on the influence of many precursors whose work they set out to document. And they see the propagation and acceptance of that work as the result of a broad range of techniques of persuasion, including funding enticements. Their overall strategy is to break a major change (e.g., a revolutionary "discovery") into numerous small changes. The same cultural sensitivity mentioned above can also lend itself to a "continuity model" of scientific development, as opposed to the revolutionary or "discontinuity model," again by breaking down the conceptual changes into smaller and smaller units. Pierre Duhem, an early exemplar of this strategy, had notoriously contended that much of the Scientific Revolution actually occurred in the fourteenth century.

Victorious scientists rewriting the history of their discipline also face a tension. On the one hand, they want to emphasize the revolutionary character of the work with which they have been heroically associated. On the other hand, in order to maintain their scientific identity, they want to make that work appear to be the natural or rational culmination of the previous history of their discipline.

Cohen (1985, Ch. 2) describes four stages of revolution:

- "the intellectual revolution" or "the revolution-in-itself," in which a radical problem-solving success leads investigators to formulate a research program that will spell out the implications;
- commitment to the new research program;
- communication to colleagues or the "revolution on paper"; and
- conversion of the sometimes resistant field to the new program and its agenda.

Cohen (chap. 3) employs four kinds of historical tests for identifying revolutions. First, contemporary witnesses, both scientists and nonscientists, testify to the occurrence of a revolution. A revolution must be recognized as such at the time. (For instance, Funkenstein (1988) notes the radicalism of authors such as Descartes, Hobbes, and Newton in claiming that metaphysical reality is totally different from what anyone before had imagined.) Second, later documentary histories of the science claim that a revolution has occurred. Third, this attribution is confirmed by the judgment of competent historians of science and philosophy. And, fourth, it is confirmed by the general opinion of scientists working in the field today. Cohen, like Kuhn, calls attention to the important fact that practitioners facing a revolutionary choice give special weight to future promise, for the established approach almost always possesses greater scope and stronger confirmation than the young challenger.

Cohen's inclusion of today's perspective excludes announced revolutions that did not pan out. In history one is usually wiser after the event. And his emphasis on historically contemporary accounts avoids the danger of later scholars retrospectively inventing revolutions where there were none. Does Cohen give contemporary accounts too much weight? An ironic consequence of his view is that the Copernican revolution was not really a revolution, since it was largely ignored for decades. And, as noted above, the modern concept of scientific revolution was not yet available in earlier times.

What stretch of historical events should be included in a revolution, and who is to decide? Rarely, at the frontier of research, can the principal investigators formulate a radical research program that stands the test of time. It typically takes

years, even decades, to distill out the core meaning of dramatic new developments, as the quantum revolution illustrates. Cohen's insistence that revolutions be highly innovative stands in tension with his claim that they are fully recognized by their makers and, to some degree, preprogrammed. If revolution is at all like biological speciation, then 'revolution' is a retrospective category. Cohen himself calls attention to the mechanisms by which scientific results and techniques can be gradually transformed, almost beyond historical recognition. Finally, how should one classify results that are not radical breaks from tradition, yet in the long run turn out to be remarkably productive? Cohen recommends a rather sharp distinction between revolutions themselves, as definite historical episodes, and their consequences.

Sociologists and cultural historians challenge standard historical and philosophical accounts of revolutions as signal intellectual achievements in much the same way that they challenge standard accounts of scientific discovery, given that revolutions are supposedly founded upon major discoveries. Like discoveries, revolutions are notoriously difficult to identify and delimit in their actual historical contexts. And like 'discovery,' 'revolution' is not simply a logical, or epistemological, or even a descriptive-historical term. Rather, it is an honorific label, retrospectively conferred by a scientific community (or its historiographers and philosophers) in order to celebrate and canonize designated authors and events as constituting the present state of the discipline and its authorized practices. As such, these social attributions serve important community and cultural functions, but they belong more to the genre of founder myths than to historiography or epistemology. No event is revolutionary by nature. That label is the product of a complex process of social negotiation (Schaffer 1994).

Revolution as a Unit for Philosophy of Science

There are also professional philosophical reasons why revolution is attractive as a unit of analysis for the philosophy of science. Paradoxically, these spring from both ahistorically and historically oriented philosophies. Kant was ahistorical. However, his introduction of the idea that the world of everyday and scientific experience is a product of a rational and specifically human conceptual scheme (the forms of intuition and the categories) immediately suggested to the historically oriented Hegel the possibility of alternative conceptual schemes, including the possibility that ancient and medieval peoples actually exemplified such alternative forms of life. In that case, human history organizes itself into distinct, stable epochs with less stable, perhaps revolutionary, transitions between them. Such an idea proved very suggestive to idealist philosophers, social theorists, and anthropologists, and it became one source of the nineteenth-century discovery of deep history and of culture. A century and a half later it would strongly influence Thomas Kuhn, who described himself as a "historicized Kantian" (Kuhn 2000). And it would become a leading heuristic of the new, anti-whiggish history of science to focus on cultural and intellectual differences rather than similarities. Revolutionary ruptures between intellectual and social formations already characterized a line of French thinkers, including Bachelard, Canguilem, and Foucault (Gutting 2003).

Prominent among ahistorical philosophers were the logical empiricists, who, between about 1930 and 1970, attempted to reconstruct scientific method in terms of fixed, formal logical systems, which permit no real conceptual growth. Thus scientific change that requires a new logical framework must appear to be revolutionary, absent any mechanism for how one logical system can evolve smoothly into another one quite different from it.

Most logical empiricists minimized the problem of change by assuming that science, at least as rationally reconstructed, develops within more or less the same conceptual framework and that theory change can be handled in terms of the logic of intertheoretic reduction (see below). Members of the operationalist movement held much the same position by virtue of the requirement that each theoretical term be fixed in advance by a permanent operational definition (see Bridgman, Percy). The physicist and operationalist Bridgman (1927) explicitly denied the need for revolutions in rightly conducted science:

> We should now make it our business to understand so thoroughly the character of our permanent mental relations to nature that another change in our attitude, such as that due to Einstein, shall be forever impossible. It was perhaps excusable that a revolution in mental attitude should occur once, because after all physics is a young science, and physicists have been very busy, but it would certainly be a reproach if such a revolution should ever prove necessary again. (2)

In the case of relativity, thought Bridgman, Newtonian physicists should have defined the concept of simultaneity more carefully in the first place and erected a corresponding physical theory

that would have avoided the later need for an Einsteinean revolution—as if scientists could be so prescient of later developments and research programs could handle full complexity from the start.

By contrast, Kuhn (1962) claimed that scientific revolutions are necessary if science is to progress beyond its present conceptual and practical framework, and therefore inevitable, assuming that it will so progress. By its nature, said Kuhn, mature scientific practice eventually produces major conceptual and practical change, and so it must break out of the old framework of theory and practice. Whereas most writers, past and present, have considered the occurrence of political and scientific revolutions to be rare and highly contingent, Hegel, Marx, and, later, Kuhn regarded them (although not their precise content) as qualitatively predictable because inevitable. The views of these individuals were of course very different in other ways. Notably, Hegel's transitions and Marx's revolutions lead inevitably to a final goal, whereas Kuhnian revolutions are nonteleological and will continue without end as long as science continues to flourish.

As noted, the later logical empiricists attempted to handle the problem of major theoretical change by means of reduction of theories (e.g., Nagel 1961) (see Reductionism). Applied to a theory and its successor, reductionism is the conservative idea that the new theory is logically more general than its predecessor and hence explains it by incorporating it as a special case. Thus Maxwell showed that electromagnetic theory entails physical optics, which in turn entails ray optics as an idealization. Somewhat similarly, special relativity theory yields Newton's laws in the limit of low velocities. Thus the conceptual framework and the empirical content of science expand cumulatively rather than being undermined and replaced (cf. Sarkar 1992).

Kuhn (1962) and Paul Feyerabend (1962) opened what became the battle of the big systems by raising two objections against this account (see Feyerabend, Paul; Kuhn, Thomas). First, major theoretical change brings meaning change. Einsteinian masses are not the same as Newtonian masses, since the former but not the latter are velocity dependent, a major conceptual difference. Hence, to claim that Newton's laws are derivable, even approximately, from Einstein's, commits the fallacy of equivocation. Second, the succession of one major theory by another always involves "Kuhn loss," that is, phenomena that were explained by the old theory but cannot be handled by the new one. For example, once early-nineteenth-century scientists accepted Dalton's view that the atmosphere is a physical mixture rather than a chemical compound, they could no longer explain why the heavier gases did not settle out (Kuhn 1962, §X).

Other philosophers, notably Popper, responded to the twentieth-century revolutions in physics in a far more positive way than did Bridgman and the logical empiricists, while denying the status of genuine scientific revolutions to Freud's and Marx's work (see Popper, Karl Raimund). Inspired by Einstein, Newton, and a few other great men of science, Popper rejected the so-called Baconian method of induction from the facts. In its place he promoted a romantic picture of creative revolutionaries who put forward bold but empirically testable theoretical conjectures in order to solve deep intellectual problems. Popper became so enamored of his "critical approach" and its motivating idea ("we learn from our mistakes") that he and his followers urged "revolution in perpetuity." For Popper, revolutionary new ideas undermine and replace their predecessors, but they must incorporate everything that seems correct in the old viewpoint, a conservative requirement that tames his revolutionary impulse.

Feyerabend took Popper's revolutionary ideas to the limit. The early Feyerabend (1962) recognized that some empirical criticism requires a deep theoretical background and contended that scientists should develop multiple, competing theory systems in order to maximize criticism of each from the standpoint of the others. This was his "proliferation thesis." Yet Feyerabend also spoke of alternative theoretical viewpoints as being "incommensurable," a term introduced simultaneously by Kuhn (see Incommensurability). The later Feyerabend (1975) became still more critical than Popper of standard conceptions of scientific method and argued on both historical and philosophical grounds that there is no permanent logic of science or theory of rationality. Rather, whole new conceptions of method and rationality have been brought into existence through the rhetorical strategies and social manipulations of such men as Galileo. Feyerabend branded this revolutionary position "methodological anarchism."

Meanwhile, Feyerabend's friendly rival, Lakatos (1970), argued for a permanent "methodology of scientific research programs." Whereas Popper considered the formulation and testing of theories more or less in isolation, Lakatos's methodology explicitly recognized the importance of long-term traditions within the history of science in the form of competing research programs that fight battles of attrition. Each research program strives

to produce more novel predictions and confirmations than its rivals. In this view there are no scientific revolutions, properly so called, wholly within a single research program. However, the splitting of an old program or the foundation of a major new program could be considered revolutionary (see Lakatos, Imre; Research Programs).

Thomas Kuhn on the Structure of Scientific Revolutions

Kuhn rejected Popper's idea of revolution in perpetuity as virtually self-contradictory, for to speak of revolution makes sense only as a reaction against a securely established, stable regime. Scientific revolution can be understood only by contrast with normal science. (Bachelard [(1934) 1984] had already allowed for "continued revolutions.") Kuhn also criticized Popper's critical approach on the ground that its thoroughgoing application would destroy science as currently practiced and turn it into something more like philosophy, complete with the latter's premium on critiquing everything, including the fundamental principles that define the field. Kuhn rejected Feyerabend's call for proliferation and, by implication, Lakatos's competing research programs (as ways of achieving a kind of perpetual revolutionary antagonism) on the economical ground that there are insufficient intellectual and financial resources to support such extravagance (Worrall 2003). After all, it is difficult enough to produce a single major framework (Newtonian, Einsteinian, Darwinian), with its associated community and sets of practices and institutions.

Besides, for Kuhn mature science distinguishes itself from other human endeavors precisely because it is monolithic: A single paradigm defines a normal scientific period, and work under a paradigm is conservative and tradition bound, convergent rather than divergent. Eventually work at this level of esoteric detail will produce anomalies that even the best practitioners fail to resolve. Long-term failures gradually weaken commitment to the paradigm to the point of crisis, allowing alternative approaches to spawn. If the relevant gatekeepers of science can be persuaded that one of these alternatives handles the major anomalies in a more promising way than the received paradigm, then a revolution will likely ensue.

Kuhn (1962) notoriously emphasized that the transition to the new paradigm cannot be wholly 'rational' in the received sense of the word, for, again, rationality and standards of good science in their domain-specific forms are relative to a paradigm, and the competing paradigms are incommensurable. The early Kuhn maintained that the victory of a new paradigm requires political argument, power plays, and rhetoric as well as something like religious conversion.

Though infrequent, Kuhn's revolutions are not merely isolated historical contingencies, for he regularized the idea of revolution as paradigm change. Many if not all mature sciences (or at least the physical and biological sciences) were born in revolt against the folk science that preceded them, and all inevitably generated crises, some of which required a paradigm change for their resolution. It is not clear whether revolutions away from folk science and revolutions within an already mature science are of the same type.

For Kuhn a large science such as physics, chemistry, or biology consists of a hierarchy of paradigms—an overarching paradigm for the field as a whole with smaller paradigms for specialties and subspecialties. Scientific revolutions can be relatively small and local, since a community of specialists may include only a couple dozen practitioners, scattered worldwide. A revolution within such a subspecialty may appear to be an incremental change to scientists working in other areas, and may be completely invisible to the general public (Hoyningen-Huene 1993, chap. 6). Thus Kuhn greatly proliferated scientific revolutions while relativizing them to specialist communities.

For Kuhn, normal scientific work does not seek profound innovation, yet unexpected major discoveries occasionally occur. These are revolutionary, since they fall outside the bounds of normal science; but they alone do not constitute full-fledged revolutions (Hoyningen-Huene 1993, chap. 6). Although Kuhn himself is sometimes guilty of telescoping historical developments in such a way that they appear more revolutionary than they were, it was Kuhn who emphasized that both discoveries and revolutions are structured events (Kuhn 1962 and 1978, Ch. 7).

Kuhn claimed that major scientific revolutions are radical changes in worldview and the associated technical practices, and that competing paradigms are incommensurable (Kuhn 1962, §X). Scientists working under competing paradigms literally live and practice their trades in different worlds. These strong claims, a product of Kuhn's "historicized Kantianism," drew a storm of protest from philosophers (e.g., Scheffler 1967; Shapere 1984, Chs. 3 and 4; Sankey 1994). Kuhn spent much of the rest of his career attempting to reformulate, clarify, and defend versions of these claims (Kuhn 2000). One of the most important critics was Stephen Toulmin,

who, prior to Kuhn, had discussed revolutionary changes in framework principles that he termed "ideals of natural order" (Toulmin 1961). Toulmin (1972) rejected Kuhn's account of scientific development as too saltatory and countered with an evolutionary model of the growth of science. Kuhnian normal science, he complained, retains the logical empiricist conception of scientific rationality as logicality within a fixed system rather than as a more biological adaptation to changing circumstances. It was precisely this unjustified rigidity of normal science that required revolutionary breaks to a new, equally rigid framework. On the other hand, Kuhn himself frequently drew on evolutionary metaphors.

In a book left unfinished at his death, Kuhn abandoned history of science as a basis for his views, relying instead on philosophy of language and his understanding of human cognition. Kuhn now claimed that revolutionary incommensurability involves a major modification of the lexical structure of scientific knowledge, the meaning of key terms and their relationships. Revolutions alter the synthetic a priori judgments, the deep, quasi-Kantian constitutive principles of normal science (Kuhn 2000). These cognitive orientations are synthetic because they carry content about the world, but they are a priori because, during the period of normal science, they are not subject to empirical test or refutation. Revolutions involve major changes in the network of similarity relations that produce one Kantian "world" or another. Incommensurability entails the impossibility of accurate, technical translation but does not completely foreclose interpretation, mutual intelligibility, and rational comparability.

In addition to the aforementioned French thinkers, revolutionary discontinuities in the history of science were introduced by Fleck ([1935] 1979), who spoke of community thought-styles and thought-collectives. Fleck's work apparently influenced Kuhn, as did Polanyi's (1958) treatment of scientific practices and the associated "tacit knowledge." In turn, many analysts have been influenced by Kuhn's treatment of scientific revolutions. Margolis (1993) reduces all cognition to pattern matching and the associated "habits of mind." Even logical reasoning is pattern matching. There is no special faculty of reason or logic. Margolis's principal thesis is that sometimes what separates two incommensurable Kuhnian paradigms and produces mutual incomprehension is not a seemingly unbridgeable logical or conceptual gap but rather a cognitive barrier, a deeply ingrained habit of mind that prevents an available argument or conceptual transformation from becoming salient. He thus attempts to explain whiggish perplexities of the type: Why did it take person or community *X* so long to recognize that *Y*? For example, why did it take so long to make the transition from the Ptolemaic to the Copernican paradigm, given that all the key steps of the argument had been available for centuries? Margolis contends that the blocking habit or intuition may be peripheral to the paradigm in question. In Margolis's account it was the availability of new maps of the world that broke the nested spheres model of the universe and finally enabled Copernicus to appreciate the power of the transforming argument. It then took the few followers of Copernicus another half century to convince others of the argument's merits. Not even known logical arguments are automatically persuasive. For Margolis, a revolutionary development need not be subversive; it may simply open up vast new territory. His chief example is the probabilistic revolution of the nineteenth century, a topic thoroughly explored by Hacking (1983 and later works).

Thagard (1992) distinguishes several types and degrees of conceptual change in science, relative to the organization of scientists' cognitive representations of the taxonomy of their domain, including part/whole and hierarchical relations. The two most significant kinds of changes are branch jumping and tree switching, both of which occur in scientific revolutions. Branch jumping moves a concept from one branch of a hierarchical tree of conceptual categories to another, as when Brownian motion was reclassified from a biological to a physical phenomenon. More revolutionary examples are Copernicus's reclassifying the sun as a star and the Earth as a planet and Darwin's reclassifying human beings as animals. Tree switching involves changing the organizing principle of the taxonomic tree, a more radical change, and is illustrated by Lavoisier's replacement of a phlogiston account of combustion by his new account in terms of oxygen. (For an account of such conceptual change based on Kuhn's later work, see Barker, Chen, and Andersen 2003.)

Business analyst Christensen (1997) does not mention Kuhn, but his distinction of two types of technologies and of technological innovation in the business world indirectly challenges Kuhn's claim that the mature sciences exhibit only one type of revolutionary scenario, for the distinction may apply to science as well. Christensen notes that well-established industry leaders who employ good business practices may nonetheless be subverted by smaller companies, an observation that is

suggestive for both the history of science and the history of technology. He distinguishes sustaining technologies from disruptive technologies. Leading companies normally pursue sustaining technologies, focusing their research and development on the improvement of established product lines. Sustaining technologies should not be considered the technological counterpart of Kuhnian normal science, however, for good companies deliberately seek innovation and the innovations can be revolutionary (consider the history of large aviation companies, for example). On the other hand, disruptive technologies need not involve breakthrough technology, only the clever assembly of "off the shelf" technology (e.g., the Sony Walkman and the personal computer). They are promoted by small, fringe companies and their scattered group of followers. Such technologies do not initially appear to threaten the large companies and their product lines. Applying these ideas to the history of science discloses many examples of once-peripheral practices that eventually overtake dominant ones without there necessarily being a direct clash, certainly not a logical one.

The usual association of scientific revolutions with major changes in the world picture is theory centered. While Kuhn (1962 §X) mentions this conception of revolutions, he also stressed the practices of the various scientific communities (Rouse 2003). Much of what scientists and other experts know is embodied in their subarticulate practices and in the "acquired similarity relations" that have shaped their cognitive faculties. In this view, a revolution alters the basic form of scientific community life and, accordingly, the basic form of human cognition. In the last quarter-century, there has been a turn away from theory-centered accounts to those emphasizing social practices, especially experimental ones (see Experiment). Here the emergence of a new technique, perhaps a practice built around a newly invented piece of equipment, can be called revolutionary in opening up new areas of inquiry, whether or not it refutes an established practice. (Note that Kuhnian paradigm replacements are not straightforward refutations either.) It is useful to speak of some developments as *revolutionary* without reifying them as *revolutions*.

Types and Characteristics of Revolutions

The following is a list of characteristics often attributed to scientific revolutions. The items overlap in various ways, and each is subject to qualification or outright challenge:

1. Revolutions achieve scientific change on a large scale.
2. Revolutions originate as major discoveries.
3. Revolutions are episodic and event-like, rather than states, standing conditions, or long-term tendencies.
4. Revolutions are relatively rapid—as in 'the Scientific Revolution' being used to designate an entire historical period and a corresponding field of historical study rather than a specific series of episodes (Hall 1954). Single revolutions do not last that long. Should not a revolution in the event sense occur on a human scale, within a human lifetime or less? Scientific and technological revolutions tend to take longer than political revolutions to achieve finality or even recognition, and it is often more difficult to decide when they are 'over.'
5. "Revolution" is normally a retrospective, success/achievement term, although 'revolutionary' is not, especially when applied to persons rather than events. There cannot be a failed revolution, but there can be failed revolutionaries and failed revolts. Sociologists and social historians conclude that being a revolution is not intrinsic to a change or process: It must be *socially* recognized as such. Social attribution is crucial (Schaffer 1994).
6. Each revolution is unique. Oliver Wendell Holmes, Jr. ([1861] 2001) once remarked, "Revolutions do not follow precedents nor furnish them," in which case historical and philosophical understanding of revolutions becomes still more difficult. Barker et al. (2003) contend that revolutions can occur slowly and can have important characteristics in common with each other.
7. Revolutions are highly innovative. They are not direct applications or simple adaptations of precedents.
8. Revolutions create fundamentally new worldviews or practical forms of life. Recent science writers have sometimes used the metaphor of creation, e.g., Crease and Mann (1996) and Judson (1979).
9. Revolutions are convulsive and subversive and, accordingly, meet strong resistance. They involve revolts against an established orthodoxy, violations of received dogmas and procedures. This view rejects the "free expansion" model of revolution as a rapid and unhindered advance into new territory. 'Revolution' is increasingly used in this latter sense today.

10. Revolutions are divergent and radical, while evolution is convergent and conservative. Revolutions constitute breaks and discontinuities, and are hence incompatible with purely evolutionary accounts of scientific development. (Yet what process is more creative in the long run than biological evolution?)
11. Revolutions are breakouts from an old conceptual framework. This is an overly intellectual, theory-centered view that gives insufficient emphasis to revolutionary practices and technologies, including organizational technologies.
12. Revolutions involve replacements rather than reductions of the previous scheme. This was the claim of Feyerabend and Kuhn against the logical empiricists and Popperians. Moreover, not all replacements are refutations.
13. Revolutions are paradigm changes or ''paradigm shifts,'' in Kuhn's sense.
14. Revolutions require incommensurability between the new and old programs. They create considerable cognitive dissonance, mutual incomprehension, and discomfort. This is the feature that Kuhn and Feyerabend always emphasized.
15. Revolutions involve reconceptualizing already familiar materials and practices (especially the constitutive principles and practices that define the paradigm) rather than introducing substantially new empirical content. Koyré and Kuhn tended to favor this characterization.
16. Revolutions are intrinsically social, not individual.
17. Revolutions involve a reorganization of scientists' cognitive representations, habits of mind, or similarity metrics, e.g., through the adoption of transformed taxonomies (Kuhn 1962 and 2000).
18. Revolutions are not mere changes in the content claims of a scientific field, however radical, for revolutions also transform goals, standards, and methods.
19. Revolutions alter the administrative and economic landscape of the field—for instance, by reorganizing the governing institutions and organs of science. Hacking (1983) contends that major scientific revolutions couple major changes in content with institutional changes. The Scientific Revolution was accompanied by the emergence of many new scientific societies and their publications. The nineteenth-century probabilistic revolution was accompanied by the appearance of government social statistics bureaus.
20. Revolutions involve the emergence of new fields or specialty areas or the splitting of a field into separate disciplines.
21. Fully genuine scientific revolutions produce a proliferation of new results across several scientific fields.
22. Fully genuine scientific revolutions change one's understanding of the universe and one's place in it and thereby challenge wider cultural values. Kuhn's technical concept of revolution denies that this feature is necessary.
23. Revolutions are nonlinearities in scientific development, including not only discontinuities but also exponential spurts, either temporal or logical (as when a relatively compact development has immensely fertile consequences). In this respect, revolutions are ''chaotic'' and unpredictable. People do not know in advance where a revolution will take them. This is a ''consequentialist'' interpretation of revolution and conflicts with the more ''generative'' views espoused by Cohen. The nonlinearity of revolutions is highlighted by Margolis's (1993) account of barriers, for what removes a cognitive barrier to revolution may be a development far-removed from the center of the scientific action.
24. Revolutions are progressive. (Kuhn and Feyerabend denied this in the sense of progress toward a predetermined truth.)

Given the multiplicity of criteria that may come into play, there need be no opposition between revolution and rapid evolution. The closer one looks at revolutionary episodes and the more carefully one explores the contextual sources of the ''revolutionary'' work (especially noting those that lie outside the field as it was previously constituted), the more numerous and relatively smaller the individual transitional steps become, however rapidly they may have progressed. Evolution is capable of producing revolutionary changes when plotted against a more course-grained timescale. One is tempted to label ''revolutionary'' any development that yields extremely fertile practices, whether or not these consequences were immediately apparent and whether or not they were subversive of an entrenched orthodoxy. Yet, less fertile but rapid developments also appear revolutionary. Again, it is partly a question of scale, of getting a large output from a small input.

The Wider Importance of the Debate about Scientific Revolution

The discussion of scientific revolutions and the attendant concepts of paradigm, conceptual scheme, and incommensurability have enjoyed wide influence within general philosophy and popular culture. Kuhn's distinction of normal from revolutionary science and his rejection of traditional conceptions of realism, rationality, and objectivity have been one resource for recent feminist movements and other postmodern cultural developments. Controversies over scientific revolutions also fuel the large debate over realism and social construction within philosophy and sociology of science—the so-called "science wars" (see Social Constructionism). Kuhn's historical Kantianism raises once again central issues concerning the nature of human cognition and one's epistemic relations to reality. For example, Rorty (1979 and 1991) makes substantial use of Kuhnian distinctions. MacIntyre (1980) brings them into the moral sphere. Scientific revolutions inform the work of Quine (1953) and Davidson (1984) on radical translation and radical interpretation. Davidson, for example, rejects the dualism of scheme and content as a "third dogma of empiricism."

There is no coherent, agreed-upon concept of scientific revolution. Accordingly, many science studies practitioners, including some philosophers of science, avoid the term as problematic; but others find it essential for accounts of the development of modern science.

SCIENTIFIC STYLE

The term 'scientific style' has been used in a number of different ways, but with a characteristic strand of interconnected concepts and connotations: historicity, worldview, world picture, *Zeitgeist*, artistic style, thought collective, thought style, episteme, conceptual schemes, paradigms, themata, pluralism, relativism, and unity and disunity of science.

In the footsteps of Kant's idealist philosophy, German culture made central the notions of worldview or world conception (*Weltanschauung*) and world picture (*Weltbild*), which emphasized an overall unified conception of meaningful life involving cognition, emotion, and volition. It had individual as well as cultural and social connotations. In particular, it stressed culture, history, and the expression of values. For instance, Windelband's (1891) *History of Philosophy* was devoted to the study of individual worldviews. Galileo is mentioned as the spearhead of the "scientific world view" based on the mathematization of nature. The priority of meaning and values in historical method raised the question of the objectivity of the worldviews and of the social sciences in general, and in *Theory of World Views*, Dilthey ([1911] 1931) extended the use of the notion of worldview beyond philosophy, to religion and art. Since the early 1880s his approach to the historical sciences included the study of cultural phenomena in terms of typology, development, and environment.

The pursuit of a unified scientific worldview or world picture became central to German-speaking scientists from Mach and Planck (protagonists of a heated debate about the true physical world picture at the turn of the twentieth century) to Einstein. In more philosophical quarters, however, the emphasis was on plurality and history. In the 1920s Mannheim ([1929] 1936) introduced the term 'thought style' (*Denkstil*). He emphasized the historical-social nature of worldviews, associated with particular groups, and how this nature determined their subject mater, ways of setting problems, and conceptual apparatus. Thought styles, like worldviews, are radically perspectival and historical. According to Mannheim, their irreducible value-ladenness forces on the social sciences a new

kind of objectivity based not on their elimination but on their critical awareness and control.

In the mid-1930s, in response to a sense of European intellectual crisis, Husserl, Heidegger, and Cassirer wrote about Galileo, revisiting what they considered the birth of modern civilization, linked to the rise of science. For Heidegger, Galileo inaugurated the exploration of the world predetermined by the mathematical. Husserl had read Windelband and referred to Galileo's scientific worldview already in the 1910s. For Husserl ([1936] 1970) the scientific worldview, the mathematization of nature, revealed the ideal essences of perceived things, but it was not the whole truth of the life-world and had be rooted in the subjective. For Cassirer (1937), Galileo's "universal style" constituted a system of symbolic forms—like those of art and religion—and reflected the ideal that the human mind was adequate to all of nature.

Also in the mid-1930s, Fleck ([1935] 1979) published the first monograph devoted to the examination of scientific *styles*, in this case applied to medicine. For Fleck it was a means of historicizing science itself, of discussing scientific change, and of doing so from a social perspective, namely, that of the "thought collective" (*Denkkollecktiv*). This approach stood in sharp contrast to Popper's (1935) unifying and demarcating emphasis on the autonomous logic of scientific method expressed in his *Logic of Scientific Discovery*. Fleck explicitly contrasted his ideas to Carnap's early notion of unified science based on ultimate elements of direct experience. A style is characterized by common features in the problems of interest to a thought collective, by the judgments that the thought collective considers evident, and by the methods that it applies as a means of cognition. It constrains individuals by determining what cannot be thought in any other way. (Fleck drew an analogy to perceptual *Gestalts*.) In this way facts can be both socially determined and factual or objective.

Toulmin (1961) argues that the style of theory and interpretation determines the terms in which one formulates the questions that are asked with provisional theories and in which one is answered with experiments. Holton (1973) speaks, by analogy with art, of scientific styles and links the stylistic commitments of a scientist with themata, preconceptions that drive theoretical and experimental work. Like many stylistic categories in art history, many themata come in opposite pairs, and, like artistic commitments, they may have characteristically aesthetic dimensions such as symmetry or simplicity. One such themata is a unified world picture or worldview, which Holton traces in Einstein's work.

Wisan (1981) has seen in Galileo's works the emergence of a new scientific style. She has developed the point by introducing an internalist analysis of the concept of scientific style by explicit analogy with the role and understanding of style in art history, especially in Wölfflin's ([1915] 1950) formalist approach. This allows her to make sense of scientific change by sorting out both innovations and continuities. Her notion of scientific style is characterized in terms of structure, content, techniques, and expressive quality. Thus, for instance, she distinguishes between Aristotle's and Galileo's treatments of motion, respectively: discursive and classificatory versus geometric and axiomatic; definitions of fundamental concepts versus unified treatment of local motions; logical analysis and explication of concepts versus geometrical derivations of mathematical consequences; substance and essence versus mathematico-physical magnitudes.

The most fully developed treatment and application of the notion of scientific style came subsequently in Crombie's (1993) *Styles of Scientific Thinking in the European Tradition*. Crombie introduces an externalistic notion of scientific style that provides a comparative intellectual anthropology of science and requires an interdisciplinary approach. This view notably contrasts with an emphasis on the logic of a unified scientific method. Crombie's notion of style is characterized by the following kinds of commitments: conceptions of nature within the general scheme of existence and its knowability by humans; conceptions of science and of the organization of scientific inquiry, argument, and explanation; a vision of what is desirable and possible in view of evaluations of nature, purpose, and circumstances of human life; and a commitment to the physical and biological environment in which humans find themselves (even if it is to change it). Crombie suggests six main styles:

(i) the Greeks' axiomatic method—the search for postulates and principles from which phenomena could be demonstrated (e.g., Euclid);
(ii) the medieval logic of experiment—the search for control and explanation of regularities (e.g., Bacon);
(iii) hypothetical argument and models—the search for analogies (e.g., Harvey);
(iv) taxonomical ordering of variety by comparison—classifications might also reveal causes (e.g., Linnaeus);
(v) probabilistic and statistical analysis of events and populations—the search for stability of chance and uncertainty in numerical regularities (e.g., Maxwell); and

(vi) historical derivation of genetic development (e.g., Darwin).

Hacking's (1985) influential concept of style of scientific reasoning originates from Crombie's and Hacking's own work on the preconditions for the emergence of probabilistic thinking, influenced by Foucault's archaeology of knowledge—a historicized Kantian epistemology of worldview-like epistemes. These preconditions included a transformation of the medieval notion of opinion into a concept of internal evidence. The new concept opened a space for theories of probability that enabled the possibility of thinking about inductive logic, statistical inference, and some interpretations of quantum mechanics. For Hacking (1985), a style of reasoning constitutes a space of intelligibility and objectivity, the precondition for truth and falsehood, prior to the truth of propositions. For instance, the proposition "Mercury salve is good for syphilis because mercury is signed by the planet Mercury, which signs the marketplace, where syphilis is contracted" is a candidate for truth-or-falsehood determination only within a style of reasoning central to the Renaissance based on the concepts of resemblance and similitude. Hacking contrasts his notion of style with Quine's (Quine and Ullian 1970) web of beliefs and Davidson's (1974) conceptual schemes, which deal only with truth; with Kuhn's (1962) paradigms, which are not cumulative and depend on specific exemplary items of knowledge; and also with logic, which deals only with truth preservation. For Hacking (1985), the historicity, pluralism, and constructive aspects of styles of reasoning do not undermine the notions of objectivity and rationality, but they do provide a model of the disunity of science (Galison and Stump 1996).

JOHN SEARLE

(31 July 1932–)

John Searle was educated at the University of Wisconsin and at Oxford University as a Rhodes Scholar. His Ph.D. was directed by Peter Geach. For almost all of his professional career, he has taught at the University of California at Berkeley, where he is Mills Professor of Philosophy.

Searle has developed sophisticated and interlocking theories of language, mind, and social reality. These theories are held together by a realist metaphysics and a correspondence theory of truth. Primarily, he has contributed to the philosophy of science (i) a criticism of the dominant project of cognitive science, (ii) a theory of the structure of consciousness, which he thinks should guide or at least constrain cognitive science, and (iii) a theory of the nature of intentionality. Although this article will focus on these three issues, it is necessary to begin by saying something about his philosophy of language, because, like many twentieth-century philosophers, he has to a large extent read off the structure of the mind from the structure of language. Once his philosophy of language is explained, his other views relevant to the philosophy of science will be explained in reverse order.

The Structure of Speech Acts

Following J. L. Austin, Searle claims that the basic unit of language is the speech act. The most explicit kind of speech acts are those that Austin referred to as explicit performatives or illocutionary acts, such as those that typically would be performed by saying, for example, "I state that Ava will be at the party," "I promise that Ava will be at the party," "I ask, you, Ava, to be at the party." Searle points out that as indicated by the grammatical structures of these sentences, the speech acts are helpfully divided into two parts. First, each has the same content, in expressing the proposition that Ava will be at the party. Second, each of the relevant propositions performed by these sentences differs with respect to the force with which each proposition is expressed: stating, promising, and asking, respectively.

Most of the utterances used to perform speech acts are not as explicit as the ones in the examples above. In the right circumstances a person may utter an expression that indicates just part of the proposition or the force and still succeed in communicating the entire thought by relying on the hearer's knowledge of the context, for example "[I request that you close] the door," "[I order you to] leave!," "I insist [that you leave now]," respectively.

As regards the analysis of specific explicit, nondefective speech acts, several fairly sharp types of conditions are detectable. For the following (simplified) analysis of nondefective promising, the various kinds of conditions are italicized:

A speaker S, in uttering a sentence T, promises an addressee H that S will perform an action A only if
Preparatory: it is not obvious in the normal course of events that S will do A; and H wants S to do A.
Sincerity: S intends that S will do A.
Propositional content: A is a future action.
Essential: S and H recognize that in uttering T, S incurs an obligation to do A, and S and H recognize that the other recognizes this.

Speech Acts and Intentionality

Searle's theory of speech acts has obvious connections with mental phenomena. The sincerity condition is always some mental state—for example, intending for promising, believing for stating, and desiring for commanding or requesting. Mental states, like speech acts, usually have propositional contents (e.g., intending that one will paint the house). Some essential conditions are connected with mental phenomena too; for example, an apology is an expression of sorrow, and a congratulation is an expression of joy.

Some general features of speech acts that also indicate a relation to mental states can be codified in four dimensions: (1) illocutionary point (purpose), (2) the direction of fit between the words and the world, (3) the type of sincerity, and (4) the propositional content; and some of these have correlates in mental phenomena (see Table 1).

Table 1 Major features of speech acts

	Illocutionary point	Direction of fit	Sincerity	Propositional content
Assertives or representatives	Commits S to truth of proposition	Word to world	Belief	Unrestricted
Directives	Commits H to do A	World to word	Wanting	H does A
Commissives	Commits S to do A	World to word	Intention	S does A
Expressives	Expression of attitude	None	Some psychological state	S or H (expand) + property
Declarations	"Declarational attitude"	Word to world	None	Some state of affairs

Assertives and beliefs have word-to-world direction of fit; both are supposed to match the way the world is. In contrast, directive and desires (or wants) have world-to-word direction of fit, as do commissives and intentions. Concerning the sincerity condition, only declarations do not have some requisite mental state. For assertives, it is belief; for directives, it is wanting or desiring; for commissives, it is intending; and for expressives, it is some pro or negative state, such as joy, anger, or resentment. Further, the four types of speech acts just mentioned and their correlative psychological states have the same propositional contents. To state that p is to believe that p, and to command that a hearer do an action A is to desire that the hearer do A.

Given these and other correspondences between language and mental phenomena, one might ask which, if either, is more basic. Some philosophers hold that language is more basic than the psychological states it expresses, because the states are made possible by the language used to describe them. Roughly, people posit the existence of psychological states in order to explain the behavior of people, and by extension some other creatures, mostly vertebrates. Psychological states and events are entities of a primitive scientific hypothesis. (It is this view that inclines some philosophers to hold that beliefs do not really exist; that is, beliefs are parts of primitive hypotheses that neurological science may show are as much a fiction as bodily humors.) In contrast, Searle thinks the opposite is the case. In his terminology, psychological phenomena have *intrinsic intentionality* (see Intentionality), by which Searle means "that feature of the mind by which mental states are directed at, or are about or of, or refer to, or aim at, states of affairs in the world" (Searle 1998, 64–65). Like force, mass, and gravitational attraction, things that are intrinsically intentional are such independently of any community of observers. It is internal to an intentional experience that it seems to be about something. Some things, notably language, have "derived intentionality." Individual words and sentences are directed at or are about things in the world because people intend them to be so. Sentences mean things because people have psychological states that are expressed by the sentences. Searle's criticism of one form of artificial intelligence, to be discussed below, turns on the claim that computers have only derived intentionality. Computer states and their output mean things only because people take those states to mean those things.

The priority of psychological phenomena over linguistic phenomena is intimately related to another property shared by speech acts and mental phenomena. Just as statements can be true, so can beliefs. Just as promises can be kept, intentions can be fulfilled. Just as directives can be obeyed, desires can be satisfied. In general, illocutionary acts and psychological states alike have conditions of satisfaction: "An intentional state is satisfied if the world is the way it is represented by the intentional state as being" (Searle 1998, 103). A belief is false, an intention is not fulfilled, a desire is not satisfied, and so on when their conditions of satisfaction do not obtain.

Although there is a connection between basic kinds of illocutionary acts with belief and desire, they are not the primary forms of intentionality. Perception and action are. At the heart of these two concepts is that of having intentional causation in their conditions of satisfaction. When a person sees something, the object causes the seeing, and the seeing represents (or, perhaps, better, presents) to the person what is seen. When a person raises an arm (in Gödel-Lob [GL] logic), the person's intention to raise it causes the arm to go up, and that intention contains a representation of that action. In short, perception and action involve both a causal and an intentional aspect, and they need to work together. If they did not work together, human survival would be impossible. Intentional causation is quite different from Humean causation, which consists of regular, contiguous conjunctions of events. It is essential to intentional causation for the cause to be a representation of the effect or the effect to be a representation of the cause. If a person drinks water as a way of satisfying (GL) thirst, then that person's (GL) mental state, that is, the desire the person drink water, causes it to be the case that she drinks water. The desire both causes and represents its condition of satisfaction. As regards intended actions, in contrast with accidental or mistaken actions, intentions form part of the conditions of satisfaction. A person who raises an arm must intend that the arm go up and that the arm's going up be caused by the intention that it go up. Actions are causally self-referential.

This causal self-referentiality also applies to perception. For someone to see something—say, a tree—that very tree must cause the visual experience of seeing it. The same holds for memory. If someone remembers playing tennis at Wimbledon, then the remembered event of playing tennis at Wimbledon must cause the memory. The causally self-referential components of seeing and remembering

Table 2 Components of international states and actions

	Seeing	Believing	Acting	Remembering
Intentional component	Visual experience	Belief	Experience of acting	Memory
Presentation or representation	Presentation	Representation	Presentation	Representation
Causally self-referential	Yes	No	Yes	Yes
Direction of fit	Mind to world	Mind to world	World to mind	Mind to world
Direction of causation	World to mind	World to mind	Mind to world	World to mind

form part of the conditions of representation of these phenomena.

As this discussion of acting, perceiving, and remembering suggests, the concept of direction of fit applies to them just as it applies to various categories of illocutionary acts. Since one's visual experience needs to fit the world, seeing has mind-to-world direction of fit; and since one tries to make the world satisfy one's desire, action has the world-to-mind direction of fit.

The various components of seeing (an instance of perceiving), believing, acting, and remembering are summarized in Table 2.

As explained thus far, it may appear that Searle has an atomistic view of mental phenomena. But that would be a misimpression. All mental phenomena take place against a backdrop of pre-intentional "capacities, abilities, tendencies, habits, dispositions, ... and 'know-how'" (Searle 1998, 107–108) and within a network of beliefs, desires, memories, and so on. Among other things the network explains what makes a particular perception a perception of some object well known to the perceiver. One of the conditions of satisfaction for seeing a familiar object is that the object causing the visual experience be a particular object that occurs as part of the conditions of satisfaction of memories in the network.

The Structure of Consciousness

Acting, perceiving, believing, and desiring are so pervasive and salient that one might ignore the fact that each requires consciousness, at least in the basic cases (see Consciousness). Paradigmatic cases of acting, perceiving, believing, and desiring are conscious. When consciousness is not explicitly present, it must be theoretically possible for the mental state to be able to become conscious. A large literature has recently sprouted about zombies, beings that are functionally like humans, but nonconscious. Searle thinks such views are absurd or dangerously misleading. As a matter of biological fact, one cannot have seeing or acting without consciousness: "In real life you cannot subtract the consciousness and keep the behavior....[W]e only understand intentionality in terms of consciousness" (Searle 1998, 63–65).

Searle uses the point that that every mental state must be theoretically or potentially conscious to criticize Noam Chomsky's claim that humans follow rules of universal grammar even though these rules are not conscious (see Chomsky, Noam). According to Searle, Chomsky's view is incoherent because he does not say what feature of these rules makes them mental rather than purely physical brain states. An even more important application of this point concerns Searle's criticism of a dominant understanding of cognitive science, as seen below.

Consider now the structural features of consciousness itself. Although Searle identifies ten features of consciousness, they may be discussed under five categories, or features.

The first is that consciousness is *ontologically subjective.* It exists only "as experienced by an agent" (Searle 1998, 73). Some contemporary philosophers want to deny this because it does not seem to fit into their world. Being physicalists, they must also be materialists. They want to avoid anything like Cartesian dualism. Searle fights against this conflation of the physical and the mental, and maintains that commitment to both the mental and the nonmental does not necessitate a commitment to dualism. For him, consciousness is just as real as material objects; but it has a first-person (subjective) ontology, in contrast with the third-person (objective) ontology of the things usually studied by natural science.

The second feature of consciousness is its unity. The various instances of awareness that a person has at one time of sight, sound, smell, thought, and so on are part of one experience. This might be called "vertical unity," and it exists at any instant. Consciousness is unified in another way: across time. Consciousness would not be coherent if there were no short-term memory. Searle calls this "horizontal unity." It is tempting to think that the unity of consciousness is achieved by hooking together discrete mental states, that unity is the result

of binding distinct elements. But Searle thinks that consciousness by its nature has a unity, and the various "contents" of consciousness are better understood as modifications of consciousness. Searle uses the metaphor of a field: "[We should] think of consciousness ... as a vast field, and think of the particular percepts, thoughts, experiences, and so on, as variations and modifications in the structure of the field" (Searle 1998, 82). Related to the unity of consciousness is the fact that experiences are normally structured. The mechanisms underlying this cause one to see a few lines as a human face or a sequence of stationary flashing lights as moving.

The third feature of consciousness connects a person to the external world (GL) in two ways: cognitive and volitive. People represent the way the world is and how they would like the world to be. Their orientation to the world is always colored in some way. People are always in some dominant mood or other that affects how things get experienced. What might cause anger in one mood might cause bemusement in another. People recognize that they are sometimes in good moods or bad moods; indeed all conscious states are "pleasurable or unpleasurable to some degree" (Searle 1998, 80). For the most part, it is difficult or impossible to describe precisely quotidian moods.

A fourth feature is that there are degrees of conscious attention, which again is in two dimensions. A person may be more or less attentive to the main focus of consciousness, say, a lecture; and a person is more attentive to that main focus than to what is peripheral. Thus, one might be paying much attention to a lecture and also be paying a little attention to the squirming child to the left.

The fifth feature seems to be closely related to Searle's idea of the network: the connectedness of all experience. People typically have a sense of their own situatedness: where they are roughly in space and time, what season of the year it is, what city and country one is in. It would be hard, if not impossible, to understand anything if one did not have some idea of where one was in space and time. Also, experiences come in varying degrees of familiarity. Entering a building, one has a sense for the kind of building it is, the kinds of facilities it will have, and where some of them are likely to be. Even otherwise strange places have their own familiarity. One would not expect to come upon a ski lodge in a jungle. A person who currently sees only the cover of a book expects to have certain tactile sensations if the person touches it; and if one opens it, one expects it to open to pages with print. Some gag gifts are "books" with provocative titles consisting of one hundred or more blank pages.

The Critique of Strong Artificial Intelligence

One of the merits of Searle's view is the fact that it accommodates both common sense and the scientific view of things. Mind is not the same as body; but mental phenomena cause, are caused by, and are realized in brain states. Consciousness is to the brain as solidity or liquidity is to molecules. One thing that guarantees the irreducibility of the mental is its place within a level of description that does not normally include talk about brain cells. It is also guaranteed, according to Searle, by the fact that consciousness, the qualitative experience of sights, sounds, and smells, is real. It is ontologically subjective but nonetheless a part of the physical world and must be explained. Comparing consciousness to the working of a four-cycle internal combustion cylinder, he says that, at the macro level of discourses, it is appropriate to talk about the spark plug firing and the explosion of the gas in the cylinder. At the micro level, the concepts of firing and exploding have no place, but "oxidation of individual hydrocarbon molecules" does. Both are causal accounts. Similarly, at the macro level it is appropriate to talk of consciousness and thinking, even though it is not appropriate at the micro level. Searle did not appreciate how central the ineliminability of consciousness was to his critique, and he rarely mentions consciousness (Searle 1980). This changed in his later publications: "The common sense objection to strong AI [artificial intelligence] was simply that the computational model of the mind left out the crucial things about the mind such as consciousness" (Searle 1992b, 45; 1998, 98).

Searle distinguishes between strong AI and weak AI. Strong AI is the view that "brain processes (and mental processes) can be simulated computationally" (Searle 1992b, 201–202). The hardware of the mind is unimportant. It could be carbon-based brain cells, as in human beings; but it could just as easily be silicon chips, vacuum tubes, water tubes, or even appropriately trained cats and dogs. What is important to being a mind, according to strong AI, is that the machinery instantiate a computer program. To do this is to think or to understand or to have desires and intentions. An appropriately programmed computer is a mind. Consequently, to understand what computer programs are is to understand what mental phenomena are.

Searle thinks that strong AI is false. In order to refute it, he constructs the following (simplified) thought experiment. Suppose that a person *C* who does not know Chinese is locked in a room and given a book, written in *C*'s native language, that correlates Chinese characters in one column with

Chinese characters in another. The book includes the instructions that when a slip of paper is passed through a slot in the room, *C* looks up the characters written on it in the book, finds their correlates, chooses another slip of paper that has the correlates written on it, and passes it back through the slot. Further suppose that *C* is so good at this operation that people outside the room who do not know what goes on inside the room would have good evidence for thinking that someone or something inside the room knows Chinese. From the external point of view, the paper output is functionally no different from what one would expect of someone or something that knows Chinese.

On this, Searle and Chomsky are on the same side. Searle now makes two observations: What *C* is doing in the room is essentially what a computer does; and *C* obviously does not understand or know Chinese. It follows that computers do not understand or know languages. QED.

One difference between Searle's original thought experiment and the rendition of it just given is that instead of talking about *C,* Searle describes the scenario in the first person: "Suppose that I'm locked in a room," etc. Searle wants readers to put themselves in the position of the person in the room. It is the reader who is looking up the characters in the instruction book and then choosing the appropriate output. The reader has a privileged perspective on what the reader knows. Further, since there is no other person or thing connected with the room that plausibly knows Chinese, the reader seems justified in concluding that instantiating a computer program is not sufficient for knowing a language, or anything else. The basis for the readers' belief that they do not know Chinese is their recognition that they do not know it.

Searle maintains that various mistakes in cognitive science, not to mention the philosophy of language, result from taking the third-person point of view, either because one thinks that that is the only scientific way to study anything or because there is no genuine first-person point of view, the latter being either epiphenomenal or an illusion. In contrast, Searle believes that the first-person perspective is not just a legitimate one but is a privileged perspective for judging what a person knows. As he says: "Remember, in these discussions, always insist on the first person point of view" (Searle 1980, 451).

In the original debate, neither Searle nor his critics called attention to the role of consciousness in this thought experiment. For all of them, the main issue was put in terms of what a computer could know and whether one could think. It is plausible that an important source of the impasse between them was a disagreement about the criteria for thinking and knowing. Searle implicitly thought that consciousness was a necessary condition for thinking. The proponents of artificial intelligence maintained that satisfying a functional or behavioral criterion was sufficient for thinking. This was why they appealed to the Turing test.

Someone trying to mediate the dispute between Searle and his opponents might suggest that the proponents of strong AI concede to Searle that computers today and for the foreseeable future will not be conscious, and that Searle concede to the proponents of strong AI the behavioral criteria they want for words like 'think' and 'know' as applied to computers. In this proposal, the different criteria applied to humans and computers would be analogous to the varying criteria that are applied to the word 'strong' in relation to humans and elephants.

At least some proponents of strong AI would probably reject the proposal, either because they think that consciousness is an illusion, so to speak, or because they think that consciousness emerges from the complex computations that would be performed by *C.* The consciousness might not attach to *C* exactly, but to the room and contents as a whole. This is the "systems" objection to the Chinese-room scenario.

However, Searle would probably reject the proposal because he thinks that the behavioral criterion suggested for thinking is so far from capturing what is essential to thinking and knowing that it changes the meaning of 'think' and 'know.' In addition to the point that thinking depends on consciousness, Searle says that thinking is intrinsically intentional, while computer states are not. The physical states or outputs of computers have derivative intentionality, as language does. What goes on within a computer are purely formal or purely syntactic operations. Therefore, the computer states are not intrinsically semantic; they are not intrinsically about anything in the world. Human beings, however, can interpret or assign a meaning to the various states or outputs of the computer, just as they do for linguistic signs. In other words, "the characterization of a [computer] process as computational . . . is essentially an observer-relative characterization. . . . It requires the assignment of a computational interpretation by some agent" (Searle 1992b, 210–211). A computer has nothing inside it that has direction of fit, propositional content, or conditions of satisfaction.

Searle's thought experiment was opposed by most cognitive scientists. Among the many objections

advanced, two are important. According to the systems objection, it is not *C* who is supposed to understand; *C* is just the central processor; rather, what understands Chinese is the entire system, which includes *C*'s ledger with the rules of correlation and *C*'s calculations. Consequently, the fact that *C* recognizes that one does not know Chinese is not decisive. Searle's reply aims to show that even when all the aspects of the system are considered together, it is obvious that nothing in or about the room knows Chinese. Suppose that everything in and about the room is put into the head of *C*, including the information in the ledger. *C* would still know that she does not understand Chinese, says Searle. Hence, no system relevant to the room understands Chinese.

The other main objection to Searle's thought experiment is the "robot" objection. The reason *C* does not understand Chinese is that one lacks substantive causal interaction with the world outside the room. *C* would know Chinese if one interacted with one's environment. According to the robot objection, if *C* can observe what is outside via a television camera and if one can move the room from place to place, say, on wheels, if *C* can manipulate objects in the environment, with armlike devices, and if *C* can do all of this in virtue of the Chinese instructions that enter the room and then get decoded via the rules in the ledger, then *C* knows Chinese. In fact, *C* is no longer needed at all. Let *C* be a computer that causes things to happen in virtue of the machinery just described. In such a case, the computer in the room would understand Chinese and have other mental states. The proponent of strong AI may then observe that a human being is just like the robot, except that a brain stands in for a computer, eyes for the television camera, and so on (Searle 1980, 420.)

Searle's response to the robot objection in effect consists of two parts. The first concerns the case in which *C* is hooked up with cameras, wheels, and levers. Searle observes that in this case *C* is starting to learn Chinese. When *C* learns from the (GL) rule book that *C* is to grab a salt shaker and pass it to someone viewed on the television screen, *C* is giving a semantic content to the previous purely formal or syntactic elements, and hence taking a step toward language comprehension. But this case is very different from the original one in which *C* was manipulating purely formal elements. The second part of Searle's reply concerns the allegation that the human (in a human body) is like a computer (in a robot). Searle does not deny that machines think. Indeed, he claims that only machines think. (Humans are machines.) Rather, he claims that it is a matter of physical fact about this world that the carbon-based structures of the brain are such that their specific composition gives rise to consciousness, and the silicon-based structures of a computer do not. Searle is not saying that no other kind of material in this world could also cause consciousness. In some solar system of some galaxy in the universe there may be conscious creatures who have a very different physical composition. Similarly, he is not saying that no silicon-based machine of a different design and complexity could not give rise to consciousness. But in this world, given their current composition and mechanisms, computers do not think.

Searle's critique of strong AI has the consequence that cognitive science should abandon the idea that computer programs are accurately representing either mental or neurological processes. His views about the structures of consciousness, identified by taking the first-person point of view, constrain any adequate study of consciousness and intelligence.

SOCIAL CONSTRUCTIONISM

The first use of the words 'social construction' to signal a theoretical orientation was by Peter Berger and Thomas Luckmann (1966), in their book *The Social Construction of Reality*. Berger and Luckmann argued that "constructed" social reality is an empirically tractable domain; an objective world of a different order than the world of natural science. They did not question the objectivity of either natural or social reality, but instead attempted to develop a distinctive theoretical approach to the latter. They drew upon phenomenology (particularly Alfred Schutz's [1972] phenomenology of the social world) but adapted it to a more conventional form of social explanation. Unlike Schutz, Berger and Luckmann did not attempt to explicate the life-world from the standpoint of a typified member. They used the word 'construction' as an Americanized and sociologized variant of the phenomenological notion of "constitution" (an acausal coordination of intentional acts and intentional objects), and they reverted to a more familiar form of structural theory, using a historical overview from which to develop a general explanation of how subjective actions give rise to stable, externally constraining, and (for all practical purposes) objective institutions. Their account of institutions

combined a critique of positivism—arguing against one-sided views of social institutions as being "out there" in a world independent of human agency—with an empirical outlook that invited investigation of how such institutions become objectified.

Berger and Luckmann assumed that their genealogy of social institutions did not apply to natural regularities. Instead, their concept of social construction described the emergence of institutions from rituals, customs, and beliefs in particular historical circumstances. For Berger and Luckmann, the compulsive and constraining force of institutional reality is no less binding than natural laws, but this force inhabits a second-order reality of norms and evaluations—a reality that becomes second nature, entrenched in the actions of properly socialized members. Berger and Luckmann deemphasized ontology and made the point that members of particular cultures who lack cosmopolitan perspicacity are unlikely to recognize the difference between socially constructed institutions and natural realities, since both make up the unquestioned background of daily practice. Decades later, John Searle (1995), in *The Construction of Social Reality*—a title with an uncanny, although apparently unintentional, resemblance to its unacknowledged predecessor—took a far more explicit interest in drawing ontological distinctions. Searle articulated two distinct lessons about socially constructed realities: first, that "institutional facts" like the value of currency or the rules of chess are both *real* and essentially dependent upon the existence and maintenance of collective ideas and actions; and second, that such socially constructed realities differ essentially from "brute facts" like the height of Mount Everest or the double-helical structure of DNA. Contemporary social constructionism in the social sciences is distinguished by an irreverent stance toward that very distinction. Like Berger and Luckmann, Searle aimed to establish that constructed reality *is* real, albeit not in the same way as heights of mountains and structures of molecules. Contemporary constructionists take for granted that social constructions are real, and are more inclined to extend reality construction to cover geological measures and molecular structures.

The Diffusion of Constructionism

In the three decades between the publication of Berger and Luckmann's and Searle's essays on social construction, the theme of 'construction' became widespread in the humanities and social sciences. The term 'construction' assumed a life of its own independent of Berger and Luckmann's theory, which one could say describes the academic institutionalization of constructionism. Especially in the 1980s and 1990s, social and cultural construction became a central theme for a movement in the humanities and social sciences. An indication of how far the movement spread is a lengthy list compiled by Ian Hacking (1999, 1) of books with 'construction' in their titles. This list includes works on topics as diverse as scientific facts, illness, women refugees, and Zulu nationalism. The various constructions include culturally prevalent ideals and ideas, as well as more substantive institutional patterns and programs.

As Hacking points out, contemporary social constructionism has little affinity with cognate developments in earlier eras. The nineteenth-century mathematicians and early-twentieth-century artists sometimes called 'constructivists' tended to favor formalistic schemes and procedures. Today's social and cultural constructionists tend to take a skeptical or critical view of rules, algorithms, and other formal structures, emphasizing the interpretive flexibility of formalisms and stressing the role of locally situated actions. Hacking recommends that the term 'constructionism' be reserved for the recent movement, in order to distinguish it from unrelated forms of 'constructivism,' but both terms continue to be used interchangeably. He argues that social constructionists typically challenge conventional sensibilities by demonstrating that a phenomenon that *appears* to be natural, determinate, or inevitable (e.g., the natural basis of sexuality/gender, the medical status of one or another mental illness, the inevitable march of technological progress) is actually more flexible and less determined than usually imagined. Often combined with such arguments is a denunciation of the state of affairs held responsible for the construction. Such denunciations encourage efforts to reform the existing state of affairs by counteracting assumptions about their natural foundations and inevitability.

Hacking's inventory demonstrates the extent to which constructionist arguments depend upon *what* they take up for analysis. To successfully provoke interest and stir controversy, a constructionist study typically starts with a subject that is taken for granted or assumed to be inevitable (Hacking 1999, 12). The challenge for the study is to demonstrate how a condition that seems inevitable might have turned out differently, and might yet be changed through concerted social action. Some subjects (e.g., technological innovations) might seem unpromising for such an argument, because everyone already knows that they are

constructed. However, successful constructionist programs can frame the subject in an appropriate way—for example, by taking aim not at technology per se but at the *idea* that technological progress is governed by rational imperatives (Bijker, Hughes, and Pinch 1987). Now that the constructionist idiom has been adopted in one field of study after another, it has *diffused* in more ways than one. While constructionist programs can be found throughout the social sciences and humanities, and also in schools of business management, law, nursing, social work, and education, and even in corporate technology research centers, just what hangs on the idea of "construction" has become quite diffuse. Depending upon which corners of the constructionist universe one explores, it is possible to find accents of idealism, realism, historicism, pragmatism, functionalism, empiricism, and instrumentalism.

The Construction of Science

Perhaps the most provocative examples of constructionism are found in the field of science studies (a transdisciplinary field including historians, sociologists, anthropologists, and a few philosophers of science). Starting in the early 1970s and inspired by Thomas Kuhn's *Structure of Scientific Revolutions* ([1962] 1970), proponents of the strong program in the sociology of scientific knowledge (SSK) argued that even the most established scientific and mathematical truths were subject to "social" explanation. David Bloor (1976) and other proponents of the strong program did not call themselves constructionists, but their writings are frequently cited in connection with the genre. Two of the most influential and controversial proposals from the strong program were that a sociologist of knowledge should attempt to be *impartial* toward the beliefs studied and should give *symmetrical* explanations of why they are believed, regardless of their (alleged) truth or falsity, rationality or irrationality, or success or failure. A practical rationale for impartiality and symmetry is that a sociologist is unlikely to know which side in a scientific controversy is on the side of truth and rationality. In scientific controversies it often is the case that proponents on both sides explain their own views as consequences of correct procedure while charging their opponents with ignorance, irrationality, and vested interests. A sociologist is in a poor position to guarantee that one or another currently accepted scientific fact or law will continue to be held true for all time. In addition, consistent with a more general policy of methodological charity, a sociologist or anthropologist may want to suspend initial preconceptions about the rationality or irrationality of a belief system when seeking to explain the origins of that belief or understand why it is accepted. Symmetry and impartiality are methodological policies, but they are often confused with metaphysical positions that deny the possibility of having true knowledge, and the strong program is sometimes accused of treating all systems of belief indiscriminately, as equally valid.

The policies of symmetry and impartiality, and the attempt to explain scientific knowledge as socially caused belief—the hallmarks of the strong program—raise many conceptual and methodological problems, such as the apparent incongruity between relativism about nature and realism about society, the puzzling meaning and implications of the claim that "true" and "false" knowledge or belief can be explained in the same general way, and the confusion that results from adopting a general explanatory term ('construction') that is commonly used to dismiss empirical claims (Laudan 1981; Coulter 1989; Lynch 1993). However, Bloor and his colleagues do not deny truth, nor do they suggest that specific scientific results are untrue, irrational, or unsuccessful. Indeed, Barnes, Bloor, and Henry (1996) identify their position with realism.

The constructionist idiom became explicit with the publication of Latour and Woolgar's (1986) study of a biochemistry laboratory at Salk Institute in San Diego. The authors framed their study with the metaphor of an anthropologist studying an exotic tribe in which the natives share esoteric knowledge, speak (technical) dialects unintelligible to an outsider, and perform arcane rituals with strange apparatuses and sacrificial animals. Latour and Woolgar spoke of facts as anthropological constructions. They defined a fact as a statement of the form '*X* is *Y*' from which qualifications, references to circumstances, and grammatical markers of uncertainty have been deleted. The main case they examined was a successful effort to identify the molecular structure of a particular growth hormone (eventually awarded the Nobel Prize). Latour and Woolgar insisted that the scientists did not begin with the fact they eventually helped establish; instead, the scientists put forward a series of tentative, and often contested, "representations," which were defended against rival efforts to "deconstruct" them, and only after the controversy was settled was the fact endowed with transcendental status and stripped of any reference

to the uncertainties and contingencies that were conspicuous at earlier times. The genealogy of the "fact" placed it within a long chain of representations (in language, in literary inscriptions) at the end of which it became settled and took its place in nature.

Latour and Woolgar attempted to avoid the suggestion that the scientific fact they studied was *merely* a product of ideology, bias, or some other discrete "social" factor. To ward off the idea that they were making a straightforward sociological explanation, they went so far as to drop 'social' from the title of their book when they published a revised edition in 1986, so that the subtitle read *The Construction of Scientific Facts*.

Nevertheless, Latour and Woolgar (1986, 237) courted confusion by making provocative claims such as, "reality is the consequence, rather than the cause," of scientists' constructive activities. Alan Sokal (2001, 16), for example, interpreted the assertion as an ontological claim implying that natural reality does not preexist its discovery. However, the assertion becomes less provocative, and less absurd, when one understands Latour and Woolgar's genealogy of fact, *not* as a causal explanation, but as a semiotic analysis of the way scientists reformulate their factual accounts over time. It makes some sense to say that "reality" comes after (is a "consequence" of) a series of referential constructions if one maintains an agnostic attitude toward the ontological status of the "fact" in question and draws no distinction between the idioms of realistic reference and their ultimately "real" referents. The source of confusion is not necessarily on the side of naïve realist readers, however, since Latour and Woolgar's grammatical formulations often seem designed to provoke shock and confusion.

Other influential studies, such as Andrew Pickering's (1984) *Constructing Quarks*, adopted the constructionist idiom. Pickering employed a Kuhnian perspective (one that Kuhn did not personally endorse) to describe a revolution in late-twentieth-century particle physics. Although sometimes cast by critics as a simple causal story of external social and political influence on a scientific community, Pickering's narrative and those of other constructionists deploy more subtle arguments involving two distinct steps (see Collins 1985 for related arguments and case studies):

1. The constructionist invokes skeptical philosophical arguments and interprets them in a sociological manner, to say that the victorious theory was underdetermined by experimental evidence (see Underdetermination of Theories), that the experimental evidence was theory-laden (see Observation), and that no crucial test was responsible for the eventual victory of one of the rival research programs.
2. Having noted the lack of unequivocal evidence supporting the victorious theory, the constructionist examines the historical record for persistent disputes about particular experimental designs and interpretations. Then, when such disputes can be found (as they frequently are), the constructionist adduces evidence of distinct theoretical commitments and experimental styles, national divisions between research groups, vested interests, and other social and cultural orientations that may account for the alignment of key parties in the controversy.

The extension of constructionism to cover the "products" of the natural sciences and mathematics proved to be highly provocative and also rather confusing. In part, the confusion stemmed from the fact that the term 'construction' already had currency in the vernacular of science. It is commonplace, and noncontroversial, to speak of the construction of models, theories, and proofs. However, 'construction' and related expressions, such as 'artifact' and 'manufacture,' are fighting words in disputes about experimental results. When used in sociological explanations of particular episodes and general developments in science, such terms can seem to imply that specific results were concocted, or even that all scientific results are dubious. Whether such confusion is deliberately fostered by attention-seeking authors or results from naive misreadings of their arguments and descriptions remains an open question.

Constructionism became very influential in science-studies circles through the 1980s and 1990s and was an important part of a broader set of developments that included new professional societies, journals, and university science-studies programs. It would be grossly inaccurate to identify such developments with a single "school" or style of explanation, though constructionism was a major theme and topic of debate at the time. As an increasing number of social-historical and ethnographic case studies of science, technology, and medicine accumulated, it became common to cite the literature as evidence that traditional *idealized* versions of scientific method have been superseded by a developing empirical knowledge of a messy, uncertain, and contingent array of scientific practices. Critics occasionally pointed out that such empirical claims about *actual* science sat uneasily

with a relativistic stance toward natural reality. In addition to being subject to variants of the *tu quoque* argument against relativism, social constructionists were accused of political quietism and dismissed for their lack of "normativity." For many feminists, constructionism was a valuable tool for opposing objectivism and male privilege, but it did not go far enough in the directions they wished to take it (Harding 1996; Haraway 1991). The question of whether a "symmetrical" stance toward science is compatible with normative programs of feminist epistemology and other efforts to democratize scientific knowledge continues to be debated.

The Science Wars and After

Social constructionism became a focus during the "science wars" in the mid-1990s. Unlike the many criticisms of constructionist science studies that had occurred over the previous twenty years, those associated with the science wars were put forward by natural scientists. The indignant missives written by a few of these scientists reached a higher level of explicit hostility and attracted much wider attention than had previous criticisms in academic journals and interdisciplinary symposia. Not only did the critics charge social constructionists with philosophical relativism and take issue with particular historical interpretations, they lumped social and cultural studies of science together with "postmodernist" attacks on "truth" and with diverse anti-science and anti-modern movements (Gross and Levitt 1994). Though often billed as a conflict between science and anti-science, the science wars involved social and natural scientists on both sides.

The vociferous critics of constructionism included a fair number of social scientists, philosophers, and other scholars who took the opportunity to pursue disputes that had been going on for many years. In addition, a number of scientists and mathematicians (as well as many historians and sociologists of science with backgrounds in science and engineering) defended social and cultural studies from some of the attacks. Physicist Alan Sokal's (1996) "hoax" article, which appeared in the cultural studies journal *Social Text*, touched off a wave of publicity about the science wars. Sokal's article claimed amazing parallels between quantum gravity theory and postmodern literary theory. When Sokal acknowledged just after his article was published that it was complete nonsense, he purported to expose the ignorance of science and lack of standards in the cultural studies field. However, his target differed from the anti-science that Gross and Levitt denounced. Sokal took delight (as well as offense) in revealing an odd variant of scientism in the arcane critical writings of French intellectuals and their American exponents. It seemed that, like more common varieties of science popularizers and science emulators, famous French intellectuals also had a tendency to couch their ideas in garbled versions of quantum theory, Einstein's theory of relativity, and chaos theory. Sokal was accused of being unimaginative and uncharitable in his readings of the authors he criticized (Stolzenberg, 2001), but he did not charge science studies with general hostility toward science. If anything, he charged particular writers and their followings with idolatry——with taking the name of Einstein in vain.

If scientism is an illegitimate extension of science into metaphysics, then the charge of scientism cuts both ways. A few of the self-proclaimed defenders of Science and Reason (who used these categories in an abstract, quasi-religious way) who joined the attack against social and cultural studies of science were authors of controversial sociobiological explanations of human capacities and sexual preferences. Others, who worked in more credible fields of physics and biology, wrote articles and books in which they disavowed philosophy while at the same time advancing their own intuitive philosophies of science. Both critics of Western science and defenders of Science and Reason could be accused of confusing science *as practiced* in specific organizational and historical circumstances with Science as an idealized worldview. In any case, the specificity of constructionism tended to get lost in the fray. Constructionist studies characteristically focus on specific historical sequences and organizational circumstances, but the science wars invited much broader claims and sweeping arguments than could ever be documented with detailed historical or sociological studies. As a philosophical debate joined by very few philosophers—in which the scientists involved rarely referred to their own specialized research, and the social scientists rarely went into detail about their historical and ethnographic research—it was not surprising that the science wars ran out of steam after a few years. The dispute had started to wane by the late 1990s, as a few participants continued a less fractious dialogue about the claims and implications of social studies of science (Labinger and Collins 2001).

By now, largely as a result of the widespread adoption and abuse of constructionism, the ideas associated with the genre have become so diffuse that the word construction and the tropes associated with it have lost their meaning, as well as much of their former cachet. In science-studies circles, strident polemical efforts to rewrite "nature" as construction, or "discovery" as "invention" appear less frequently and provoke less interest than they once did. Latour and Pickering, who helped establish the constructionist idiom in social studies of science, now pursue postconstructionist attempts to re-introduce nonhuman sources of agency into their theoretical schemes (Pickering 1995; Latour 1999). More interesting, perhaps, are continuing efforts to trace how variants of the nature/society and science/nonscience distinctions are deployed in specific institutional settings with tangible practical, political, and legal consequences (Gieryn 2000).

It is tempting to think of constructionism as a coherent epistemology, roughly akin to classic idealism but with more emphasis on the constitutive roles of embodied practices, social alignments, and technological instruments. However, in its current incarnation, constructionism has become too diffuse to support a single philosophical perspective. Moreover, the orientation of many social-historical and ethnographic studies to particular settings, and the emphasis on the specificity of research in different fields, is not easily subsumed under a single theory of knowledge. Instead of being a coherent epistemology, constructionism might better be considered an approach to "epistemography" (Dear 2001): an empirical study of particular historical and institutional settings in which participants organize and deploy what counts, for them, as observation, experimental evidence, truth, and knowledge.

PHILOSOPHY OF THE SOCIAL SCIENCES

Social scientists study the group behavior of human beings. Philosophers of social science study the methods of inquiry and patterns of explanation appropriate for the social sciences. A perennial topic of interest to philosophers of social science is the question of how different the methodology of the social sciences should be from that of the natural sciences. Aristotle believed that final causes played a crucial role in the explanation of human behavior, whereas natural scientists need look for only efficient and material causes. At the beginning of the twentieth century there was a concerted attempt to naturalize the social sciences (see Unity of Science Movement). The debate about whether social science requires a special form of understanding still resonates in current philosophical discussions.

What are some of the reasons for believing that social inquiry poses unique problems? In *The Poverty of Historicism* Karl Popper (1957) argues that attempts to predict human behavior are undercut by a radical openness of the system that has no parallel in the physical sciences (see Popper, Karl Raimund). What people do is influenced by the ideas they have about what is possible. It is also known that a person in a practical problem situation may come up with a completely novel solution to that problem and act on it. But by definition, it is impossible for anyone today to predict what will only be discovered or first thought of tomorrow! The ability of human beings to create new ideas and the responsiveness of human systems to those ideas seems to be different in kind from the openness of the solar system to asteroids.

Philosophers have also noted the phenomenon of "reflexive predictions," in which the very act of making a prediction can change the behavior it was trying to foretell. Such considerations have convinced many philosophers that social scientists should devote more attention to explanation than to prediction; but as will be discussed, there is little agreement about exactly which models of explanation are appropriate.

Another distinctive feature of social science is the fact that many of the basic phenomena to be studied come into existence only because people in a given society agree to their existence. What counts as money, marriage, or murder depends on a complex system of mutual understandings and trust that floats on top of and is largely autonomous from the physical and biological world. These important constituents of social life are created, maintained, and destroyed according to the shared intentions of the people who are being studied. For J. L. Austin a key feature of the social world is the ability to create obligations by means of "performative utterances." John Searle (1995) has proposed an analysis of institutions that is rooted in the collective intentions of members of a society (see Searle, John). The fact that so much of social reality is socially constructed strongly suggests that the methods and structure of social science will exhibit distinctive features.

So there are certainly prima facie reasons for expecting that the typical problems faced by social scientists may turn out to be quite different from the challenges found in the physical sciences that have formed the basis for most philosophizing about the nature of science. But various traditional philosophical misgivings about the very possibility of a science of human societies are undercut by the current success of social scientists who have been getting on with their job. For this reason much current philosophy of social science deals with issues that arise in the daily practice of social inquiry.

Varieties of Social Explanation

Philosophers of social science have worked with theorists in clarifying basic features of various research programs and exhibiting their strengths and weaknesses. The following approaches are discussed by Little (1991). Martin and McIntyre (1994), Salmon (1992), and Gasper (1991) also offer good summaries of various kinds of explanatory approaches.

Rational Choice Program

On a daily basis people interpret the activities of others around then by attributing to them beliefs

and desires such that their behavior becomes an appropriate choice, given their situation as they perceive it. Economists have developed the basic tenets of "folk psychology," as this form of common sense reasoning is called, into a theory of Rational Choice. In its mathematical form the theory proposes normative solutions to problems about combining preferences and group decision-making and tackles long-standing paradoxes, such as the Prisoner's Dilemma (see Game Theory). Social scientists use rational choice theory (RCT) to provide descriptive models of dating behavior, the deterrence of criminal behavior, and the economics of everyday life.

However, philosophers and social theorists have raised many critical queries about the status of rational choice explanations. To take one much-discussed example: If one applies a straightforward RCT analysis to the decision of an individual to vote in a nationwide election, it seems that it is almost always irrational for any individual to vote. The probability that one vote will make a difference is so small that any minor inconvenience accompanying the process of voting quickly outweighs the expected utility of taking the trouble to vote. Yet people do cast votes. Does this mean that RCT fails to explain their action? Rational choice theorists have a variety of responses. The most popular one is to say that individuals living in a democracy feel they have a duty to vote and so this factor enters into their decision. But duties do not fit smoothly into the mathematical machinery of RCT. And it seems ad hoc to introduce such factors only to save the model. If one admits that duties can simply override the factors more traditionally invoked by economists, the explanatory program of RCT is seriously weakened.

The approach has been faulted on other methodological grounds. On the one hand, RCT accounts are very narrow in scope. Since one must feed into the model of the situation the beliefs and desires or subjective probabilites and utilities of the actors, RCT leaves unanalyzed and unexplained some of the most important aspects of socialization, namely, the formation of value systems and worldviews. Yet in other respects the RCT approach seems too widely applicable. Since only the choice is presumed to be rational, one is as free to apply it to the behavior of impulsive and delusional people as to more typical instances of rational decision making, such as that of a champion blackjack player or master politician.

Nevertheless, RCT remains one of the most popular explanatory approaches in social science. Philosophers who endorse the approach include Popper (1994a) (who somewhat surprisingly does not worry about the lack of falsifiability of the rationality principle) and Jon Elster (2000).

Functional Analyses

This approach was especially popular with anthropologists in the first half of the twentieth century. In its starting points it seems quite different from RCT because it deals with societies, not individuals, and is most impressive in cases where the stated motives of the participants are quite different from the so-called latent, or hidden, functions of the behavior (see Function). A standard example of a functionalist explanation goes something like this: Given the obvious ineffectiveness of rain dancing, why do certain cultures persist in this activity? The functionalist reply is that the custom has the latent function of promoting social cohesion, an important social need for people facing a drought.

But as philosophers have pointed out, by its very nature a functionalist account cannot tell why rain dancing, as opposed to some other functionally equivalent ritual such as a sacrifice to the gods, was adopted. Functionalists would relegate that question to the historian. Neither can it explain the persistence of customs long after their original function is no longer operative. For example, even if one grants that religious taboos against eating pork served a health function in days before trichinosis was understood, that explanation cannot explain the persistence of the taboo, and one must once again invoke something like social cohesiveness. It is very difficult to bring evidence to bear on the question of whether some long-standing custom contributes to social cohesiveness or not. If not a tautology that such customs at least do not detract seriously from social well-being, positing that they cement society together is certainly not very explanatory.

Even functional attributions that are more specific may be difficult to test. Consider for example the feminist claim that one reason that rape in this society persists is that it has the function of "keeping women in their place." Thus the threat of rape is said to benefit male graduate students by posing obstacles to the use of the library at night by female graduate students. How could one even begin to bring evidence to bear on this allegation? This latter example also refutes the common claim that the use of functionalist analyses is inherently conservative because it seems to underwrite the optimality of the status quo. Social critics also use functional methodology when they explain the

presence of an unfair social practice by asking *Cui bono?* Who benefits most from the practice, and who would have the most to lose if it were discontinued? Thus, although the original explicit functionalism of anthropologists such as Malinowski (see Jarvie 1984) and sociologists such as Talcott Parsons (see Merton 1973) has been abandoned, this general type of analysis continues to be widely employed in more informal accounts of social phenomena.

Cultural Materialism

In the functionalist approach, institutions are seen as serving a wide variety of social needs. In what Marvin Harris (2001) has called the cultural materialist approach, the focus of the analysis is on much more carefully defined material requirements, such as the need for dietary fats and protein. Harris also systematically looks for data to support or refute his analyses. Many of his cases offer explicit alternatives to explanations in terms of vague needs such as social cohesion. For example, he proposed that the taboo on eating beef in traditional Indian culture is held in place by straightforward material considerations, not religious needs. He then conducted a census of infant mortality among male calves in various parts of India and found that in areas where oxen were used primarily as draft animals, more male calves than females survived. In areas where cattle were particularly valued for their milk, male calves were less likely to survive. Yet the villagers' support for the sacredness of all bovines was equally enthusiastic in both locales.

As was the case with explanations in terms of latent functions, cultural materialists often end up completely overriding the actors' own accounts of the variables that are influencing their behavior. In these postcolonial times when ethics codes often require the researcher to share results with the people studied, it becomes increasingly difficult to ignore *ab initio* the participants' own commentaries on their cultural practices. By limiting their explanatory factors to properties of the infrastructure, cultural materialism gains in specificity, but it becomes increasingly implausible when the explananda are far removed from basic needs such as food and shelter.

Interpretive Methodologies

All of the approaches sketched above search for modes of explanation that bear strong similarities to those employed in the natural sciences. Cultural materialists talk un–self-consciously about causes. Functional explanations are very common in biology (see Wright 1976 for an early account of functional explanations that uses both biological and cultural examples). Popper (1994a) compares explanations in terms of the rationality principle to those provided by Newtonian mechanics: One describes a more or less complex set of initial conditions (positions and momenta or beliefs and desires) and then "activates" the model to obtain the state of the system at a later time.

But there is also a strong tradition within philosophy of social science of arguing that an entirely different mode of understanding (*verstehen*) must be brought to bear on social phenomena. In his influential *The Idea of a Social Science,* Peter Winch (1958) claimed that the correct description of social phenomena, such as an individual saying a prayer or a mob attacking the citadel, has to include the actors' intentions and cultural categories. A wink is not a blink, a rosary is not a string of beads, and a riotous sports event is not an uprising of the proletariat. It is impossible to separate the description of an act from the variables that supposedly explain it. What is called for instead is a mode of quasi-empathetic understanding and interpretation, which is brought to bear on a richly detailed social characterization of the activity, sometimes called a *thick description.*

A widely cited example of this kind of interpretive activity is Clifford Geertz's (1973) essay in *The Interpretation of Cultures* on Balinese cockfights, in which he draws parallels between the structure of the participants' reactions and other parts of Balinese culture. One is not looking for the causes or rational roots or beneficial consequences of this activity. Rather, one is using a hermeneutical method common to those employed by a literary critic analyzing a poem in order to find the *meaning* of the practice. The end result is not explanation as is found in natural science; rather, it is an understanding of a particular activity in terms of the cultural system as a whole.

It is easy to agree that the phenomena that social scientists study are typically meaningful in a sense that goes beyond superficial physical descriptions. A cricket bat in the hands of a batsman is not just a strange sort of constrained bar pendulum. Furthermore, the proper understanding of such activities may well require one to consider their broad cultural ramifications. The anguish in Britain when armed conflict first broke out between two cricket-playing nations provides a window into the wider cultural significance of this sport. So, part of what the batsman is doing is participating in an activity intended to instill the gentlemanly virtues.

This seems worth mentioning. But just how thick should the descriptions be, and how can one evaluate interpretations that go well beyond common sense?

Commentators searching for symbolic meaning have remarked on the parallels between American football, where gaining yards, thereby decreasing the turf controlled by the other team is a central strategy, and the crucial project in American history of pushing the frontier steadily west and occupying native American lands. Others with a Freudian bent find great significance in the way that linesmen expose their bottoms to their own backfield, with the center even going so far as to let the quarterback grab the ball from between his legs. One need not take such examples of interpretation very seriously (although it would be interesting to understand why soccer has been so slow to gain popularity in the United States), and they are sometimes offered in a playful fashion. But they illustrate a basic dilemma for interpretive studies of social phenomena. If the interpretation is close to the meanings to which the actors readily assent, then it goes little beyond the commonsense understandings of the actors. (It might still be quite informative to someone outside the culture, of course.) But if the interpretation posits structures and symbols that are novel to the participants, then one may well wonder whether there is any empirical basis for the proposed "reading" of the cultural text.

Foundational Problems

The philosophical work described above responds to methodological issues arising within specific research programs found in current social science. There is another important strand of philosophy of social science that takes as its departure classic works in philosophy of mind and philosophy of language, such as Wittgenstein's (1957) *Philosophical Investigations*, and applies them to the analysis of the concepts that seem to underlie much of the thinking about society.

For example, it is often said that part of socialization is learning to follow both the explicit and the tacit rules of the culture—an especially vivid example is learning to speak a language (see Linguistics, Philosophy of). Or one speaks of the shared values, beliefs, attitudes, and norms of a society. It is difficult enough to explicate the notion of *following* a rule (as opposed to merely behaving in accordance with the rule), but when philosophers try to unpack the notion of a *tacit* rule and to speculate about how it might be instantiated in either the mind or the brain, these familiar and useful concepts start looking very suspect.

There is also a vast philosophical literature trying to make sense out of the idea of *shared* meanings. Can one speak meaningfully of *collective* intentionality? All of the standard problems in philosophy of mind are exacerbated when one starts theorizing about societies instead of separate individuals (see Consciousness; Intentionality).

As discussed above, there are ongoing disputes about whether the methods of social science differ fundamentally from those appropriate to the natural sciences. A closely related debate concerns the ontological unity of the two sorts of science. Are there such things as social facts that somehow exist above and beyond the properties of individuals? Proponents of methodological individualism call for explanations of all social phenomena in terms of the doings of individual people while admitting that recourse to large-scale social factors is necessary in the short run (see Methodological Individualism). Searle (1995), however, argues that both institutional facts, such as the value of money, and simple group actions, such as going for a walk together, can be analyzed only in terms of shared intentions. (He finds the roots of this kind of collective intentionality in animal behavior, such as that of a pack of dogs hunting together.) Philosophical arguments in social science about reductionism, emergence, and supervenience (Rosenberg 1995) often parallel discussions about the relationship between biology and chemistry (see Reductionism). McIntyre (1996) presents a thoroughgoing naturalist approach to social science.

New Directions

Although the development of science sometimes generates new philosophical enigmas, scientific research can also shed new light on perennial philosophical puzzles. In a recent book subtitled *Social Theory after Cognitive Science,* Stephen Turner (2002) argues that the connectionist account of how learning affects the brain provides a clearer way to think about "shared" social practices. If each person's path to linguistic competence, for example, is unique, then there are no transcendent rules that are somehow embodied in individuals within that society. Other models, such as computational theories of mind, would have different implications. The important moral is that social theory needs in general to be aware of results from cognitive science.

Biology continues to be a valuable correlative discipline for scientists interested in explaining

human behavior. Although the early claims coming from sociobiology faced severe criticism for a variety of reasons, more recent studies in what is now called evolutionary psychology are directly applicable (see Evolutionary Psychology). For example, the biological notion of *reciprocal altruism* helps clarify how human responses to the Prisoner's Dilemma vary with the situation. Comparative studies in animal behavior are also indispensable for understanding cross-cultural similarities and differences in, for example, the expression of human emotions.

Since scientific inquiry is an excellent example of highly organized social behavior, social scientists and historians have sometimes engaged in empirical and interpretive studies of science itself. Robert Merton's (1973) work on the norms of science launched the field of sociology of science. Philip Kitcher's (1993) *The Advancement of Science*, which presents economic models of the organization of cognitive labor and the attribution of scientific authority, can be viewed either as a piece of theoretical social science or as a part of naturalistic philosophy of science. As epistemologists become more interested in models of group rationality and societies of knowers, such work in sociology of science becomes increasingly relevant to philosophical models of the development of science.

There has also been a resurgence of interest in the sociology of knowledge tradition associated with Karl Mannheim (see Couvalis 1997). Feminist critics of science claim that gender ideology influences the content of science as well as its values, methods, and organization (for a critical survey, see Pinnick, Koertge, and Almeder 2003). Proponents of the so-called Strong Program look for the causal influence of interest groups on the content of science (see Social Constructivism). Scholars working in the new field of *science, technology, and society* (STS) try to combine interpretive accounts of scientific practice with political criticisms of both the applications of scientific findings and the directions of scientific inquiry. They find that traditional scientific values have produced a science that serves powerful elites at the expense of ordinary people. Some STS proponents argue that the aim of science should be emancipation, not explanation, and call for a revolution in both the methodology and the value structure of science.

Such dramatic proposals for both science policy and science education have led to a public debate sometimes called the "Science Wars," in which scientists and philosophers have objected vehemently to the portrayal of science coming out of recent work in the sociology of knowledge tradition (see Koertge 1998). They argue that the move from the underdetermination of theories by evidence to relativism is philosophically unsound (see Underdetermination of Theories). They also fault many of the case studies coming out of STS on the grounds that there are typically good empirical or theoretical reasons for the acceptance of scientific results that are ignored by those who look primarily for ideological factors or narrow professional interests. The defenders of traditional scientific methods warn that privileging political considerations over empirical considerations in the evaluation of scientific claims would seriously undermine both the explanatory power and the pragmatic usefulness of science.

The field of research ethics is an area of growing interest and one in which philosophers of social science might appropriately play a more important role (see Popper 1994b.) Professional organizations of social scientists took the lead several decades ago in adopting codes of ethics for their members. Issues of informed consent, the humane treatment of animal subjects, and the responsibility of researchers to share their results with human subjects have been brought to the forefront, and ethical procedures for dealing with them have been institutionalized by scientific societies. Various countries have also put in place governmental review boards to regulate research. As the prolonged debate over cloning illustrates, philosophers can be of service by providing scholarly analyses of the ethical and moral issues that have an impact on scientific research.

In conclusion, the problems studied by philosophers of social science are both intellectually challenging and socially relevant. New scientific developments, both in the social sciences as traditionally defined and in new areas such as cognitive science, lead to new issues and new perspectives on old problems. There are increasingly sophisticated historical analyses of the contributions of the founders of modern social science, such as Marx, Durkheim, and Weber (Gordon 1991). The growth of interest in issues arising out of the individual sciences has led to new specialized societies and journals.

SPACE-TIME

Space-time is the set of all actual and possible locations, in space and time, of all actual and possible events. The notion was formally introduced by Minkowski (1908 and 1909), who noted that "no one has ever observed a time except at a place, nor a place except at a time." In other words, the occurrence of an event is not completely "located" except when both the place and the

time are specified. Therefore, locations of all possible and actual events necessarily form a four-dimensional set, with three spatial dimensions and one temporal. Against this background, the history of any individual object—idealized, for simplicity, as a point-particle—may be represented as a trajectory in space-time, or a "worldline" connecting all the spatiotemporal locations that the object successively occupies. If space and time are assumed to be continuous, it is obvious that space-time can be represented as a model of the real-number manifold $\Re^4$, so that each point is represented by an ordered quadruple of real numbers, namely, its three spatial and one temporal coordinates.

Newtonian Space-Time

The notion of space-time is thus a very simple and natural one that accords well with ordinary intuitions about events that occur in space and time. One might even wonder that it did not develop earlier than it did. It is true that Kant took a step in this direction by noting that "if time is represented by a straight line produced to infinity, and simultaneous things at any point of time by lines drawn perpendicular to it, the surface so generated would represent the *phenomenal world* in respect both of substance and of accidents" (Kant [1770] 1911, 401n). But it was not until Minkowski's work (1909), which represented Einstein's (1905) special theory of relativity as the theory of a four-dimensional "world-structure," that the notion became an essential part of physics.

The reason for this is fairly straightforward: Until Einstein's special theory of relativity, both science and common sense viewed space-time events as standing in *relations* that effected a clear conceptual separation of space from time. The most important of these relations are *sameness* of time and place. That events could be identified as having happened at different spatial locations at the same time, or at the same spatial location at different times, seems intuitively completely obvious. Regarding sameness of time, there would appear to be direct sensory evidence of simultaneous events, or at least of events whose temporal separation is too small to discriminate. This is because, relative to the distances separating the events of ordinary experience, the signals carrying information about these events are generally extremely fast; in the case of visual perception through the propagation of light, the velocity is immeasurably great, and the time delay between the occurrence of an event and the perception of it could always be neglected. In the context of Newtonian mechanics, it was natural to think that even this delay was merely a practical problem, surmountable in principle by means of signals that may travel arbitrarily fast. In the first place, the laws of motion state that the acceleration produced in a given body by a given force is independent of the body's initial velocity, which entails that velocities may be increased arbitrarily; in the second place, universal gravitation appeared to be an actual instance of instantaneous action at a distance, or an effect that is simultaneous with its cause. Therefore, the Newtonian picture of physical causation divides space-time into space and time in a way that seems to justify the intuitive picture: For any moment, there is an objective partition of all events into those that have already happened, those that will happen, and those that are now happening; all events in the past are capable of influencing the present, but not vice versa; future events may be influenced by events in the present and the past, but not vice versa; present events may influence other present events, but only in case there are instantaneously propagating signals. In other words, Newtonian physics seems to confirm an intuitive trichotomy: For any two events A and B, either A precedes B, B precedes A, or A and B happened at the same time (see Figure 1).

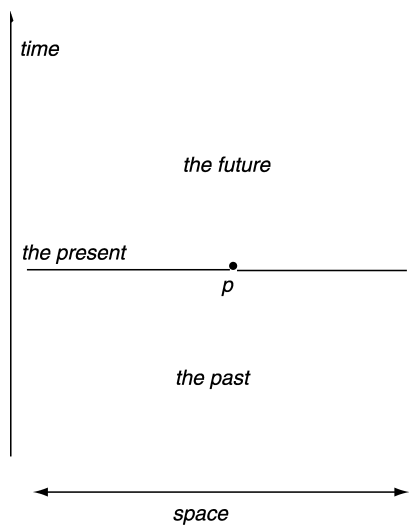

Fig. 1. The Newtonian view of simultaneity. The "present" represents an objective division among all events in space-time, separating "what is happening now" from what will happen in the future and what has happened in the past. It is a causal division, because it thereby separates what may still be influenced by events in "the present" from those that are already determined.

Thus, the notion of simultaneity may be thought of as decomposing four-dimensional space-time into an infinity of three-dimensional "slices" (spatial "hypersurfaces"), one corresponding to each moment of time and representing "space" at that moment. This "foliation" makes it possible to view space-time not as an integrated geometrical structure, but as a succession of states of space. Absolute simultaneity thus effects a "projection" of space-time onto time (i.e., a function that identifies three-dimensional subspaces of space-time with the same temporal coordinate), and the simultaneity slices are the fibers of the projection (see Figure 2).

Regarding sameness of place, Newtonian physics corrects the intuitive picture and shows it to be without physical foundation—the effect of mistaking a local perspective for an objective point of view. It is apparent to ordinary perception that a purely spatial change can always be canceled by a movement of the perceiver. That is, unlike a change in temporal perspective, a change in spatial perspective can be done and undone arbitrarily, so that for every spatial displacement of an object, there is an "inverse" displacement that restores the object to "the same place." Even though such motions necessarily take some time to accomplish, their possibility is central to the conceptual separation of space from time. The question is whether such combinations of displacements can ever be said to return an object to the same part of space, as opposed to merely restoring it to its former material surroundings. If the Earth could be assumed to be at rest, or if the laws of motion provided some dynamical measure of velocity, it could be inferred that some combination of displacements can lead from a given spatial point back to the same point at a later time. Analogously to the case of simultaneity, there would exist what amounts to a projection of space-time onto space, identifying one-dimensional subspaces each with the same spatial coordinates (so that the fibers of the projection would be the worldlines of particles at rest) (see Figure 3).

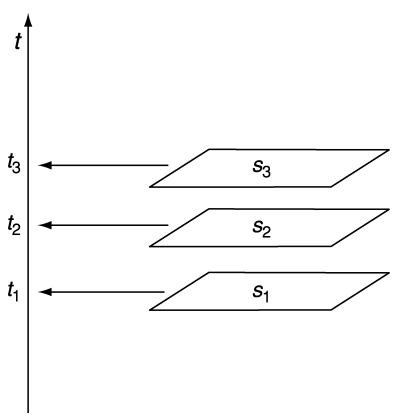

Fig. 2. Absolute simultaneity. By identifying events at different places at the same time, the relation of simultaneity is a "projection" of space-time onto time, identifying each hypersurface s as "all of space" at a corresponding time t.

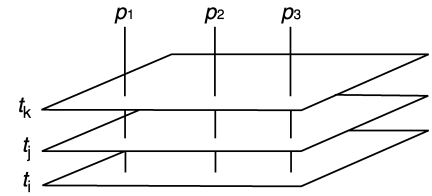

Fig. 3. Absolute space: If it were possible to discern the state of absolute rest, there would be a projection of space-time onto space, identifying certain worldlines as the histories of particular places in space. Each point p would represent a particular point in space at all times t.

As Galileo first argued convincingly, however, experience is incapable of discriminating rest from quasi-uniform motion (Galileo [1632] 1996). This principle, now known as the principle of Galilean relativity, was established in Newtonian physics as a corollary to the laws of motion. If this were not so, it might be supposed that the projection of space-time onto space had some objective empirical foundation. In that case, space and time could be thoroughly disentangled and space-time could be dispensed with altogether. But this is not possible, according to Newtonian physics, and the distinguished state of motion is uniform unaccelerated motion rather than rest. Therefore, space-time must be viewed as a four-dimensional affine space, that is, a space with a distinguished class of straight lines and a well-defined notion of parallelism: Straight lines (geodesics) represent the trajectories of bodies in uniform motion, not subject to forces; and parallel lines represent trajectories of particles that are relatively at rest (cf. Stein 1967; Ehlers 1973).

So, the relativity principle means that any family of parallel space-time geodesics may be regarded as being at rest, while none can be distinguished as absolutely at rest. Any family of parallel geodesics defines an "inertial frame," and all inertial frames are equivalent for the description of physical phenomena; the equivalence of inertial frames (the Galilean relativity principle) expresses the arbitrariness of the projection of space-time onto space, while the agreement of all inertial frames on which events are simultaneous expresses the

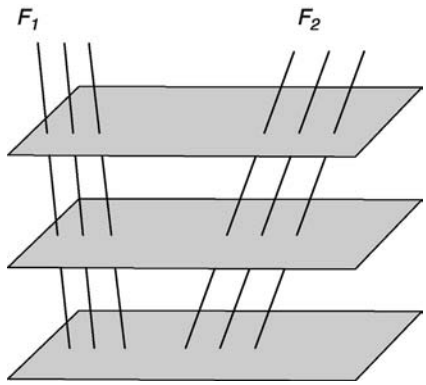

Fig. 4. Galilean relativity: F_1 and F_2 are distinct families of parallel space-time geodesics, that is, distinct inertial frames. They are in uniform motion relative to one another, but they agree on simultaneity, and therefore on the division of space-time into spatial hypersurfaces.

nonarbitrariness of the projection of space-time onto time (see Figure 4). The spatial and temporal coordinates of any two inertial frames, x, y, z, t and x', y', z', t', are related by the "Galilean transformations":

$$\begin{aligned} x' &= x - vt \\ y' &= y \\ z' &= z \\ t' &= t \end{aligned}$$

These relations express the absolute character of time, and the relative character of velocity, in a straightforward way.

The concept of space-time ought to place the philosophical controversies about space and time attendant on the birth of Newtonian physics in a clear perspective. Some of Newton's contemporaries were justifiably troubled by his concepts of absolute space and time, which he viewed as integral to his dynamical theory. From a modern perspective, in Newton's own construal of the term "absolute," his physics requires only "absolute space-time" (the aforementioned affine space) and absolute time, while absolute space involves the entirely superfluous assumption that some particular inertial frame is truly at rest. The space-time structure thus expresses only what is implicit in the dynamical assumptions shared by Newton, Huygens, Leibniz, and their contemporaries. Deeper philosophical analyses of space and time would, in later centuries, follow the critical analysis of only those assumptions. Thus it took profound transformations in the theories of electrodynamics and gravitation to displace this picture of space-time from its central place in physics.

Space-Time in Special Relativity

From the spatiotemporal perspective, the projection of space-time onto time—absolute simultaneity—might appear to be just as much in need of justification as the projection onto space. Yet it passed almost without comment until the early twentieth century, even from those with a broad philosophical commitment to "relativity" and a professed philosophical aversion to "absolute" structure in general; for example, Leibniz (1716) and Mach (1883) objected to Newton's conceptions of absolute space and time but never questioned the possibility of identifying simultaneous events or of specifying the relative positions of things "at a moment." Before Einstein, believers in the relativity of motion were, in effect, presupposing a continuous space-time, decomposable into instantaneous Euclidean spaces on which the momentary relative positions of bodies were well defined—otherwise their very conception of "relative motion" would have made no sense; their skepticism concerned, in effect, only whether space-time had the Newtonian affine structure as well. That is, they questioned only the existence of distinguished trajectories in space-time—the inertial motions—not the distinguished foliation of space-time into spaces at each moment of time. This is hardly surprising, given the apparent clarity of the intuitive distinction between past, present, and future. Moreover, Newtonian physics, while making no distinction between motion and rest, seemed to provide, at least in principle, a basis for determining simultaneous events. With Einstein's (1905) critique of the Newtonian concept of simultaneity, the basis for the intuitive separation of time from space was undermined. If simultaneity is relative, so that different inertial frames determine different spatial hypersurfaces, then the projection of space-time onto time is as arbitrary as the projection onto space, and for the same kind of reason.

Einstein introduced the special theory of relativity by proposing to unite two seemingly incompatible principles: the "relativity postulate," that is, that physical laws do not distinguish uniform motion from rest; and the "light postulate," that is, that the speed of light is the same in every inertial frame. In Newtonian mechanics, obviously, no velocity could possibly be invariant, since velocity is essentially a relative quantity. In classical electrodynamics, velocity relative to the ether was assumed to be a privileged velocity, but, here again, it could not possibly be an invariant velocity, as the velocity measured by any observer must depend on the observer's own velocity relative to the ether. Yet

when experiments were devised (e.g., by Michelson and Morley) to measure such differences in the velocity of light, their results were consistently null. For Einstein, these results were only one aspect of the general pattern in electrodynamics—that much theory, but no phenomena, appeared to depend on motion relative to the ether. But it was not so straightforward in the case of electrodynamics, as it had been in the case of mechanics, simply to eliminate the privileged frame of reference and accept the equivalence of inertial frames. For the reasons already noted, the idea of an invariant velocity seemed absurd. To eliminate the absurdity, and so to reconcile his two postulates, Einstein had to uncover the assumptions that had made them seem incompatible in the first place.

The key assumption was that of absolute simultaneity. The claim that observers in different states of inertial motion cannot agree on an invariant velocity, Einstein realized, rests on the assumption that they must agree on which events are simultaneous. Conversely, they can agree on the invariant velocity of light if they differ on which events are simultaneous. The criterion for simultaneity is provided by light signals: In Einstein's definition, two events are simultaneous if light signals from each event, traveling equal distances, reach the same observer at the same time. If a signal is sent from A to B and reflected back to A, the reflection is defined to be simultaneous with that moment of time halfway between the transmission and the reception at A (see Figure 5). Since the velocity of light, like all electromagnetic phenomena, is apparently the same in every inertial frame, Einstein's criterion seems to have a sound basis in physical law. Moreover, it agrees with the most familiar intuitive criterion of simultaneity. Using the same criterion of simultaneity, however, observers in different states of inertial motion must determine different sets of events to be simultaneous. In short, simultaneity is relative. Frames of reference that agree on the velocity of light will be related not by the Galilean transformations, but by the Lorentz transformations:

$$\begin{aligned} x' &= \frac{x - vt}{\sqrt{1 - v^2/c^2}} \\ y' &= y \\ z' &= z \\ t' &= \frac{t - vx/c^2}{\sqrt{1 - v^2/c^2}} \end{aligned}$$

Evidently these transformations preserve the velocity of light, but time and length will vary according to the relative velocity of the frames.

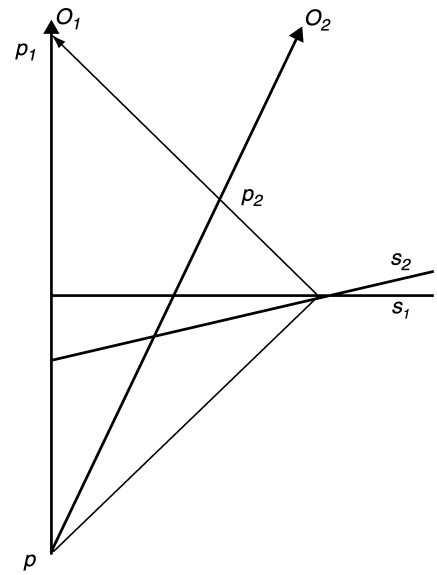

Fig. 5. The relativity of simultaneity: By Einstein's criterion, inertial observers and O_2 will disagree on which events are simultaneous. If a light signal is emitted from p (where their paths cross) and is reflected back to them, each will determine the time of reflection by halving the interval measured between the emission and the moment when the reflection is seen. For O_1 the interval will be from p to p_1; for O_2 the interval will be from p to p_2. Therefore for O_1 the events on the surface s_1 will be simultaneous, while for O_2 the events on the surface s_2 will be simultaneous.

The relativity of simultaneity is such a dramatic implication that one would seem to have good reason to reject the principle that implies it. The invariance of the velocity of light, before Einstein, was regarded as a mere appearance that must be explained by the interactions of bodies with the ether. Lorentz regarded the Lorentz transformations as expressing the contraction of measuring rods and the slowing of clocks in proportion to their velocities with respect to the ether. It could be argued, then, that there is a frame-independent fact of the matter about which events are simultaneous, but that light signals cannot determine it, and therefore they make a poor criterion. Einstein forestalled this argument by his conceptual analysis of simultaneity and its role in physical measurements. The very construction of a frame of reference must begin with some criterion for the measurement of time, and this is impossible unless one understands what one means by "simultaneous." Light signals were typically used for practical reasons; Einstein argued that their invariance properties make them uniquely suitable as the criterion of simultaneity. If this criterion is to be rejected, because of its surprising consequences,

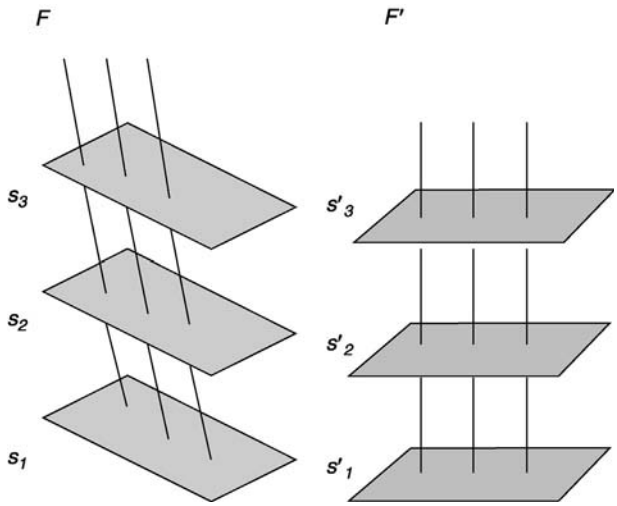

Fig. 6. Inertial frames in special relativity: Inertial frames F and F' disagree on simultaneity, so their frames correspond to two distinct decompositions of space-time into spatial hypersurfaces, s and s'.

there must be some other way of explicating the meaning of simultaneity, sufficient to make the concept applicable to the empirical world (cf. Einstein 1917, chap. 8). That is what neither Lorentz nor anyone else had been able to provide.

Einstein's theory leads directly to a new conception of space-time. The relativity of simultaneity means that for the worldline of each inertial observer (or family of parallel such worldlines), there is a distinct decomposition of space-time into space and time (see Figure 6). Relative to any given choice of a foliation, the spatial distance between any two points is given by Euclidean geometry, which implies that length is relative to the choice of inertial frame. Similarly, the relativity of simultaneity implies the relativity of time intervals. The invariant physical quantity is an inherently *spatiotemporal* quantity, the speed of light in vacuo, c. This follows simply from applying the familiar formula rate $\times$ time $=$ distance: Letting c = the speed of light; x, y, z the spatial coordinates; and t the time, the formula becomes:

$$ct = \sqrt{x^2 + y^2 + z^2}$$

or, squaring both sides:

$$c^2t^2 = x^2 + y^2 + z^2.$$

In a relatively moving frame with coordinates t', x', y', z', the formula becomes

$$c^2t'^2 = x'^2 + y'^2 + z'^2.$$

Then the invariance of the speed of light can evidently be represented by the expression

$$c^2t^2 - x^2 - y^2 - z^2 = c^2t'^2 - x'^2 - y'^2 - z'^2.$$

(Note the purely conventional choice to represent the temporal component as positive and the spatial as negative; the objective fact is only that they are opposite in sign.)

This aspect of Einstein's theory suggested to Minkowski, schooled in Klein's (1872) view of geometry as a theory of structure and automorphisms (structure-preserving maps), that special relativity may be understood as a theory of space-time geometry. The physical invariant (in units where $c = 1$)

$$t^2 - x^2 - y^2 - z^2$$

has a natural interpretation as the metrical invariant of a four-dimensional pseudo-Euclidean space, that is, in a four-dimensional flat affine space with an indefinite metric. In fact, the metric appears in pseudo-Euclidean guise as

$$ds^2 = x_1^2 + x_2^2 + x_3^2 + x_4^2$$

through the identification $x_1 = ict$. This underscores the analogy between the Lorentz transformations between inertial frames, as the isometries of the four-dimensional space-time, and the group of Euclidean isometries that preserve the Pythagorean metric. The slices of simultaneous events for any inertial observer become the hyperplanes that are orthogonal, as determined by Minkowski's inner product, to the corresponding geodesic worldline; Einstein's criterion of simultaneity naturally corresponds to the orthogonality criterion in Minkowski's geometry. It should be noted, however, that Einstein's criterion is based on the *stipulation* that the speed of light is the same in every direction; the only empirically measurable quantity is the total travel time of light in two directions—for example, to a mirror and back. That the time in each direction is exactly one-half of the total has, therefore, been thought to be a matter of arbitrary choice. This would imply, over and above the relativity of simultaneity, a kind of conventionality of simultaneity (see Conventionalism).

The peculiar role of light propagation, as a finite invariant velocity, determines a distinctive causal structure for Minkowski space-time (see Causality). From any given point, the possible paths of light signals in all directions (or arriving from all directions) form a hypersurface, the light cone, that divides space-time analogously to the way in which "the present moment" divided Newtonian space-time; since the velocity of light is an invariant

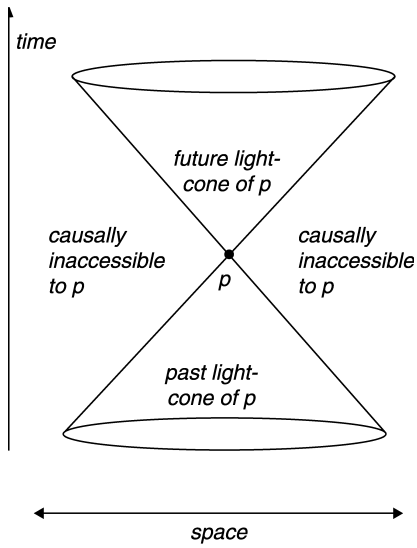

Fig. 7. The causal structure of Minkowski space-time: Since the speed of light is an invariant limit on the velocity of causal propagation, the regions that are causally accessible to point p are the past and future light cones at p.

limiting velocity, all causal propagation is confined to the surface (for electromagnetic signals) and the interior (for all slower motions, i.e., of massive particles) of the cone. In other words, the light cone divides space-time around a given point into causally accessible and inaccessible regions (see Figure 7). This clarifies the status of Newtonian space-time as a limiting case of relativistic space-time, since, in the limit as c is imagined to become infinite, the past and future light cones at a point collapse together into the plane of absolute simultaneity passing through that point. Mathematically, the cone structure corresponds to a division of all vectors at a point according to their lengths as measured by the Minkowski metric: "Timelike" vectors inside the light cone have positive length (assuming the sign convention adopted above), "spacelike" vectors outside the light cone have negative length, and "null" or "lightlike" vectors on the light cone have zero length. Curves whose tangents are everywhere timelike (spacelike, lightlike) are called timelike (spacelike, null) curves.

The difference between the Newtonian and relativistic space-times can now be easily summarized. In both cases, space-time is a flat four-dimensional affine space on the real numbers, where the distinguished geodesic trajectories represent the possible paths of free particles, and any family of parallel geodesics determines a global inertial frame. The differences concern metrical structure. Newtonian space-time has a preferred foliation into spatial hypersurfaces, with separate temporal and spatial metrics. Thus any two space-time points have a temporal separation—that is, the interval between the hypersurfaces in which they lie; but spatial separation is defined only for points that lie in the same spatial slice. In the relativistic setting, in contrast, there is only a single space-time metric, defining the space-time interval between any two points. The time elapsed between two events depends—much as the spatial separation of two points in space—on the path taken from one to another; instead of an invariant absolute time interval, there is only a measure of the "proper time" along a trajectory that connects the events.

The Minkowski metric has several counterintuitive features. One is that the trajectories of light rays have zero "length" and are orthogonal to themselves; another is that among timelike curves, the straight line represents the *greatest* distance between two points. (The latter is the root of the "twin paradox": Two observers can separate, and rejoin at some later time, only to find that more time has passed for one than for the other. The reason is that they have followed two different trajectories, and the proper time along one differs from the proper time along the other. So it is no more paradoxical than the fact that two people can take different routes from one place on Earth to another, and find that they have not traveled the same distance.) But the Minkowski metric also integrates the structures of space-time in a remarkably simple way. In the Newtonian case, the dynamical structure is completely extraneous to the kinematical structure of basic spatial and temporal measurement. This raised the question, for philosophers such as Ernest Mach, whether the dynamical space-time structures can be dispensed with in a theory that admits only changing "spatial relations" (see Mach, Ernest). In Minkowski space-time, however, the dynamical structure is inseparable from the kinematical structure, as the geometry of light propagation is the basis for all spatial and temporal measurement. And by Einstein's epistemological analysis of simultaneity, the classical notion of an immediately given structure of spatial relations, prior to any dynamical space-time structure, is revealed to be illusory.

Space-Time in General Relativity

The transition from special to general relativity is, in some respects, less dramatic than the one just outlined from Newtonian space-time to special relativity. For general relativity does not overturn special relativity's basic conception of space-time structure, but, rather, reveals it to be only the local

structure of space-time, which, on larger scales, can become inhomogeneous. The dramatic difference is that the inhomogeneity of space-time is a function of the distribution of matter: Instead of Minkowski's metric as the global structure of space-time, there is Einstein's equation, which relates the geometry of space-time to the distribution of mass and energy. This comes about as a result of the connection that Einstein perceived between inertia and gravity: The gravitational field is no longer represented as a field disturbing the motions of particles in space-time, but as the curvature of space-time itself. In other words, a particle falling toward a large mass is not being forced by gravity to deviate from a space-time geodesic, as Newton's theory supposes; rather, it is following a geodesic in a space-time that is curved by the presence of that mass. Therefore, Newton's law of gravitation, according to which the gravitational field depends on the masses of bodies and their relative distances, was replaced by Einstein's field equation, according to which the geometrical structure of space-time depends on the distribution of matter and energy. The Newtonian law makes no mention of time; it implies that any variation in mass distribution immediately alters the gravitational field to arbitrary distances. By Einstein's equation, gravitational effects are "ripples" in the structure of space-time that propagate like waves at the speed of light. In short, where Newton had represented gravity as force acting instantaneously within a fixed space-time background, the general theory of relativity incorporates both gravity and the geometry of space-time in a single local field theory.

The motivation for this view comes from Einstein's analysis of the equivalence principle, that is, the principle of the equivalence of gravitational and inertial mass. The empirical significance of the principle is that the trajectory of a body in a gravitational field is independent of its mass and composition—a fact already known to Galileo and tested fairly precisely by Newton through the timings of pendulums of many different masses and materials. And as Newton also recognized, this implies that a system of bodies that is freely falling in a quasi-uniform gravitational field (e.g., Jupiter and its moons falling toward the sun) will be locally indistinguishable from one in uniform motion. Thus, free fall is locally indistinguishable from inertial motion. It also implies, however, that a frame of reference at rest in a gravitational field with acceleration g is indistinguishable from a frame that is uniformly accelerating with acceleration—g, since the weights of bodies in the first frame would not be distinguishable from their inertial resistance to acceleration in the second. Indistinguishability of inertial motion from gravitational free fall would undermine the entire Newtonian distinction between gravity and inertia, and therefore between the background structure of space-time with its privileged trajectories and the gravitational field that is supposed to force particles to deviate from those trajectories. Einstein boldly proposed, as subsequent experiments have shown to high precision, that the equivalence principle applies to all forces of nature. From here, the first step toward general relativity is to identify free-fall trajectories as the geodesics of space-time. This is analogous to the move Einstein had made with special relativity: As light had been held to be the only invariant criterion for simultaneity, free fall provided the only invariant instantiation of the idea of inertial motion; the equivalence principle implies that the geodesics of flat space-time are as inaccessible to observation as absolute simultaneity had proved to be. The concept of inertial frame is replaced by the concept of "local" inertial frame, that is, the frame defined in the neighborhood of a freely falling particle.

The second step is to acknowledge that the geodesics, thus identified, behave in ways that are characteristic of the geodesics of curved spaces. Unlike the geodesics of Newtonian or Minkowski space-time, these geodesics exhibit relative accelerations. This is because, relative to a given freely falling particle, another freely falling particle will generally not be moving uniformly; but this means that relative to one local inertial frame, another local inertial frame is in general relatively accelerated. In Newtonian or Minkowski space-time, flatness implied that any given inertial frame could be extended to a global inertial frame with respect to which all inertial trajectories remained inertial. In general relativity, however, this global extension is impossible, because of the relative accelerations of local inertial frames. In fact, these relative accelerations provide a measure of the curvature, just as, for example, the convergence of geodesics toward the poles provides a measure of the curvature of the Earth. Similarly, the impossibility of imposing a global inertial frame is analogous to the impossibility of imposing a single plane coordinate system on the surface of the Earth. Thus, instead of forcing bodies to deviate from geodesic motion, the presence of mass forces geodesics into non-Euclidean relations. In short, mass curves space-time.

Einstein initially thought that general relativity would establish a certain philosophical point about

the "general relativity of all motion," eliminating Newtonian ideas about the objective character of space, time, and inertia. In particular, it would rid physics of the idea that there are privileged states of motion. Where Newtonian mechanics and special relativity had each identified an equivalence class of privileged frames of reference—the inertial frames—general relativity would place all frames of reference on an equal footing. In this manner space and time would lose "the last trace of physical objectivity" (Einstein 1916; Schlick 1917). This thought proved to be somewhat misleading. As was noted above, the notion of inertial frame was indeed fatally undermined—not because of the general relativity of motion, but because of the identity of inertia and gravity. There remained a privileged state of motion, the freely falling trajectory; what had to be abandoned was the privileged *frame*—again, because the local frame of a falling observer could no longer be extended. So it was the nonuniformity of space-time that made the inertial frame untenable, not the elimination of privileged states of motion. Questions about motion asked by Newton were still meaningful: Does the Earth rotate? Does the Earth revolve around the sun, or the sun around the Earth? But the answers were no longer supposed to depend on the background structure of flat space-time; instead, they depended on the relations between the geodesics of curved space-time and the distribution of matter and energy.

In retrospect, it was perhaps unreasonable to expect a "general relativization" from a theory in which the notion of a space-time geodesic plays such a fundamental role. Already Newton had pointed out that a dynamics that appeals to the notion of a distinguished trajectory postulates, *ipso facto*, some objective spatiotemporal structure. Nonetheless, the most profound philosophical consequences follow upon the transformation of space-time structure from a fixed background to something that is in dynamic interaction with its material contents. An especially important implication—not least for its bearing on contemporary research on quantum theories of gravity—is that space-time has a *history*, that is, a dynamical evolution of its states. This notion makes no sense in the previous theories, which countenance only the evolution of matter and fields *within* space-time. But the implication is a necessary consequence of Einstein's equation combined with what is known of the relative motions of the galaxies and the large-scale distribution of matter and energy. Moreover, the dynamic aspect of space-time in general relativity, and its consequent nonuniformity, means that

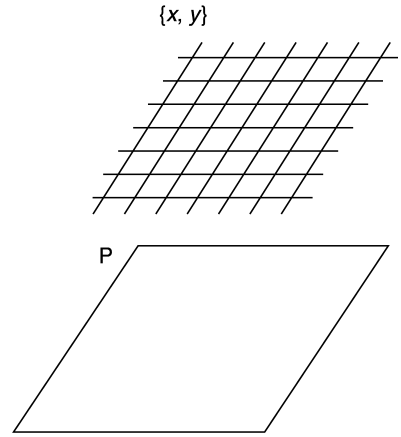

Fig. 8. Coordinates in a flat space: On the plane P, a rigid Cartesian coordinate system $\{x, y\}$ may be simply "set down" over the entire plane.

space-time can no longer be adequately understood from the point of view of symmetry groups and their invariants. Yet the mathematical structure of general relativity places its relation to the earlier theories in an illuminating perspective. Instead of beginning with $\mathfrak{R}^4$, defining coordinates on it in the obvious way (see Figure 8), then defining simple geometrical relations among its points, general relativity begins with an arbitrary differentiable manifold (cf. Bishop and Goldberg 1980), which is (very roughly) a topological space that is locally homeomorphic to $\mathfrak{R}^4$; it can therefore be coordinatized by "charts" that map it onto $\mathfrak{R}^4$ in any number of overlapping pieces (see Figure 9).

Then Newtonian or Minkowski space-time arises simply from introducing appropriate geometrical objects that impose symmetrical global structures upon it, making it globally homeomorphic to $\mathfrak{R}^4$.

In general relativity, however, space-time is not assumed to have any symmetries, but only the automorphisms of the manifold itself. Thus there is in principle no symmetry at all, but only general covariance, or covariance under the transformations that preserve the differentiable structure of the manifold. Additional geometric structure is not imposed in advance, but determined by mass distribution in accord with Einstein's equation. A symmetrical space-time geometry could arise in the case of a highly symmetrical distribution of matter, but that would be a contingent matter for empirical investigation. As Eddington (1920) pointed out, even though coordinate systems do not have any intrinsic physical meaning in general relativity, the possibility or impossibility of imposing coordinates reflects an important physical property, i.e., the nonuniformity of the curvature

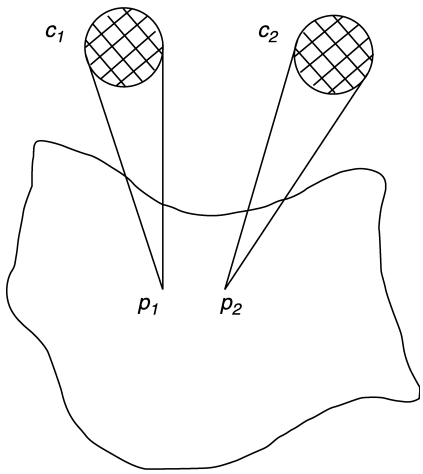

Fig. 9. Coordinates in curved space-time: In a non-uniform space, it will be impossible to lay a rigid Cartesian coordinate system over any finite region. The space must be coordinatized by overlapping "coordinate charts." For any two points p_1 and p_2 there will be local coordinate systems c_1 and c_2 that, in general, are "disoriented" relative to one another.

imposed by any nonsymmetrical distribution of mass.

Given these considerations, the general covariance of general relativity reflects a profound philosophical departure from earlier conceptions of space-time. At the same time, it is important to bear in mind what a contingent principle this is: It depends on the strict validity of the equivalence principle. An experimental violation of the equivalence principle—perhaps at higher levels of precision or energy than have been achieved up to now—would open the way for a distinction between inertial motion and free-fall motion, and so between an inertial frame and a freely falling frame. And that would open the way again for a separation of the gravitational field from the space-time background. This is only one of the respects in which present and future developments in physics promise to reopen questions about the nature of space-time that general relativity had seemed to resolve in such a compelling way. To Einstein, the unification of inertia and gravity in a single continuous field seemed to be a philosophically satisfactory as well as a physically convincing model for the treatment of all physical interactions, and this was the basis for his efforts toward a unified field theory. But those efforts failed, and since then the presumption has been that the next theory of space-time and gravity will be a quantum theory rather than a continuous field theory of the sort that Einstein was hoping for. The construction of such a theory may eventually lead to the replacement of general relativity's differentiable space-time manifold by some kind of discrete space. String theory holds out the possibility of a still more radical transformation, in which space-time as now conceived is not even a fundamental structure, but only the most obvious phenomenal expression of an underlying structure of as many as 26 dimensions. The radical changes that have occurred in the previous history of space-time theory, it should be recalled, were occasioned by radically new ideas about which physical processes reveal the structure of space and time: from the displacement of ordinary measuring rods, to electrodynamic propagation, to gravitational free fall. New approaches to this question are the likely result of further fundamental changes in physics.

SPECIES

The most fundamental question with respect to *species* as this term functions in biology is whether or not a single level of organization exists, across all organisms, that counts as the species level. Is there a single definition of the concept 'species' that is equally applicable to all species, or must biologists resort to several different concepts to satisfy a variety of purposes? A second issue is the need for such a concept in the first place. What good are species? Why do biologists think they need a univocal concept of species that applies across all organisms?

Species Taxa

First and foremost, particular species (species taxa) must be distinguished from the species category. Species taxa are composed of particular organisms. *Homo sapiens* is the name of a particular species. It is made up of all human beings past, present, and future. Traditionally, the names of particular taxa such as *Homo sapiens* have been defined in terms of the phenotypic characteristics possessed by their constituent organisms. For example, people walk upright. They have a plantigrade foot, an opposable thumb, and a highly developed brain. For most of the history of biology, biologists have assumed that the names of all taxa, including species, can be defined in terms of phenotypic traits that are severally necessary and jointly sufficient. All human beings have each of the characteristics listed, and only human beings have this entire suite of characteristics. In addition, these characteristics incorporate the essence of the class. The conviction that all genuine class terms can be defined in this way is called 'typology' or 'essentialism'.

Typologists were well aware that species as characterized by biologists do not live up to this high standard of definition, but they were convinced that the only thing standing between them and essentially defined taxa was more work and greater knowledge. With the advent of evolutionary theory, this conviction became difficult to sustain. Before that, the phrase 'past, present, and future' did not represent much of an impediment to defining species taxa. Species come and species go, but not in ways that imply that they change gradually in the process. Once biologists came to realize that species can change through time, one species evolving into two or more, sometimes quite gradually, they were forced to abandon their typological assumptions. More study produced more, not fewer, problems. The phenotypic boundaries between species are sometimes quite fuzzy.

One modification of the essentialist position was to treat species taxa as polythetic; that is, the phenotypic characteristics used to define species covary only statistically. To repeat, the boundaries between species taxa in phenotypic space are fuzzy, not sharp. It is important to note that these boundaries exist in phenotypic space, not physical space. This can be made clearer by distinguishing between the range of a species and its distribution in character space. For example, a particular kind of tree might be limited to the Wabash Valley, which is formed by the Wabash River, flowing from Ohio

through Indiana and along the border between Indiana and Illinois, to empty into the Ohio River. Systematists construct phenotypic space by mapping character distributions on a multidimensional graph. When they do, most organisms belonging to a particular species cluster in the center of the graph and become less prevalent as the conceptual boundaries of the species are approached. In short, *Homo sapiens* and the names of all other taxa are "cluster" concepts. They cluster not only at any one time but also through time, as species gradually change. The problem then becomes how to discern these fuzzy boundaries.

The foregoing considerations concern the distribution of ordinary phenotypic traits such as number of legs, color of hair, and the like. When characters—such as gene exchange and geographical distribution—that imply spatiotemporal relations are taken into account, the boundaries between species become real boundaries in space and time. The range of a species consists of the distribution of the organisms it comprises. Sometimes these spatiotemporal boundaries and the relations that define them are reasonably sharp, sometimes not—for example, there are degrees of reproductive isolation. However, the important change is the shift from ordinary phenotypic characters to relations that require spatiotemporal continuity and contiguity, a shift from character distributions to lineages. To be sure, character distributions are used to infer lineages, but the goal is to discern lineages. Taxa consist in chunks of these lineages.

The Species Category

All of the preceding discussion has concerned species as taxa, as groups of organisms defined in terms of their characteristics, but at bottom the problem of species concerns the category itself. How are we to define 'species' so that this term can fulfill the needs of biologists, in particular natural historians and evolutionary biologists? When one hears of the 'species problem,' this is the issue. Not all scientists, let alone all biologists, have the same concerns. Systematists who are interested in cataloging organismic diversity are willing to use rough-and-ready methods that make their job feasible. They did not in the past and do not at present have the workforce necessary to trace gene flow or establish ranges for all the taxa under investigation.

The labors of traditional systematists produced reasonably good classifications (Claridge, Dawah, and Wilson 1997). For many needs—Which species of mosquitoes can transmit malaria? How many species of fruit flies are there?—largely intuitive classifications were good enough. However, as time went by, systematists grew increasingly ambitious. They wanted their classifications to be more than just summaries of phenotypic variation. Some systematists wanted to retain the traditional goals of systematics but fulfill them more completely. Others wanted to expand the role of systematics in biology. They wanted to discern entities that functioned in natural processes, particularly the evolutionary process. As they viewed them, species were not just the basic units of classification, but also the basic units of evolution. Species were what evolved, speciated, and became extinct (Otte and Endler 1989).

The Concept of Phenetic Species

One group of systematists who proposed to change the orientation of biological systematics were the numerical pheneticists (Sneath and Sokal 1973). They are called "numerical" because they introduced mathematical techniques into systematics, especially the use of computers. Systematics is an ideal subject area for the use of computers. Millions of species exist, and each species has a different suite of characters. All these data can be maintained, readily accessible, in computer databases. Numerical pheneticists want their classifications to be constructed explicitly so that they can be tested by other workers. They want the classifications to be more objective, repeatable, and quantitative—in a word, more "scientific."

They are called "pheneticists" because they believe that organisms should be classified according to observable phenotypic characteristics. More important, these characteristics must be individuated without any theoretical input. One can discern the scales of fish and the scales of birds, and scales are scales. If classifications are to become objective, quantitative, and operational, then theory (or at least a technical approach such as evolutionary theory, and in the early stages of classification) has to be set aside as much as possible. As genetic information became more readily available, the notion of "phenetic" characters was expanded to include genetic characters as well (Sneath and Sokal 1973). However, the antipathy of numerical pheneticists toward scientific theories, especially evolutionary theory, remained.

The main problem with numerical phenetics was an embarrassment of riches. Early on, numerical pheneticists thought that something called "overall

similarity'' existed out there in nature. They assumed (or hoped) that alternative analytic procedures (e.g., parsimony, compatibility, neighbor joining, least-squares, likelihood) would zero in on the same classification or, if not, that one of these methods would prove superior to all others. But classifications reflecting overall similarity remained an elusive goal. Different clustering procedures produced different classifications even when applied to the same group of organisms, and there was no reason within numerical phenetics for preferring one procedure over another. Too many different distributions had an equal right to be described as overall similarity.

In addition, phenetic methods did not always mark the distinctions that biologists find absolutely essential. For example, in numerous cases, males and females of the same traditional species were placed in different taxa on the basis of character covariation alone; in response, the pheneticists allowed low-level biological distinctions to be introduced into systematics, even in the early stages of classification. No matter how different males and females may appear, and no matter how they differ genetically, they must be included in the same basal taxon. Allowing the results of phenetic methods to be overridden by issues such as sexual dimorphism seems to introduce the sort of theoretical speculation that pheneticists claimed to abhor. Granted that the distinction between male and female is very basic and frequently easy to discern, it is still more than just look, see, and cluster.

For pheneticists, is there a single level of phenetic covariation that is the same across all organisms? The answer is yes—and no. There are numerous levels of phenetic covariation. The trouble is that no level is any more ''real'' than any of the others. There is certainly no reason to choose any one level of phenetic covariation and call it the species level. Different clustering procedures produce different classifications, and there is no reason for choosing any one of these classifications over any of the others.

The Concept of Reproductive Isolation

Other definitions of the species category are more heavily laden with theory than the phenetic species concept is. The theories on which they are based concern both phylogeny and the evolutionary process. The most popular definition of the category during the past half century has been Ernest Mayr's ([1942] 1964) concept of biological species in terms of gene flow and reproductive isolation. In sexual species, boundaries of varying degrees of permeability exist in nature. According to Mayr:

> A species consists of a group of populations which replace each other geographically or ecologically and of which the neighboring ones intergrade or interbreed wherever they are in contact or are potentially capable of doing so (with one or more of the populations) in those cases where contact is prevented by geographical or ecological barriers. (120)

Or, in other words, species are groups of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups.

Mayr's definition is clearly committed to the evolutionary process. Gene flow or the cessation of gene flow is what really matters in sexual organisms. One common objection to this definition is that gene flow may not be as important in the evolutionary process as Mayr thinks. A second objection is that the definition can be very difficult to apply in particular cases. Gene flow is difficult to measure. One minor issue concerns ring species. A series of populations can be discerned in a circular course around some geographic barrier such as a large lake or mountain. Eventually, the termini of these courses meet. Population *A* can mate with population *B*, *B* can mate with population *C* around the geographic barrier until population *M* meets population *A*—and these two populations cannot mate! However, all these populations belong to the same species because mutations that occur anywhere in the ring can find their way into more distant populations.

''Potential interbreeding'' is especially problematic. Species can be made up of numerous populations that at the moment are totally isolated from each other. Perhaps they formed contiguous sequences of populations in the past, as in the case of ring species, but they are now completely disjunct. No gene flow is taking place. However, later on they may come into contact again and reinstate gene flow. Cessation of gene flow alone is not enough to ensure total isolation. In order to belong to the same species, disjunct populations must retain the ability to mate successfully so that if they ever came into contact again, gene flow would resume. Discerning actual gene flow is difficult enough. Trying to estimate ''potential'' gene flow is even more difficult.

Aside from difficulties in application, the most fundamental objection to Mayr's definition is that gene flow really does not matter all that much in the evolutionary process. If this can be shown to be the case, Mayr's definition is in real trouble. In addition, it does not apply even in principle to

organisms that never reproduce sexually. In his definition, these organisms do not form species. Hence, during the first half of life on Earth, no species existed. Evolution occurred, but in the absence of species.

In response to these and other objections, Mayr (1969, 26) modified his definition. He no longer refers to "potential interbreeding." Since that term is simply the negation of "reproductive isolation," he need not mention both in the definition. Mayr also limits his definition to species that are "nondimensional" in space and time: The definition applies only to sympatric and synchronous species, that is, those existing at the same place and time. However, nondimensionality is too strong a requirement. All species are extended to some extent in space and time. According to Mayr, species are not totally nondimensional, just minimally so (e.g., the chipmunks in my valley for the past few breeding seasons). These nondimensional species might well be organizable into more inclusive entities, but Mayr's definition applies literally only to nondimensional species per se. Although his definition remains popular among many taxonomists, other definitions have arisen to challenge it. Each turns on a different aspect of phylogeny or the evolutionary process.

The Concept of Evolutionary Species

As Mayr delineated them, species are time-slices of evolving lineages. G. G. Simpson (1961) presented a definition designed to portray species as evolving lineages: "An evolutionary species is a lineage (an ancestral-descendant sequence of populations) evolving separately from others and with its own unitary evolutionary role and tendencies" (153). The strength of Simpson's definition is that it is designed to delineate the basic lineages in phylogeny. Gene flow is one mechanism that can promote evolutionary unity, but it is not the only one. Simpson's definition also applies to asexual organisms. They too can form lineages that exhibit evolutionary unity, but without the aid of interbreeding. As might be expected, most objections to Simpson's definition concern difficulties in applying his notions of evolutionary roles and tendencies. It is not very operational. Discerning gene flow is difficult enough. Determining the influence of all the other mechanisms that promote evolutionary unity is even harder.

In sum, Mayr treats species as cross sections of evolving lineages, whereas Simpson treats them as temporally extended lineages. (See Wiley 1981 for an expanded version of Simpson's definition.)

Phylogenetics

In the past few decades a revolution has taken place in systematics, with the introduction of the views of Willi Hennig (1966). Both Mayr and Simpson wanted classifications to somehow reflect phylogeny, but for them these correlations were more than a little impressionistic. As Simpson stated numerous times, biological classification is as much an art as a science. Hennig proposed principles of classification that would be unequivocal. He decided that it was better to represent one relation clearly than numerous relations poorly. To do this he had to limit classification to reflect one and only one phylogenetic relationship:common ancestry as indicated by sister-group relations, for which he devised the notion of a cladogram (see Figure 1).

In the figure, the lines represent species. For example, if this cladogram is viewed as a phylogenetic tree, then an unnamed species splits into species *C* and a second, unnamed species. This second, unnamed species in turn splits into species *A* and *B*. Neither cladograms nor cladistic classifications can represent these relations. Instead, as a cladogram, the figure implies that *A* and *B* belong to a more inclusive taxon, such as a genus. All that the cladogram shows is that this genus is more general than any of the taxa mentioned previously. It does not imply that any species is ancestral to any other species. If species *A* is more closely related to species *B* than either is to species *C*, then *A* and *B* must be classified together at a more basic level before they can be classified with species *C*, because, on the basis of the preceding argument, *A* and *B* have a more recent common ancestor than either has with *C*. However, as shall be seen shortly, the role

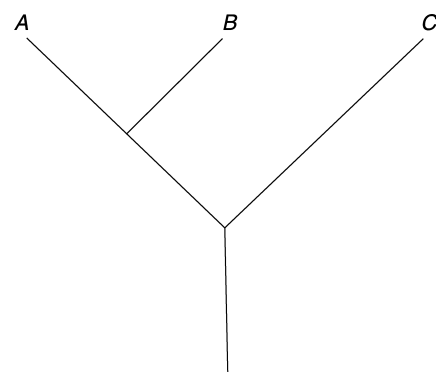

Fig. 1. A standard three-taxon cladogram. *A*, *B*, and *C* represent species. All this cladogram implies is that species *A* and *B* are more closely related to each other than either is to species *C*.

of common ancestors in phylogenetic classifications is problematic.

For cladists, cladograms and cladistic classifications are isomorphic to each other. They have the same information content. Hennig's crucial insight was that neither cladograms nor cladistic classifications can be isomorphic to phylogenetic trees. In trees, ancestral species split into descendant species. The forks in a phylogenetic tree represent speciation events. The lines represent species. For example, species *C* splits into species *A* and *B*. Thus, *C* is ancestral to *A* and *B*. Neither cladograms nor cladistic classifications represent this relation, nor can they. Genus *C* is more general than either species *A* or species *B*, but it is in no sense ancestral to these species.

At this juncture two sorts of cladists must be distinguished: *pattern cladists*, emphasizing patterns of the sister-group relation, and *phylogenetic cladists*, emphasizing the common ancestry that such relations imply. Both use Hennig's notion of cladograms but intend their cladograms to imply different relations—strict sister-group relations and common ancestry, respectively. For pattern cladists, nodes in a cladogram represent not ancestral species but increased generality, and nothing more. For phylogenetic cladists, such forks represent common ancestry but not actual common ancestors. The difference between pattern and phylogenetic cladists may not seem all that momentous. It stems from a different philosophical outlook about the goals of classification. Pattern cladists want their classifications to be as parsimonious as possible. The less information a classification presupposes, the less error can creep in. Pattern cladists limit their classifications to nested sets of characters. Such nested sets quite obviously imply something about common ancestry, but the pattern cladists are not willing to incorporate this additional element into their classifications. Phylogenetic cladists are willing to take that chance.

For higher taxa, Hennig reworked the notion of monophyly. A higher taxon is monophyletic if and only if all and only the species derived from an ancestral species are included in this single higher taxon. One result of this definition of monophyly is that such familiar taxa as Dinosauria and Reptilia cease to count as genuine taxa because they are not considered monophyletic. According to Hennig, all higher taxa must be monophyletic in his sense, but he was not willing to extend monophyly to the species level. However, several more recent authors have extended the notion of monophyly to cover species as well (Donoghue 1985; Mishler 1985; Mishler and Brandon 1987; Rosen 1979). According to the *monophyletic species concept*: A species is the least inclusive monophyletic group diagnosable by at least one autapomorphy, that is, a trait found in only one of two sister groups. This concept is designed to distinguish monophyletic groups and count them as species even if they are less inclusive than traditional species.

A second species concept that stems from Hennig's work is the *diagnostic species concept* (Cracraft 1983; Eldredge and Cracraft 1983; Nixon and Wheeler 1990). According to the diagnostic species concept: "A species is the smallest diagnosable cluster of individual organisms within which there is a parental pattern of ancestry and descent." As in the case of the sophisticated phenetic species concept, more than diagnostic characters matter. A parental pattern of ancestry and descent must also be present.

One virtue of the monophyletic and the diagnostic species concepts is that they apply to both plants and animals. In addition, they are formulated to be as operational as possible; for instance, the presence of at least one autapomorphy is involved in the case of the monophyletic species concept, and a diagnosable cluster is involved in the case of the diagnostic species concept. However, neither of these species concepts always delineates traditional species. For example, when birds of paradise (Paradisaeidae) were reclassified according to the diagnostic species concept, the number of species went from roughly 40 to 90. Practicing taxonomists are a conservative lot. Stability of classifications is one of their major principles. As a result, they remain a bit leery of all these new species definitions.

A Unified Species Concept

The two final species concepts in the recent progression are Templeton's *cohesion species concept* and de Queiroz's *lineage species concept*. According to Templeton's concept (1989): "A species is the most inclusive population of individuals having the potential for phenotypic cohesion through intrinsic cohesion mechanisms" (12). Templeton contrasts phenotypic cohesion with the intrinsic (or genetic) mechanisms that produce it. For example, descent from common ancestors promotes phenotypic cohesion. The organisms belonging to a species fill the same niche because they are identical by descent. Templeton does not list all possible mechanisms that are responsible for the intrinsic potential in his definition. He thinks that they do not belong in the definition but should be appended to it, depending on the current state of empirical knowledge.

Among these intrinsic cohesion mechanisms are gene flow and natural selection, as well as ecological, developmental, and historical constraints. Asexual organisms form species, in this definition, through their adaptation to particular ecological niches.

De Queiroz (1999, 53) sees all preceding concepts as converging on a single unified species concept—the general lineage species concept, according to which species are segments of population-level lineages. De Queiroz acknowledges that his conception of the species category is very general, but this is its chief virtue. He sees no reason to include in the definition of 'species' all the causal processes that are responsible for their existence or the operational criteria used to discern them. Thus, he agrees with Simpson (1961) and Wiley (1981) that species at bottom are segments of population-level lineages. In addition, Mayr's nondimensional species are time-slices of these lineages. The monophyletic species concept is designed to distinguish phylogenetic structure within these lineages, and the diagnostic species concept emphasizes the need for distinguishing such lineages.

According to de Queiroz, too often what pass for species concepts are either specifications of the causal processes that produce these lineages or operational criteria used to recognize them in practice. As important as both these aspects of species are, they do not belong in the definition, any more than all the various ways to measure space and time belong in the definitions of these species concepts.

Pluralism

The preceding definitions are only a small sample of species concepts in the taxonomic literature (e.g., see Mayden's [1997] twenty-two species concepts and de Queiroz's [1998] thirteen). Philosophers have used this plethora of species concepts to support their preference for pluralism. They claim that no one species concept is useful for all the numerous legitimate contexts in biology; numerous species concepts are needed. Some of these authors go on to conclude that in this account, species are not real but a matter of convenience, depending on the context. Others respond that numerous different species concepts are necessary to understand natural phenomena, and for this reason all of them are equally real (Kitcher 1984).

As Mishler and Brandon (1987) have argued, one way to decrease the apparent multiplicity of species concepts is to distinguish between criteria used for grouping organisms into taxa and other criteria that serve to rank these taxa. According to these authors, the appropriate criterion for grouping organisms into taxa is monophyly, but monophyletic taxa can be found at numerous levels of inclusiveness. Quite different criteria are needed to decide which level of monophyletic taxa counts as the species level. Similarly, Templeton (1989) insists that what matters for species is internal cohesiveness. Pluralism comes into play only with respect to the various mechanisms that bring about this cohesiveness. Finally, de Queiroz (1999) presents a parallel position. All species are lineages, but the causal forces that produce these lineages and the criteria used to discern them vary. The species concept is monistic; pluralism enters in elsewhere.

If any and all species concepts formulated through the years are treated as equally legitimate, then the presence of so many species concepts certainly supports pluralism; but even the most pluralist philosophers acknowledge that some species definitions are philosophically inadmissible, such as those that claim to be totally operational and theoretically pure (Ereshefsky 1992; Kitcher 1984; Wilson 1999). Even among the species concepts that pass philosophical muster, some fail as far as scientists are concerned. Except for practical species concepts, the remainder of recent definitions of species seem to converge on a single concept: Species fundamentally are lineages. They are produced by a variety of mechanisms and are recognized by an equally wide range of techniques, but this variety need not be reflected in the definition itself.

Are all lineages equally extensive and cohesive? The answer is clearly no. Some sexual species have huge ranges and form extremely large lineages. At the other extreme, some sexual species consist of no more than a single population. They are a good deal more cohesive than their larger counterparts but much smaller in scope. As always, asexual organisms pose a major problem. They form lineages; but in the absence of gene exchange, other factors such as ecological constraints must produce the cohesiveness that these lineages may or may not exhibit.

Recent species concepts do seem to be converging on a unity. But even if all the concepts that biologists take seriously are held to delineate different species concepts, they do not make a long list, nor do they produce species that are very different from each other. In science a little bit of pluralism seems to go a long way. Most present-day philosophers revel in pluralism. If one species

concept is good, two dozen are better. Scientists, on the contrary, are much less enthralled by being told that they must work with numerous different concepts delineating slightly different entities and groups of entities. Physicists put up some resistance when two different senses of 'mass' were proposed. How would they respond to two *dozen* different senses of 'mass?'

Why Does It Matter?

The literature on the species concept is huge, stretching from Aristotle to the present. Why the continuing controversy? Why the continuing fascination with species? Why does it matter? One reason is that different biologists want species to fulfill different roles. Many practicing systematists want simply a clear and easy way to identify their specimens. In which drawer does this specimen belong? No highly technical, theoretical species concept is needed to answer such a question.

Biologists as well as others are interested in conservation. One would like to slow down the current rate of mass extinction. For better or worse, the response of the U.S. Congress was to pass the Endangered Species Act, emphasizing the survival of individual species rather than more theoretically appropriate objects of concern such as entire ecosystems. But even ecosystems are not enough. Conserving biodiversity is also important. However, given current law, how inclusive we make species matters. ''Splitters'' produce numerous species, each of which has some claim to protection. ''Lumpers'' produce very few species, resulting in the vulnerability of what splitters consider species and what lumpers consider varieties or subspecies. Species definitions do matter even at this practical level.

Even more importantly, species play a role in the evolutionary process. Perhaps the situations in which species can serve as units of selection may be quite rare, but at the very least species are a result of various evolutionary mechanisms, including selection. Evolutionary biologists want to estimate such things as how common sexual reproduction is. To do so, they must be able to count entities that are comparable. If different systematists classify organisms in quite different ways, the results of any counting will be misleading. For example, if the level at which reticulation gives way to splitting is considered basic, then sexual species are comparable to asexual organisms. Suddenly, sexual reproduction becomes quite rare, instead of common. Species do matter.

The Evolution of Species: Philosophical Implications

People, including scientists, recognize all sorts of kinds, but not all these kinds are equally fundamental. For example, physicists recognize more than a hundred elements. Helium, hydrogen, lead, and gold are all elements. Numerous general statements can be made about these kinds, which have been viewed traditionally as natural kinds, important because they function in numerous general statements. 'Element' is more general than 'gold' or 'lead.' Even so, the names of individual elements are also general enough to function in laws of nature. For a long time, finding new elements aroused considerable attention. As we reach the level of radioactive elements, this quest has become greatly reduced. Such elements can exist for only nanoseconds and are produced under extremely artificial conditions.

Traditionally, species taxa have been viewed as natural kinds, akin to the physical elements. Species taxa, however, differ from elements in two important respects. First, there are many more species than elements—roughly a hundred or so elements versus millions of species—and new species continue to be discovered. Discovering a new species is rarely a significant occurrence. No one is going to become famous for discovering yet another species of fruit fly.

A second difference between the physical elements and biological species is that elements are spatiotemporally unrestricted, while species as evolvers are not. Physical elements are found scattered throughout the universe. One need not know where an atom of gold is before deciding that it is gold. Time and place do not matter. Hence, physical elements are very good candidates for natural kinds of the sort that function in natural laws. Just the opposite is the case with species as evolving lineages. They are spatiotemporally localized, and must be if they are to evolve.

Because of these differences, several authors have argued that species are not natural kinds, in fact not kinds at all, but spatiotemporal individuals, historical entities, or particulars (Ghiselin 1974; Hennig 1966; Hull 1976). The proponents of several of the more recent species concepts discussed above take this view of the metaphysical nature of species. From this perspective, particular species should not count as kinds, let alone natural kinds. Nor should their names function in any genuine laws of nature—and they do not. One reason for the continuing ''species problem'' is that it has taken professionals more than 2,000 years to realize

that they have been putting taxa names in a metaphysical category to which such names do not belong. Instead of being highly aberrant classes, they are typical individuals (see Individuality).

But this discussion does not entail anything about the metaphysical nature of the species category itself. Species taxa are spatiotemporally restricted; the species category is not. It has all the generality needed to count as a kind. Species as evolvers are not restricted to Earth. In all probability, they have evolved numerous times throughout the universe. A particular lineage cannot evolve more than once, but lineages as such can recur. In addition, if species are that which evolves, then they function in an important scientific theory. The net effect is that species as such are a natural kind. *Homo sapiens* as a taxon is not a natural kind; the species category is.

PHILOSOPHY OF STATISTICS

Philosophy of statistics may be seen to encompass the epistemological, conceptual and logical problems revolving around the use and interpretation of the methods of mathematical statistics. In contrast to the better known philosophies of science, physics, and mathematics, work in philosophy of

statistics is as likely to be engaged in by practicing statisticians as by philosophers of science. Accordingly, contributions to philosophy of statistics might be regarded just as much as contributions to statistics as to philosophy of science. To make this entry useful and of manageable length, it focuses on the main philosophical debates relating to the modern methodology for *statistical inference:* significance tests, hypothesis testing, confidence interval estimation, likelihood, and Bayesian methods. This still leaves a huge territory marked by seventy years of debates widely known for reaching unusual heights both of passion and of technical complexity. To get a handle on the movements and cycles without too much oversimplification or distortion, three main waves of debates in philosophy of statistics will be distinguished: 1930–1960, 1960–1980, and 1980 to the present.

A core question that underlies the debates is: What is the nature and role of probabilistic concepts, methods, and models in making inferences in the face of limited data, uncertainty, and error? The different answers to this question have immediate ramifications for all of the central issues around which much of the debates revolve: what tasks do mathematical methods of statistics perform? And what criteria or principles are appropriate for evaluating them?

Two Roles for Probability in Inference

There are two distinct philosophical traditions regarding the role of probability in statistical inference in science. In one, probability is used to provide a post-data assignment of degree of probability, confirmation, support, or belief in a hypothesis, while in a second, probability is used to assess the probativeness, reliability, trustworthiness, or severity of a test or inference procedure.

Confirmation Theory

Conceding that all attempts to solve the problem of induction (see Induction, Problem of) suffered from circularity (Salmon, 1967), philosophers of induction (e.g., in the 1970s) turned their attention instead to constructing *logics of induction* or *confirmation theories* that would, ideally, reflect "inductive intuition." The goal would be to supply means to compute the degree of *evidential relationship* between given evidence statements, e, and a hypothesis, H (see Confirmation Theory). A natural place to look for such a computation is the definition of conditional probability, or *Bayes's theorem:*

$$P(H \mid e) = P(e \mid H)P(H)/P(e)$$

where $P(e) = P(e \mid H)P(H) + P(e \mid \neg H)P(\neg H)$.

Computing $P(H \mid e)$, the *posterior probability*, requires starting out with a probability assignment to all of the members of $\neg H$, and a major source of difficulty through all three waves is how to obtain, justify, and interpret these prior probabilities. Insofar as the computed degrees of confirmation are viewed as analytic and a priori, their relevance for predicting and learning about empirical phenomena is problematic; insofar as they measured subjective degrees of belief, their relevance for giving objective guarantees of reliable inference is unclear (see Bayesianism; Confirmation Theory; Inductive Logic).

The Error-Probability Philosophy ('Sampling Theory')

A distinct philosophical tradition uses probability to characterize a procedure's overall reliability in a series of (actual or hypothetical) experiments or in *repeated sampling* (hence, 'sampling theory'). These probabilistic properties of statistical procedures are called *error frequencies* or *error probabilities* (e.g., significance levels, confidence levels). Deliberately designed to reach conclusions about statistical parameters without invoking prior probabilities in hypotheses, error probabilistic methods use probability to quantify how *frequently* methods discriminate between alternative hypotheses and how *reliably* they facilitate the detection of error. As with logics of confirmation, there are connections with philosophy of induction, as in Peirce, Braithwaite, and, to some extent, Popper (see Popper, Karl Raimund). These two contrasting philosophies of the role of probability in statistical inference correspond to the core issues at the heart of the debate in all three waves of philosophy of statistics.

The First Wave

Quantitative methods of statistical inference involve drawing conclusions about parameters on the basis of the observed values of random variables. Statistical methods may be seen to connect questions about the phenomenon or data-generating source to questions about distributions of random variables that model the data-generating source or population. Thus the conception of a statistical model wherein these parameters are defined is an important component of statistical

inference methods. The area of model specification and model selection has its own set of philosophical issues that will not be taken up here. A statistical hypothesis cannot be just any claim, but must give probability assignments to the different experimental outcomes or sample space Ξ, typically in terms of the parameters of the model. That is, for any x in Ξ, H assigns "the probability of x *under H,*" written $P(x;H)$. This notation helps avoid confusion between a probabilistic computation under a model and conditional probabilities needed for Bayes's theorem, $P(x \mid H)$, without prejudging issues. (An alternative notation some find useful is $P(x \,||\, H)$; see Friedman 1995).

Fisherian "Simple" Significance Tests

The modern approach to statistical inference was initiated by Fisher, who introduced the main concepts and procedures of statistical significance tests. Fisher's strong objections to Bayesian inference (Fisher 1935, 1955), and in particular to the use of prior distributions, led Fisher to develop ways to express the uncertainty of inferences without deviating from frequentist probabilities.

The significance test is a procedure with the following components: there is a null hypothesis H_0 that is an assertion about the distribution of the sample $X = (X_1, \ldots, X_n)$, and a function of the sample, $d(X)$, the *test statistic,* which measures the difference between the data $x_0 = (x_1, \ldots, x_n)$, and null hypothesis H_0. The larger the value of $d(x_0)$, the further the outcome is from what is expected under H_0, with respect to the particular question being asked (x_0 represents a particular realization of X). For an observed difference $d(x_0)$, the test computes the p-value, or the probability of a difference larger than $d(x_0)$, computed under the assumption that H_0 is true:

$$p(x_0) = P(d(\mathrm{X}) > d(x_0); H_0).$$

The p-value may be regarded as a measure of discordancy from H_0: the smaller the significance level, the greater the discordance between x_0 and H_0 (Kempthorne and Folks 1971).

Fisher described the significance test as a procedure for rejecting the null hypothesis and inferring that the phenomenon has been "experimentally demonstrated" (Fisher 1935, 14), where the latter inference corresponds to finding a small p-value, such as .05 or .01. How to justify this is a point of philosophical debate. One highly influential example is this. Suppose that x_0 is evidence against H_0 just in case x_0 is statistically significant at a small level p (or smaller). Then p is the maximal probability of rejecting H_0 when H_0 is actually a correct description of the underlying data-generating mechanism. So there is only a small probability of erroneously rejecting H_0, i.e., committing what Neyman-and Pearson call a *type I error* (Cox, 1958). Commonly used significance tests—Pearson's chi-square goodness of fit, the Student t test, the F test in analysis of variance—are regularly used to distinguish real effects of importance from apparent effects actually due to random sampling or uncontrolled variability.

The Alternative or "Non-Null" Hypothesis

Evidence against H_0 would seem to indicate evidence for some alternative, if only for a directional departure from the null value in a given direction. Although Fisherian significance tests strictly consider only the null hypothesis, Neyman and Pearson tests introduce as well an alternative H_1. Despite the bitter disputes with Fisher that were to erupt soon after their early developments of tests, Neyman and Pearson, at the outset, regarded their work as merely placing Fisherian tests on firmer logical footing by taking explicit account of an alternative to the null hypothesis.

Neyman-Pearson (N-P) Tests The N-P hypothesis test, mathematically considered, is a rule that maps each possible outcome $x = (x_1, \ldots, x_n)$ onto one of two hypotheses, the test or null hypothesis H_0 or an alternative hypothesis H_1. As in the Fisherian (simple) significance test, there is a test statistic $d(X)$, in terms of which the test rule is defined. In the N-P test, however, the values of $d(X)$ that will be taken to reject H_0 are fixed at the outset, by a predesignated choice of significance level. Most importantly, the null and alternative of an N-P test exhaust the parameter space of the statistical model, whereas in the Fisherian test there is the single null hypothesis, as against its logical complement.

The N-P error probabilities are computed under the assumption that the statistical model is adequate; what is being tested are the values of one or more parameters governing the distribution. For simplicity, illustrations here keep to the case of only one unknown parameter. Although N-P theory provides distinct tests of the assumptions of the statistical model, and the whole issue of model validation is important philosophically, the matter will not be explicitly discussed here.

Example, Test T(α): Consider a random sample of size n, $\boldsymbol{X} = (X_1, \ldots, X_n)$, where it is assumed that each X_i is normal $N(\mu,\sigma^2)$, independent and identically distributed (IID). Test $T(\alpha)$ denotes the familiar test of H_0: $\mu \leq \mu_0$ against H_1: $\mu > \mu_0$, where H_0 is the null, and H_1 the alternative hypothesis. Because H_1 includes only positive discrepancies from H_0, this is called a one-sided test. For simplicity, let the standard deviation σ be known—for instance, let $\sigma = 1$. The test statistic for T(α) is: $d(\mathbf{X}) = (\bar{X} - \mu)/\sigma_x$, where $\bar{X}$ is the sample mean with standard deviation $\sigma_x = (\sigma\sqrt{n})$. The N-P test with *significance level* α rejects H_0 with data x_0 if and only if $d(x_0)$ reaches the preset significance level α—for instance, $c_\alpha = 1.96$ for $\alpha = .025$, so

$$\text{Test T}(\alpha)\text{: if } d(\boldsymbol{x}_0) > c_\alpha, \text{ reject } H_0,$$
$$\text{if } d(x_0) \leq c_\alpha, \text{ accept } H_0,$$

The set of all outcomes that lead to "reject H_0" is called the *rejection region*. "Accept" and "reject" should be regarded as parts of the mathematical apparatus whose interpretation must be separately considered.

The test is specified so that the probability of a type I error, α, is fixed at some small number, such as .05 or .01, the *significance level* of the test:

$$\text{Type I error probability} = P(\text{Test T}(\alpha) \text{ Rejects } H_0; H_0) \leq \alpha.$$

Since "Test T(α) Rejects H_0" iff $\{d(X) > c_\alpha\}$, it follows that

$$\text{Type I error probability} = P(d(X) > c_\alpha; H_0) \leq \alpha.$$

N-P test principles then seek out the test that at the same time has a small probability of committing a type II error, β. Since the alternative hypothesis H_1, as is typical, contains more than a single value of the parameter, it is *composite*, the type II error probability is evaluated at a specific point $\mu = \mu_1$, and thus is abbreviated $\beta(\mu_1)$:

P(Test T(α) does not reject H_0; $\mu = \mu_1$) = $P(d(X) \leq c_\alpha; H_0) = \beta(\mu_1)$, for $\mu_1 > \mu_0$.

The "best" test with significance level β (if it exists) is the one that at the same time minimizes the value of β for all $\mu_1 > \mu_0$, or equivalently, maximizes the *power*:

$$\text{POW}(\text{T}(\alpha); \mu_1) = \text{P}(d(\text{X}) > c_\alpha; \mu_1), \text{for all } \mu_1 > \mu_0.$$

T(α) is said to be a *uniformly most powerful* (UMP) α significance level test. Letting $\alpha = .025$, $T(\alpha)$ If $d(x) > 1.96$, reject H_0. The rejection region for the corresponding two-sided .05 test, H_0: $\mu = \mu_0$ versus H_1: $\mu \neq \mu_0$, abbreviated as T(2α) is: $\{x : |d(x_0)| > 1.96\}$.

Error Probabilities Versus Conditional Probabilities

Confusion often results from interpreting the type I error probability: $\text{P}(\text{d}(\boldsymbol{X}) > c_\alpha; \text{H}_0)$ as a conditional probability statement of the form: $P(d(\boldsymbol{X}) > c_\alpha|H_0)$. From the definition of conditional probability it follows that

$$P(d(\boldsymbol{X}) > c_\alpha|H_0) = [P(d(\boldsymbol{X}) > c_\alpha, \mu = \mu_0)]/P(\mu = \mu_0).$$

However, neither the numerator $P(d(X) > c_\alpha, \mu = \mu_0)$ nor the denominator $P(\mu = \mu_0)$ of this ratio are meaningful unless the parameter may be assumed to be a random variable, as in a Bayesian approach (see Bayesianism).

In the N-P testing paradigm, there is no probability assignment to the conjunctive event $(d(\boldsymbol{X}) > c_\alpha, \mu = \mu_0)$ or to $(\mu = \mu_0)$. The statement $P(d(X) > c_\alpha; H)$, should be interpreted as the probability of rejecting H_0 when evaluated under the hypothetical scenario that the observed outcome x_0 has arisen from the distribution described in H_0. Within the error probability (frequentist) framework, a statistical hypothesis H either does or does not adequately describe the process generating the data. There is no suggestion that any H is precisely true; indeed, the purpose of tests is to evaluate discrepancies of specified sorts. But probabilities enter in this evaluation only as error probabilities.

Inductive Behavior Philosophy

Philosophical issues and debates arise once one begins to consider the uses to which these formal statistical tools might be put, the interpretations of the formal apparatus, and the justifiability of associated principles of tests. The proof by Neyman and Pearson of the existence of best tests set the stage for the mathematical development of statistical tests as rigorous rules for "deciding" to accept or reject hypotheses. In this conception, to infer the conclusion of the significance testing argument, 'data x_0 is evidence against H_0' or 'x_0 indicates the falsity of H_0,' is to take a decision of a sort, with a calculable risk. Wishing to draw a stark contrast between this conception of tests and those of Fisher as well as Bayesians (Jeffreys), Neyman declared that the goal of tests is not to adjust beliefs but rather to "adjust behavior" to limited amounts of data. Tests, accordingly, are not rules of inductive inference but rules of behavior. The value of tests as

rules of behavior is that "it may often be proved that if we behave according to such a rule ... we shall reject H when it is true not more, say, than once in a hundred times, and in addition we may have evidence that we shall reject H sufficiently often when it is false" (Neyman and Pearson 1933, 142).

Debates Between Fisher and Neyman and Pearson: The 1950s

The dispute between "inductive behavior" and "inductive inference" coming on top of the break between Fisher and Neyman, which began in 1935, commingled philosophical, statistical, and personality clashes. Fisher (1955) denounced the way that Neyman and Pearson transformed "his" significance tests into "acceptance procedures," wherein tests are viewed as mechanical rules or recipes for deciding to accept or reject statistical hypothesis H_0, and the concern has more to do with speeding up production or making money than in learning about phenomena. In responding to Fisher, Pearson clearly distanced himself from Neyman's "inductive behavior" jargon, calling it "Professor Neyman's field rather than mine" (Pearson 1955, 207). However, Pearson protested that neither he nor Neyman were "speaking of the final acceptance or rejection of a scientific hypothesis on the basis of statistical analysis. ... Indeed, from the start we shared Professor Fisher's view that in scientific enquiry, a statistical test is 'a means of learning'" (204–205).

Neyman, too, despite promoting "inductive behavior as a major concept in philosophy of science" (1957a), clearly denounced "mechanical" uses of significance tests (in responding to Fisher), and had no hesitation in using N-P tests for "inference" or reaching "conclusions." Tracing out the thrust and parry between Neyman, Pearson, and Fisher in the 1950s will amply reward those interested in what the key players "really thought." Later on, the N-P tests became so formally entrenched in the decision-theoretic framework of Wald (1950) that many of the qualifications by Neyman and Pearson in the first wave have been overlooked in the philosophy of statistics literature.

Confidence Interval Estimation Procedures

Statistical inference can take the form of estimation procedures as well as tests. In confidence interval (CI) estimation procedures, a statistic is used to set upper or lower (one-sided) or both (two-sided) bounds. The concept of a confidence interval with a frequentist interpretation was first introduced by Neyman (1935) as a way to extend point estimation to interval estimation, with a predesignated error rate. For a parameter, say, μ, a (1-α) confidence interval estimation procedure leads to estimates of form:

$$\mu = \bar{X} \pm \mathrm{e}$$

Different sample realizations x lead to different estimates, but one can ensure that $(1-\alpha)$ 100% of the time the true parameter value μ, whatever it may be, will be included in the interval formed.

Dualities Between One- and Two-Sided Intervals and Tests

There exists a duality relationship between CIs and hypothesis tests that can be used to derive optimality properties for CIs analogous to those of tests. The general correspondence between a $(1-\alpha)$ confidence intervals and tests is this: the confidence interval contains the values that would not be rejected by the given test at the specified level of significance (Neyman 1935); they would not be rejected because they would not be statistically significant (from the observed x_0) at significance level α, by the corresponding test. Consider test $\mathrm{T}(\alpha)$. It follows that the $(1-\alpha)$ one-sided interval corresponding to test $\mathrm{T}(\alpha)$ is $\alpha > \bar{X} - \mathrm{c}_\alpha(\sigma\sqrt{\mathrm{n}})$. In particular, the 97.5% confidence interval estimator corresponding to test $\mathrm{T}(\alpha)$ is:

$$\mu > \bar{X} - 1.96(\sigma\sqrt{\mathrm{n}}).$$

To grasp the duality, one must think not of a fixed null hypothesis, e.g., $\mu = 0$, but rather of different values for μ_0 that might have been tested. In particular, were the test of null hypothesis.

H_0: $\mu < (\bar{\tilde{x}}\mathrm{c}_\alpha(\sigma\sqrt{\mathrm{n}}), \mathrm{H}_0$ would have been rejected at level α. Similarly, the 95% CI for μ corresponding to the two-sided test, $\tilde{\mathrm{T}}(.05)$ is:

$$(\bar{X} - 1.96(\sigma\sqrt{\mathrm{n}}) \leq \mu < \bar{X} - 1.96(\sigma\sqrt{\mathrm{n}})).$$

These dualities will figure importantly in wave III.

Fisher's Criticism of Confidential Intervals: Fiducial Intervals

Calling $(1-\alpha)$ the "confidence level" of the estimation procedure was infelicitous. It encourages the supposition that $(1-\alpha)$ is the degree of confidence to be assigned the particular interval *estimate* formed, once $\bar{X}$ is instantiated with $\bar{x}$. That would be fallacious. Once the estimate is formed, either the true parameter is or is not contained in it. One can say only that the particular estimate arose from a procedure which, with high probability, $(1-\alpha)$,

would contain the true value of the parameter, whatever it is.

Fisher, in what is regarded as one of the most puzzling episodes in philosophy of statistics, seemed to advocate this fallacious instantiation for certain contexts. Fisher (1955) claimed N-P confidence interval methods are guilty of violating the principles of deductive logic by allowing

$$P(\bar{x} - c_\alpha(\sigma\sqrt{n}) \leq \mu < \bar{x} - c_\alpha(\sigma\sqrt{n})) = 1 - \alpha \quad (1)$$

and yet upon observing a particular $\bar{x}$, denying that the probability holds for the resulting CI estimate:

$$(\bar{x} - c_\alpha(\sqrt{n}) \leq \mu < \bar{x} - c_\alpha(\sqrt{n})) \quad (2)$$

Fisher claimed that, at least in certain special cases, it *was* possible to assign a probability or "fiducial distribution" to the interval statement about μ, while keeping within the sampling distribution perspective, a move that Savage (1962) described as "an attempt to make the Bayesian omelet without breaking the Bayesian eggs." Although the possibility of nonfallaciously instantiating into statement (1), to arrive at (2), without introducing a prior probability distribution, has tantalized researchers in philosophy of statistics, Fisher's fiducial argument is generally regarded as a lapse, even by Fisher's most ardent admirers (Hacking 1965; Seidenfeld 1979).

The Second Wave

The set of issues that swirled around the philosophy of statistics debates from the early 1960s through the late 1970s echoed the earlier debates but reflected as well changing problems in philosophy of science, statistics, and the statistical practices in the social sciences. Foundational debates of this period are noteworthy for the amount of direct interactions between philosophers of science and statistics; as is in evidence in the two significant collections of Godambe and Sprott (1971) and Harper and Hooker (1976).

As the most impressive mathematical developments of N-P theory occurred in a decision-theoretic framework, generalized further by Wald (1950)—the Neyman-Pearson-Wald (NPW) approach—it was the behavioristic-decision paradigm that bore the brunt of criticism from philosophy. Critics aimed at two central features of the "accept-reject" behavioristic conception of N-P tests: first, the justification of tests in terms of low (long-run) error rates alone, and second, the function of tests as routine, mechanical, or automatic accept-reject routines. While these features, taken strictly, give a caricature of tests—even as their founders intended and used them—they are at the heart of the philosophical criticisms of N-P testing. Not all critics call for tools that are more inferential and less decision-theoretic; some complained that N-P theory was at best a halfway house to a full-blown decision theory, with explicit loss functions, and prior probabilities that would be combined with measures of evidence (see Decision Theory). Because critics from both these camps hold a degree of confirmation stance, while error statisticians look to probability for objective measures of reliability of procedures, the disputants often talk past each other.

Error Probability Principle Versus Likelihood Principle

Hacking (1965) framed the main lines of criticism by philosophers in charging "Neyman-Pearson tests as suitable for before-trial betting, but not for after-trial evaluation" (99). Analogous charges are put in terms of distinctions between "initial precision" versus "final precision," and "before-data vs. after data" evaluation. According to such "post-data criticisms," N-P tools license inferences that while satisfactory from the pre-data viewpoint, seem unsatisfactory according to one of the post-data measures of (absolute or relative) evidential strength. The more general point may be put as follows:

- Data sets $\boldsymbol{x}$ and $\boldsymbol{y}$ may have exactly the same evidential relationship to hypothesis H, on a given degree of support measure, yet warrant different inferences according to significance test reasoning because x and y arose from tests with different *error probabilities*.

Such charges have weight, of course, only to the extent that one accepts the particular degree of support measure involved, the most common being based on the likelihood function of H, often written $L(H; \boldsymbol{x})$, where $L(H; \boldsymbol{x}) = P(\boldsymbol{x}; H)$. There is often confusion about likelihoods. Unlike the probability function, which assigns probabilities to the *different* possible values of the random variable of interest X, under some *fixed* value of the parameter(s) such as μ, the likelihood function gives the probability (or density) of a *given* observed value of the sample under the different values of the unknown parameter(s) such as μ.

Hacking (1965) championed an account of comparative support based on his "law of likelihood": Data $\boldsymbol{x}$ support hypotheses H_1 more than H_2 if the latter is *more likely* than the former, i.e.,

$P(\boldsymbol{x}; H_1) > P(\boldsymbol{x}; H_2)$. When there are many hypotheses, one takes the one that maximizes the likelihood. A problem is that there is always the rival hypothesis that things had to turn out the way they did. If such an alternative can always be constructed, then it will be possible to find H less well supported than some other hypothesis, even if H is true. Hacking (1965) rejected this likelihood approach on these grounds, but likelihoodist accounts are advocated by others and remain the focus of active interest (Birnbaum 1961; Royall 1997).

The likelihood function has an important role in all of the statistical accounts, but for those who endorse the likelihood principle, likelihoods suffice to convey "all that the data have to say." That is the gist of the *likelihood principle*—a pivot point around philosophy of statistics discussions:

> According to Bayes's theorem, $P(x|\mu)$...constitutes the entire evidence of the experiment, that is, it tells all that the experiment has to tell. More fully and more precisely, if y is the datum of some other experiment, and if it happens that $P(x|\mu)$ and $P(y|\mu)$ are proportional functions of μ (that is, constant multiples of each other), then each of the two data x and y have exactly the same thing to say about the values of μ .... (Savage 1962)

By contrast, the error probabilist must consider, in addition, the sampling distribution of the likelihoods (under hypotheses of interest). Thus, as Savage (1962) argued, significance levels and other error probabilities all violate the likelihood principle, leading to one of the most crucial philosophical controversies.

Debate Over the Relevance of the Stopping Rule

The conflict between significance levels and the LP is often illustrated by a variation on the two-sided test $T(2\alpha)$: a random sample from a normal distribution with mean μ and standard deviation 1, that is, $X_i \sim N(\mu, 1)$; with H_0: $\mu = 0$, and H_1: $\mu \neq 0$. However, instead of fixing the sample size n in advance, n is determined by a *stopping rule*:

$$\text{Keep sampling until } |\bar{x}| \geq 1.96/\sqrt{n}.$$

The probability that this rule will stop in a finite number of trials is 1, regardless of the true value of μ; it is a *proper* stopping rule. Whereas with n fixed in advance, such a test has a type 1 error probability of .05, with this stopping rule, the actual significance level differs from, and is greater than .05. Significance levels are sensitive to the stopping rule; and there is considerable literature on error probability adjustments for "optional stopping," that is, on *sequential tests* (e.g., Armitage 1961). By contrast, since likelihoods are unaffected by this stopping rule, the LP proponent denies there is an evidential difference between the two cases. For some, this was yet further grounds to embrace a Bayesian account:

> The likelihood principle emphasized in Bayesian statistics implies,...that the rules governing when data collection stops are irrelevant to data interpretation. It is entirely approprioate to collect data until a point has been proved or disproved. (Edwards, Lindman, and Savage 1963, 193)

For others it only underscored the point raised by Pearson and Neyman, that "knowledge of [the likelihood ratio] alone is not adequate to insure control of the error involved in rejecting a true hypothesis" (Pearson and Neyman 1930, 106). The literature here is vast; at best one can list sources (beyond those already mentioned) with fairly broad citations (Cox and Hinkley 1974; Mayo and Kruse 2001).

The key difference between the two perspectives is that the holder of the LP considers the likelihood of the *actual* outcome, that is, just $d(\boldsymbol{x})$, whereas the error statistician considers the likelihoods of values *other than the one observed* in order to assess the properties of the test procedure. The calculation of error probabilities, the sampling distribution, all depend on the relative frequency of outcomes other than the one observed, for example, outcomes as or more statistically significant—the "tail area." This remains a pivot point around which controversy in philosophy of statistics revolves. It is not a matter of one side being right and the other wrong, it is a matter of holding different aims, which in turn grow out of different philosophies of statistics.

The Significance Testing Controversy

Morrison and Henkel (1970) stands as a hallmark to the foundational issues wrestled with by social and behavioral scientists of this period. Where philosophers directed most of their criticisms to N-P tests, the focus here tended to center on simple Fisherian significance tests that had been widely adopted in psychology and other social sciences. Chastising social scientists for applying significance tests in slavish and unthinking ways, contributors call attention to a cluster of pitfalls and fallacies of testing. These fallacies are at the center of the philosophical controversies in this and later waves:

(i) *Large N Problem*: With large enough sample size, an α significant rejection of H_0 can be

very probable, even if the underlying discrepancy from μ_0 is substantively trivial. In fact, for any discrepancy from the null, however small, one can find a sample size such that there is a high probability (as high as one likes) that the test will yield a statistically significant result (for any p-value one wishes). Nevertheless, as Rosenthal and Gaito (1963) document, statistical significance at a given level is often (fallaciously) taken as more evidence against the null the larger the sample size (n). In fact, it is indicative of *less* of a discrepancy from the null than if it resulted from a smaller sample size. The "large n problem" is also the basis for the "Jeffrey-Good-Lindley" paradox brought out by Bayesians: even a highly statistically significant result can, as n is made sufficiently large, correspond to a high posterior probability accorded to a null hypothesis (see Bayesianism). Some suggest adjusting the significance level as a function of n, others, introducing some measure of the size of the discrepancy or "effect size" indicated. These issues return in the third wave.

(ii) *Fallacy of Non-Statistically Significant Results*: Test T(α) fails to reject the null, when the test statistic fails to reach the cutoff point for rejection, that is, $d(\boldsymbol{x}_0) \leq c_\alpha$. A classic fallacy is to construe such a "negative" result as evidence of the correctness of the null hypothesis. The problem is that merely surviving the statistical test is too easy, occurs too frequently, even when the null is false. One can always find a sufficiently small discrepancy δ from the null such that the test has low power to detect it. Thus, it would be fallacious to regard insignificant results as evidence that the discrepancy is less than δ, much less that there is no discrepancy at all. With publishers demanding at least a .05 significant result for publication, many of these studies remain tucked away, the so-called "file-drawer problem" (Meehl 1990).

The Power Analytic Movement of the 1960s

In their attempt to inculcate the calculation of power in psychology Cohen (1988) and others began, in the 1960s, the "power analytic" movement. The attention to power, of course, was a key feature of N-P tests, but apparently the prevalence of Fisherian tests in the social sciences, coupled, perhaps, with the difficulty in calculating power, resulted in power receiving short shrift.

Although this was less well advertised, the power analysts used power not only for planning but for interpreting nonsignificant results post-data: If a non-statistically significant result occurred with a test with low power to detect discrepancies of interest, the power analysts urged, then such a nonsignificant result should not be taken to rule out such departures from the null. In so doing, one is codifying a means to avoid the fallacy of taking "no evidence against" the null as "evidence for" the null.

It may be surprising to include Neyman, but one finds just such a post-data use of power in the occasional papers of Neyman in the 1950s. In one, Neyman addresses Carnapian confirmation: "In some sections of scientific literature the prevailing attitude is to consider that once a test, deemed to be reliable, fails to reject the hypothesis tested, then this means that the hypothesis is "confirmed". Calling this "a little rash" and "dangerous," he claims "a more cautious attitude would be to form one's intuitive opinion only after studying the power function of the test applied" (Neyman 1955, 41).

One is advised to consider: (i) how large a discrepancy from the null is considered "important" or non-trivial on substantive grounds (to be determined by the tester) $\delta_{\text{non-trivial}}$, and (ii) the power of detecting a $\delta_{\text{non-trivial}}$ with the test actually used, for example, Power($T(\alpha)$,$\delta_{\text{non-trivial}}$). If the power is low, "the fact that the test failed to detect the existence of δ "does not mean very much. In fact, [$\delta_{\text{nontrivial}}$] may exist and have gone undetected" Neyman (1957b, 16). So here in Neyman are the basic outlines of the post-data "power analytic" movement, admittedly, largely lost in the standard decision-behavior model of tests.

However, even the post-data use of power retains an unacceptable coarseness: power is always calculated relative to the cutoff point $c_\square$ for rejecting H_0. Consider test T($\alpha = .025$), $\sigma = 1$, $n = 25$, and suppose $\delta_{\text{non-trivial}} = .2$ is deemed "substantively important". To determine if "it is a little rash" to take a nonsignificant result, say $d(\boldsymbol{x}) = -.2$, as reasonable evidence that $\delta < \delta_{\text{nontrivial}}$ (i.e., an important discrepancy is absent), one is to calculate POW(T($\alpha = .025$), $\delta_{\text{nontrivial}}$) which is only .16! But why treat the particular non-significant result the same no matter how close it is to μ_0 (i.e., 0)? In fact P($d(\boldsymbol{x}) > -.2$; .2) $\approx$ .93. That is, were μ as large as .2, the test very probably would have detected

a more significant result. This suggests that rather than calculating

$$\mathrm{P}(d(\boldsymbol{X}) > \mathrm{c}_\alpha; \mu = .2), \qquad \text{(A)}$$

one should calculate

$$\text{(B)}\mathrm{P}(d(\boldsymbol{X}) > d(\boldsymbol{X}_0); \mu = .2). \qquad \text{(B)}$$

Even if (A) is low, (B) may be high. Whether Neyman and Pearson did or would have endorsed this modification of the pre-data error probabilities is an open question. The issue reappears in the "reforms" of the third wave.

The Third Wave: Relativism, Reforms, Reconciliations

Statistics in Meta-Methodology

In the 1980s and 1990s statistical inference began to figure in rational reconstructions of scientific episodes, in appraising methodological rules e.g., the value of novel evidence, the prediction versus accommodation debate (e.g., Howson and Urbach 1989; Glymour 1980; Mayo 1991) and in attempts to solve classic philosophical problems, such as Duhem's problem (Howson and Urbach 1989). The recognition that science in general, and statistical inference in particular, involves subjective judgments and values, the statistical method, most often appealed to here is largely one or another subjective Bayesian account. One can explain historical cases wherein anomalies are blamed on background rather than a hypothesis H, some argue, by showing how plausible prior beliefs could still permit H to have a reasonably high posterior degree of belief. Others charge that the very flexibility Bayes's theorem offers in reconstructing cases as rational is to sidestep the question at hand: Which hypothesis *ought* to be blamed for an anomaly? (Mayo 1997; Worrall 1993).

Bayesian Advances and Controversy

The heat of the old debates is less in evidence in the third wave. For the most part statisticians are comfortable with an eclecticism, wherein different methods may be suitable for different functions, for example "pure" (Fisherian) tests in some cases, N-P "decision procedures" in others, along with good-sense, informal recommendations for their interpretation. To others, particularly nonstatistician practitioners (e.g., in psychology, ecology, medicine), the situation seems less one of joyful eclecticism, and more one of "unholy hybrids" yielding a mixture of ideas from N-P methods, Fisherian tests, and Bayesian accounts that is "inconsistent from both perspectives and burdened with conceptual confusion" (Gigerenzer 1993, 323). Because increasingly philosophers of science come to these issues by way of subject matter fields, they are more likely to be users of the latest methods rather than occupy their historical role as outside critic.

The use of Bayesian methods has grown exponentially both because of the philosophical problems with error statistical methods as well as the development of effective computational tools such as a Markov Chain Monte Carlo (MCMC). The rise in statistical computer packages means that Bayesian and non-Bayesian methods are readily available, encouraging the practitioner to view them as simply enriching the statistical toolkit rather than as reflecting different perspectives on philosophical foundations. In this sense the use of high-powered statistical tools increases the distance between the use and philosophical foundations of the methods. But when competing interpretations arise, as they often do, the philosophical questions from the first and second waves re-emerge. Most especially are debates about the role and justification of Bayesian prior probabilities. Operating with mathematically convenient priors is common but, as Bayesians are well aware, more is needed to justify them. One important argument put forward shows that with sufficient data, posterior probabilities will converge even if they are based on different priors (see Bayesianism). As Kyburg (1993, 146) shows, however, for any body of data there are non-extreme prior probabilities that will result in posteriors that differ by as much as one wants.

A related argument defending the use of priors shows that it is possible to ascertain the influence different priors may have, and so long as the posterior remains relatively insensitive the Bayesian inference is *robust* to the prior. A question that arises is this: if when the choice of prior is found to matter one must seek a different procedure, and if there are sufficient data such that the choice of prior scarcely matters, then why is the prior relevant at all? Does not this revert to the goal that drove Neyman, namely, to find procedures whose validity does not depend on the priors? The appeal of error statistical methods, despite problems, is that they apply for the kinds of uncertain cases scientists often face. Granted it is appealing to enlist the beliefs of "experts," but the question is how to retain the ability to critique and hold them accountable—a growing concern in evidence-based policy. Error probabilities can be calibrated against empirical frequencies, but can one equally well calibrate the opinion of the experts?

Reforms Within Error Statistics

There is an extensive movement to retain error statistical tools and yet reform them in order to avoid the well-known fallacies and shortcomings. The significance test fails to convey the effect of discrepancy warranted, and thus many journals require they be supplemented with measures of effect size. The most fruitful idea seems to be to appeal to two sided CI estimation procedures, even in interpreting the one-sided test T(α).

Consider interpreting non-significant results. Since all elements of the CI "fit" or are consistent with the outcome at the given level, the interpreter is deterred from thinking there is evidence for 0. But, as critics note, this will not go far enough to block fallacies of acceptance in general. For example, the $(1 - 2\alpha)$ CI for the parameter μ in test T(α) with $\alpha = .025$ is: $[\bar{x} - 1.96(\sigma\sqrt{\mathrm{n}}), \bar{x}1.96(\sigma\sqrt{\mathrm{n}})]$ $\sigma = 1, n = 25, (\sigma\sqrt{n}) = .2$. Outcome $\bar{x} = .39$ just fails to reject H_0 at the .025 level, and correspondingly 0 is included in the two-sided 95% interval: $(-.002 < \mu < .782)$ (see duality between tests and CIs, above). Consider now the inference $\mu < \mu_1$ for μ_1 within the CI, say, $\mu < 0.2$. The hypothesis $\mu < 0.2$ is non-rejectable by the test—it is a survivor, as it were. But the construal is dichotomous: In or out, plausible or not; all values within the interval are *on par*, as it were (Mayo 1996). This does not adequately prevent fallacious interpretations of non-significance (fallacies of acceptance). Although $\bar{x}$ is not sufficiently greater (or less) than any of the μ values in the confidence interval to reject them at the α-level, this does not imply there is evidence *for each* of the values in the interval (Mayo and Spanos 2005).

Severity Assessments

The power analyst would seem to do better here. For each value of μ_1 in the confidence interval, there would be a different answer to the question: What is the power of the test against μ_1? Thus the power analyst makes distinctions that the CI interval theorist does not. The power analyst blocks the inference $\mu < 0.2$ since POW(T($\alpha = .025$), .2) is low (.16). But, as seen in the second wave, there is an important weakness of the use of power to avoid fallacies of acceptance. Were the result not $\bar{x} = .39$, but rather $\bar{x} = -.2$, the test again fails to reject H_0, but the power analyst, looking just at $\mathrm{c}_\alpha = 1.96$ is led to the same assessment denying there is evidence for $\mu < 0.2$. (power analysts commonly recommend a power of .8 as high). Although the "prespecified" power is low, .16, it seems clear that the interpretation, post-data, should reflect the actual outcome, and there is a high probability for a more significant result than the one attained, were μ as great as 0.2! Rather than construe "a miss as good as a mile," parity of logic suggests that the post-data power assessment should replace the usual calculation of power against μ_1:

$$\mathrm{POW}(\mathrm{T}(\alpha), \mu_1) = P(d(\mathbf{X}) > \mathrm{c}_\alpha; \mu = \mu_1),$$

with what might be called the *power actually attained* or, to have a distinct term, the *severity (SEV)*:

$$\mathrm{SEV}(\mathrm{T}(\alpha), \mu_1) = \mathrm{P}(d(\mathbf{X}) > d(x_0); \mu = \mu_1),$$

where $d(x_0)$ is the observed (nonstatistically significant) result (Mayo and Cox 2005). SEV(T(α), $d(\boldsymbol{x}_0)$, $\mu < \mu_1$) is a shorthand for "the severity of the test which $\mu < \mu_1$ has passed on the basis of the insignificant result $d(x_0)$ from test T(α)." This is the post-data measure of a test's *severity* for detecting discrepancies as large as $\gamma = \mu_1 - \mu_0$. Since T(α)'s probativeness would be even higher for greater values of μ, it follows that SEV(T(α), $\mu < \mu_1$) > P($d(\mathbf{X}) > d(x_0)$; $\mu = \mu_1$) Mayo and Spanos 2005).

The philosophical position here is that error probabilities serve a function in a post-data interpretation of statistical inferences, by characterizing the probativeness of the particular test result with respect to a particular interpretation or particular inference on may wish to consider: Pre-data, one is balancing the two types of errors; but post-data, the concern shifts to evaluating if particular inferences are warranted. Figure 1 compares power and severity.

Conversely, for any non-significant result from test T(α), one may find the value of μ against which the test has high severity, say .975. This is solved by $\mu_1 = \bar{x} + 1.96\sigma_{\mathrm{x}}$, which is noticed to be the same value as the upper bound of a two-sided .95 level CI, μ. However, unlike the use of CIs, the severity analysis discriminate between inferences $\mu < \mu_1$ for different values of μ_1 within the interval. The computations related to delineating a series of observed CIs at different levels can be found in Kempthorne's "consonance intervals" (Kempthorne and Folks, 1971) and "confidence curves," "*p*-value functions" (Birnbaum 1961; Poole 1987). These strategies are motivated by the desire to move away from (i) having to choose a particular confidence level (or corresponding *p*-value), (ii) the dichotomous, "up"/"down" interpretations of tests. There would appear to be an important difference with these approaches, at least in emphasis. If one is thinking of values "consistent" with the observed data x_0, then a value μ' near the center of the CI is more in accord with x_0 than is μ'' near the upper CI bound;

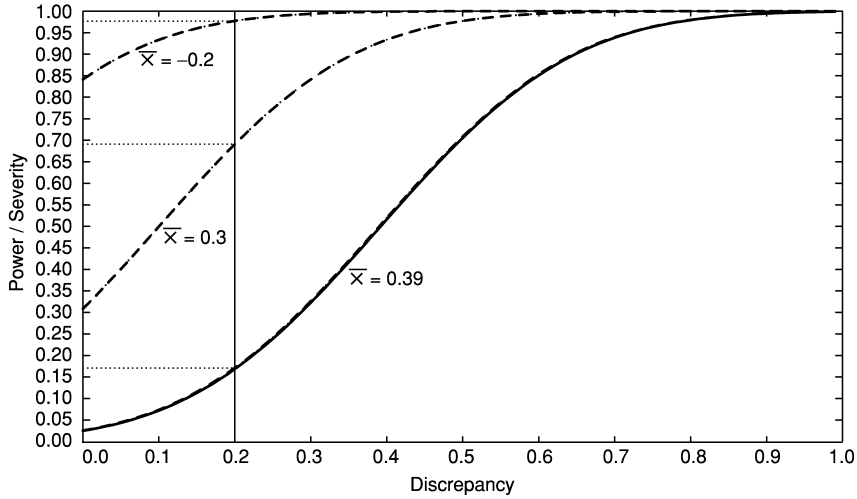

Fig. 1. The graph shows that whereas $\mathrm{POW}(\tilde{\mathrm{T}}(.025), \mu_1 = .2) = .168$, irrespective of the value of $d(\boldsymbol{x}_0)$ (or $\bar{\mathrm{x}}$); see solid curve, the severity evaluations are data-specific: for $\mathrm{d}(\mathrm{x}_0) = 1.95(\text{or } \bar{\mathrm{x}} = .39), \mathrm{SEV}(\tilde{\mathrm{T}}(.025), \mu < .2) = .171$; for $\mathrm{d}(\mathrm{x}_0) = 1.50(\text{or } \bar{\mathrm{x}} = .30), \mathrm{SEV}(\tilde{\mathrm{T}}(.025), \mu < .2) = .691$, and for $\mathrm{d}(\mathrm{x}_0) = -1.0(\text{or } \bar{\mathrm{x}} = -.2), \mathrm{SEV}(\tilde{\mathrm{T}}(.025), \mu < .2) = .977$.

however the inference $\mu < \mu''$ has passed a more probative test than has $\mu < \mu'$.

Fallacies of Rejection: The Large n *Problem*

While with a nonsignifi*cant* result, the concern is erroneously inferring that a discrepancy from μ_0 is absent; with a *significant* result x_0, the concern is erroneously inferring that it is present. Rejection need not be discussed separately here (see Mayo 1996), since for any H: $\mathrm{Sev}(\neg H) = 1 - \mathrm{Sev}(H)$, it follows for the particular case of H_1: $\mu > \mu_1$ $\mathrm{Sev}(\mu > \mu_1) = 1 - \mathrm{Sev}(\mu < \mu_1) = 1-$ (actual power at $(\mu = \mu_1)$.

The "large n" problem already made its splash in the second wave: With large enough sample size, an α significant rejection of H_0 can be very probable for any discrepancy α from μ_0, even if it is *substantively* trivial. Utilizing the severity assessment, an α-significant difference with n_1 passes $\mu > \mu_1$ less severely than with n_2 where $n_1 > n_2$.

Figure 2 compares test $\mathrm{T}(\alpha)$ with three different sample sizes: $n = 25$, $n = 100$, $n = 400$, denoted by $\mathrm{T}(\alpha, n)$; where in each case $d(x_0) = 1.96$ − reject at the cutoff point.

More generally, if two (otherwise identical) tests with different sample sizes give rise to rejections of H_0 at the same p-value, the result from the smaller sample experiment indicates a greater extent of a discrepancy from H_0 than from the larger. This immediately scotches the "large n problem," and simultaneously provides a way to supply p-values with assessments of population discrepancy (or effect size) that can be compared across different tests.

P-*values and Bayesian Posteriors*

Severity is an error probability calculation *based on* the actual data (and inference of interest) but it must be distinguished from what has sometimes been called the *conditional* "error probability" understood as a posterior probability. The most well-known fallacy in interpreting significance tests is to equate the p-value with a posterior probability on the null hypothesis. The p-value assessment refers only to the sampling distribution of the test statistic $d(X)$; and there is no use of priors. The Jeffrey-Good-Lindley "paradoxical" examples (see above) shows that attaining a fixed p-value, with a sufficiently large n, can correspond to large posterior probabilities for H_0. More recent work generalizes the result (Berger and Sellke 1987). Although from the degree-of-confirmation perspective, it follows that p-values come up short as a measure of evidence, the significance testers balk at the fact that use of the recommended priors can result in highly significant results being construed as no evidence against the null—or even evidence for it! An interesting twist in recent work is to try to "reconcile" the p-value and the posterior (e.g., Berger 2003).

The conflict between p-values and Bayesian posteriors often considers the familiar example of the two-sided $\mathrm{T}(2\alpha)$test, H_0: $\mu = \mu_0$ versus H_1:$\mu \neq \mu_0$. The difference between p-values and posteriors

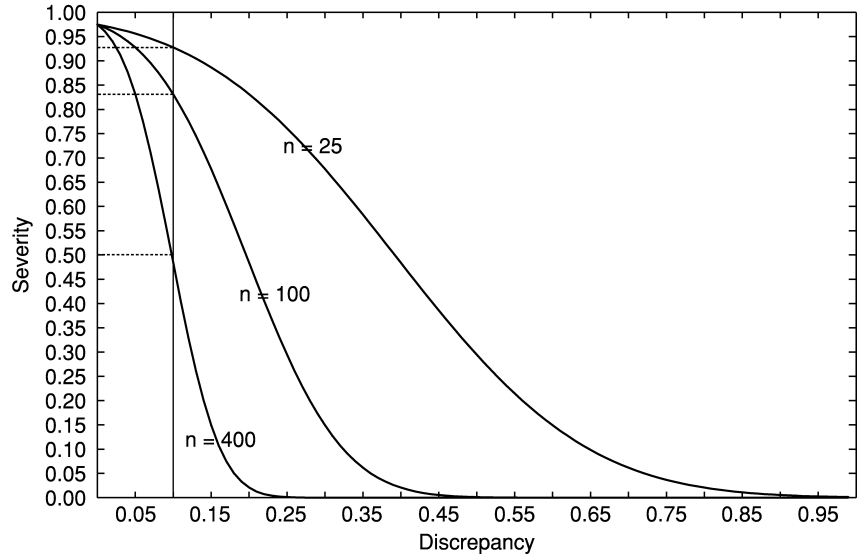

Fig. 2. In test $\mathrm{T}(\alpha), (\mathrm{H}_0 : \mu \leq 0$ against $\mathrm{H}_1 : \mu > 0,$ and $\sigma = 1), \alpha = .025, \mathrm{c}_\alpha = 1.96$ and $\mathrm{d}(\boldsymbol{x}_0) = 1.96$. Inference under evaluation:
$\mu > 0.1 : \mathrm{SEV}(\mathrm{T}(\alpha, 25), \mu = 0.1) = .93; \mathrm{SEV}(\mathrm{T}(\alpha, 100), \mu = 0.1) = .83; \mathrm{SEV}(\mathrm{T}(\alpha, 400), \mu = 0.1) = .5$

are far less marked with one-sided tests (e.g., Pratt 1977). "If $n = 50$ one can classically 'reject H_0 at significance level $p = .05$,' although $\mathrm{P}(\mathrm{H}_0|x) = .52$ (which would actually indicate that the evidence favors H_0)" (Berger and Sellke 1987, 113, replace *Pr* with *P* for consistency). Thus, data that the significance tester would regard as evidence against H_0, would, on the Bayesian construal being advocated actually indicate that the evidence favors H_0. If $n = 1000$, a result statistically significant at the .05 level leads to a posterior to the null of .82!

What makes the example so compelling to many is its use of an "impartial" or "uninformative" Bayesian prior probability assignment of .5 to H_0, the remaining .5 probability being spread out over the alternative parameter space, e.g., as recommended by Jeffreys (1939). Others charge that the problem is not *p*-values but the high prior. Moreover, the "spiked concentration of belief in the null" is at odds with the prevailing view "we know all nulls are false." Note too the conflict with CI reasoning since *0* is outside the corresponding CI.

Some examples strive to keep within the frequentist camp: to construe a hypothesis as a random variable, it is imagined that there is random sampling from a population of hypotheses, some proportion of which are assumed to be true. The percentage "initially true" serves as the prior probability for H_0. This gambit is common across all philosophy of statistics literature, and yet it commits a fallacious instantiation of probabilities:

> 50% of the null hypotheses in a given pool of nulls are true.This particular null hypothesis H_0 was randomly selected from this pool. Therefore $\mathrm{P}(H_0$ is true$) = .5$.

Faced with conflicts between error probabilities and Bayesian posterior probabilities, the error probabilist would conclude that the flaw lies with the latter measure. This is precisely what Fisher argued, and it seems fitting to end up this retrospective with a return to him.

Discussing a test of the hypothesis that the stars are distributed at random, Fisher takes the low *p*-value (about 1 in 33,000) to "exclude at a high level of significance any theory involving a random distribution" (Fisher 1956, 42). Even if one were to imagine that H_0 had an extremely high prior probability, Fisher continues—never minding "what such a statement of probability a priori could possibly mean"—the resulting high posteriori probability to H_0, he thinks, would only show that "reluctance to accept a hypothesis strongly contradicted by a test of significance" (ibid, 44) "is not capable of finding expression in any calculation of probability a posteriori" (ibid, 43). It is important too to recognize that sampling theorists do not deny there is ever a legitimate frequentist prior probability distribution for a statistical hypothesis: one may consider hypotheses about such distributions and subject them to probative tests. Indeed, if one were to consider the claim about the a priori probability to be itself a

hypothesis, Fisher suggests, it would be rejected by the data!

Concluding Comment

Underlying the central points of controversy in the three waves of philosophy of statistics lie two contrasting philosophies of the role of probability in statistical inference. In one tradition, probability is used to provide a post-data assignment of degree of probability, confirmation, support or belief in a hypothesis (e.g., Bayesian and likelihood accounts); while in a second, probability is used to assess the probativeness, reliability, trustworthiness, or severity of a test or inference procedure (e.g., significance tests, N-P tests, CI). This basic contrast in underlying aims corresponds to conflicting principles for appraising methods: satisfying the likelihood principle, as opposed to controlling error probabilities. Whether statistical methodology should be regarded as supplying different tools depending on the task at hand, or whether the different methods can or should be reconciled in some way, are likely to remain questions of debate for a good while longer.

SUPERVENIENCE

The term 'supervenience,' as appropriated by the philosophical community, denotes a relation between two families of properties. Roughly stated, the *A*-properties supervene on the *B*-properties just in case there can be no difference in *A*-properties without some difference in *B*-properties. Equivalently, if two things are exactly alike in *B*-properties, they must be exactly alike in *A*-properties.

A simple and uncontroversial example of supervenience may help fix ideas: the case of aesthetic and nonaesthetic properties. If any two objects are exactly alike with regard to their nonaesthetic properties, they must be exactly alike with regard to their aesthetic properties; indiscernibility in nonaesthetic properties requires indiscernibility in aesthetic properties. Other normative properties

display the same supervenience; for instance, any two actions that differ morally must differ in some nonmoral aspect as well.

The normative domain in fact was the original focus of philosophical musing on supervenience. The notion has more recently been found to be a useful tool in many areas of philosophy. In the philosophy of science in particular, supervenience is most prominent as one option for thinking about the ways in which various scientific domains might be related to each other. The idea that biological phenomena are entirely dependent on chemical phenomena, for example, might be clarified by talk of the supervenience of biological properties on chemical properties. Such claims are apt to be found attractive by those who want to endorse some sort of unity of science thesis without committing themselves to reductionism. Much of the contemporary discussion of supervenience has, after all, been prompted by Davidson's (1970) suggestion in his 'Mental Events' paper that supervenience might capture a kind of dependence of the mental on the physical that does not amount to reducibility. Whatever exactly reduction is, of course, is subject to considerable debate; and in certain views it is not clear that a supervenience thesis can avoid the commitment (see especially the work of Kim 1993) (see Reductionism).

The attractions of supervenience can be understood independently of any desire to avoid reductionism, however. Two aspects of the notion make for its appeal. First, when one family of properties supervenes on another, this often seems to reflect a more fundamental relationship of determination, where the supervenient properties are determined by the properties on which they supervene. The way in which these properties (sometimes called the "subvenient" properties) are distributed fixes the way in which the supervenient properties are distributed. Second, a supervenience thesis is quite minimal in character; it says very little about exactly how the one family of properties is a function of the other. This minimal character is responsible for the avoidance of reduction, but it can be counted as a virtue on its own.

Supervenience, Determination, and Explanation

Philosophers are often engaged in a distinctive explanatory project wherein they want to say that one sort of property is instantiated in virtue of the instantiation of others. A handful of typical philosophical questions makes this obvious: What makes a theory well confirmed? When does an action count as voluntary? What is it in virtue of which something has a mind? When two events are related as cause and effect, what constitutes their being thus related? The sort of explanation sought here is plainly not a causal one; this is especially evident in the last question (see Causality).

While these questions are ubiquitous, they are not very well understood. Nonetheless, one salient fact about them is this: They call for answers that would cite facts that fix or determine the fact to be explained, where this fixing is of a distinctively noncausal sort. Consequently, any proposed answer to a question of this distinctive sort carries with it an associated supervenience claim. Consider again the clear case of aesthetic supervenience: The supervenience of the aesthetic on the nonaesthetic is a reflection of the fact that whenever something has an aesthetic property, it has that property *because* of its nonaesthetic properties. Similarly, if the distribution of biological properties is indeed a result solely of the way things are chemically, then the supervenience of biological properties on chemical properties is assured.

Is this noncausal relation itself definable in terms of supervenience? Since supervenience is defined in terms that many philosophers count as relatively clear and unproblematic, such a feat would certainly help in addressing the sorts of philosophical questions at issue. Few now think, however, that any sort of supervenience is sufficient for the noncausal fixing relation in question. A certain historical irony is to be borne in mind. Philosophers' interest in supervenience can be traced back to meta-ethical discussions, especially those instigated by G. E. Moore. Famously, Moore held that ethical properties were "nonnatural"; he would deny that something's being good was constituted solely by its having certain nonethical properties. Nonetheless, he accepted the supervenience of the ethical on the nonethical. In light of this, the hope that supervenience might capture the right sort of dependence can seem fundamentally misguided.

History aside, there are independent reasons for thinking that no variety of supervenience can suffice for the determination relation in question. The simplest point to bear in mind is that supervenience is fundamentally nothing more than a holistic sufficiency relation. While no particular subvenient property is said to suffice for any particular supervenient property, each possible combination of all subvenient properties is sufficient for some possible combination of supervenient properties. Since it is well known that sufficiency by itself does not guarantee causation, it can seem

unlikely that supervenience alone could guarantee the desired noncausal relation (Horgan 1993).

Even if no sufficiency relation can capture the right determination relation, the point remains that answers to the sorts of questions gestured at above seem to imply supervenience theses in a way that may help clarify the plausibility or significance of those answers.

Supervenience and Neutrality

The other aspect of supervenience that makes it appealing is its convenient neutrality, which comes into play when one generalizes over a variety of explanations of a similar sort. Consider the question of what makes something a law of nature. One may want to commit oneself to the claim that such a definition would be limited to facts about actual regularities. In doing so, one may want to avoid specifying exactly which facts about such regularities make the difference or how those facts make the difference; one may even want to avoid commitment to the claim that any particular facts about regularities can be picked out as especially salient to that determination. In this case, it is useful to clarify one's position by saying that any two worlds in which the very same actual regularities hold must be exactly alike with regard to their laws of nature—in other words, that the laws supervene on the regularities (see Laws of Nature). Supervenience thereby provides a relatively tidy and widely applicable way of capturing disputes about what determines what.

Occasional complaints about supervenience theses seem to ignore this feature. The infamous "wayward atom" example employed to raise doubts about the utility of "global" supervenience might be such a complaint (Kim 1987). Consider the thesis that any two worlds that are physically indiscernible are mentally indiscernible. This is consistent with there being a pair of worlds that differ physically in only one very small way (say, an atom in one location in the first world is displaced to a different location in the other), but differ radically in mental respects. The example is meant to cast doubt on the utility of the supervenience thesis. The proper response is to stress that the whole point of offering a supervenience thesis instead of a detailed account of which subvenient properties determine others is to avoid taking a stand on what, exactly, makes a difference. As a result, such theses will make room for bizarre theories about what makes a difference. Consider the example of laws and regularities suggested earlier. One might want to say that the laws supervene on the regularities; it is consistent with this claim, however, that there be a world differing from this one in its regularities in only the smallest fashion (say, there is just one fewer instance of the regularity that aspirin relieves headache) while differing radically in its laws of nature (say, there are no laws at all—everything happens by chance). If one wants to rule out such worlds, one needs to take a more definite stand on the initial explanatory claim, thus removing the motivation for appealing to supervenience in the first place.

An Approach to Taxonomy

One good way to approach the variety of supervenience relations is by first distinguishing three parameters that must be specified in formulating any particular supervenience thesis.

1. The *relata*: Which two families are at issue?
2. The *modal status* of the claim: When it is said that indiscernibility in subvenient properties requires indiscernibility in supervenient properties, what is the force of the requirement?
3. The mechanism of comparison: What sorts of objects are to be compared for (in)discernibility, and how exactly are the relevant pairs to be selected?

The first two parameters are relatively straightforward matters of stipulation. The options available for the third are less straightforward; the discussion will focus on these. Throughout, A will be the family of supervenient properties, and B will be the family of subvenient properties. For simplicity, the assumption will be that the modal parameter is absolute necessity, so that the range of possible worlds at issue is *all* of them.

There are two well-known options for the third parameter. One might compare particular individuals or entire possible worlds. A third option is to compare regions of space-time (Horgan 1982), but this may be left aside for the sake of space and because it introduces no fundamentally new issues.

Individual Comparison Supervenience

Say that two particular individuals are "F-indiscernible" just in case they are indiscernible with respect to family F of properties. More precisely, the notion may be defined for individuals at times as follows: x at t_1 and y at t_2 are F-indiscernible just in case, for every property P in family F, x has P at t_1 if and only if y has P at t_2.

The following is, then, the nonmodal core of what may be called *individual comparison* (IC) supervenience:

> For any individuals x and y and times t_1 and t_2, if x at t_1 and y at t_2 are B-indiscernible, then x at t_1 and y at t_2 are A-indiscernible.

Kim (1984), in his seminal "Concepts of Supervenience," has made famous three varieties of supervenience he dubs weak, strong, and global. His strong and weak supervenience relations are varieties of IC supervenience that differ in the way in which they select the individuals to be compared. The weak version compares individuals only *within* worlds, while the strong version compares individuals *across* worlds as well. Instead of weak and strong, one might call them

1. *intraworld IC supervenience*: For any possible world w, for any individuals x and y and times t_1 and t_2, if x at t_1 in w and y at t_2 in w are B-indiscernible, then x at t_1 in w and y at t_2 in w are A-indiscernible; and
2. *crossworld IC supervenience*: For any possible worlds w_1 and w_2, for any individuals x and y and times t_1 and t_2, if x at t_1 in w_1 and y at t_2 in w_2 are B-indiscernible, then x at t_1 in w_1 and y at t_2 in w_2 are A-indiscernible.

Intraworld IC supervenience ensures that any two objects within a given world are A-indiscernible if B-indiscernible. This is consistent with there being a pair of objects drawn from two distinct worlds that are B-indiscernible yet A-discernible. Crossworld IC supervenience rules out this latter situation.

Few philosophers have found occasion to appeal to an intraworld IC supervenience thesis. It is not difficult to see why. Suppose a supervenience thesis is wanted because it is thought that the A-properties are always instantiated in virtue of B-properties. Suppose there is only one A-property P_A and only one B-property P_B; now consider two worlds (Figure 1) such that each contains only two objects o_1 and o_2 existing for a span of time during which they undergo no change, having at all moments the following array of properties:

w_1	w_2
o_1 has P_B and P_A.	o_3 has P_B and lacks P_A.
o_2 lacks P_B and lacks P_A.	o_4 lacks P_B and has P_A.

Fig. 1. Intraworld without crossworld 1C supervenience.

The intraworld IC thesis is consistent with the existence of these worlds. Yet if objects o_1 and o_2 have their A-properties solely in virtue of their B-properties, it is hard to see what could explain the difference between the distribution of A-properties in w_1 and w_2. One presumably wants to rule out such a pair of worlds, but an intraworld IC thesis will not rule it out.

Crossworld IC theses, by contrast, may seem to rule out too much. Suppose the A-properties are the aesthetic properties pertaining solely to paintings, and the B-properties are all the visual properties an object might have. One might be tempted to the thesis that when something has an A-property it has it solely in virtue of its B-properties and subsequently venture the crossworld IC supervenience thesis: Any pair of individuals, drawn from the same or differing worlds, are A-indiscernible if B-indiscernible. Suppose, however, that perfect forgeries are aesthetically inferior to originals, so that the history of a painting makes a difference to its aesthetic value. If so, then the crossworld IC supervenience thesis is false: There could be two paintings that are visually indiscernible that could be aesthetically discernible—whether drawn from the same world or not.

It does not seem fair to blame this sort of problem on the choice of a crossworld IC supervenience relation. The problem, rather, seems to be the choice of supervenience *relata*: The subvenient family is insufficiently broad. A natural fix is to expand that family to include relational properties such as having such-and-such a history. Nonetheless, examples of this sort have directed attention to global supervenience theses—that is, supervenience theses that compare entire worlds.

A good question is whether every supervenience thesis can be, as it were, hammered into a crossworld IC form by building into the subvenient family more complex relational properties. It is clear that some cases could be thus accommodated only if one were willing to include very gruesome-looking subvenient properties. Beyond those—which may be especially unlikely to arise in the philosophy of science—there are others that demand a global treatment, *viz.,* those in which the properties in question are not even properly said to be possessed by individuals in a world but only by the worlds themselves. The law thesis considered earlier illustrates this. If one sets out the thesis that the laws of nature supervene on the regularities, one must take care to note that the two families of properties can be attributed only to worlds: being such that all Fs are Gs, or being such that it is a law that all Fs are Gs.

Global Supervenience

The sort of supervenience that compares entire worlds is usually called global supervenience. The claim that *A*-properties globally supervene on *B*-properties can be initially expressed by saying that any two possible worlds that are *B*-indiscernible are also *A*-indiscernible. If, however, the two families of properties include properties that are normally attributed to individuals, talk of two *worlds* being indiscernible with respect to those properties is not immediately comprehensible.

The most straightforward way to make sense of such talk presumes that the two worlds contain the very same individuals. In that case, one may say that w_1 and w_2 are *F*-indiscernible just in case, for each individual x that exists in w_1 and each time t, x at t in w_1 and x at t in w_2 are *F*-indiscernible. However, if one endorses a global supervenience thesis using this notion of global indiscernibility, one should be aware of one unhappy way in which it is weaker than might have been expected. Recall the scenario involving just two objects and two properties earlier set out in demonstrating the weakness of intraworld IC supervenience. Now consider a similar one (Figure 2), with the sole difference being that the two worlds contain numerically distinct individuals.

If the claim that *A*-properties were instantiated in virtue of *B*-properties earlier motivates rejecting the first scenario, it should presumably motivate ruling out this one as well. (A possible exception is when the supervenient properties include impure properties—those defined by reference to particular individuals.)

What is wanted is a one-one mapping between worlds that does not require numerical identity. There are two different routes one might take here. The first is to impose, from the outside as it were, a way of establishing what counts as a relevant mapping; the other is to allow the character of the subvenient family to do the work. As for the first route, one natural suggestion is to appeal to spatiotemporal location. One might define the relevant mapping between w_1 and w_2 as that which ensures that each individual x in w_1 is mapped to an individual in w_2 that exists at the same times and places in w_2 as does x in w_1. (Note that if spatiotemporally coincident entities can exist, this approach will not result in a unique mapping.)

w_1	w_2
o_1 has P_B and P_A.	o_3 has P_B and lacks P_A.
o_2 lacks P_B and lacks P_A.	o_4 lacks P_B and has P_A.

Fig. 2. *B*-discernibility by means of numerical supervenience.

If one adopts such a spatiotemporal mapping, it is presumably because one wants to allow that the spatiotemporal location of an individual is relevant to how its *B*-properties determine its *A*-properties. In general, however, the factors that one thinks relevant to the determination of the supervenient properties are meant to be built into the subvenient family. Of course, this means one option one might want to take is to return to a crossworld IC thesis with an appropriately expanded subvenient family. For example, if one thinks that spatiotemporal location is relevant, one may include in the subvenient family properties *encoding* such location—the property of having existed at such-and-such places and at such-and-such times. But if one prefers a global thesis, this point suggests an alternate approach. One might use only those mappings that match individuals in one world to those in another according to their being indiscernible with respect to those properties deemed relevant in determining the facts about the supervenient properties. These will, of course, be exactly those properties placed in the subvenient family. If one has included in the *B*-family those factors that one believes relevant to determining the instantiation of *A*-properties, it is natural to suppose that a relevant mapping is one that pairs up *B*-indiscernible individuals.

More precisely: Say that a one-one mapping M from w_1 to w_2 is a "*B*-isomorphism" just in case, for any property P in B, if an individual x in w_1 has P at a time t, then $M(x)$ in w_2 has P at t. One may then want to say that two worlds are *F*-indiscernible just in case there exists an *F*-isomorphism between them. Using this definition of indiscernibility to define global supervenience in the usual way results in this formulation:

> For any two possible worlds w_1 and w_2, if there is a *B*-isomorphism between w_1 and w_2, then there is an *A*-isomorphism between w_1 and w_2.

This thesis is much weaker than one might have expected. Indeed, it is compatible with the pair of worlds considered earlier as a way of showing how weak intraworld IC supervenience is (see Figure 1). In that case, there is a *B*-isomorphism between w_1 and w_2, i.e., the function that maps o_1 in w_1 to o_1 in w_2 and o_2 in w_1 to o_2 in w_1. There is also an *A*-isomorphism, i.e., the function that maps o_1 in w_1 to o_2 in w_1 and o_2 in w_1 to o_1 in w_2. If allowing this scenario made intraworld IC supervenience too

weak to be of interest, then the present global thesis is also too weak to be of interest.

The sort of supervenience just considered has been dubbed "weak global supervenience" (Sider 1999; Shagrir 2002). Its weakness lies in the fact that it quantifies over two one-one mappings without relating them to each other. By contrast, the following "strong global supervenience" thesis relates them quite closely:

> For any two possible worlds w_1 and w_2, every *B*-isomorphism between w_1 and w_2 is also an *A*-isomorphism.

This latter thesis rules out the pair of worlds described in Figure 1 and seems to be the most promising notion of global supervenience.

THEORIES

Scientific theories, as carriers of scientific knowledge, were at the focus of philosophy of science throughout the twentieth century. In particular, philosophers argued about how scientific theories should be formalized or reconstructed. At first, only the most successful scientific theories (such as Newtonian theory, relativity theory, and quantum theory in physics, and evolutionary theory in biology) were considered as candidates for reconstruction; more recently a much wider range of scientific constructs has come under consideration. This article will review the three most prominent approaches to the reconstruction of scientific theories in the philosophy of science. Each attempts to portray the content of theories using formalisms of various kinds. Criticisms of the approaches are also reviewed. First to be discussed is the leading approach to scientific theories in the first half of the twentieth century.

The Received View

Logical empiricist approaches to theory structure are known as the *received view* or the *syntactic view* (see Logical Empiricism). These "syntactic" approaches characterize scientific theories as linguistic entities. They explicate scientific theories as being axiomatic logical systems with a set of rules of interpretation or of correspondence tying the theoretical language in the system to the observation language. Suppe (1977) has given a useful characterization of the later versions of the logical empiricists' view, as presented by Hempel (1958) and Carnap (1956). Under this view, theories can be reconstructed as satisfying the following conditions:

1. The theory is formulated in terms of a first-order language L and a logical calculus K defined in terms of L. (L may be expanded by modal operators.)

2. The terms of L are divided into two exclusive categories: V_O, which contains just the observation terms, and V_T, which contains the theoretical terms.
3. This allows the language L to be divided into two parts: the observation language, L_O, which contains terms from V_O but no terms from V_T, with an associated logical calculus; and the theoretical language, L_T, which does not contain any V_O terms, also with an associated logical calculus. In addition, L contains mixed sentences, in which at least one term from both V_T and V_O occurs.
4. L_O and its associated logical terms, K_O, are given a semantic interpretation, in which the domain of interpretation consists of concrete observable events or things. This interpretation is a partial semantic interpretation of L and K.
5. Central to the reconstruction of the theory T in L are a special set of sentences of L_T, which express the axioms or laws of the theory. The axioms of the theory T, in which only terms of V_T occur, and the correspondence rules, C, which are mixed sentences, make up a partial interpretation of the theoretical terms and the sentences of L. The correspondence rules must be finite in number and logically compatible with T. In addition, each rule in C must contain at least one V_O term and one V_T term, and C must contain no extralogical term that does not belong to either V_T or V_O.

In summary, if L is the language and A is the conjunction of all the axioms of the theory, while C is the set of correspondence rules, the conjunction $T \wedge A$ is the scientific theory.

This last version of the received view differs from earlier versions. In particular, earlier notions of the correspondence rules were construed in terms of explicit definitions that identified the content of theoretical claims with complex observation conditions. Later, correspondence rules were formulated as reduction sentences that partially defined theoretical language in terms of particular experimental setups. Finally, as presented above, correspondence rules were seen as interpretive systems; under this approach, theoretical terms were not coordinated with individual observable conditions. Rather, the inclusion of theoretical terms in the theory had to make a difference to the theory's observable consequences.

Note that the syntactic view characterizes theories both syntactically and semantically. The syntactic characterization consists in the axiomatic calculus. Theorems of the theory are derived from the set of axioms. The syntactic specification is followed by a semantic interpretation, which involves an interpretation of the signs of the axiomatic calculus in terms of various empirical entities and properties.

The received view of theory structure has been used to represent various pieces of physical theory, including Newtonian mechanics, as well as economic theory and evolutionary theory (see Suppe 1989 for references).

Criticisms of the Received View

Although the received view had the merit of being relatively clear, its clarity, which it owed in large part to its association with the standards and ideas of formal logic, came at a price. The account came in for a number of criticisms from the 1960s onward. A sample of the most serious are listed below.

As noted above, correspondence rules require the use of both an observation term and a theoretical term. These parts of the language of theories were considered distinct and nonoverlapping. But the received view's distinction between observational and theoretical language was sharply criticized by Achinstein and Putnam in the 1960s Hanson and Feyerabend also attacked the logical empiricists' view, arguing that observations were theory-laden and that the observational/theoretical distinction was untenable. Kuhn argued that the connections between theory and phenomena could not be represented by explicit correspondence rules. He favored the view that exemplars of applications of theories were the basis for much of science (see Suppe 1977, 4).

Putnam and Achinstein also criticized the notion of partial interpretation as it was used in the liberalized correspondence rules. These rules were also criticized by Schaffner (1969), who attacked the logical empiricist view by arguing that it merged together experimental procedures, meaning, and causal relations. The received view was also criticized for failing to individuate theories correctly. Under the syntactic definition of theories, any change in the syntax of a theory is taken to introduce a new theory (Suppe 1977).

A general problem with the received view of theories is that the Löwenheim-Skølem theorem implies the existence of unintended models of any theory, which is a result of the use of the first-order languages that the logical empiricists insisted upon. For example, first-order theories of arithmetic on

the natural numbers have uncountable models. These unintended models were, in turn, sources of potential counterexamples. As Suppe (1998) puts it, ''Positivistic syntactical analyses of theories, confirmation and explanation persistently were plagued by problems of unintended models'' (345) (this paper also has a useful and large bibliography concerning theories).

To make matters worse, standard formulations of most theories do not take the form of axiomatic calculi with attached interpretations. In fact it is doubtful whether some theories can be formalized in this manner. Van Fraassen (1980, 65–67) emphasizes the ''enormous distance'' between research on the foundations of science and any ''syntactically capturable axiomatics.'' In addition to these pragmatic concerns, it has been argued (French and Ladyman 1999, following van Fraassen 1989, 211) that the received view is the wrong way to represent scientific theories altogether. It is not merely practically unworkable, it is technically impossible, in the sense that any scientific theory that makes use of the real numbers (i.e., theories that take space-time to be continuous) will not be axiomatizable in any first-order language. Given that the majority of scientific theories do make use of the real numbers, this result constitutes a major difficulty for the received view.

In sum, the received view has been beset since the 1960s with objections to the possibility of formalizing theories in the preferred manner. The important distinction between theoretical and observational vocabularies turned out to be untenable, as was the adherence to first-order languages. The problem of having unintended interpretations of the axiomatized theory haunted these accounts; a great deal of energy was spent simply trying to eliminate the unintended interpretations. These problems were taken to be serious by many philosophers of science, and when an alternative came along, the received view quickly fell into disfavor.

The Semantic View

The semantic view was originally developed by Suppes (1957 and 1967), and further developed by Suppe (1977), van Fraassen (1970 and 1972), and Giere (1988). Suppes proposed that when analyzing a theory, one directly specifies the intended models, without reference to a particular axiomatic calculus. In other words, one should characterize theories as specifications of the kinds of systems to which they can be applied. As van Fraassen (1972) puts it,

> The essential job of a scientific theory is to provide us with a family of models, to be used for the representation of empirical phenomena. On the one hand, the theory defines its own subject matter—the kinds of systems that realize the theory; on the other hand, empirical assertions have a single form: the phenomena can be represented by the models provided (310).

This fixes one problem with the logical empiricist account, namely, the problem of unintended models, but it also raises the issue of what a model is. Technically, a semantic model is an interpretation that makes all sentences in a theory true. But in the semantic account, the mapping relation is implicit, and the model is conceived as an independent structure. As van Fraassen (1989) makes clear, ''A model consists, formally speaking, of entities and relations among those entities'' (365).

The semantic approach is really a family of related approaches, all having two assumptions in common: first, that scientific theories are best conceived not primarily as axiomatized linguistic systems, but rather in terms of their models; and second, that the appropriate tool for the formal explication of scientific theories is not first-order logic and metamathematics, but rather mathematics. Advocates of the semantic view differ in the mathematics they use to present the models that make up theories. Choices range from the state space approach taken by van Fraassen (1989) and Suppe (1989) to set theory (Suppes [1962], Sneed [1971], Stegmuller [1976]) to set theory supplemented by category theory (Balzer, Moulines, and Sneed 1987). These latter two approaches are characteristic of a branch of the semantic view called the structuralist approach, which shall be treated in its own section below.

Models

In Suppe's and van Fraassen's views, models are presented by specifying a state space and the laws and parameters on it. The various variable values (or states of the system) are limited by the laws of the model, which portray either the possible states of the system (coexistence laws) or the successive states of a system over time (laws of succession). The structure of the theory is thus presented as a family of related state space models and their laws.

Van Fraassen (1980) differentiates between the model-theoretic use of ''models'' and scientists' use of the term. Model-theoretic models are ''specific structures, in which all relevant parameters have specific values,'' while a physicist's model is ''a type of structure, or class of structures, all sharing certain general characteristics'' (44). And

what physicists call a model is what van Fraassen would call a *model-type*. (See McMullin 1985, 257, on different uses of the term "model"; also Achinstein 1965.)

Although his approach has great overlap with other semantic-view theorists, for Giere (1988, 47–48) a model is both a structure *and* an interpretation, a mapping from elements of a linguistic formulation to elements of the structure. Other semantic-view theorists do not include the interpretation as part of the model, and see models only as structures that satisfy the linguistic formulation. Giere's approach is also distinctive in the way it characterizes the relation between the model and the system being modeled. In his formulation of the semantic view, models must be "similar" to the systems that they represent in nature. Scientific models are understood as idealized systems (and thus as abstract entities), while "real systems" refer to nature. The relationship between models and real systems is one of similarity in certain respects and to certain degrees. A theory is characterized by the models it uses, and a theoretical hypothesis asserts a similarity between a real system and some aspects of one of these models. Giere is interested in the similarity relation because it captures the use of idealization and approximatizations in scientific modeling. Besides, one cannot claim isomorphism between mathematical structures on one hand and real systems in nature on the other; it would be a category mistake.

The role of a hierarchy of models (Suppes 1967) that intervenes between the system in nature and the theoretical structure is especially important here. Suppes (1962) emphasizes that there is a hierarchy of representations between theories and phenomena. As van Fraassen (1985) puts Suppes' point, the "theory is not confronted with raw data but with models of the data and . . . the construction of these data models is a sophisticated and creative process" (271). As described by Suppes (1967, 62–63), the hierarchy of models constitutes a methodology for the transformation of observational and experimental data into a form that can be compared with theory. He includes models of the experiment, models of data, experimental design, and *ceteris paribus* conditions. In this view, data models are the low-level structural representations of the natural world. As such, they involve processed information regarding the natural system that is then formulated into a mathematical structure. It thus becomes possible to compare various models in the hierarchy with one another, because they all represent mathematical structures. Giere's similarity relation can be understood in terms of a subfamily of relations that stand in correspondence to certain of the relevant family of relations in the total model that completely represents the system (French and Ladyman 1999, 111).

There is still a problem of how to understand the relationship between the lowest-level data model and the world, but this problem is shared by all systems of representation and is not unique to the semantic approach. At any rate, the notion of similarity can be understood in terms of a partial isomorphism holding between the families of relations concerned. Bueno (1997) proposed a formalization of the hierarchy of partial structures. Thus, as French and Ladyman (1999) conclude, "The relationship between theory and empirical reality is mediated by a series of representations and so the use of isomorphism and related notions is perfectly legitimate" (113). What binds the Suppes, Suppe, Giere, and van Fraassen views together is the overall claim that theories are best thought of as families of models, rather than as partially interpreted axiomatic systems.

Several advantages of the semantic approach have been claimed. First, theories are "extralinguistic entities which may be described or characterized by a number of different linguistic formulations" (Suppe 1974, 221). In other words, the particular linguistic formulation does not affect the content of the theory. The semantic approach thus avoids the linguistic puzzles and problems of unintended models that dominated discussions within the received view of theories. Second, the semantic view is argued to be more easily and naturally applied to scientific theorizing than the received view. This can be seen in the numerous applications of the semantic view to various scientific theories, including quantum mechanics (van Fraassen 1991), evolutionary theory (Beatty 1980; Lloyd 1988; Thompson 1989), economic theory (Hausman 1981), ecological theory (Castle 2001), chaos theory (Kellert 1992), and sex and gender (Crasnow 2001).

Third, proponents of the semantic view claim that it is compatible with any epistemology of science, whether realist, empiricist, or instrumentalist. The received view, in contrast, was taken by many to be tied to the antimetaphysical ontology of logical empiricism. Finally, the semantic view "offer[s] the possibility of incorporating the various senses of the word 'model', as used in scientific practice, within a single, unitary account" (French and Ladyman 1999, 106). This is done through the semantic-view argument that being "true in some respects" can be characterized in

terms of "partial" truth (Da Costa and French 1990, 259). The proponents of the semantic view argue that this accords well with scientific practice and captures various senses of the term "model" in science.

Before turning to challenges to the semantic view, something must be said about a variant of a semantic approach, the structuralist view.

The Structuralist View

The structuralist view was launched by Sneed (1971), in his set-theoretic analysis of physical theory. The view has since been elaborated, and numerous applications have been made to various scientific theories (Balzer, Sneed, and Moulines 2000). One of the fundamental aspects of the approach is that the close association of system specifications and empirical applications is taken into account. Theories are characterized in terms of exemplary or paradigmatic applications of the system that is specified. A theory consists of a structure and a set of intended applications.

Under the structuralist view, the first step in analyzing the structure of a scientific theory is to start by presenting a class of models in set-theoretic terms. The class of structures that settle the formal properties of the scientific concepts in the theory are called potential models, or M_p. The class of structures that also satisfy the substantial laws of the theory are called actual models, or M. The structuralists determine M_p and M by defining a set-theoretic predicate by means of the method of axiomatization. But the theory's identity is given by M, and not by the set-theoretical predicate. The theory's identity is associated with the theory's *empirical claims*, which start with a certain domain of empirical systems being investigated, called the domain of intended applications, I. A theory's central empirical claim, under structuralism, is that a certain M_p-conceptualized domain I can be subsumed under M. Thus, the claim has empirical content, and can be true or false. In this sense, structuralism also involves statements.

The "formal core" K of a theory is an array of structures that include M_p, M, partial potential models M_{pp}, constraints C, links with other theories L, and approximations A. Thus, the refined view of the empirical claim of a theory is that it consists in the global statement that the domain of intended applications I can be subsumed under K. Many intertheoretic relations can be represented within the structuralist approach, including specialization, reduction, equivalence, and approximation (Moulines 2002; for detailed presentations of the structuralist view, see Stegmuller 1979 and Balzer et al. 1987).

The structuralist approach is intended to be useful in addressing relationships among theories, "their connections to empirical data, the methods used to check them, the pragmatic aspects of their use by the scientific community, their evolution in historical time, and related matters" (Moulines 2002, 2). This approach has been especially important in work on intertheoretic reduction (Stegmuller 1976; Balzer, Pearce, and Schmidt 1984; Balzer et al. 1987). The accounts of intertheoretic reduction are regarded by some as having proved useful in very detailed reconstructions of episodes in the history of science (Balzer et al. 1984 and 1987). For example, Bickle (1993) uses this account of intertheoretic reduction to analyze the connectionist eliminitavist arguments (see Reductionism).

While both the semantic view and the structuralist view are "variants of semantic metatheory," the distinction between M_p and M_{pp} is treated differently by the two approaches (Sintonen 1990, 679). In addition, structuralists have argued that mature scientific theories form "theory nets," which are theories related to one another by certain intertheory relations, whereas semantic-view theorists do not make this claim.

Finally, the structuralists read Suppe and van Fraassen as denying any role for syntactic analysis. A more substantive disagreement with the other variants of the semantic view is that structuralists think that pragmatic analysis plays an important role in understanding the theoretical structure of science, whereas semantic-view theorists do not use pragmatic analysis.

Criticisms of the Semantic View

Despite the fact that the semantic view is today more or less the accepted view, it is not without its critics. There are at least three major areas of concern: Is the semantic view as free of the linguistic entanglements as it claims to be? Can the semantic view really account for the diversity of models seen in science? and, Does the semantic view misrepresent the place of models in science?

Hendry and Psillos (1998) note that the "semantic view" seems to be a misnomer, as theories are not really nonlinguistic in the semantic conception. Giere's theoretical hypotheses, wherein abstract

structures are claimed to represent given classes of real systems, are linguistic entities. If models are seen purely abstractly, the theory's content is divorced from its applications, and theories are not representational. Thus, the theory cannot be seen as equivalent simply to a class of models. Giere's formulation avoids this problem and is endorsed by van Fraassen (1989, 222), and Suppe (1989, 4), but only by allowing linguistic components into the theory. In other words, the mapping claims made on behalf of the models are themselves linguistic in form.

A pervasive criticism of the semantic view is that it cannot account for the wide array of models used in scientific practice. The semantic view uses only a narrow logical meaning of modeling, while there are many other types of models in scientific use, such as scale models, analogue models, iconic models, Watson and Crick's wire model of DNA, Kuhnian exemplars, and Griesemer's biological "remnant" models, which are actual specimens in a museum (Griesemer 1990) (see Scientific Models). Downes (1992) argues that since these models cannot be accommodated within the semantic approach, its strong form should be rejected (Weinert 1999). This is an echo of Achinstein (1968), who rejected the semantic approach to theories, arguing that there could be no theory of scientific models.

The claim is that there is a difference between the mathematical structures that make up the model in the semantic view and scientific models more broadly. The concept of isomorphism is especially problematic, because while isomorphism may easily be applied to mathematical models, it is unclear how it could apply to the relationship between empirical systems and theoretical models (Downes 1992, 147). But French and Ladyman (1999, 107) take it that the challenge is whether a set-theoretical description can capture the kinds of models used in scientific practice. They argue that this is possible and demonstrate how to do it with various types of models. This usually involves a partial isomorphism between the partial structures used in representing the models, where a partial structure is a set-theoretical structure that satisfies a Suppes-style set-theoretical predicate. This approach even works with DNA models and remnant models (or so it is claimed), in that they represent structure, which can be formalized in the appropriate way.

An additional worry about models and the semantic view, though, is that models are relatively independent of theories (Morgan and Morrison 1999). When constructing models, more than theories are relied upon—model construction also involves data, technological design, and intuitive insight (Cartwright, Shomar, and Suarez 1995). Because models are relatively independent of each source, they can serve as mediators between them. In addition, it is possible to have a number of possibly mutually inconsistent models of a system or phenomenon covered by a theory. Morgan and Morrison (1999) emphasize that constructing models and manipulating them are important scientific activities that are not adequately addressed by a view of models purely in terms of their relation to theories. This is not actually a direct criticism of the semantic view, but it does emphasize the limits of its utility in understanding how models work in science.

Conclusion

The most fundamental implicit criticism is that perhaps theory structure is not the thing to study in the philosophy of science, and that more analytical effort should be spent on looking at the various uses of scientific models. Nevertheless, it would seem that the semantic view of theory structure has been applied successfully in a number of cases, and is still generating more solutions than problems. The same cannot be said of the logical empiricists' approach to theory structure, which collapsed under its own set of formal problems. The semantic view is widely accepted presently, and it is unclear that any of its critics have offered new ways to characterize scientific theories. There is a promising sketch of an alternative, "interactionist view" by Hendry and Psillos (1998): "As historical individuals, theories are complex consortia of different representational media: words, equations, diagrams, analogies and models of different kinds" (1). According to Hendry and Psillos, both the semantic and received views fail to tackle the complexity of the ways that scientific theories represent the world, which can only be represented by these complex groupings of representational media. So far, though, no developed alternative to viewing theories has been offered outside of the semantic and structuralist approaches.

TIME

What is the relationship between time and space? What times exist? What does it mean to assert that time had a beginning? What explains why causation proceeds from past to future? These questions will serve to introduce some central debates in the study of time. It is best to begin with the relationship between time and space in special relativity.

Time and Special Relativity

Special relativity asserts that the backdrop on which physical happenings are arrayed is a four-dimensional space-time manifold (see Space-Time). To get used to thinking about manifolds, consider the following prerelativistic example.

Flatland (Abbott 1884) is a world consisting of just two spatial dimensions. Think of Flatland's space-time as a three-dimensional block, and think of the block as a stack of two-dimensional time-slices. Each time-slice determines the state of Flatland at a particular time, and each point of a slice determines what happens at a particular place at a particular time (see Figure 1).

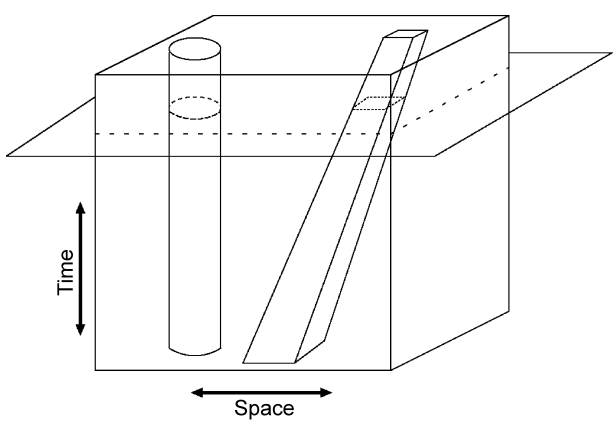

Fig. 1. Flatland. Flatland's space-time can be thought of as a three-dimensional block. Each two-dimensional slice corresponds to the state of the world at one time. In the history depicted, a circle sits unmoving on the left, while a square both moves to the right and shrinks over time. Also shown is the intersection between these objects and a sample time slice.

Flatland's space-time can be divided into slices in many different ways—horizontally; at another angle, into surfaces that each contain happenings at many different times. Notice that the horizontal time-slicing is special in that it alone guarantees that points on the same slice are simultaneous.

Like Flatland, a special relativistic world is associated with a space-time manifold. But there is no single privileged way of dividing a special relativistic manifold into time-slices. Instead, many candidate slicings are equally deserving of the title.

A contrast with Flatland is helpful at this point. Take any two instantaneous Flatland events—let them be flashes of light. Flatland's space-time determines which flash happened earlier (and the elapsed time between them). It also determines the spatial distance between their locations. Now consider two flashes of light in a relativistic space-time. Unlike Flatland's space-time, relativistic space-time does not in general have enough structure to determine which flash happened earlier (see Figure 2). Nor does it have enough structure to determine the spatial distance between the flash locations. Instead it determines a single magnitude of separation between the flashes: the space-time interval between them. So in the following (limited) sense, special relativity combines time and space: Special-relativistic space-time does not separately determine the spatial and temporal intervals between events.

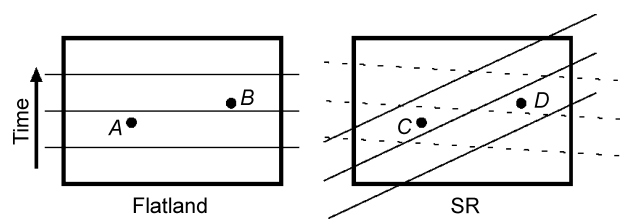

Fig. 2. Flatland Versus Special Relativity. Flatland space-time has a preferred decomposition into time-slices, compared with a special relativistic space-time, which does not. In each space-time, two instantaneous events are marked with dots. In Flatland, *A* occurs before *B*. In the relativistic space-time, relative to one system of time-slices (dotted lines), *C* occurs before *D*. But relative to another system of time-slices (solid lines), *C* occurs after *D*.

But in another sense, special relativity distinguishes sharply between time and space, for not all ways of slicing a special-relativistic manifold are on a par. Certain slicings (and associated labelings of the slices by spatial coordinates) are distinguished. These inertial frames are associated with lengths and time intervals as measured by unaccelerated observers (see Space-Time). Furthermore, although special relativity does not separately determine the time and space intervals between events, it does pick out the timelike curves, that is, those paths through space-time that correspond to slower-than-light travel. And it determines how much time elapses along any such path.

For example, consider a pair of clocks, initially synchronized and sitting next to each other. Suppose that clock *A* never accelerates but that clock *B* zooms far away and returns. The geometry of space-time determines the total elapsed time along the path of each clock. In this case, more time is elapsed along the path of clock *A* (the stay-at-home clock) than along that of clock *B*. As a result, when clock *B* returns, clock *A* will display a later time.

This example illustrates again that in a certain limited sense, special relativity mixes together time and space: The time elapsed for each clock depends on its trajectory through space. But the example also illustrates that special relativity does distinguish between time and space, for it picks out those paths along which it makes sense to speak of an elapsed time, and it determines how much time elapses along them.

One further issue deserves mention. As explained above, it makes no sense in special relativity to assert that two events are simultaneous in any absolute sense. It does make sense to assert that two events are simultaneous relative to some particular inertially moving observer. That much is uncontroversial. But a question remains: Once an observer has been fixed, does that alone determine which events are simultaneous? Or is it that in order to settle which events are simultaneous relative to an observer, one needs to adopt a *convention of simulteneity*? (For discussion of this question, see Malament 1977, Sarkar and Stachel 1999, and Janis 2002.)

Time and General Relativity

General relativity allows time and space to get mixed up in additional ways. Like special relativity, general relativity has it that space-time is a four-dimensional manifold. But manifolds in general relativity may be curved, in order to take gravitation into account. Furthermore, the way that matter is distributed through space-time constrains the way it is curved. For example, where there is a heavy and dense star, there is extreme curvature.

The constraint also goes in the other direction: The curvature of space-time constrains the way matter is distributed through it. For example, the extreme curvature of space-time near the above-mentioned star constrains the trajectories of particles floating in the star's vicinity. (It bends the trajectories of the particles toward the star.) Thus the dynamical laws of general relativity come in the form of a consistency condition—expressed by Einstein's field equations—between the curvature of space-time and its contents.

That form of law stands in sharp contrast to the form of the laws of classical mechanics, in which (as in special relativity), the geometrical structure of space-time is fixed, and the laws specify what states follow any given initial state. Such laws are compatible with time-slice generation: The state of one time-slice of the world produces or generates (via the laws) the states of subsequent time-slices (Maudlin 2002).

Since general relativity does not impose a fixed space-time geometry, it allows for universes with exotic temporal structures. The simplest example is that one can obtain circular time by pasting together two temporal ends of a special relativistic manifold (Earman 1986). The resulting ''cylindrical'' space-time has closed timelike curves: paths associated with slower-than-light travel that loop back on themselves. A particle traversing such a path returns to its own past.

Closed timelike curves also appear in rotating dust space-times (Gödel 1949) and in some space-times with wormholes—throats that provide shortcuts connecting one part of a manifold to another (Thorne 1995), all of which are consistent with the Einstein field equations. The physical possibility of such exotic space-times is in tension with the time-slice generation picture. Some such space-times—including rotating dust space-times and wormhole space-times—cannot be sliced into surfaces well suited to playing the role of time-slices. More precisely, they cannot be foliated into Cauchy surfaces: spacelike hypersurfaces that intersect every inextendible timelike curve exactly once (Arntzenius and Maudlin 2002). Other space-times cannot even be equipped with a temporal orientation: a structure that determines for each timelike curve which direction time elapses along that curve (Earman 1974; Sklar 1993).

One response to this tension is (a) to point out that the exotic universes are highly physically unrealistic and (b) to conclude that although the Einstein field equations allow them, they should be discarded as physically impossible on other grounds (Maudlin 2002; Callender 2000). Another response is to give up the time-slice generation picture and rest content with thinking that the laws of nature constrain what total histories of the world are allowable (Price 1996).

The Beginning of Time

Modern "big bang" cosmologies entail that time itself had a beginning. How is that claim to be understood? It should not be understood as the (contradictory) claim that there was a time before time began. It is better understood as there being an upper bound on the temporal distance between current events and any past event. (Here the temporal distance between two events is understood to be the time elapsed along a geodesic that connects the space-time locations of the events.)

How could it be that the past has finite extent? Consider a universe with such a past. For such a universe, it is tempting to think of the space-time as embedded in some larger, background space-time, just as a curved surface of finite extent might be embedded in an infinite Euclidean space. If so, then the larger space-time might have an infinite past after all.

But *this picture should be resisted.* The curvature and extent of space-time can be completely characterized by spatiotemporal relations that hold among its parts. It is *not* necessary to posit a "container" space-time, and modern cosmologies posit no such things. Nor is it necessary to posit a first time, for it may be that (though the universe has a finite past in the above sense) every moment is preceeded by earlier ones (Earman 1995, chap. 7).

Presentism

According to relativity theory, space-time is a four-dimensional manifold. Interpreted literally, this entails that there exists a four-dimensional manifold. It follows that there exist some things that do not presently exist (e.g., the part of the manifold corresponding to 1776). *Presentists* deny this, and claim that whatever exists at all, exists now (Markosian 2002). So, unlike their opponents, presentists cannot interpret literally relativity's claim that space-time is a four-dimensional manifold. (Relationalists about space-time also deny that there exists a four-dimensional space-time manifold, but do so for different reasons than presentists.)

In addition, presentism is apparently incompatible with the lesson of special relativity that there is no privileged notion of simultaneity. For if presentism is correct, it makes sense to speak of what exists now, without specifying a frame of reference. So presentism provides the following criterion of simultaneity: Two events are simultaneous if and only if they are both currently occurring.

Some respond to the apparent incompatibility between presentism and special relativity by concluding that presentism is false. (See Putnam 1967 for a treatment of this kind; Stein 1968 for a response; and Callender 2000 for a rejoinder.) One presentist response is to adopt a theory that is observationally equivalent to special relativity but in which there is a preferred reference frame (Markosian 2002; Bell 1989). Maudlin (1994) suggests that quantum nonlocality may provide independent motivation for such a replacement (see Locality).

Temporal Asymmetry

An important cluster of questions concern various asymmetries in time. One such asymmetry is the irreversible nature of certain thermodynamic processes (such as the cooling of a hot cup of tea) (see Irreversibility). Another asymmetry is causal asymmetry: earlier events cause later events, but not the other way around. What explains causal asymmetry?

According to one answer, time itself has a built-in past→future orientation that is constitutively tied to the direction of causation (Maudlin 2002). To illustrate what it means for time to have a built-in past→future orientation, consider the following specification of a Flatland space-time (based on an example in Maudlin 2002):

> The space-time contains nothing but two stationary spheres (X and Y) and a particle that makes a single trip from one to the other.

It might be thought that this specification is incomplete by failing to determine whether the particle travels from X to Y or the other way around. Whether the specification is incomplete in this way depends on whether each Flatland space-time has a past→future orientation. Such an orientation would determine which temporal end of the space-time is the past end and which end is the future. If Flatland space-times have past→future orientations, then the specification

was incomplete in the manner described, for in that case, there are two space-times meeting the specification: one in which the particle travels from X to Y, and one in which it travels from Y to X.

On the other hand, if Flatland space-times lack past→future orientations, then the specification was *not* incomplete in the manner described, for in that case, the above two possible space-times collapse into a single one. This space-time has two temporal ends, and nothing determines which is the past and which is the future. At one temporal end, the particle is located at X. At the other end, it is located at Y. And at intermediate times, it is located at various places in between.

Of course, in speaking about a Flatland space-time with no past→future orientation, one might adopt the convention of treating one end of the space-time as past and the other as future. But nothing in the structure of the space-time itself privileges that convention over the one that labels the ends in the opposite way (Price 1996).

If time—actual time—has a built-in past→future orientation, then one might explain the asymmetry of causation by an analysis in which the direction of causation necessarily aligns with the past→future direction (Maudlin 2002). If not (if time has no built-in past→future orientation), then that explanation is unavailable. One might in this case adopt perspectivalism about causation. According to perspectivalism, the term "cause" picks up its temporal asymmetry from the manner in which one—a temporally asymmetric agent—is embedded in space-time (Price 1996).

To illustrate perspectivalism, consider a pair of agents who are temporally reversed with respect to each other. (For example, one agent's biological processes proceed in the opposite temporal direction from the other agent's.) According to one version of perspectivalism, the two agents possess different concepts of causation. The difference in their concepts arises because what one agent counts as the past→future direction of time, the other agent counts as future→past. Since in this view time has no built-in past/future asymmetry, both concepts of causation are on a par.

A third explanation of causal asymmetry agrees with perspectivalism that time has no built-in past/future asymmetry. But it insists that the asymmetry of causation is not just a consequence of the particular perspective that one adopts. Instead, it appeals to an analysis of causation in terms of the distribution of matter over space-time. According to that analysis, special features of the actual matter distribution entail that causation proceeds only in one direction. But other distributions of matter would have yielded causation proceeding in the opposite direction. And still other distributions would have yielded no pervasive causal asymmetry at all (Lewis 1986).

ALAN TURING

(23 June 1912–7 June 1954)

The work of the British mathematician Alan Turing stands as the foundation of computer science. Turing's (1936–1937) definition of computability remains a classic paper in the elucidation of an abstract concept into a new paradigm. His 1950 argument for the possibility of artificial intelligence is one of the most cited in modern philosophical literature. These papers, his best known, have led his contributions to be defined as theoretical. But his work was highly practical, both in codebreaking during World War II and in the design of an electronic digital computer. Indeed Turing's expression for the modern computer was "practical universal computing machine," a reference to his 1936 "universal machine." This combination of theory and practice meant that Turing's work fit no conventional category of "pure" or "applied." Likewise, his life involved many contradictions. Detached from social and economic motivations, and perceived as an eccentric, apolitical, unworldly innocent, he was swept into a central position in history as the chief scientific figure in the Anglo-American mastery of German communications.

The Matter of Mind

Amidst this complexity there is one constant theme: Turing's fascination with the description of mental action in scientific terms. His computational model can be seen as a twentieth-century renovation of materialist philosophy, with a claim that the discrete state machine is the appropriate level of description for mental states. However, it did not begin in that way: Turing's interest in the material embodiment of mind comes first in a private letter of about 1932 (Hodges 1983, 63), in which he alluded to the newly elucidated quantum-mechanical nature of matter and then, influenced by Eddington, speculated on "will" as a physical effect in a region of the brain. It was after studying von Neumann's axioms of quantum mechanics, then Russell on the foundations of mathematics, that he learned of logic, and so of the question that was to make his name.

The question, proposed by Hilbert but transformed through the 1931 discovery of Kurt Gödel, was that of the *decidability* of mathematical propositions. Is there a definite method or procedure that can (in principle) be applied to a mathematical proposition and will decide whether it is provable? Turing learned of this outstanding *Entscheidungsproblem* from the lectures of the Cambridge mathematician Max Newman. The difficulty of the question was that it demanded an unassailable definition of the concept of method, procedure, or algorithm. This is what Turing supplied in 1936 through the definition of what came to be called the *Turing machine.* Specifically, he modeled the action of a human being in following a definite method, either through explicit instructions or through following a sequence of "states of mind."

Turing's definition came shortly after another elucidation of "effective calculability" by the United States' logician Alonzo Church. Thus, in a narrow sense, Turing was preempted. Church's definition turned out to be mathematically equivalent to Turing's definition of computability. But Church (and Gödel) agreed that Turing's definition gave an intuitively compelling account of why this definition encompassed "effectiveness."

The Turing machine breaks down the concept of a procedure into primitive atomic steps. The exact details are somewhat arbitrary, and nowadays other equivalent formulations are often used. The essential point is that the machines should have finite descriptions (as "tables of behavior") but be allowed unlimited time and space for computation.

Church's thesis, that his definition of effective calculability would capture any natural notion of that concept, became the Church-Turing thesis, and opened a new area for mathematical "decision problems." But the work had much wider consequences: Turing's bold modeling of states of mind opened a new approach to what are now called the cognitive sciences (see Cognitive Science). It is often asserted that modeling the mind with a computer shows the influence of a dominant technology, but in fact Turing's work went in

the reverse direction—for a striking and visionary aspect of Turing's paper was his definition of a "universal" Turing machine, which led to the computer. A machine is universal if it can read the table of behavior of any other machine and then execute it. This is just what a modern computer does, the instructions in programs being equivalent to tables of behavior. It was essential in Turing's description that the instructions be stored and read like any other form of data; and this is the idea of the internally stored program. It is now hard to study Turing machines without access to the programmers' mindset, and to remember that when Turing formulated them, computers did not exist.

Turing and Machines

Turing's work, being based on answering Hilbert's question, modeled the *human being* performing a methodical computation. However, the imagery of the teleprinter-like "machine" was striking. Newman (1955), in stressing the boldness of this innovation, said that Turing embarked on "analyzing the general notion of a computing machine" (256). This was criticized by Gandy (1988) as giving a false impression of Turing's approach. But Newman's account of the flavor of Turing's thought should not be entirely discounted; Turing certainly became fascinated by machines and engineered machines with his own hands in 1937–1939. Church also makes it clear that the notion of a computing machine was current at this time. Church (1937) wrote (while Turing was working with him at Princeton) that Turing

> proposes as a criterion that an infinite sequence of digits 0 and 1 be 'computable' that it shall be possible to devise a computing machine, occupying a finite space and with working parts of finite size, which will write down the sequence to any desired number of terms if allowed to run for a sufficiently long time. As a matter of convenience, certain further restrictions are imposed on the character of the machine, but these are of such a nature as obviously to cause no loss of generality—in particular, a human calculator, provided with pencil and paper and explicit instructions, can be regarded as a kind of Turing machine (42).

Yet neither Turing nor Church *analyzed* the general concept of a computing machine with "working parts." Turing (1939), giving a definitive statement of the Church-Turing thesis, used the expression "purely mechanical" without further analysis. Only in 1948 did he give some more discussion.

This topic has recently been made controversial by B. J. Copeland, who holds that the Church-Turing thesis is widely misunderstood, because it was never intended to apply to machines. Copeland overlooks Church's characterization of computability, as quoted above, which assumes that all finitely defined machines fall within the scope of computability. To support his claim, Copeland points to the "oracle" defined by Turing (1939), which supplies an uncomputable function, and holds that it gives a broader characterization of computation. But the whole point of Turing's oracle is that it facilitates the mathematical exploration of the *uncomputable.* The oracle, as Turing emphasized, cannot be a machine. It performs *nonmechanical* steps. His "oracle-machines," defined so as to call upon oracles, are not purely mechanical.

Turing's oracle is related to Gödel's theorem, which seems to show that the human mind can do more than a mechanical system when it sees the truth of formally unprovable assertions. Turing described this as mental "intuition." The oracle, as Newman (1955) interpreted it, can be taken as a model of intuition. But Turing left open the question of how intuition was to be considered as actually embodied. He was not at this stage committed to the computability of *all* mental acts, as came to be his position after 1945. His 1936 work had considered the mind only when applied to a definite method or procedure. Turing had to resolve this question before embarking on his artificial intelligence program.

Copeland has gone even further and has described Turing's oracle as heralding a new revolution in computer science, illustrating "what Turing imagined" by sketching an oracle supposed to operate by measuring a physical quantity to infinite precision. But Turing's oracle models what machines *cannot* do, and the question for him was, and always remained, whether machines can do as much as minds. He did not suggest the opposite idea, stated in Copeland (1997), that "among a machine's repertoire of atomic operations there may be those that no human being unaided by machinery can perform."

Naturally, one must distinguish between the historical question of what Turing thought and scientific truth. It is a serious (and unanswered) question as to whether actual physical objects do necessarily give rise to computable effects. Nowadays we demand a closer analysis of "finite size." Gandy (1980) arrived at conclusions that generally support Church's assumptions: The limitations of computability follow from quite general assumptions about the construction of a machine. But if the constraint of finiteness is interpreted so as to allow a "machine" with infinitely many subcomponents built

on smaller and smaller scales, or working faster and faster without limit, then it is easy to show that Turing's computability can be surpassed in a finite time. In any imaginary universe, such a construction might be possible; such examples may therefore be said to show that the Church-Turing thesis has a physical content.

"Effective" means "doing" (as opposed to postulating or imagining), thus depending on some concept of realistic action, and hence on physical law. Quantum computation has already shown that the classical picture of "doing" is incomplete. The nature of quantum mechanics, still mysterious because of its nonlocality and the "reduction" during measurement, means that there may yet be more to be found out, and in recent years the work of Penrose (1989 and 1994), who like Turing focuses on the mind and brain, has drawn new attention to this question (see Locality; Quantum Mechanics; Quantum Measurement Problem).

Turing's Practical Machinery

It is perhaps surprising that Turing himself did not, in this 1936–1939 period, say anything about the physics of the machine concept, in view of his interest in quantum mechanics. He might have done so but for the war. War disrupted Turing's investigation of the uncomputable, along with his conversations with Wittgenstein on the foundations of mathematics (Diamond [1939] 1976), which never extended, as many now wish they had been, into the philosophy of mind. But war work gave Turing an intimate acquaintance with the power of algorithms and with advanced technology for implementing them, for Turing became the chief scientific figure at Bletchley Park, the British cryptanalysis center and a key location in modern history.

Turing had anticipated this development in 1936. He had applied his ideas to "the most general code or cipher," and one of the machines he made himself was to implement a particular cipher system (Hodges 1983, 138). This, together with his Cambridge connection with influential figures such as J. M. Keynes, may explain why he was the first mathematician brought into the codebreaking department.

Turing transformed the Government Code and Cypher School with the power of scientific method. His logic and information theory, applied with advanced engineering, achieved astounding feats, with particular effect in decrypting the U-boat Enigma signals, for which he was personally responsible. By 1944 the power, reliability, and speed of electronic technology showed Turing that his universal machine could be implemented. The plethora of advanced algorithms employed in cryptanalysis also supplied ample practical motivation.

In 1945, Turing was appointed to the National Physical Laboratory, with the commission of designing an electronic computer. Turing's plans soon emerged as the ACE (Automatic Computing Engine) proposal (Turing [1946] 1986). Again, Turing was preempted by work in the United States, for his publication had been preceded in 1945 by the report of EDVAC (the Electronic Discrete Variable Automatic Computer). Turing's plans, however, were independent, more detailed, and more far-reaching. Furthermore, a recent survey (Davis 2000) suggests that von Neumann needed his knowledge of Turing's work when shaping EDVAC. As a point of interest in the history of science, none of the mathematical leaders—Turing, von Neumann, Newman—clearly defined the stored program concept or its debt to symbolic logic in treating instructions as data (see von Neumann, John). Turing never published the book on the theory and practice of computation that he might have done, and so neglected his own good claim to be the inventor of the computer.

It is an unobvious fact, long resisted, but now familiar, that more complex algorithms do not need more complex machines, only sufficient storage space and processor speed. This was Turing's central idea. In a world familiar with the power of a universal machine, one can better appreciate the remark by Turing ([1946] 1986, 44) that "every known process has got to be translated into instruction table form at some stage." Turing emphasized that arithmetical calculations were only one aspect of the computer's role—partly the influence of nonnumerical Bletchley Park work, but more deeply, his base in symbolic logic. His hardware design was probably impractical in detail, but he far surpassed von Neumann in seeing the significance of software and that this would use the computer itself, a fact now familiar in compilers and editors:

> The work of constructing instruction tables should be very fascinating. There need be no real danger of it ever becoming a drudge, for any processes that are quite mechanical may be turned over to the machine itself. (Turing [1946] 1986, 44)

Turing's insight into programming by modifying instructions led to the idea of simulating learning, training, and evolution by an extension of these ideas. As he put it, human intelligence required something other than "discipline," namely

"initiative." By 1945 Turing had convinced himself that human faculties of an apparently nonmechanical nature did not require explanation in terms of the uncomputable. Turing was well aware of the paradox of expecting intelligence from a machine capable only of obeying orders. But he believed that with sufficient complexity, machines need not appear "mechanical," as in common parlance.

A crucial point is that Turing had by this stage formulated an argument from human "mistakes" to explain why Gödel's theorem did not show the existence of an uncomputable human intuition; indeed, remarks in Turing ([1946] 1986) show the early influence of this view in his project for artificial intelligence (Hodges 1999). He now expected self-modifying machines to exhibit the apparently "nonmechanical" aspects of mental behavior.

With this as his strategic goal, Turing sketched networks of logical elements, to be organized into function by "training" or by an analogy with evolution. Although he did not develop his specific schemes, he anticipated the "connectionist" approach to artificial intelligence. Nowadays the term "nonalgorithmic" is confusingly used for systems in which the program is implicitly developed, rather than explicitly written by a programmer. Turing was, however, quite clear that such operations still lie within the realm of the computable. All these developments were sketched in Turing ([1948] 1969). He also in this paper gave his only systematic account of the concept of a machine. In doing so, he introduced the possiblility of random elements into the Turing machine model, but he made no reference to a need for uncomputable elements in randomness. Indeed he indicated that pseudo-random elements, clearly computable, would suffice.

Turing's Intelligent Machinery

Disappointed with the lack of progress at the National Physical Labotratory, Turing moved to Manchester in 1948. There Michael Polanyi stimulated Turing to write for a more general audience on the question of whether machines could in principle rival the human mind. The idea in Turing (1950) was to cut through traditional philosophical assumptions about 'mind' by the thought experiment now known as the Turing test, but which he called "the imitation game." A human and a programmed computer compete to convince an impartial judge that they are human, by textual messages alone. Turing's position was that thought or intelligence, unlike other human faculties, is capable of being fairly tested through a communication channel like a teleprinter.

Critics have raised questions about nonverbal communication, cultural assumptions, animal intelligence, and other issues. Turing's principal defense against all such arguments was that one can judge the intelligence of other humans only by making such external comparisons, and that it is unfair to impose more stringent criteria on a computer. But it may be held that when addressing human consciousness with moral seriousness, there is something inadequate about a definition of intelligence that depends upon deceit (see Consciousness). Turing also confused the issue by introducing the imitation game with a poor analogy: a parlor game in which a man has to pretend to be a woman under the same conditions of remote questioning. In such a game, imitation proves nothing, so the analogy is misleading and has confused many readers. However, Turing's drama has the merit of expressing the full-bloodedness of his program. His wit has attracted lasting popular interest. Turing's references to gender have also fascinated cultural critics, who speculate widely on biographical and social issues in their commentaries (Lassègue 1998).

A drier but stronger feature of Turing (1950) lies in his setting out the level of description of the discrete state machine, and his emphasis on explaining computability and the universal machine. Critics who point out that the brain is not structured like a computer miss his essential point that any algorithm can be implemented on the computer. This applies to explicit algorithms and to those arrived at by processes as in neural networks; Turing described both. Another strength of Turing's paper lies in his advocating both approaches, never seeing programming as standing in opposition to the modeling of intelligence by learning and adaptation. Artificial intelligence research has tended toward division between the two camps dominated by expert systems and neural networks, but recently hybrid approaches have appeared (see Artificial Intelligence). Thus Turing's ideas still have force. Also futuristic was Turing's prophecy that by the end of the century "one will be able to speak of machines thinking without expecting to be contradicted." It is probably true to say that this prophecy was not fulfilled in 2000, but Turing was prepared to take this risk:

> The popular view that scientists proceed inexorably from well-established fact to well-established fact, never being influenced by any unproved conjecture, is quite mistaken. Provided it is made clear which are proved facts and which are conjectures, no harm can

> result. Conjectures are of great importance since they suggest useful lines of research. (Turing 1950, 442)

Turing's conjecture was that the brain's action is computable. If this is true, then it is hard to refute his argument that given sufficient storage space, a computer can perform the function of the mind. Turing emphasized this argument by putting a figure on the storage capacity of the brain. But he still did not directly address that underlying question of whether physical objects necessarily have computable behavior. Artificial intelligence research has generally accepted without question the assumption that they do. But Penrose (1989 and 1994), linking the still ill-understood "reduction" in quantum mechanics with Gödel's theorem, has thrown the spotlight back on the problems that Turing himself found most perplexing.

Turing's Unfinished Work

Turing (1951) did refer to the problem of quantum mechanics when giving a popular radio talk. As Copeland (1999) has noted, he gave a more qualified assertion of the computability of mental action than in Turing (1950). But this was not because of believing oracles to reside in the brain; it was because of quantum unpredictability. Harking back to his schooldays reading, he referred to Eddington in connection with the mechanism of the brain. This brief allusion may explain why Turing thereafter gave fresh attention to quantum theory. His friend, student, and colleague Gandy ([1954] 2001) wrote in a letter to Newman of Turing's ideas, in particular of his attention to the question of the "reduction" or "measurement" process and the "Turing paradox" that according to standard theory, continuous observation should prevent a system from evolving.

These ideas were not developed into publication. They were curtailed by his suicide in 1954. One of many ironies of Turing's life, lived for science, was that he suffered in 1952–1953 a "scientific" treatment by estrogen supposed to negate his homosexuality. This treatment was the alternative to prison after his arrest in February 1952. His openness and defiance did not command the admiration of authority, and there was at least one further crisis when he found himself under watch. One may regret that he did not write more of his own sense of liberty and will. Indeed it is remarkable that he, so original and unconventional, should champion the possibility of programming the mind. But he left few hints as to the personal dilemmas on the roads to freedom. He was of course constrained by intense state secrecy, as the most privileged insider to Anglo-American secrets in a sphere then kept totally secret.

Besides his new enquiries in physics, he had a large body of incomplete theory and computational experiment in mathematical biology. This, neglected until the 1970s, is now the foundation of a lively area of nonlinear dynamics. Turing described his theory as intended to oppose the "argument from design." It was a theme parallel to (and through his interest in brain function connected with) his quest for a new materialism of mind. He had not exhausted his ideas, and their impact has not yet been fully absorbed.

UNDERDETERMINATION OF THEORIES

The *underdetermination of theory by data* allegedly reveals something important about science. Although a philosophical commonplace, the term 'underdetermination' is used in different ways by various authors. At the same time, many authors write as if it were a single, well-understood phenomenon. Some write as if underdetermination were the problem that every theory has empirically equivalent rivals. Others write as if it were the problem that theories entail predictions only in conjunction with auxiliary hypotheses. Others write as if it were the problem that methodological rules may be ambiguous, vague, or circular. Thus, the problem of underdetermination is best understood as an extended family of potential problems.

To put it crudely, underdetermination obtains when scientists are unable to decide responsibly which theory to believe, that is, the choice between rival theories is underdetermined if scientists cannot make a responsible choice of one over the others. So underdetermination is always relative to some standard for what will count as *responsible theory choice*.

There is a banal kind of underdetermination that obtains any time scientists are ignorant about something. They are, in that situation, unable to decide responsibly what to believe. So they do some research; they gather relevant evidence; and the question is resolved. The underdetermination of interest to philosophers is something more trenchant than this: suppose scientists were not able to decide between rival theories in a broad range of circumstances. Yet there is no general agreement about how broad this range of circumstances must be in order for a choice to be underdetermined. It is often stipulated that a choice is underdetermined if it could not be responsibly made even after all evidence had been collected (as in Quine 1970). Other authors (such as Stanford 2001) write of "transient underdetermination" that obtains only at certain times. To take in these and other permutations, say that underdetermination is always relative to a *scope* or range of circumstances across which responsible choice is impossible. The banal kind of underdetermination obtains for a scope that contains only present circumstances, but not for a broader scope containing circumstances in which the further research has been conducted.

In the most general terms, underdetermination obtains for a set of rival theories, a standard, and

a scope. In order to be pernicious, a case of underdetermination must obtain between rivals worth taking seriously, according to a reasonable standard, and with a scope that includes not only present circumstances but also most any plausible, future circumstances. However, such a case of underdetermination would not show anything about the whole scientific enterprise. It would show only that science could not settle that particular question.

Philosophers have used two general strategies to try to show that underdetermination is a problem for all of science. Some arguments operate at the level of science generally, attempting to show directly that all or most scientific theory choice is underdetermined and thus that a successful scientific theory is not any better than its losing rivals. Other arguments begin from alleged examples of underdetermination and generalize, suggesting that all or most scientific theory choice is underdetermined in the same way. Since these bottom-up arguments diagnose science as rife with underdetermination, they are often used to support the same conclusions as direct, top-down arguments.

Empirical Equivalence

The problem of empirically equivalent theories is one variety of underdetermination problem. The worry takes this form:

(1) Every theory has indefinitely many empirically equivalent rivals;
(2) There is no good reason to believe a theory over its empirically equivalent rivals;
(3) Therefore, there are never decisive reasons to believe any theory—that is, theory choice is always underdetermined.

Premise (1) states that, for any theory, there are rival theories of a particular sort. This gives us a set of rivals for the underdetermination scenario. Premise (2) states that permissible standards of judgment are insufficient to distinguish between empirically equivalent theories. The conclusion brings these two together: The choice among the set of rivals given by (1) is, by (2), underdetermined. The implicit scope here is all observationally possible circumstances. The ultimate conclusion that one may accept but not believe successful theories turns on a substantive principle about what one should do in the face of such underdetermination. The argument thus presupposes a division between circumstances that are observationally possible and those that are not. This boundary is vague, historically variable, and—some have argued—unprincipled (see, e.g., Churchland and Hooker 1985 and Laudan and Leplin 1991).

Some arguments for (1) proceed by offering an algorithm for producing empirically equivalent rivals. For example: For any theory T, let T^* be the theory "T is false, but all observations are just as if T were true." This is like a Cartesian skeptical scenario, akin to worries about dreams or evil demons. With (1) interpreted in this way, (2) would be true only for an implausibly strict standard; all manner of ordinary belief choice would be underdetermined.

Many philosophers have argued against (2) by offering nonempirical criteria by which one might decide between empirically equivalent rivals: simplicity, breadth of scope, explanatory power, heuristic fecundity, practical success, and so on. It is possible to accept the further criteria but argue that they still result in a kind underdetermination. Rival theories might beat one another according to different criteria, such that no choice between them is possible. If scientists are aiming at accurate and simple theories, for example, then they will be stymied by cases where the simpler theory is less accurate. It is then essential to ask whether real scientific theories face this kind of underdetermination or whether scientific controversies are typically resolved in favor of a theory that is superior according to all or most criteria (contrast Doppelt 1978 and Kitcher 1993, esp. ch. 7). It is also possible to reject these further criteria. For instance, the constructive empiricist admits that these criteria are pragmatically important while denying that they have anything to do with the truth of theories. One should accept the theory that best satisfies these super-empirical desiderata, but—according to the constructive empiricist—one need not believe it (van Fraassen 1980).

Other philosophers have argued against (2) by noting that even when two theories are empirically equivalent considered in isolation, they may have divergent empirical consequences when conjoined with other accepted theories (Laudan 1990). This point is often answered by alleging that background theories are themselves underdetermined—this is a form of the Duhem-Quine thesis. A similar response is to concede that background theories resolve the underdetermination between theories, but to argue that underdetermination recurs between rival "total sciences" or complete systems of theories.

The argument from empirical equivalence is primarily a matter between realists and antirealists. At most, it shows that every theory faces underdetermination against some possible rivals. It does *not*

show that underdetermination obtains between all rival theories or that any theory is as good as any other. It has few implications for broader questions about the authority enjoyed by science.

The Duhem-Quine Thesis

Quine is often mentioned as having established the force of underdetermination. Since he first introduces it without much positive argument (Quine 1953, 41, 17n) and attributes it to Duhem ([1914] 1954), one variety of underdetermination is called the Duhem-Quine thesis (see Duhem Thesis).

Scientific theories typically do not yield observable consequences on their own. Suppose biologists observe an amoeba under a microscope, and it looks as if it is performing tricks that contradict their theory of amoeba behavior. They may accept this as a refutation and decide that their theory of microbial behavior needs revision. The observation refutes their theory only insofar as they assume that the microscope gives an accurate glimpse into amoeboid life. From the standpoint of deductive logic, the observation shows only that their theory is incorrect *or* that the microscope is deceptive.

Of course, instruments sometimes produce erroneous results. The worry is that scientists might *always* plead instrument error to discount recalcitrant observations. Biologists could maintain a theory of microbial behavior in the face of any would-be refutations if they were willing to dismiss all those observations as experimental artifacts.

The underdetermination obtains between any rival theories that are sophisticated enough to require auxiliary assumptions in order to yield testable predictions, with a standard that demands that scientists accept deductive consequences of observations, and with a scope that includes all possible observations. Yet a standard that requires scientists to accept only deductive consequences would leave a great deal underdetermined. Given such a standard, it would be impossible to make any predictions about the future based on observations that are always of the present or of the past. Arguably, the underdetermination disappears given a more plausible standard. In the example, there is no absolute principle that requires biologists to blame the anomaly on their theory rather than on the microscope. Yet, when an accepted instrument is used in a usual way, its reliability is assumed. A pattern of strange results might lead them to worry about this assumption, but no science would be possible if everything were up for grabs at the same time (see Kitcher 1993, Ch. 7, §6).

Some philosophers, such as Longino (1990), have argued that this reliance on background assumptions, although unavoidable, makes science rest on implicit value commitments. They argue that these commitments should be ones that scientists can reflectively endorse.

Bottom-Up Arguments

The arguments about empirically equivalent theories and the Duhem-Quine thesis proceed in a top-down fashion, moving directly to the conclusion that all or most theory choice is underdetermined. Other arguments work in the opposite direction, starting from specific examples of underdetermination in science. Since underdetermination is present in the cases considered, then perhaps it is elsewhere as well. This final step is often implicit, and one may doubt whether a grab bag of cases should ignite worries about science generally. (Contrast Ellis' contribution to Churchland and Hooker 1985, 63, Earman 1993, 31, and Stanford 2001, 6.)

Standard examples have concerned the geometrical structure of space. For instance, general relativity treats space-time as non-Euclidean, such that seemingly curved paths like planetary orbits are described as straight paths in a curved space-time. However, objects would follow the same trajectories if space-time were Euclidean and "universal forces" distorted the paths of the objects. Note, of course, that a physics with universal forces would look very different from physics as it is usually formulated. Regardless, it is unclear whether the alleged underdetermination (the "conventionality of geometry") tells us anything about sciences besides mechanics (see Conventionalism).

An impressive panoply of historical cases has been offered by philosophers and other authors writing in the area of science studies: the rivalry between classical Newtonian and relativistic mechanics, between phlogiston and oxygen theories of combustion, between caloric and kinetic theories of heat, between particle and wave theories of light, between the germ theory of disease and its various rivals, and so on. One lesson of these studies has been that single experiments are rarely, if ever, completely decisive.

Certainly, there is a kind of underdetermination that obtains in cases like these. There is a time when the old theory is sagging under the weight of anomalies but before the new theory has accrued its eventual successes, during which there is legitimate disagreement about which theory to accept. Considering a scope that includes only this period of legitimate controversy, these are cases of

underdetermination. The underdetermination is of historical interest only if it also obtains for a wider scope that includes the present scientific situation. Even vague standards may have been decisive in the long run, as adherents of the old theory were unable to salve its troubles and the new theory accrued successes.

Bottom-up arguments thus face two challenges: first, to show that the case is underdetermined with a wide enough scope that it has not been and cannot be resolved by further research; second, to show that the underdetermination present in specific cases generalizes to the rest of science.

UNIFICATION

See **Explanation; Reductionism; Unity and Disunity of Science**

UNITY AND DISUNITY OF SCIENCE

What kinds of integration are manifested, or sought after, in the claims and practices of the different sciences? This question should be carefully distinguished from any of the different specific theses addressing it, and yet it should be stressed as the linking thread of a time-honored philosophical debate. The question belongs to a tradition of thought that can be traced back to pre-Socratic

Greek cosmology, in particular to the preoccupation with the question of the one and the many. In what senses are the world and, thereby, our knowledge of it one? A number of representations of the world in terms of a few simple constituents considered fundamental emerged: Parmenides' static substance, Heraclitus' flux of becoming, Empedocles' four elements, Democritus' atoms, Pythagoras' numbers, Plato's forms, and Aristotle's categories. The underlying question of the unity of our types of knowledge was explicity addressed, for instance, by Plato: "Surely science too is one, but that which ranges as a part over some bit of it, once it is made distinct (isolated), each severally gets a name peculiar to itself. It's for this reason that arts and sciences are spoken of as many" (Sophist, 257c, in Benardete 1986).

With the advent and expansion of Christian monotheism, the organization of knowledge reflected the idea of a world governed by the laws dictated by God, creator and legislator. From this tradition emerged encyclopedic efforts such as the *Etymologies*, compiled in the sixth century by Isidore, Bishop of Seville, the works of Ramon Llull in the Middle Ages, and of Petrus Ramus in the Renaissance. Llull introduced tree diagrams and forest encyclopedias organizing different disciplines (including law, medicine, theology, and logic). He also introduced abstract diagrams in an attempt to encode combinatorially the knowledge of God's creation in a universal language of basic symbols; their combination would then generate knowledge of the secrets of creation. Ramus introduced diagrams representing dichotomies and gave prominence to the view that the starting point of all philosophy is the classification of the arts and sciences. The search for a universal language would continue to be a driving force behind the project of unifying knowledge.

The emergence of a distinctive tradition of scientific thought addressed the question of unity through science's designation of a privileged method, set of concepts, and language. In the late sixteenth century Francis Bacon held that a unity of the sciences was a result of the organization of material facts in the form of a pyramid with different levels of generalities; these would be classified in turn according to disciplines linked to human faculties. In accordance with the Pythagorean tradition as well as with the Bible's dictum in the Book of Wisdom, Galileo proclaimed at the turn of the seventeenth century that the Book of Nature had been written by God in the language of mathematical symbols and geometrical truths; and in it the story of Nature's laws was told in terms of a reduced set of primary qualities: extension, quantity of matter, and motion. In the seventeenth century, mechanical philosophy and Newton's work became the most promising framework for the unification of natural philosophy. After the demise of Laplacian molecular physics in the first half of the nineteenth century, this role was taken over by energy physics.

Descartes and Leibniz gave this tradition a rationalist twist centered on the powers of human reason; it became the project of a universal framework of exact categories and ideas, a *mathesis universalis*. Like Llull's, their conception of unity was determined by rules of analysis of ideas into elements and their synthesis into combinations. According to Descartes, the science of geometry, with its demonstrative reasoning from the simplest and clearest thoughts, constitutes the paradigm for the goal of unifying all knowledge. Leibniz proposed a General Science in the form of a Demonstrative Encyclopaedia. This would be based on a "catalogue of simple thoughts" and an algebraic language of symbols, *characteristica universalis*, which would render all knowledge demonstrative and allow disputes to be resolved by precise calculation.

Belief in the unity of science, along with the universality of rationality, was at its strongest during the European Enlightenment. The most important expression of the encyclopedic tradition came in the mid-eighteenth century from Diderot and d'Alembert (1751–1772), editors of the *Encyclopédie, ou dictionnaire raisonné des sciences, des arts et des métiers*. Following earlier classifications by Nichols and Bacon, their diagram presenting the classification of intellectual disciplines was organized in terms of a classification of human faculties. Diderot stressed in his own entry, "Encyclopaedia," that the word signifies the unification of the sciences. The function of the encyclopedia was to exhibit the unity of human knowledge. Diderot and d'Alembert, in contrast with Leibniz, made classification by subject primary, and introduced cross-references instead of logical connections.

For Kant the unity of science was not the reflection of a unity found in nature; rather, it had its foundations in the unifying nature or function of concepts and of reason itself. Kant saw one of the fuctions of philosophy as determining the precise unifying scope and value of each science. For instance, he contrasted the methods employed by the chemist, organized by empirical regularities, with those employed by the mathematician or physicist, organized by a priori laws, and held that biology is not reducible to mechanics (as the former involves

explanatons in terms of final causes). A devoted follower of Newton's achievements and insights, he maintained through most of his life that mathematization and a priori universal laws were preconditions for genuine scientific character (like Galileo and Descartes earlier, and Carnap later, Kant believed that mathematical exactness constitutes the main condition of the possibility of objectivity). By the end of his life, after having become acquainted with Lavoisier's achievements in chemistry, Kant thought of the unification of physics and chemistry not so much in terms of mathematization but, rather, in terms of the a priori principles regarding the properties of a universal ether (Friedman 1992). With regard to biology—insufficiently grounded in the fundamental forces of matter—its inclusion requires the introduction of the idea of purposiveness. More generally, for Kant, unity was a regulative principle of reason, that is, an ideal guiding the process of inquiry toward a complete empirical science with its empirical concepts and principles grounded in the so-called concepts and principles of understanding that constitute and objectify empirical phenomena.

Kant's ideas set the frame of reference for discussions of the unification of the sciences in German thought throughout the nineteenth century. He gave philosophical currency to the notion of worldview (*Weltanschauung*) and, indirectly, worldpicture (*Weltbild*), thereby establishing among philosophers and scientists the unity of science as an intellectual ideal. (In the German intellectual tradition culminating in philosophers such as Windelband, Ricket, and Dilthey, a worldview often included elements of evaluation and life meaning.) This tradition influenced the physicists Max Planck and Ernest Mach, who engaged in a heated debate about the precise character of the unified scientific worldpicture, and culminated in the first two decades of the twentieth century with the work of Albert Einstein. Mach's (1897) view, which was more influential, was phenomenological and Darwinian: The unification of knowledge took the form of an analysis of ideas into elementary sensations (neutral monism) and was ultimately a matter of adaptive economy of thought (see Mach, Ernest). Planck adopted a view that took as fundamental the principles of energy and entropy. These worldpictures constituted some of the alternatives to a long-standing mechanistic view that since Newton had affected biology as well as most branches of physics. In the same German tradition, amidst the proliferation of books on the unity of science, the German energeticist Wilhelm Ostwald (1913) declared the twentieth century the "Monistic century."

In the twentieth century the unity of science is a distinctive theme of the scientific philosophy of logical positivism. The logical positivists, notably the members of the Vienna Circle, adopted the Machian banner of "unity of science without metaphysics," a model of unity based on a demarcation between science and metaphysics, consisting of a unity of method and language that included all the sciences, natural and social (see Vienna Circle). Notice that a common method does not imply a more substantive unity of content involving theories and their concepts. A stronger model, recommended by Rudolf Carnap (1934), was seen in Hilbert's axiomatic approach to formulating theories in the exact sciences and in Frege's and Russell's logical constructions in mathematics. This model was predicated on the formal values of simplicity, neutrality, and objectivity and was characterized by axiomatic structures and rigorous reductive logical connections between concepts and laws of the different sciences at different levels. Physics, with its genuine laws, was fundamental and lay at the base of the hierarchy. Because of the emphasis on the formal and structural properties of representations, their individuality, like that of nodes in a railway network, was determined by their place in the whole structure and, hence, presupposed connective unity. Alternatively, all scientific concepts could be constructed out of classes of elementary experiences—not atomic in the Machian sense—but derived from the field of experience as a complex whole in the manner proposed by Gestalt psychology. This construction of scientific knowledge took into account the possibility of empirical grounding of theoretical concepts and testability of theoretical claims. Carnap was influenced by the empiricist tradition (especially Russell and Mach) and the ideals of simplicity and reductive logical analysis in the early works of Russell and Wittgenstein. From the point of view of a formalistic neo-Kantian tradition, Carnap's models of unity express his concern with the possiblity of objectivity of scientific knowledge.

Otto Neurath, by contrast, favored a more realistic and less reductive model of unity predicated on the complexity of empirical reality. He spoke of an "encyclopedia model" instead of the classic ideal of the pyramidic "system model" (see Neurath, Otto). The encyclopedia model took into account the presence within science of ineliminable and imprecise terms from ordinary language and the social sciences and emphasized a unity of language and

the local exchanges of scientific tools (specifically, Neurath stressed the material-thing-language called "physicalism," not to be confounded with the emphasis on the vocabulary of physics). Thus, it was not constrained by Carnap's ideals of conceptual precision, deductive systematicity, and logical rigor; it was meant as a tool for cooperation and was motivated by the need for successful treatment (prediction and control) of complex phenomena that involved properties studied by different theories or sciences, in a conception of unity of science at the point of action. Neurath spoke of a "boat," a "mosaic," an "orchestration," a "universal jargon" (see Unity of Science Movement). For both Carnap and Neurath, the ideal of unified science had deep social and political significance. It supported a kind of thinking and, in particular, a social and political ideology, that was free of the obscurantist metaphysics responsible for much social unhappiness. At the same time, Karl Popper was defending a demarcation criterion based on the falsifiability of all genuinely scientific propositions (see Popper, Karl Raimund).

After World War II, a discussion of unity engaged philosophers and scientists in the Inter-Scientific Discussion Group in Cambridge, Massachusetts (founded by Philip Frank, himself one of the founders of the Vienna Circle), which would later become the Unity of Science Institute. The group was both an extension of the Vienna Circle and a reflection of local concerns in a culture of computers and nuclear power (Galison 1998a). The characteristic feature of the new view of unity was the idea of cross-fertilization, instantiated in the creation of war-boosted interdisciplines such as cybernetics, computation, electroacoustics, psychoacoustics, neutronics, game theory, and biophysics.

Two new views developed by logical positivists in the United States again placed the question of unity of science at the core of philosophy of science: Carl Hempel's (1965) deductive-nomological model of explanation and Ernest Nagel's (1961) model of reduction (see Explanation; Reductionism). Hempel's model characterizes the scientific explanation of events as a subsumption under an empirically testable generalization. In the 1950s, when positivism was extending to the social sciences, the model was offered as a criterion of demarcation. Explanations in the historical sciences too had to fit the model if they were to count as scientific. The applicability of Hempel's model was soon contested, notably by William Dray, and this opened a debate about the nature of the historical sciences that remains unresolved. In the process, some have claimed as historical some of the natural sciences such as geology and biology. It has been argued that Hempel's model, especially the requirement of empirically testable strict universal laws, is satisfied neither in the physical sciences nor in the historical sciences, including biology. Nagel's model of reduction was a model of explanation as well as of scientific progress. It required extensional equivalence between descriptions; bridge principles between coextensive but distinct terms in different theories; and a deductive relation between the laws involved in the reduction. Feyerabend promptly rejected the demand of extensional equivalence as inadequate for "meaning invariance" and, moreover, believed such meaning invariance between theories to be unattainable.

Since Nagel's influential model of reduction by derivation, most dicussions of the unity of science have been cast in terms of reductions between concepts and between theories. The hierarchy of levels of reduction was set by the levels of aggregation of entities all the way down to atomic particles, thus rendering microphysics the fundamental science. Oppenheim and Putnam (1958) intended to articulate an ideal of science as a unity reductive to the most elementary concepts and laws. They also defended the empirical claim that the evolution of science manifested a trend in that direction. The rejection of such models and their emendations has occupied the last three decades of philosophic discussion about unity in physics, and especially in psychology and biology. Initially the availability of laws and theories and the feasibility of global reductions within the latter two was contested. The status, form, and interpretation of bridge principles connecting different levels was called into question. Arguments concerning new notions such as supervenience and multiple realizability by Putnam, Kim, Fodor (1974), and others led to a distinction between type-type and token-token reductions and the examination of its implications (see Reductionism). The possibility and the necessity of reductions in a number of forms have been widely discussed in connection with issues of explanation, realism, and scientific progress. A number of discussions of specific sciences have addressed the question of the inconsistencies between some of their theories or models—for instance, the problem of the relation between Newtonian mechanics and thermodynamics, or between relativity theory and quantum physics as the conceptual foundation of quantum gravity (Maudlin 1996). Other discussions have focused on the search for unification—for instance, of quantum field theory and cosmology in physics, or of theories of evolution and development in biology. A focus of some projects has been on the

value and variety of kinds of approximations and the difficulties of extending to different theories specific methodological standards, models of explanation, and even abstract categories such as rationality, lawlikeness, determinism, causality, locality, or individual and separable particles (see Causality; Determinism; Laws of Nature).

Debates on unification and reduction have taken place as part of discussions of specific sciences and also within the sciences themselves. The success of the unified theories of fundamental forces in the 1970s revived the ideal of reductionism in physics. The view has found its most vocal proponents among elementary particle physicists such as Steven Weinberg (1993) and has been contested by condensed-matter physicists such as Philip Anderson (1972). What is fundamental? Can there be unity without fundamentality? The form that unity, especially in physics, takes and should take is a controversial matter that has led to pluralism within the physics community (Batterman 2002). At the same time, along with a common (unifying) concern, techniques and models are shared even if their significance is understood differently (Cat 1998; Galison 1998b; Maudlin 1996). It has also been argued that unity is not a form of explanatory power and cannot guarantee an ontological unity of nature (Morrison 2000).

Similar ideals and debates have also regained force in biology, especially in molecular genetics and sociobiology, in light of successes in evolutionary and genetic explanations and the interest in genetic mapping, exemplified by the Human Genome Project. Beyond the attempts earlier in the century to synthesize genetics and evolutionary biology in the so-called evolutionary synthesis, the renewed reductionist trend has been explained in part by the personal and intellectual connection between biology and physics (Keller 1990). In fact, the connection between the trends in both fields can be traced to the institutional links between the Manhattan Project and the Human Genome Project. Proponents of reductionist views such as E. O. Wilson (1999) have encountered the opposition of other biologists such as Ernest Mayr (1982) and R. C. Lewontin (1992). This atmosphere has stimulated debates and detailed work in philosophy of physics and of biology, and more recently the emergence of philosophy of chemistry.

In antireductionist quarters, models of unification without reduction have appeared. For instance, the notion of "interfield theories" (Darden and Maull 1977) is based on the idea that theories and disciplines do not match neat levels of organization within a hierachy; rather, many, in fact, cut across different such levels. Others have emphasized the idea of science as a process, manifesting a historical unity with a Darwinian-style pattern of evolution (Hull 1988). Concepts of unity have also been defended on the cognitive grounds that unification, measured as the number of independent laws conjoined in a theoretical structure, contributes understanding and confirmation (Friedman 1974) or explanatory power in terms of few derivation or argument patterns (Kitcher 1981). Distinctions have been introduced among different categories of reduction and reductionism, such as global/partial, constitutive/theoretical/explanatory, and ontological/epistemological (Mayr 1982; Schaffner 1993; Sarkar 1998). More recent proposals address concerns with complexity and emergence and locate unity in the common framework of abstract categories and idealizations for characterizing systems running through physics, biology, and economics (Auyang 1998).

A more radical departure is the recent criticism of the methodological values of reductionism and unification in science and its position in and effect upon society. This view argues for the replacement of the emphasis on global unity—including unity of method—by an emphasis on disunity and epistemological and ontological pluralism. Some suggestions link disunity with instrumentalism about higher-level sciences such as biology and sociology (Rosenberg 1994). Another picture comes from the members of the so-called Stanford School, such as John Dupré (1993), Ian Hacking (1996), Peter Galison (1998b), and Nancy Cartwright (1999). Dupré (1993) has argued that the disunity of science can be given adequate metaphysical foundations that make pluralism compatible with realism. He criticizes a mechanistic paradigm characterized by determinism, reductionism, and essentialism and defends the views that science depends on metaphysical assumptions and that scientific and nonscientific empirical inquiries suggest that science does not and cannot constitute a unified single project. This is supported, in turn, by three pluralistic theses: (1) Against essentialism, there is always a plurality of classifications of reality into kinds; (2) against reductionism, there exists equal reality and causal efficacy of systems at different levels of description; and (3) against epistemological monism, there is no single methodology that supports a single criterion of scientificity, nor a universal domain of its applicability, but only a plurality of epistemic and nonepistemic virtues. The concept of science should be understood, following the later Wittgenstein, as a family-resemblance concept.

Hacking distinguishes a plurality of scientific styles to argue for a disunity of science (Hacking 1996) (see Scientific Style). Maxwell had remarked in the nineteenth century that unity of science is the "cross-fertilization of the sciences." Galison has replaced traditional analyses that consider the observational domain as homogeneously underpinning theoretical structures and their developments and replacements by an anthropological analysis of the subcultures of experimentation. He explains the strength, coherence, and continuity of science in terms of local coordinations of intercalated symbolic procedures and meanings, instruments, and arguments, which he calls "trading zones" (Galison 1998b). Cartwright has argued that laws cannot be both universal and true; there exist only patchworks of laws and local cooperations. Like Dupré, Cartwright adopts a kind of scientific realism but denies that there is a universal order, whether represented by a theory of everything or a corresponding metaphysical principle. The empirical evidence, she argues, suggests far more strongly the idea of a patchwork of laws, often in local cooperation. Theories apply only where and to the extent that their interpretive models fit the phenomena studied (Cartwright 1999). She explains their more or less general domain of application in terms of causal capacities and arrangements she calls "nomological machines." On these grounds she rejects strong distinctions between natural and social sciences. Whether as a hypothesis or as an ideal, the debates continue over the form, scope, and significance of unification in the sciences.

UNITY OF SCIENCE MOVEMENT

The ideas and projects that constituted the unity of science movement were launched in 1934 as part of the intellectual life of the Vienna Circle (see Vienna Circle). The movement was spearheaded by Otto Neurath, although the theme of unity of science had been central to the concerns of other members of the Circle since its inception. In the founding manifesto of the Vienna Circle, Neurath, Hans Hahn, and Rudolf Carnap (1929) laid out a scientific world-conception and a constructive agenda that would combat the obscurantist metaphysical and theologizing trends in German culture, proclaiming that "the goal ahead is unified science." They also stressed the importance of unity of science for social and political life. In particular, Neurath recurringly wrote on the connections between the project of unity of science and the movements for economic socialization, educational reform, and peaceful and cooperative internationalization and unification of mankind.

At the end of the Eighth International Congress of Philosophy held in Prague in September 1934, Neurath proposed a series of International Congresses for the Unity of Science. These took place in Paris in 1935 and 1937; Copenhagen in 1936; Cambridge, England, in 1938; Cambridge, Massachusetts, in 1939; and Chicago in 1941. For the organization of the congresses and related activities, Neurath founded in 1936 the Unity of Science Institute, renamed in 1937 the International Institute for the Unity of Science, a special department of his Mundaneum Institute at The Hague. Neurath had founded the Mundaneum in 1934, after fleeing Vienna, and it already included the International Foundation for Visual Education, founded in 1933. The Institute's executive committee was composed of Neurath, Philip Frank, and Charles Morris. The Organization Committee for the International Congresses for the Unity of Science was composed of Neurath, Carnap, Frank, Joergen Joergensen, Morris, Louis Rougier, and Susan Stebbing.

In the contexts of scientific philosophy, unity of science, and social and educational reform, Neurath's work on museums and exhibits was devoted to the divulgation of information—typically of a social and demographic nature—in statistical and pictorial languages, known as the Vienna Method. The pictorial language was renamed in 1937 ISOTYPE (International System of Typographic Picture Education) (Reich 1995).

The central and most emblematic project of the Unity of Science Movement was the publication of the *International Encyclopedia of Unified Science*. The Encyclopedia was an early idea of Neurath's, which he had discussed with Einstein, and was inspired by the French *Encyclopédie* of the eighteenth century. It was meant to promote international cooperation among scientists through the exchange of methods and concepts from different fields of inquiry and instantiate an ideal model of society "a republic of scientists." The editorial board was composed of Neurath as editor-in-chief and Carnap and Morris as assistant editors. Morris negotiated its publication by the University of Chicago Press. It would consist of twenty volumes each containing ten monographs of historical and foundational content (with a systematic logical analysis of the sciences and a survey of their development, stressing connections to other disciplines and suggesting new directions). Eventually, between 1937 and 1970 twenty monographs were published, including T. S. Kuhn's *The Structure of Scientific Revolutions*.

After World War II, the Unity of Science Movement continued and developed around Philip Frank's Inter-Scientific Discussion Group, created in 1944 in Cambridge, Massachusetts, and then his Institute for the Unity of Science, under the auspices of the American Academy of Arts and Sciences in Boston, with support from the Rockefeller Foundation and royalties from the Encyclopedia through Marie Neurath's transfer of her inheritance rights. The list of associates and participants in discussions included Birkhoff, Bridgman, Carnap, Conant, Feigl, Frank, Hempel, Holton, Jakobson, Leontieff, Morris, Nagel, Quine, Santillana, Skinner, and Wiener. The Institute held several conferences, planned a dictionary presenting the operational meaning of three hundred concepts, promoted the development of new interdisciplines such as cybernetics, neutronics, and electroacoustics, and

introduced enhanced integrated models of university general education (adopted by Conant at Harvard). Gradually the movement, as well as the political engagement of logical empiricism, suffered in the political climate of the McCarthy era, losing funding while philosophy of science emphasized logical or formal dimension and value neutrality. In 1958 the Institute moved with Feigl to the Minnesota Center for Philosophy of Science, being replaced in Boston by what became the Boston Colloquium for Philosophy of Science, organized by Robert Cohen and Marx Wartofsky at Boston University. Finally, in 1973 what remained of the Institute was absorbed into the Philosophy of Science Association of the United States.

V

VERIFIABILITY

Verifiability is often linked to questions about empirically verifiable statements as a basis for claims to knowledge, and hence it is also linked to notions like verifiably true, confirmation, and inductive verification, as well as to disputes about "foundationalism" (Reichenbach 1976). But it is usually connected with the logical positivists' verifiability criterion (theory) of cognitive meaning, which was derived from the classical empiricists' analyses of traditional notions of material substance and causality and their accounts of the origin of ideas.

Berkeley argued for idealism by claiming that, as one does not and cannot have an idea of material substance, one cannot meaningfully assert that physical objects exist independently of an apprehending mind. Hume developed the empiricist theme by construing causation so as to dismiss mental substance as a causal agent while, as Berkeley had done earlier, rejecting causal accounts of perceptual experience in terms of material objects, as well as claims about causal powers linking physical events and objects. The arguments of the empiricists developed the theme, implicit in earlier philosophical works, that ideas are of two types: *simple ideas*, which are not composed of other ideas; and *complex ideas*, which are composed of other ideas. Complex ideas can be associated with defined terms of a language, while simple ideas can be seen as correlates of primitive or basic terms. Berkeley took simple ideas to be derived from experience. Thus, his dismissal of the term 'matter' as meaningless depended on denying the experience of material substance (as Descartes had done in his often cited discussion of a melting piece of wax) and on claiming that there was no tenable analysis of the concept. It was meaningless to take material substance as Locke's "I know not what" supporting the properties of an object.

For Hume, the linguistic base of undefined terms was more closely restricted to what was presented in experience, and simple ideas became copies of sensory and "inner" impressions. Since complex ideas still resulted from combinatorial and associative mental operations, one could have an idea of, say, a golden mountain or a centaur but could not have an idea of matter, or of causal powers linking material objects and events. Nor could one have a Berkeley-like "notion" of mental substance. The logical positivists (empiricists) of the Vienna Circle were influenced by Russell's (1956) "principle of acquaintance" (58), which required every understandable proposition to be composed of constituents that one was already acquainted with. Accordingly, they attempted to formulate a

tenable verifiability criterion for meaning that would dismiss classical philosophical (metaphysical) statements as meaningless while retaining the statements of science. This conformed to an intellectual current of the time that held that "philosophy of science is philosophy enough" (Quine 1953, 446, cited out of context) and, like Hume, relegated metaphysical works to "the flames."

The focus on verifiability was not just a reaction against traditional philosophy. Einstein had brought on a conceptual shock, which some people attributed, in part, to the introduction of meaningless concepts into the conceptual framework of scientific theories. One example was the notion of "absolute (nonlocal) simultaneity"; no such conceptual shock would have resulted if temporal concepts had been tied to specified procedures of measurement. Construing simultaneity in suitable terms would ensure speaking of temporal events relative to a framework of "clocks." The verifiability criterion was designed to provide a conceptual cushioning against any further shocks. But it bred an extreme offspring, operationism. As the term implies, this required meaningful scientific terms to be defined operationally, that is, by conditional statements with antecedents specifying an operational procedure (e.g., using a thermometer) and consequents specifying a resulting observation (e.g., a reading of a thermometer). Operationism spread, and "positivists" in the human, or behavioral, sciences argued that if these fields were to rise to scientific respectability, they had to be purged of meaningless concepts (Bergmann 1954; Bridgman 1927; Feigl 1949). An empiricist criterion of meaning was seen as a key to the door of scientific development.

The verifiability criterion ran into obvious problems. No statement of general law, covering "all" cases of some kind, could be verified, even in principle. At best, one could talk in terms of obtaining stronger degrees of confirmation or, like Karl Popper, in terms of falsifiability.

An early reformulation of verifiability in a popular version is found in Ayer's (1946) *Language, Truth, and Logic*. Building on a familiar distinction, Ayer took all "cognitive" statements to be either synthetic or analytic. Analytic statements were those of mathematics and logic, along with stipulative "definitions." (Misconstruing Frege and Russell's diverse forms of logicism, Ayer took arithmetical truths to be true by definition.) With the addition of statements true by the "semantic" rules of a language, these would correspond to Carnap's (1956) *L*-truths. Synthetic statements were divided into two kinds. Observation statements, such as "This is a swan" (O_1) and "This is white" (O_2), could be "verified" as true or false by observation. Nonobservation statements, such as a generality like "All swans are white" (G), would qualify as empirically meaningful if they were appropriately linked to observation statements. Thus, a statement Q would be meaningful if the conjunction of Q and some observation statement O logically entailed an observation statement O^* that was not entailed by O. Statement G would then qualify, because the conjunction of G and O_1 entails O_2, which is not entailed by O_1 (Ayer 1946, 13).

Ayer's criterion did not succeed in ruling out a variety of unacceptable statements. (For example, a conditional with O_1 as antecedent and a conjunction of O_2 and any meaningless statement as consequent would qualify as empirically meaningful.) Numerous attempts to repair the criterion elicited counterexamples exposing deficiencies in the revisions (Church 1949). Another problem was that the statement of the criterion did not itself satisfy the criterion. One response to this objection, derived from considerations of "liar"-type paradoxes, was that no statement could be expected to apply to itself. Another response was that the criterion was a "proposal," not a claim, and therefore did not have a truth value.

Hempel's attempt to revitalize the criterion was more radical. Developing early ideas of Russell and Carnap, he took a cognitively significant statement as one that could be transcribed into an empiricist language grammatically modeled on Russell and Whitehead's *Principia Mathematica*. Hempel considered Russell's principle, the "requirement of definability," too restrictive; he required only some descriptive (nonlogical) primitive predicates of such a schema to be correlated with observable properties. Hempel sought to resolve two further problems facing the empiricists' verifiability criterion, posed by dispositional predicates (such as 'temperature' and 'soluble') and by theoretical terms (such as 'electron'). Both kinds of terms were empirically meaningful: The former could be embedded in an empiricist language as terms "implicitly defined" by means of reduction sentences like Carnap's, and the latter could be connected to an empiricist ("observation") language as "theoretical constructs" belonging to a "partially interpreted" calculus in which some statements were correlated with those of an empiricist language (Carnap 1936–1937, 1937, 1956, and 1967; Hempel 1951 and 1952). But Hempel did not resolve the philosophical issues posed by causation and dispositions, and questions arose about the justification of his criterion for cognitive significance, along

with technical issues regarding the reduction of theoretical terms through explicit definitions or reduction sentences (Bergmann 1951).

Dispositions, Laws, and Reduction Sentences

Carnap's and Hempel's logical apparatus included the familiar truth-table conditional used in lawful generalities like $(\forall x)(Fx \rightarrow Gx)$ and in definitions of dispositional predicates. That gave rise to familiar problems derived from the "paradoxes" of material implication. Defining 'is soluble' S in terms of dissolving D if put into water P would force one to take a destroyed piece of wood, or any object never put into water, as satisfying the defining clause. Carnap proposed resolving the problem by introducing dispositional predicates into an empiricist language by means of pairs of reduction sentences. The simplest case is illustrated by the pair

$$Px \rightarrow (Dx \rightarrow Sx)$$

$$Px \rightarrow (\neg Dx \rightarrow \neg Sx)$$

which introduces but does not define S. A burned wooden match that was never put into water need not then be taken as soluble.

But Carnap's analysis raised new problems. As S is introduced by a reduction pair or a set of reduction pairs, it is supposedly implicitly defined by such "semantic rules." Yet implicit definitions amount to axioms using an uninterpreted term, of which they provide neither an analysis nor an explication, irrespective of the transcription of S by the ordinary-language expression 'is soluble.' Moreover, by using various reduction pairs for a predicate, Carnap (1956) was forced to take factual claims as "rules" for the use of the term (228). Reduction sentences, unlike designation rules or explicit definitions, are problematic candidates for semantic rules. Unlike a theoretical term such as 'electron,' 'soluble' is a philosophically problematic term linked to questions about dispositions, powers, and causality. Introducing it into an empiricist schema as a primitive term would seem to introduce such problems as well, the resolution of which, along empiricist lines, requires the elimination or analysis of such terms. This can be done partly by appealing to lawful generalizations. What problems remain are about the laws themselves, which must be faced in any case (see Laws of Nature).

When it is said of a piece of sugar that it is soluble, it is implicitly asserted that sugar is soluble: that the object is of a soluble kind, sugar. Dispositional predicates like 'soluble' are used in a context of such lawful generalities. Construing causal laws in terms of regularities, one will also use a standard conditional and reject a primitive causal conditional, expressing either a basic causal relation (nomic necessity, i.e., having the force of natural law) or a primitive counterfactual conditional (had p occurred, q would have occurred). Neither would fit the conditions for an empiricist language using a standard conditional and requiring "modal" concepts to be construed metalinguistically (Carnap 1956, 175, 243; Hochberg 1981; Reichenbach 1976).

Consider the statement that sugar S^* is soluble. The problematic ordinary-language statement can be unproblematically analyzed in terms of the claim that

$$(\forall x)(S^* x \rightarrow (Px \rightarrow Dx)) \qquad (1)$$

is a lawful generality. The assertion that wood W is not soluble can be taken, in one sense, as denying that

$$(\forall x)(Wx \rightarrow (Px \rightarrow Dx)) \qquad (2)$$

is a statement of law. This is distinguished from the claim that wood is insoluble, analyzed as the claim that

$$(\forall x)(Wx \rightarrow (Px \rightarrow \neg Dx)) \qquad (3)$$

is a lawful generality. Of course, (3) is what one might mean by saying that wood is not soluble, but this is irrelevant to the fact that the distinctions resolve the problems posed by dispositional predicates, without introducing the problems raised by Carnap's reduction sentences. Purported dispositional properties and problematic primitive predicates are avoided by acknowledging various lawful generalities and denials of such generalities.

'Soluble' and 'insoluble' can be said to constitute a disposition pair. Structurally, it is like a Carnapian reduction pair in that both $Px \rightarrow Dx$ and $Px \rightarrow \neg Dx$ are required, as in (1) and (3) above. The point can be emphasized when we note that the Carnapian reduction pair for S, used earlier, is logically equivalent to the pair $Sx \rightarrow (Px \rightarrow Dx)$ and $\neg Sx \rightarrow (Px \rightarrow \neg Dx)$. Thus a reduction pair can be considered as implicitly acknowledging the distinction between not-soluble and insoluble, and hence the disposition pair.

However, one need not take various pairs of Carnapian reduction sentences, connecting diverse "tests" for a single dispositional predicate, as semantic rules for such a term. One also avoids introducing terms like S as primitive terms, since one can introduce diverse explicit definitions of different predicates, such as S and I, or $Sx = df\ Px \rightarrow Dx$, or $Ix = df\ Px \rightarrow \neg Dx$. This is unproblematic if one does not take S and I as transcriptions of the

problematic terms 'soluble' and 'insoluble' (as Carnap does with *S*) and does not take the definitions of *I* and *S* as providing analyses of the problematic terms (as Carnap's reduction sentences purport to do). The context of the relevant laws, like (1) and (3), and further laws connecting the various explicitly defined terms (specifying other procedures for determining solubility), will furnish the analyses. This makes explicit the point that the empirical connections between the various reduction pairs Carnap and Hempel use for a single primitive term are not semantic rules (Bergmann 1951; Hochberg 1967; Reichenbach 1976).

VERISIMILITUDE

The concept of verisimilitude, or truthlikeness, attempts to capture the idea that one scientific theory may be closer to the truth than a rival theory. Karl Popper thought that this idea was a key to the analysis of scientific progress and the growth of knowledge. In spite of the failure of Popper's own attempt, many philosophers of science share the view that the possibility of explicating the notion of verisimilitude is vital to the success of scientific realism (see Popper, Karl Raimund; Scientific Realism).

Historical Introduction

The concept of verisimilitude was introduced within the ancient debates about scepticism. The official doctrine of the Academic skeptics was that, in order to avoid error, the wise man should not assent to any propositions. However, in the first century B.C.E., Carneades argued that some impressions may be more or less "convincing" or "persuasive," and the wise man may follow such '*pithane*' beliefs in practical action. The Greek term '*pithanon*' was translated by Cicero into Latin by '*probabile* and *veri simile*' (i.e., "like the truth").

When the modern calculus of probability was developed in the seventeenth century, the Latin terms '*probabilitas* and *verisimilitudo*' were used as synonyms. Similar terminology can be found in many Western languages. For example, in German, '*Wahrscheinlich*' means literally "truth seeming,"

and in Swedish, '*sannolik*' means "truthlike." The English words '*likely* and *likelihood*' belong to the same etymological family. The term '*veri simile*' occurs also in Cicero's poetic and rhetoric, indicating a narrative that is "possibly true" or "plausible" in the sense that it conforms to the expectations of the public. This doctrine is still alive in the notion of verisimilitude ('*vraisemblance*' in French) of modern theories of literature.

In the philosophy of science, Karl Popper introduced the notions of verisimilitude and truthlikeness in 1960 (Popper 1963). In developing his falsificationism, he wanted to find a concept that differs from the notions of probability and confirmation used in Rudolf Carnap's inductive logic (see Carnap, Rudolf; Inductive Logic). According to Popper's fallibilism, one never has any degree of certainty or even probability that the best theories in science are true. As an admirer of Tarski's definition of truth, which he interpreted as a satisfactory explication of the correspondence theory of truth, Popper's (1963) notion of verisimilitude was intended to express "the idea of a degree of better (or worse) correspondence to truth" (233).

Some nineteenth-century coherence theories of truth confused the notions of truth and complete truth by claiming that every partial truth is also partly false—for instance, "This rose is red" does not tell everything about this rose. Popper (1963) made it clear that his concept "represents the idea of approaching comprehensive truth" (237). It differs from probability, since it combines truth and information content, while "probability combines truth with lack of content" (ibid). Verisimilitude is an objective or semantic notion, not an epistemological one, but sometimes there may be arguments to appraise that "we may have made progress towards the truth" (Popper 1972, 58). Like Carneades and Cicero, Popper further suggested that, in cases where one must make a pragmatic preference between theories, it is rational to act upon that theory that can be claimed to be most truthlike.

Popper's attempted definition was refuted by David Miller (1974) and Pavel Tichý (1974). A new approach, based upon the notion of similarity, was then initiated by Tichý, Risto Hilpinen, and Ilkka Niiniluoto. Debates about the details of the definition of truthlikeness, including the possibility or desirability of such a definition, have continued ever since. The first monographs on the subject were published by Graham Oddie (1986), Niiniluoto (1987), and Theo Kuipers (1987). Surveys of more recent work are given by Niiniluoto (1998), Kuipers (2000), and Sjoerd Zwart (2001).

Popper's Definition

Popper's qualitative criterion is applicable to theories as deductively closed sets of statements. Let T and F be the sets of the true and false statements, respectively, in some interpreted language L. Then, for a theory A in L, the *truth content* of A is the intersection $A \cap T$, and the *falsity content* of A is the intersection $A \cap F$. According to Popper, theory A is *more truthlike* than theory B if and only if $B \cap T \subseteq A \cap T$ and $A \cap F \subseteq B \cap F$, where one of the set-inclusions is strict. Intuitively, A should have larger truth content than B, but smaller falsity content than B, or A should have (set-theoretically) more true consequences and fewer false consequences than B. An equivalent formulation of this criterion states that the symmetric difference $A\Delta T = (A - T) \cup (T - A)$ should be a proper subset of $B\Delta T$.

Popper's definition has some nice properties. The complete truth T has the maximal truthlikeness among all theories. If A and B are true, and A is logically stronger than B (i.e., A logically entails B, but not vice versa), then A is more truthlike than B. If A is false, then its truth content $A \cap T$ is more truthlike than A itself. However, Miller (1974) and Tichý (1974) proved that this definition does not work in the intended way, since it cannot be used for comparing false theories: If A is more truthlike than B in Popper's sense, then A must be true. The problem with Popper's approach turns out to be the fact that, by increasing the truth content of a theory, one at the same time increases its falsity content.

A model-theoretic modification of Popper's approach has been proposed by Miller and by Kuipers (1987). Let $Mod(A)$ be the class of models of A, i.e., the L-structures in which all the sentences of A are true. Then define A to be at least as truthlike as B if and only if $Mod(A)\Delta Mod(T)$ is a subset of $Mod(B)\Delta Mod(T)$. This is equivalent to Popper's original definition with the following modification: Popper's requirement for truth content is preserved, but in the requirement for falsity content the class F of false sentences is replaced by the logically weakest false theory Φ in L. If the truth is finitely axiomatizable by a sentence τ in L, so that $T = \mathrm{Cn}(\tau)$, the set of sentences that are logically entailed by τ, then Φ can be defined as $\mathrm{Cn}(\neg\tau)$, i.e., Φ is the theory axiomatized by $\neg\tau$.

If T is a complete theory, then the model-theoretic definition has an implausible consequence: Among false theories, if theory A is logically stronger than B, then A is also more truthlike than B. It is thus vulnerable to the "child's-play objection":

It allows a theory to be improved simply by joining new falsities to it.

Kuipers applies this definition to what he calls "nomic truthlikeness": A theory A asserts the physical possibility of the structures in $Mod(A)$, so that in this context T is usually not a complete theory. However, he admits that the "naive definition" is simplified in the sense that it treats all mistaken applications of a theory as equally bad. For this reason, in his recent work Kuipers has developed a "refined definition," which, by using a qualitative treatment of similarity, allows that some mistakes are better than others (Kuipers 2000).

The Similarity Approach

Popper's approach to truthlikeness employs the concepts of truth and logical consequence, but not the notion of likeness or similarity. Hilpinen (1976), instead, represented theories by classes of possible worlds and assumed, as a primitive notion, the concept of similarity between possible worlds. If possible worlds are replaced by maximally informative descriptions of states of affairs in a given language L, and such descriptions are called *constituents* in L, then the basic problem of the similarity approach is to introduce a distance between the constituents of L (Niiniluoto 1987). For numerical statements (including singular sentences and quantitative laws), such a distance can be defined by means of the underlying metric. In a simple propositional language with three atomic sentences p, q, r, the constituents are conjunctions of the form $\binom{+}{\neg}p \wedge \binom{+}{\neg}q \wedge \binom{+}{\neg}r$, where the atomic sentences occur as negated or unnegated, and the distance between two constituents is the number of diverging claims about the atomic sentences. Jaakko Hintikka (1973) has shown that the notion of constituent can be generalized to full first-order logic. The technicalities in defining the distance between first-order constituents is discussed in Oddie (1986) and Niiniluoto (1987).

The next step is to extend the distance measure to arbitrary theories. Each theory H in a first-order language can be expressed as a disjunction of constituents. Then the distance of a theory H from the truth depends on the distances from the truth of those states allowed by H. Let C^* be the complete truth τ, i.e., the true constituent of L, and let theory H be the disjunction of the states C_1, C_2, ..., C_n. Let d_{i*} be the distance of C_i from C^*. Then, in the approach of Tichý and Oddie, the distance of H from C^* is defined by the average function $\sum d_{i*}/n$ (Oddie 1986). This definition does not satisfy Popper's requirement that, among true theories, truthlikeness covaries with logical strength. In Niiniluoto's approach, 'truthlikeness' is defined by the weighted average of the minimum distance $\min d_{i*}$ and the (normalized) sum $\sum d_{i*}$ of all distances ($i = 1, \ldots, n$) (Niiniluoto 1987; Kuipers, 1987). Here the minimum distance alone serves to define the notion of *approximate truth*, while the additional sum-factor defines penalties for all the mistakes allowed by the theory. Complications of this min-sum-definition, arising from cases involving continuous quantities, are discussed by Kieseppä (1996).

When the similarity approach is applied to cases where the true constituent is a modal statement with a nomic necessity operator, it gives an explication of what L. J. Cohen (1980) calls *legisimilitude*. This gives also the possibility of interpreting Kuipers' account of nomic truthlikeness within the similarity approach.

The min-sum-definition of degrees of truthlikeness satisfies Popper's basic conditions, but it is also stronger than Popper's approach in the sense that all rival theories (in language L) are comparable with respect to their verisimilitude. The Miller-Tichý refutation and the child's play objection are avoided. Moreover, by this definition it is possible that some false theories are so close to the truth that they are more truthlike than weak true theories.

Zwart (2001) notes that the followers of Popper's explication give "content definitions" in the sense that the least truthlike of all theories is the negation $\neg\tau$ of complete truth τ (i.e., the disjunction of all false constituents), while the "similarity definitions" imply that the worst theory is the "complete falsity" (i.e., the constituent at the largest distance from the truth). If $\tau = p \wedge q \wedge r$, then these two alternatives are represented by $\neg p \vee \neg q \vee \neg r$ and $\neg p \wedge \neg q \wedge \neg r$.

The most famous objection against the similarity account of truthlikeness is Miller's (1974) argument about *language-dependence*. Miller shows that, by a suitable translation between two languages, truthlikeness ordering may be reversed. This argument is related to the more general point that metric properties need not be preserved in one-to-one mappings between quantitative spaces. It has provoked a lot of discussion about the invariance properties of truthlikeness measures (Niiniluoto 1998; Zwart 2001).

Applications

The logical definitions of 'verisimilitude' attempt to tell how close alternative theories are to a given target. If the complete truth is unknown, as is always the case with scientific research problems, then a measure of truthlikeness does not yet indicate how one could know that one is close to the truth. Still, such measures of truthlikeness may be useful as tools in debates concerning scientific realism (Niiniluoto 1999; Kuipers 2000). In particular, they prove that it is meaningful to speak about *scientific progress* toward the truth (see Scientific Progress), and they can be used to define the notion of *convergence* to the truth for scientific theories. Truthlikeness serves to clarify the principle of charity that can be used to defend *reference* invariance in scientific change (see Scientific Change). These notions can be applied to sequences of theories from the history of science. Measures of verisimilitude allow the study of whether truthlikeness explains the success of science. They also help to make sense of the idea that *idealized theories*, which are known to be false, may still be close to the truth. The technical notion of similarity between statements provides a general framework for the study of *approximation* in science (see Approximation).

Epistemological and Methodological Approaches

To solve the epistemological problem of truthlikeness, Niiniluoto (1987) has proposed that the distance $Tr(H,C^*)$ of a hypothetical theory H from the unknown truth C^* can be estimated by the expected value of the degree of verisimilitude of a theory. For this purpose, it has to be presupposed that there is a probability measure P such that $P(C_i \mid e)$ is the epistemic probability (rational degree of belief) of constituent C_i given the available evidence e. Then the *expected verisimilitude* $ver(H \mid e)$ of theory H given evidence e is defined by the sum $\sum_i p(C_i \mid e)Tr(H,C_i)$, where i ranges over all constituents and $Tr(H,C_i)$ is what the degree of truthlikeness of H would be if C_i were the true constituent. If the evidence e entails that C_j is the true constituent, then the expected verisimilitude of H on e equals $Tr(H,C_j)$. Expected verisimilitude differs from the notions of posterior probability, confirmation, and corroboration, since $ver(H \mid e)$ may be high even when theory H is incompatible with evidence e.

The measure $ver(H \mid e)$ makes it possible to integrate the theory of truthlikeness to the Bayesian framework where scientific inference is analyzed as the maximization of expected epistemic utilities (see Niiniluoto 1987; Festa 1993).

A different methodological approach is proposed by Zamora Bonilla (1992), who defines "truthlikeness without truth" by measuring directly the distance of a theory from the available experimental laws.

VIENNA CIRCLE

The Vienna Circle consisted of a group of about three dozen researchers drawn from the natural and social sciences, logic, and mathematics, which met regularly in Vienna between the two world wars to discuss philosophy. The work of this group constitutes one of the most important and influential philosophical contributions of the twentieth century, in particular in the development of analytic philosophy and history and philosophy of science (Stadler 2001 and 2003a).

The Vienna Circle was first publicly announced in 1929 with the publication of what came to be called its manifesto, *Wissenschaftliche Weltauffassung. Der Wiener Kreis* [The Scientific Conception of the World: The Vienna Circle], edited by the Verein Ernest Mach (the Ernest Mach Society) and authored by Carnap, Hahn, and Neurath (1929). The Vienna Circle was essentially a modernist movement, at the center of which was the "Schlick Circle," a discussion group organized in 1924 by Moritz Schlick. Rudolf Carnap, Herbert Feigl, Philipp Frank, Kurt Gödel, Hans Hahn, Otto Neurath, Felix Kaufmann, Viktor Kraft, Karl Menger, Friedrich Waismann, and Edgar Zilsel belonged to its inner circle (see Carnap, Rudolf; Hahn, Hans; Neurath, Otto; Schlick, Moritz). Their meetings were also attended by Olga Taussky-Todd, Olga Hahn-Neurath, Rose Rand, Gustav Bergmann, and Richard von Mises, and on several occasions by visitors such as Hans Reichenbach, Alfred J. Ayer, Ernest Nagel, Quine Willard Van, and Alfred Tarski. Members of the periphery, most of them as participants, were Egon Brunswik, Karl Bühler, Josef Frank, Else Frenkel-Brunswik, Heinrich Gomperz, Carl Gustav Hempel, Eino Kaila, Hans Kelsen, Charles Morris, Arne Naess, Karl Popper, Frank P. Ramsey, Kurt Reidemeister, and the alleged "genius," Ludwig Wittgenstein, who had a special influence on some members of the group (see Ayer, Alfred Jules; Hempel, Carl Gustav; Nagel, Ernest; Popper, Karl Raimund; Quine, Willard Van; Ramsey, Frank Plumpton; Reichenbach, Hans). In addition, the mathematician Karl Menger organized in the years 1926–1936 an international Mathematical Colloquium, which was attended by Kurt Gödel, John von Neumann, and Alfred Tarski among many others (Menger 1994).

This international and interdisciplinary discussion circle was pluralistic and committed to the ideals of the Enlightenment. It was unified by the aim of making philosophy scientific with the help of modern logic on the basis of experimental and everyday experience. The general aims of the movement were expressed in its publications such as *Schriften zur Wissenschaftlichen Weltauffassung* [Publications on the Scientific Conception of the World], 1929–1937, in eleven volumes; *Einheitswissenschaft* [Unified Science], 1933–1938, in seven volumes; the journal *Erkenntnis,* 1930–1940 (the 1939 volume was called *Journal for Unified Science*); and the *International Encyclopedia of Unified Science*, 1938–1970 (Neurath, Carnap, and Morris 1971).

Given this story of scholarly success, the fate of the Vienna Circle was tragic. The Verein Ernest Mach was suspended in 1934 by the Austrian Nazis; Schlick was murdered in 1936; and, around this time, many members of the Circle were forced to leave Austria for racial and political reasons. Thus, soon after Schlick's death, the Circle disintegrated. As a result of the emigration of so many of its members and adherents, however, the Circle's ideas became more and more widely known, especially in Scandinavia, Britain, and North America, where they contributed hugely to the emergence of modern philosophy of science (Timms and Hughes 2003; Hardcastle and Richardson 2003). In Germany and Austria, however, the break that was caused by the forced emigration of the Vienna Circle's members was felt on the philosophical and mathematical scene for a long time (Heidelberger and Stadler 2003).

"Logical Positivism" and/or "Logical Empiricism"

The name 'Vienna Circle' was used for the first time in 1929 in the manifesto mentioned earlier. It was suggested by Neurath and was supposed to have a pleasant connotation similar to *Vienna Woods* or *Viennese Waltz.* At the same time, the term was to indicate the origin of this philosophical movement and its collective orientation (Frank 1949). In the programmatic essay of 1929 the position of the antimetaphysical "radical" left wing

around Carnap, Neurath, Hahn, Frank, and others was especially prominent. This group supported the idea of a physicalist unity of science, most commonly referred to as "logical empiricism" as found later in the program of the *International Encyclopedia of Unified Science* (Neurath 1946). By contrast, the more moderate wing of the Vienna Circle, around Schlick, Waismann, Feigl, and others, emphasized their adherence to a dualism of science and philosophy with different names like "consistent empiricism" (Schlick 1950, 462f) or 'logical positivism' (Kraft 1950).

The widely used term "logical positivism" actually originated in Blumberg and Feigl's (1931) article of that title. Here both authors gave a concise description of the new anti-Kantian synthesis of logical and empirical factors proclaiming the impossibility of synthetic a priori truths. They went on to describe the philosophical transformation from the old to the new positivism with the adoption of symbolic logic, epistemology, and research into the foundations of science. Finally, they explained, following Wittgenstein, "the purpose of philosophy as the clarification of the meaning of propositions and the elimination of ... meaningless pseudo-propositions" (269).

Scientific Philosophy and Philosophy of Science

Proponents of "scientific philosophy" thought of philosophy not as an autonomous discipline existing prior to science but as a critical discipline dependent upon the results of the natural and social sciences, logic, and mathematics. Turning around Kant's dictum, they claimed that philosophy without science is empty, and science without philosophy is blind. Adoption of this scientific conception of philosophy does not, however, determine what epistemology, methodology, and ontology one is committed to. Nonetheless, all adherents of scientific philosophy demanded exact methods, a critical attitude, and a more or less empirical orientation. They opposed irrational and theological systems of philosophy (*Systemphilosophie*) and viewed science in general in a positive way.

Historically, Mach's philosophy provided the foundation for the development of the positions adopted within the Vienna Circle (see Mach, Ernest). The term 'logic of science' (Carnap's [1934] *Wissenschaftslogik*), known since the mid-1930s as "philosophy of science," was later used to describe these positions (see Carnap, Rudolf). This implied a general scientific conception of philosophy as well as an attempt to provide a philosophy for all sciences (including human sciences). In addition, within the Vienna Circle, philosophy was regarded both as a form of linguistic analysis and as a discipline drawing on the foundations of the natural and social sciences.

At the same time, there were divergences of philosophical approaches within the Vienna Circle. Those such as Schlick defended a methodological dualism of philosophy and science, and those such as Neurath sought to integrate philosophy altogether within a scientific conception of the world (see Neurath, Otto; Schlick, Moritz). In Schlick's view, the classical philosophical positions of empiricism and rationalism were integrated with the help of modern logic and mathematics, but a distinction between philosophy and science still remained. Neurath's more radical physicalism, or "encyclopedism," of logical empiricism aimed at overcoming philosophy itself within his collective project of an *International Encyclopedia of the Unity of Science* (Neurath 1946). This divergence in philosophical approaches left room for debates within the Circle on such topics as the merits of phenomenalist and physicalist languages, coherence and correspondence theories of truth, logical syntax and semantics, verification and confirmation, and ideal and natural languages. At the same time, there was a certain consensus on the merits of logical analysis of language, a fallibilist epistemology, a scientific attitude to the world, and the unity of scientific explanation and knowledge in general.

The rivalry between Schlick's "consistent empiricism" and Neurath's physicalist unified science is a complex matter. Certain views were shared by both, such as the view of philosophy as a critique of language in accordance with Wittgenstein's philosophy of the *Tractatus* of 1922. However, while the principle of verification (see Verifiability), logical atomism, and the picture theory of language are constitutive features of the entire movement, by themselves they do not characterize the Vienna Circle. Theoretical elements like logicism, verifiability, methodological phenomenalism and physicalism, a fallibilist theory of knowledge, conventionalism, and realism, together with an empiricist encyclopedism, were cornerstones of the internal pluralistic development of logical empiricism from the 1930s onward (see Logical Empiricism). This development also reflected the influence of Neurath's pragmatic point of view within the Circle. In particular, the objection toward any dualism of "language" and "world" (as *Wirklichkeitsphilosophie*), with the attendant denial of any absolute "foundation of knowledge" (Schlick 1934) is representative of this nonreductive naturalism and methodological holism in the spirit of Pierre Duhem's and Henri

Poincaré's philosophy of science (see Conventionalism; Duhem Thesis; Poincaré, Henri). This form of relativism and naturalism already anticipated the pragmatic and historical turn after World War II in the philosophy of science, which contributed to overcoming the linguistic turn and the so-called received view of philosophy of science.

The rejection of synthetic a priori judgments remained an important element of the logical empiricism of the Vienna Circle. According to Russell and Whitehead in the *Principia Mathematica* (see Russell, Bertrand), symbolic logic and mathematics were regarded as purely analytical and a priori (independent of any experience). Analytic truths of these kinds were contrasted with contingent statements of the natural sciences and ordinary everyday experience, as synthetic *a posteriori* judgments (see Analyticity). But there was no further class of synthetic a priori judgments; instead there was thought to be an important class of "meaningless" sentences, without any cognitive content. The elements of this class were seen as "metaphysical" in the sense that they are not part of knowledge at all, even though they may express some realm of commonsense experience (see Cognitive Significance).

This position of the classical Vienna Circle is most prominently represented by Carnap's (1931) "Elimination of Metaphysics through Logical Analysis of Language," which developed a program for a unified rational reconstruction of science (see Rational Reconstruction). But the question as to whether an empirical basis could serve as the foundation for all knowledge received strongly divergent answers from coherence theorists about truth (influenced by Neurath) and correspondence theorists (influenced by Schlick) (Hempel 1993). Also, the apparently strict distinction between analytic and synthetic sentences was questioned (Menger 1979, 1–60). The ideal of one language of science, logic, and mathematics was radically weakened within the Vienna Circle itself with Menger's and Carnap's principle of tolerance long before Quine (1953) put forward his critique of the "Two Dogmas of Empiricism" (see Quine, Willard Van). Thus, contrary to popular belief, a heterogeneous pluralism of views was in fact characteristic of the Vienna Circle—for example, regarding ethics (Schlick, Menger, Kraft), the alternatives of realism versus positivism (Schlick, Carnap, Feigl, Kraft, Kaufmann) and verificationism versus falsificationism (both positions criticized by Neurath), and last, but not least, matters of ideological and political preference, such as conservative liberalism versus leftist socialism. In the later period of the Vienna Circle, the contested verification principle was gradually abandoned and replaced by some form of a probabilistic confirmation methodology based on the principle of "connectibility" (von Mises 1951) (see Cognitive Significance; Verifiability).

Scientific Conception of the World and Scientific Humanism

The unity of science movement, with its six International Congresses for the Unity of Science, held from 1935 to 1941, and the ambitious publication project of the *International Encyclopedia of Unified Science,* 1938–1970, had a broader cultural meaning and goal, most notably the attempt to improve the human condition and to promote social reform and the intellectual struggle against irrationalism and the totalitarian worldview (see Unity and Disunity of Science; Unity of Science Movement). It was a manifestation of a late-Enlightenment conception of science with a socially inspired antimetaphysics. Between the two world wars, metaphysics was seen as a correlative feature of German idealism as well as of Austrian fascist "universalism," as represented by the economist Othmar Spann.

The practical impulse behind this therapeutic destruction of metaphysical systems, then, was the desire for a scientific attitude based on human experience, directed against the *Zeitgeist* of totalitarian universalism and cultural pessimism (as criticized by Neurath [1921] and [1931]). Therefore, traditional philosophy, first of all, had to be reduced to a critical analysis of language, because most proponents of logical empiricism thought that an exact and sober usage of the scientific language is a precondition for all problem-oriented philosophizing—and moreover a sort of moral obligation.

Social criticism and collective work in philosophy of science formed a programmatic unity striving for a sweeping improvement of the human condition. Whereas in the natural sciences considerable progress had already been made, the situation in the social and cultural sciences was not so transparent, and was influenced by the ongoing *Methodenstreit* since the turn of the century (Kaufmann [1936] 1999). Although some members of the Vienna Circle, like Kaufmann, Neurath, and Zilsel, contributed essentially to this neglected field, their contributions have been largely ignored in the historiography on the Circle for a long time. In this respect it is worth mentioning that after the disintegration of the Vienna Circle, its former members still occasionally made reference to the "scientific conception of the world" when speaking about general ideological questions. For example, Carnap spoke about "scientific humanism" as a view shared

by the majority of the logical empiricists (Carnap 1963, 81ff). After the dissolution of the Vienna Circle, the forced migration of most of its members, and the dispersion of the logical empiricist movement from its centers in Central Europe, the twin aims of transforming philosophy and establishing a philosophy of science could be envisaged only once the ties to their previous cultural context and audience had been severed. But even in these difficult times the proponents of the exiled Vienna Circle organized six well-attended, prestigious International Congresses for the Unity of Science: Paris (1935 and 1937), Copenhagen (1936), Cambridge, UK (1938), Cambridge, Massachusetts (1939), and Chicago (1941). One can thus say that the demise of the Vienna Circle in the German-speaking world was accompanied by the transformation of Viennese *Wissenschaftslogik* into philosophy of science in the Anglo-Saxon scientific community.

Recent Reassessments

The new historiography on logical empiricism started with the rediscovery of Ernest Mach (1838–1916) as a precursor of Gestalt theory, evolutionary epistemology (possibly radical), constructivism, and the modern historically oriented philosophy of science. Already in Mach's reception in the Vienna Circle one can see not only a certain pluralism of views but also a polarization of the various positions (Mach's influence on Carnap's [1967] *Aufbau/Logical Structure*, the critical distancing to "psychologism" in the manifesto, the alternative to the principle of economy, etc.).

Even prior to World War I, the predecessor of the Vienna Circle—the "First Vienna Circle"—had begun to take shape both as an organization and as a philosophy (Uebel 2000). Within a discussion circle (*inter alia*, with Frank, Hahn, and Neurath) at a coffeehouse, traditional "academic philosophy" grew more scientific. This so-called First Vienna Circle met regularly as of 1907 to discuss the synthesis of empiricism and symbolic logic as modeled after Mach, Boltzmann, and the French conventionalists (Pierre Duhem and Henri Poincaré) (see Conventionalism; Duhem Thesis; Poincaré, Henri). This was also seen as an indirect answer to Lenin's polemical remarks against Mach in his book, *Materialism and Empirio-Criticism*, which remained very influential in eastern Europe from its publication in 1909 to the "Velvet Revolution" of 1989–1990.

This early phase in the development of logical empiricism can also be interpreted as an anti-Cartesian turn in epistemology and philosophy of science, which undermined both the synthetic a priori and the secure foundations of knowledge. In the middle of the permanent crisis of philosophy between reform and revolution in society and science, the further development of this "scientific philosophy" had, in any case, been initiated.

With the conflict-laden appointment of the physicist and philosopher Moritz Schlick (1882–1936) to Mach's chair for natural philosophy of the "inductive sciences" in Vienna in 1922, the heyday of scientific philosophizing in the post–World War I period was prolonged. Even though Schlick ([1918, 1925] 1974) felt committed to an epistemological realism in his main work, *General Theory of Knowledge*, he began his inaugural lecture with a programmatic allusion to Mach, under the sway of the Viennese tradition up to Wittgenstein, that almost all philosophy is natural philosophy.

In the phase during which the Schlick Circle became a veritable institution, there was already a pluralism of positions that had emerged in the field of tension between Wittgenstein's *Tractatus* and Carnap's *Logischer Aufbau der Welt* [Logical Construction of the World] (Carnap 1967). Yet notwithstanding all the discrepancies between Carnap's "rational reconstruction" and the philosophy of ideal language (Wittgenstein), all those involved came to identify with a philosophical reform movement as opposed to academic philosophy.

This radical program, in turn, left an indelible mark on avant-garde art (i.e., constructivism, associated with Gerd Arntz, the artist of Neurath's pictorial language) (see Neurath, Otto) and literature, as well as architecture (*Werkbund* and Bauhaus), centering around Ludwig Wittgenstein, Paul Engelmann, Adolf Loos, Josef Frank, and Neurath's efforts within the Congrés International d'Architecture Moderne (Nemeth and Stadler 1996). Clarity and precision as ends in themselves and features of scientific philosophy bridged both Wittgenstein's cultural pessimism and the socio-culturally enlightened impetus of the modernist Vienna Circle.

With this convergence of various elements of philosophy of science, theoretical innovation was accelerated in the phase in which the Vienna Circle made public appearances and expanded its international contacts. The latter development was accompanied by the disintegration and uprooting of logical empiricism in the German-speaking world. In this sense, the phenomenon of the Vienna Circle is a prototypical case study of intellectual emigration (Stadler 2003b, c).

To all appearances, there seem to be two diametrically opposed trends. While the international influence of the Vienna Circle was steadily growing,

the group had been systematically marginalized in Austria and Germany starting in the early 1930s. The murder of Schlick and the disgraceful, for the most part anti-Semitic, reactions to it brutally ushered in the process that can be described as the "demise of scientific reason" (Stadler and Weibel 1995). This took place in parallel with the general trend at universities, which at the time were increasingly coming under the influence of a growing antidemocratic and racist discourse dominated by clerical-fascist and National Socialist forces. This development led to the anschluss of Austria by the Third Reich, which culminated in systematic dismissals, banishment, and annihilation of many leading intellectuals and others (Stadler 2002).

Concluding Remarks

Looking at the current definitions of the Vienna Circle, one can quickly recognize the difficulty of providing a representative description of the Circle and of logical empiricism in its entirety. Even the autobiographical accounts of Vienna Circle members since the classical period of the Schlick Circle show a remarkable variance—depending on focus and underlying motivations.

What these texts have in common is the refutation of metaphysics as well as of philosophy as a discipline in its own right. As an alternative, one finds a tendency toward a (physicalist) unified science that later culminated in an empiricist encyclopedia project and includes the principle of tolerance as applied to logic and scientific languages. Here, the contours of epistemological options emerge. If one also takes into account that the manifesto represents only one variant of the Vienna Circle at the end of the 1920s, then it becomes amply clear that there existed only a limited consensus.

In addition, it is obvious that neither the autobiographical accounts of contemporaries nor the historical accounts originating shortly after 1945 were able to provide an adequate picture of the Vienna Circle. Moreover, there exists only a partial, albeit broad, overlap of the concept of the Vienna Circle with that of logical empiricism in general when one takes into account the related movements of the Berlin Circle around Hans Reichenbach and the Warsaw Group around Alfred Tarski (Danneberg, Kamlah, and Schäfer 1994).

Is it still possible to find a sort of basic agreement here to unite the members of the Vienna Circle, both the central figures and those on the periphery? First of all, the Vienna Circle method is a way of philosophizing based on linguistic analysis and a great amount of problem-oriented, open-ended discussion. This was experienced personally by Arne Naess, who focused several times on the Circle's "thought style," which, in (not only) his opinion, leads to an inherent "pluralism of tenable worldviews" (Naess 2003). Second, the use of an unambiguous language, together with exact methods, is certainly a main legacy of the Circle and those associated with it. It is only when this exact formal approach is adopted that the content and positions can be constructively criticized and refuted—a characteristic that most current modern and postmodern philosophies lack.

The explicit and hidden history of the Vienna Circle from *Wissenschaftslogik* to the recent philosophy of science documents the wide range, pluralism, and diversity of the Viennese heritage and message. Be it called "scientific philosophy" (as initiated by Schlick), "scientific humanism" (according to Carnap), or a "republic of scholars" (following Neurath), it is a guide to an intellectual journey that continues through the present day and probably on into the future.

VISUAL REPRESENTATION

Graphs, diagrams, drawings, sonographs, and x-rays are commonly used in contemporary science in the process of research, in communicating results, and in education. In contrast to more familiar images—paintings, snapshots, children's drawings—visual representations in science often, though not always,

depict phenomena that cannot be seen: structures too small to see with visible light (electron micrographs), relations among properties (graphs), steps in a mechanism (diagrams). Philosophers of science have studied linguistic and mathematical representations in order to understand science, but they have only recently begun to investigate what visual representations contribute, and how they do so. Visual representations appear to play philosophically significant roles in scientific reasoning. They are prevalent in journal articles, where scientists express and defend hypotheses. These papers are relatively formal communications, subject to disciplinary standards of clarity and objectivity, and reviewers scrutinize figures as well as text in evaluating the arguments presented. Some figures appear to express scientific hypotheses (e.g., the diagram of the double helix), while others are presented to provide support for a hypothesis. Can a visual representation express a hypothesis? What kind of inferences can a visual representation support? How does the visual format of a figure relate to its role? Scientists frequently express concern about the accuracy of figures, just as they do about the accuracy of linguistically or mathematically expressed claims. Can pictures be accurate—or true? In general, what advantages do visual representations offer over linguistic and mathematical representations?

In order to answer these questions, it is essential to understand the nature of visual representations as such, and to know in what ways they differ from other types of representations. An analysis that can apply to all symbols used in science is required to avoid dependence on assumptions about the kinds of representations involved. Thus, the first step in understanding visual representations in science is clarification of key representational features. Different kinds of visual representations can then be compared with each other, and with linguistic representations. This preliminary step is also required in order to understand the epistemic roles played by figures—fundamentally, to explain how visual representations express and support scientific claims.

Visual Symbols

Visual representations, like written or spoken sentences and numerical formulas, are external objects that function as symbols. No object conveys content on its own; symbols must be interpreted. Goodman (1976) shows that resemblance is neither necessary nor sufficient for representation: Just about any thing can be designated to refer to some other thing—Wellington does not represent his portrait even though they resemble one another. Comprehension of symbols, including pictures, involves interpretation, which is conventional in the sense that the relation between symbol form and content is not determined just by either intrinsic features of the symbol or a resemblance relation between the form of the symbol and its referent; something extrinsic to both objects (symbol and referent) is necessary to determine that one refers to another. This is obvious for linguistic representations, whose form does not bear a visible relation to its referent. Comprehension of pictures often feels so natural and automatic that viewers are not conscious of it, but application of the appropriate interpretive conventions is necessary to comprehend visual representations. For example, in order to understand a watercolor of a landscape, one has to apply the appropriate interpretive conventions to the colors and shapes in order to comprehend it as a representation of a landscape. These are *different* conventions from those used to interpret a different kind of picture, such as a black-and-white photograph. A gray tone in the watercolor must be interpreted differently from a gray tone in the photo. All forms of representation used in a scientific article share this most general feature of symbols: They require application of the appropriate interpretive conventions in order to know what the symbol refers to. The interpretive conventions govern relations between symbol and referent for particular systems of symbols, so that although it is tempting to try to analyze pictures by focusing on individual specimens, the full understanding (as with linguistic representations) requires knowing the systems of which they are components.

The content of visual representations is not *entirely* conventional in the above sense; relations between the visible form of visual symbols and their referents are also involved in determining the content of pictures. There is a fundamental difference between textual and visual symbol systems. Visual systems are based on a spatial format: Visual representations are symbols in which some spatial relations are interpreted to mean something about the referent. In some visual symbol systems, spatial features of the symbol refer to spatial features. For example, spatial relations among circles in a ball-and-stick diagram of a molecule refer to spatial relations among the atoms in the molecule. In other visual systems, however, spatial features of symbols refer to nonspatial features of the object represented. A spatial feature of a time line—length—represents a temporal feature: duration. Graphs are visual symbols in which spatial features represent relations among properties, like the

relation between gas volume and pressure. Other visible features such as color may also contribute to the meaning of visual representations. However, the referential role of spatial relations is the fundamental feature of visual representations.

For this reason, the visible *forms* of visual representations are related to their referents. This relation varies among visual symbol systems, but each system is characterized by a relation between symbol form and content that holds for that system, and this relation is the basis for interpreting, and thus comprehending, the symbol as such. This relation holds between the *interpreted* visible features of the symbol, on the one hand, and the properties and relations represented, on the other (not between all features of the symbol and all those of its subject).

In contrast to the spatial format of visual representations, linguistic representations have a sequential format; the sequence of letters and spaces alone is sufficient to determine the meaning of text. Serial symbol systems typically comprise symbols whose spatial form is arbitrary with respect to their meaning. Though some serial systems, such as written Chinese, include pictographic characters, this is not necessary for serial representation, and the relationship between symbol form and referent in the pictographic characters serves a mnemonic purpose, but is not systematic (not all Chinese characters are pictographic). Chinese is a serial system because the meanings of statements are determined by the ordering of characters, rather than by spatial relations among them. For serial systems like alphabetical and numerical symbol systems, the shapes of letters are entirely unrelated to the referents of the words and sentences they compose. Relative spatial position of serial characters can contribute to meaning—poets might vary between-word spacing for emotional effects—but it is not necessary; the sequence of characters is sufficient to determine symbol meaning.

Types of Visual Symbols

This difference in format does not account for important differences *among* visual representations, so it cannot explain why scientists use different kinds of visual representations. Further analysis of the properties of visual symbol systems allows for categorizing two different kinds of visual representation and explaining what makes them differ from each other, as well as identifying an important feature that one of these visual types, but not the other, shares with serial representations. Diagram systems, such as those of electrical circuitry and chemical structures, *look* different from visual representations that appear much more like pictures, such as electron micrographs and satellite photos. This is because the former symbol systems share some features with linguistic representations—in addition to having the spatial format shared by all visual representations.

Some symbol systems consist only of markings that can each be identified as instances of a particular character—unless they are simply illegible (Goodman [1976] calls these syntactically articulate systems). Text, numerical formulas, and wiring diagrams have this type of syntax. It allows for compositionality: All these systems consist of unambiguously recognizable atomic characters (e.g., numerals, letters, Chinese characters) combined in rule-governed ways. In a visual symbol system with this kind of syntax, some spatial relations among the atomic characters will also be interpreted to refer to some relation among the referents of the atomic character. The meaning of a molecular diagram is a function of the reference of the atomic characters and how they are arranged (see Figure 1). These are compositional symbol systems, like written languages and numerical systems, all of whose symbols consist of atomic characters that are always identifiable as particular characters. Their meanings are a function of the identity and composition of atomic characters, whether the composition is sequential (for serially formatted systems) or

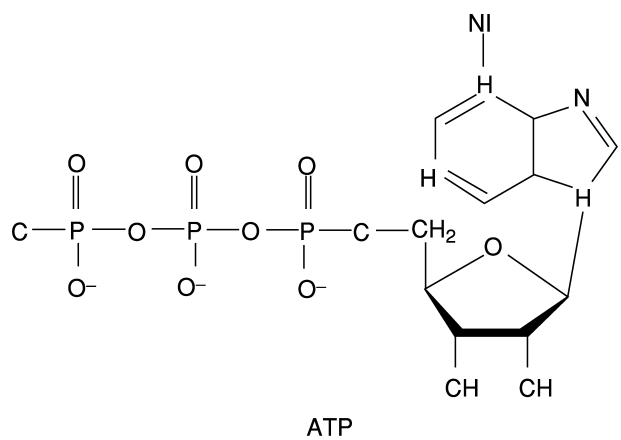

Fig. 1. Diagram of adenosine triphosphate (ATP). In this diagram, lines and letters serve as atomic characters that refer to bonds and different kinds of atoms, respectively. Spatial relations among those atomic characters are also interpreted: for example, contiguity of a P, a single line, followed by an O, to refer to the bond between a phosphorous and an oxygen atom. In this way, the atomic characters and spatial relations among them are used to represent the structure of the molecule.

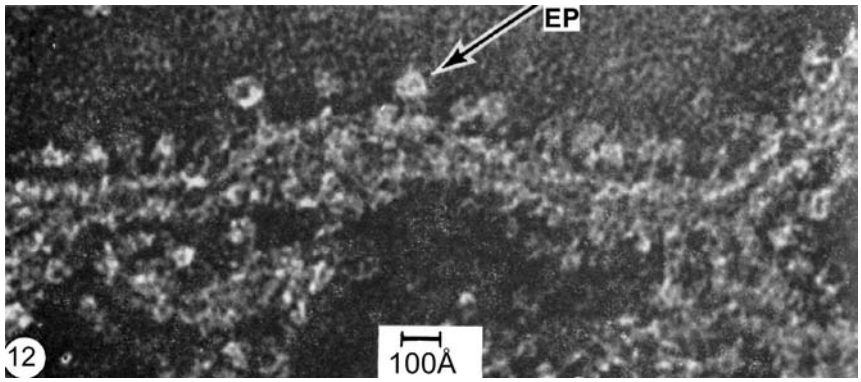

Fig. 2. Electron micrograph of inner mitochondrial membranes. The image is produced by a process in which a very thin sample is prepared with a stain that does not mix well with biological material, and also repels electrons. A beam of electrons is aimed at the sample, and electrons go through the areas where biological material is present but are deflected by the stain. This process produces a pattern of light areas on the image whose shape matches the way the electrons passed through the sample. From Fernández-Morán 1962.

spatial. Because of this compositionality, which is in part due to the fact that visible forms of atomic characters are arbitrary with respect to their meaning, diagrams have some of the convenience and flexibility of textual representations (whose spatial features are entirely arbitrary with respect to meaning). These are formats with which it is easy to express very abstract or general ideas. For this reason they are useful for representing mechanisms.

Photographs, natural history drawings, and electron micrographs have some important syntactic and semantic differences (Figure 2 is an example of this type of figure). These images are not composed of discrete atomic elements. They are characters from systems in which any difference—for *at least one* interpreted spatial feature of the figure, such as the shape of a curve on a graph—corresponds to a difference in the character that figure instantiates. And every different character has a different referent. So two electron micrographs with different two-dimensional arrays of light-to-dark scaling represent different structural features. Because the smallest spatial difference correlates with a different referent, visual representations from these systems can represent very complex properties (like the particular shape of a subcellular structure), and these systems comprise symbols that together represent a dense range of these properties.

Another prominent difference among visual representations is their degree of abstraction. It is not possible to explicate this difference in terms of discrete categories, but studies of the relation between abstractness of symbol form and symbol content in scientific contexts have presented some interesting results. Michael Lynch (1988) discusses figures in which an electron micrograph and a schematic drawing are paired together, showing that figures with different degrees of abstraction can play different epistemic roles. In these pairs, the micrographs serve as evidence for the more abstract visual representation. Lynch describes the visible differences between the two and relates those differences in symbol form to differences in the content each conveys, in order to support his claim that the inferential move from less to more abstract representation is not a matter of mere simplification of form in terms of a reduction of visual stimuli. The schematic drawings are idealizations, generalizations, or extrapolations from the pictures that support them. There is a difference in the kind of fact depicted by each of the two representations in the pair. The picture refers to a particular case, while the schematic drawing expresses a claim that is general (applying to multiple cases), in addition to being more abstract (leaving out features represented in the picture).

The use of figures that vary in abstraction also raises questions about the relationship between abstractness of representation and accuracy. Hall (1996) argues that the degree of naturalism of a pictorial style is distinct from its capacity for accurate representation. He supports his thesis with contrasts of realistic pictorial styles that misrepresent human anatomy with very schematic diagrams that convey accurate information. Given the role of interpretation in comprehension of visual representations, this phenomenon can now be explained. Accurate visual representations are interpreted to represent a state of affairs that obtains. There is no warrant for assuming that

visual representations are meant to represent *all* properties of their subjects; the properties represented, as well as the visible features of the symbol used to convey them, vary among visual symbol systems. Very schematic figures, then, are not inaccurate just because they do not represent in detail the features of their referents. Thus, understanding figures as elements of visual symbol systems that vary according to system conventions clarifies the relation between representational styles and semantic value.

Scientific Reasoning and Visual Representations

Model-Based Reasoning

Most contemporary philosophers of science who have discussed the use of figures focus on the content of the figures, rather than presenting an analysis of how that content is conveyed—what the visual format contributes. Nersessian (1992) and Giere (1996) discuss scientific visual representations, and, while these papers also focus on content, their model-based accounts of scientific reasoning offer a promising route to understanding how figures might be involved in that reasoning. (see Scientific Models). Nersessian (1992) discusses the development of the theory of electromagnetism, arguing for an important role for analogical reasoning, which involves a systematic mapping of relations between a source and a target domain. Nersessian supports her claim with a discussion of Maxwell's figure, which she describes as "a *visual* representation of an *analogical* model" (Nersessian 1999, italics in original.). Nersessian suggests that analogical thinking involves mental models, which embody the relations holding among the events and entities involved in the object of thought (see Scientific Metaphors). The usefulness of a visual representation to this kind of analogical reasoning can be explained by the distinctive feature of visual representations: their spatial formatting. A visual representation of a model might be particularly efficient for mental modeling, since the content is conveyed through spatial and other visible relations.

Comprehending the representation requires mapping the perceived visible features to the appropriate relations and properties of the referent. An independent step of generating a mental image of the model is not required, as it would be if the model were conveyed through a serial representation. Consider the difference between a linguistic description of an analog clock face and a picture of one. The statement that the big hand is on the eight and the small hand is just below the ten provides information from which it is possible to infer the time. Most people would comprehend the description, then create a mental image of the clock, and from that image determine the time. Comprehending a picture of a clock seems to eliminate a step by combining the comprehension of the representation with the construction of the mental image.

Giere (1996) focuses on external, rather than mental, models: Scientific theories are abstract objects that need not have linguistic character. Judgments about models are made by comparing them with real objects, because a model serves as a prototype to assess similarity to putative instances of the model. Giere considers diagrams embodiments of completely abstract models; he claims that, as such, they can serve as prototypes for similarity judgments. The ubiquitous nature of resemblance relations makes it difficult to account for the *particular* similarities that are relevant for a particular judgment. This is another area in which further study of scientific visual representations as such could have an interesting payoff: understanding visual representations as isomorphic symbols provides some resources to explain how diagrams make certain features salient. The isomorphic relation stands between some, but not all, of the visible features of the figure and its content, as determined by the interpretive conventions for that symbol system. So the capacity to understand a figure as a representation explains the capacity to identify the features by which similarity should be assessed.

Evidential Roles

Visual representations often appear to be presented as support for scientific claims. Brown (1997) describes several diagrams from mathematics and argues that they function as proofs. Folina (1999) responds by pointing out that these diagrams are not proofs in the sense of deductive demonstrations, though she concedes that the diagrams may contribute some other form of support. Some diagram *systems* have been shown to support proofs. Hammer (1995) presents analyses of several logical diagram systems (Venn, Euler, and Peirce), including soundness and completeness proofs. However, these demonstrations do not shed light on how an individual visual diagram could function as a proof.

Giere (1996) presents examples of figures from research in geology, in which the patterns of two different types of data are placed in visible correspondence with one another, in accordance with the model in question. However, while in this case

the *form* of the figures is recognized as important to confirmation, the relation between form and content that distinguishes visual representations is not discussed.

Wimsatt (1991) provides examples of figures from various disciplines that facilitate inferences, including cases in which the use of multiple kinds of figures are involved. Wimsatt does not give an explicit account of how figures support inferences, but the paper emphasizes the usefulness of visual representations in handling data that vary along more than one dimension. The analysis of visual representations can clarify how figures do this: For making inferences from a single figure, the two-dimensional format is an advantage, because the dimensions can be used to express relations that hold among the data. For example, by plotting experimental results on a graph, in which the position of each data point is determined by its value on each of the axes, relations among the data can be determined very efficiently. Thus graphs provide a way to represent the data themselves, by using spatial location along the axes to refer to values. In addition, graphs facilitate inferences of *higher-order* properties, because the spatial relations *among* the plotted points are meaningful: They are interpreted according to the conventions governing the interpretation of location with respect to the two axes. So spatial relations among the plotted points support inferences about relations among the properties represented by individual data points.

In addition to being spatially formatted, and thus representing relations among parts of their referents, some figures provide evidence for a hypothesis because the figure is causally related to what it represents. An electron micrograph, for example, is made by beaming electrons through a very thin biological sample stained with material that does not mix with biological material and that deflects electrons. The electrons can go through the slide only in areas without stain, so the array of detected electrons reflects the array of unstained area on the slide, thereby producing the light areas of the image. The process of producing the micrograph correlates the form of the image (light versus dark areas) with the shape of the sample. The micrograph thus represents the structure of the sample. Note that this does not guarantee that the sample has the structure the micrograph represents: The procedure might produce such an image, due to problems in staining or machine malfunction. Accuracy is not guaranteed.

But if researchers think their procedure is reliable, they will take the micrograph as an accurate representation of the sample structure. One could draw the same structure, but the fact that the form of this visual representation is *causally related* to the sample that the figure represents is an important source of the epistemic warrant of the micrograph. Pictorial representations generated by imaging techniques gain this status because of the causal relation between symbol and object. For this reason pictorial representations can play a role very similar to evidence claims: Their epistemic warrant derives primarily from causal interactions between the object studied and a detector, rather than by inference from other representations. This is similar to perceptually grounded linguistic observation statements. The veracity and the evidential relevance of such figures depend on the procedure by which they are produced. In order for a figure to serve as evidence, scientists need some assurance that the technique that produced the image generates accurate representations of the subject matter. This assurance can come in the form of understanding appropriate causal connections between the technique and the representations it generates, or through experience of the reliability of a method. The critical difference between a figure like a micrograph and a linguistically expressed observation claim is that the *form* of the figure is causally related to its content.

The micrograph also exemplifies another way in which the *kind* of visual symbol involved makes an important contribution to science. Imaging techniques produce visual symbols with distinctive, "pictorial" representational features described above. The characters are not composed of unambiguously identifiable atomic characters, and these systems have the capacity to represent a dense set of referents, due to the precise correlation between symbol form and referent.

This system-level feature grounds another important advantage of visual representations: Many imaging techniques provide an experimental method that results in a comprehensible representation of a state of affairs, even if the precise vocabulary needed to describe that state of affairs through linguistic representations does not yet exist. Their content is a function of the visible form of the symbol and does not depend on a vocabulary of arbitrarily associated symbols and meanings. So a person who knows how to interpret such a symbol can do so even if it represents a novel phenomenon. For example, a person who knows how to interpret micrographs like Figure 2, in which the light areas represent biological material, can comprehend a micrograph from the same system even if it has a shape the viewer has never seen or heard of before. That means that the person can comprehend the

micrograph, as a representation of the form of the sample structure, even if it represents a structure that was completely unknown prior to the production of the micrograph. This is quite different from alphabetical systems; because the connection between symbol form and referent is arbitrary, one cannot comprehend an unfamiliar word simply by looking at it. Pictorial symbol systems offer an important advantage in science, allowing newly discovered and extremely complex phenomena to be represented and fully comprehended. Once a representation of the phenomenon is in hand, it is possible to assign a linguistic name to it, but having a *hypothesis* about this structure is not a prerequisite. Imaging techniques provide tools to comprehensibly represent phenomena that do not yet have a linguistic label.

Finally, the capacity of visual representation to support scientific knowledge requires that such representation be usable objectively. Like linguistic representations, pictures can be used for both rhetorical and nonrhetorical purposes. The capacity of figures to represent phenomena gives them the potential to contribute objective support for a scientific hypothesis. Identifying *how* to use visual representations objectively is not a trivial matter, and scientists have expressed active concern in this area. A historical study by Daston and Galison (1992) shows that choices about what images to publish can be influenced by scientists' beliefs about appropriate ways to avoid subjectivity in scientific communication.

Necessity

Are visual representations necessary for contemporary science? In some cases, human cognitive limitations make the use of visual representations necessary for *comprehension* of the content the author wishes to convey (Perini 2001). For example, diagrams of macromolecular structures are external representations whose contents can be expressed through serially formatted symbols: The coordinates for atomic locations can be printed out as a list as well as used to make a diagram. But, while humans readily understand the diagrammatic representation and can understand the individual items on the serially formatted list of atomic coordinates, they cannot use that list to generate a mental representation of the structure of the molecule. Comprehension of the structure requires a representation of the spatial relations among the parts of the molecule, and the computational task involved in calculating those relations from the list of individual atomic coordinates is simply too complicated.

A different set of circumstances that would make visual representations necessary is if they conveyed content that was both essential to science and not expressible with serial representations such as linguistic or numerical symbols. There are two different reasons why the content of visual representations might fail to be expressible with serial representations. First, pictorial content would not be linguistically expressible if pictures conveyed a different *kind* of content from linguistic representations. However, the analysis in terms of symbol system features provides no reason to think that there is such a difference. The difference between linguistic and visual representations concerns features of the symbol system (of its characters on the one hand and of the referent set on the other), and not the nature of the content conveyed. Second, pictorial content would not be linguistically expressible if the *amount* of content conveyed by the visual representation could not be symbolized with serial representations. If an infinite set of representations were the *only* possible linguistic translation of a figure, actual expression with physical symbols would be impossible. Kitcher and Varzi (2002) argue that a map of Manhattan is worth a nondenumerable set of linguistic representations. They reach this conclusion after claiming, without support, that the real map is not the physical symbol, but an abstract object. This abstract object amounts to a shape consisting of infinitely many contiguous line segments, each of which can be linguistically described. The question of necessity does not turn on whether the map is really the physical symbol or an abstract object, so this aspect of their paper can be taken as given. The paper does not show that the map is necessary due to amount of content, however, because Kitcher and Varzi's analysis does not provide any reason to think that the map could not also be expressed by a finite serial symbol. There is no reason why one complicated linear expression describing that shape would not serve equally well as a translation.

The question of translatability tends to draw philosophical attention because of the disciplinary focus on linguistic representations, but it is important to bear in mind that the philosophical significance of visual representations in science does not depend on whether or not they are necessary to convey the content they do. Diagrams and tables both can be easily translated into serially formatted linguistic or mathematical representations, yet they are the preferred expression of the data. This suggests that the visual format itself contributes to scientific reasoning. Perini (2004) offers a preliminary analysis of the role of two-dimensional

formatting in the presentation of evidence, and concludes that tables—consisting entirely of numerical symbols, but formatted in two dimensions—serve as evidence in part because that way of presenting the data facilitates inferences of higher-order relations among the data. Furthermore, while the same conclusion can be drawn from the data set presented serially, the reasoning involved would be different. Thus those wishing to understand the reasoning actually presented in a scientific paper employing a table would need to consider the data in their two-dimensional presentation. The previous section showed that imaging techniques like electron microscopy have distinctive capacities for evidential support because of the pictorial nature of the representations they produce. Even if figures are fully translatable, they still make philosophically significant contributions to science *as visual representations*—and must be understood as such in order to understand the reasoning contemporary scientists actually use.
